Preface by the General Chair

August 25, 2015

Welcome to the 2015 Conference on Empirical Methods in Natural Language Processing. EMNLP is annually organized by SIGDAT, the Association for Computational Linguistics' special interest group on linguistic data and corpus-based approaches to NLP. This year the conference will be held on September 17–21 in the enchanting city of Lisbon, Portugal.[1]

EMNLP has continued to increase in prominence as one of the most important conferences in Natural Language Processing (NLP). This year the conference has experienced an unprecedented boost in submitted papers. I believe that this reflects both the growth of the NLP field and also the health and strength of the conference itself, with a history of many years of solid work. With this level of interest at submission time, we are also expecting a record attendance. The conference will span a five-day period this year, and it requires a growing organization structure.

Some of the features introduced in EMNLP 2014 will continue this year (e.g., tutorials, new chairs, posters as parallel sessions, flat rates and flexibility for tutorials and workshops, etc.). We also introduce some innovations, like a revised selection process for which talks are presented as talks versus posters.

This year I had the privilege of coordinating the conference from my General Chair position. This has been a very instructive and enriching exercise which showed me the conference as a whole, from many different angles. Prefaces in the proceedings invariably praise the team of organizers. This one will not be an exception. Organizing a large conference as EMNLP requires excellent people working as a team in multiple interrelated tasks. I have been lucky to work with an outstanding team of people, from whom I learnt a lot. These aren't empty words. I would like to thank each and every chair for the hard work that made the conference a reality.

The Program Chairs, Jian Su and Chris Callison-Burch, did an excellent job at putting together a very interesting program with over 300 papers. They had to deal with a very large number of submissions, which exceeded even our most optimistic expectations. As a consequence, they were forced to be creative and to find solutions on the fly to adapt to the situation. They recruited the largest ever program committee and successfully managed a huge reviewing and decision making process under a very tight schedule. A real gift for the general chair. They complemented the program with very interesting keynote speakers, Yoshua Bengio and Justin Grimmer who will present exciting research topics for our community.

The EMNLP 2015 main conference is accompanied by 7 workshops and 8 tutorials during the first two days. The Workshops Chairs, Zornitsa Kozareva and Jörg Tiedemann, and the Tutorials Chairs, Maggie Li and Khalil Sima'an, conducted the selection processes in a joint effort with the other ACL conferences in 2015 (NAACL and ACL-IJCNLP). This has been the standard procedure from last years. It has the advantage of starting early, avoiding duplicated reviewing and allowing a more balanced selection among conferences. EMNLP attracted a varied and interesting set of workshops and tutorials, which gives more value to the conference.

Daniele Pighin and Yuval Marton were responsible for the always difficult and sometimes thankless task of putting together the conference publications. This is a very complex effort which involves coordination with almost everyone in the team under the pressure of hard publication deadlines. Yuval is serving in this position for a second year. Staggered two year terms for publication chairs is a new addition for

[1] Conference website: `http://www.emnlp2015.org`

EMNLP starting this year, and we hope that it will be a permanent feature. In the first year, publication chairs will learn and do the bulk of proceedings compilation. During the second year their role will be more advisory, instructing and helping the first-year chair. This procedure will help the transmission of the necessary know-how from year to year. Thanks to Yuval and Daniele for accepting the challenge and making it work wonderfully. Finally, this is the second year that EMNLP uses a mobile app for the conference program (Conference4me). The publication chairs also coordinated the integration of the app with SoftConf, which is now smoother and more seamless.

The local organization team was led by André Martins and João Graça. They did an amazing job, working hard and with all the complexities and subtleties of local arrangements. One of the keys for the success was the creation of a large team of local organizers with clearly defined roles and responsibilities. They appointed very committed people: Isabel Trancoso (Local Publicity Chair), Fernando Batista (Handbook Chair), Bruno Martins (Website and App Chair), Luísa Coheur (Student Volunteer Coordinator), and Helena Moniz (Local Arrangements Chair). Thanks to all. I am especially pleased about the new website, which was revamped and looks more professional everyday. This is certainly a good investment for the future.

A large conference as EMNLP needs to focus on dissemination activities too. Barbara Plank acted as the international Publicity Chair. She did a fantastic job and coordinated very well with the local publicity and the website chairs. The calls for papers, calls for participation, and main news of the conference were timely distributed through ACL, the usual distribution lists, and also through the conference website and two Facebook and Twitter accounts. The EMNLP2015 Twitter account garnered more followers than in previous years.

I am really grateful to SIGDAT. Its secretary, Noah Smith, acted as the liasion between SIGDAT and the conference organizers. He was always available and ready to help with very good advice. SIGDAT also provided the funds for the student scholarship program. These grants help covering traveling expenses to a dozen of students. The committee appointed for collecting the applications and making the decisions was formed by Francisco Guzmán and Lluís Padró, who had to analyze all the information and decide the awardees in only a few days.

Another sign of the health of EMNLP and the field in general is the interest showed by sponsors. Thanks to the work of our sponsorship team, formed by João Graça and Hang Li, in coordination with the ACL International Sponsorship Committee, we got a record number of 13 sponsors for EMNLP 2015 (2 platinum, 3 gold, 6 silver and 2 bronze). In addition to these direct sponsors, we also have several smaller supporters, exhibitors, and institutional partners. We are extremely grateful to all these companies and institutions, which make a better conference possible at a more affordable registration fee.

Additionally, we counted on the invaluable help of Priscilla Rasmussen, supporting the local organization in all fronts with her broad experience. She took care of the registration process too. We also got very good advice, know-how, and helpful software and forms from last year general chair and local organizers, Alessandro Moschitti and Kareem Darwish. Thank you.

Finally, I would like to thank the authors of submitted and accepted papers, and all the attendees to the conference, who will be the main actors from September 17 to September 21, 2015. I am convinced that we will experience a fantastic conference, scientifically exciting and full of fond memories, in the unique environment of Lisbon.

Lluís Màrquez
EMNLP 2015 General Chair

Preface by the Program Committee Co-Chairs

August 25, 2015

Welcome to the 2015 Conference on Empirical Methods in Natural Language Processing! This year we received a record number of submissions. There were 1300 valid submissions. The 600 long papers and 700 short papers were allocated to one of 15 areas. The most popular areas this year were Semantics, Statistical Models and Machine Learning Methods, Text Mining and NLP applications, and Machine Translation.

Reviewing for a conference this size involves an enormous volunteer effort from many individuals. We are very grateful to our 30 area chairs and to the more than 900 researchers who reviewed the submissions. We accepted 312 papers (157 long and 155 short papers), representing a global acceptance rate of 24%. An additional 17 papers accepted by the TACL journal were presented at the conference as well.

To decide whether the accepted papers should be presented as talks or posters, we asked the area chairs, the reviewers, and the authors of accepted papers to vote on which papers they would like to attend. We showed the title of each paper and its abstract, but not its authors. 400 people provided their input. We selected talks based on popularity, while ensuring that each area was represented by at least one session. Our rationale for taking a vote was that papers that many people wanted to attend would be better served by presenting a talk in a large room, while papers with more specialized interest would benefit from the one-on-one interactions facilitated by posters. Rather than doing large plenary poster sessions, we have scheduled two parallel poster sessions with small batches of thematically similar papers that will be run simultaneously with the talks.

We selected best papers from a shortlist of 20 papers that were nominated by the area chairs. The best paper committee ranked the nominees, and based on their rankings we selected the following papers for the best paper awards:

- Best paper - *Broad-coverage CCG Semantic Parsing with AMR* by Yoav Artzi, Kenton Lee and Luke Zettlemoyer.
- Best paper - *Semantically Conditioned LSTM-based Natural Language Generation for Spoken Dialogue Systems* by Tsung-Hsien Wen, Milica Gasic, Nikola Mrkšić, Pei-Hao Su, David Vandyke and Steve Young.

IBM has provided a cash scholarship for us to award to the best student paper. This will go to Tsung-Hsien Wen, since he is currently a student. The following papers received an honorable mention for the best paper award:

- Honorable mention for best paper - *Traversing Knowledge Graphs in Vector Space* by Kelvin Guu, John Miller and Percy Liang.
- Honorable mention for best paper - *Building a shared world: mapping distributional to model-theoretic semantic spaces* by Aurélie Herbelot and Eva Maria Vecchi.
- Honorable mention for best paper - *Language Understanding for Text-based Games using Deep Reinforcement Learning* by Karthik Narasimhan, Tejas Kulkarni and Regina Barzilay.
- Honorable mention for best short paper - *Joint Lemmatization and Morphological Tagging with Lemming* by Thomas Müller, Ryan Cotterell, Alexander Fraser and Hinrich Schütze.

- Honorable mention for best short paper - *Semi-Supervised Bootstrapping of Relationship Extractors with Distributional Semantics* by David S. Batista, Bruno Martins and Mário J. Silva.

This year we created a new "Best data set or resource" award, since so much work in our community is driven by data. The paper that receiving this inaugural distinction is:

- Best data set or resource - *A large annotated corpus for learning natural language inference* by Samuel R. Bowman, Gabor Angeli, Christopher Potts and Christopher D. Manning.

With two honorable mentions:

- Notable data set or resource - *That's So Annoying!!!: A Lexical and Frame-Semantic Embedding Based Data Augmentation Approach to Automatic Categorization of Annoying Behaviors using #petpeeve Tweets* by William Yang Wang and Diyi Yang.
- Notable data set or resource - *Modeling Reportable Events as Turning Points in Narrative* by Jessica Ouyang and Kathy McKeown.

We decided to give more awards than in past years by recognizing papers with honorable mentions and by creating the new best data or resource award. Our goal was to recognize roughly the top 1% of all of the submissions to the conference with awards (recognizing approximately the top 5% of accepted papers). We are very grateful to our invited speakers Yoshua Bengio and Justin Grimmer.

Yoshua Bengio is professor of Computer Science and Operations Research at the Université de Montréal. He is the author of two books and more than 200 publications, the most cited being in the areas of deep learning, recurrent neural networks, probabilistic learning algorithms, natural language processing and manifold learning. He co-directs the Canadian Institute for Advanced Research's program on deep learning. He is on the board of NIPS. Professor Bengio's research into deep learning has had a dramatic impact on the field of NLP in the past few years, and has invigorated interest in AI through machine learning.

Justin Grimmer is an associate professor of Political Science at Stanford University. His research uses statistical methods to examine American politics. He is the author of two books on the topic "Representational Style in Congress: What Legislators Say and Why It Matters" and "The Impression of Influence: How Legislator Communication and Government Spending Cultivate a Personal Vote." His work has appeared in the American Political Science Review, American Journal of Political Science, Journal of Politics, Political Analysis, Proceedings of the National Academy of Sciences, Regulation and Governance, and Poetics. Professor Grimmer's research points to exciting new directions for computational social science and how the field of NLP can facilitate research in many areas.

We thank them in advance for coming to the conference and sharing their insights.

We would also like to thank our general chair Lluís Màrquez, André Martins and João Graça and colleagues for their excellent work with the local organization, and Yuval Marton and Daniele Pighin for doing an excellent job assembling these proceedings.

We thank SIGDAT for inviting us to serve as Program Co-Chairs of EMNLP 2015. We hope that the conference is an excellent one. Enjoy your stay in Lisbon!

Chris Callison-Burch and Jian Su
EMNLP 2015 Program Committee Co-Chairs

Organizing Committee

General Chair
Lluís Màrquez, Qatar Computing Research Institute

Program Co-Chairs
Chris Callison-Burch, University of Pennsylvania
Jian Su, Institute for Infocomm Research (I2R)

Workshops Co-Chairs
Zornitsa Kozareva, Yahoo! Labs
Jörg Tiedemann, University of Helsinki

Tutorial Co-Chairs
Maggie Li, Hong Kong Polytechnic University
Khalil Sima'an, University of Amsterdam

Publication Co-Chairs
Daniele Pighin, Google Inc.
Yuval Marton, Microsoft Corp.

Publicity Chair
Barbara Plank, University of Copenhagen

Sponsorship Team
João Graça, Unbabel Inc.
Hang Li, Huawei Technologies (ISC Representative for EMNLP)

Student Scholarships Co-Chairs
Fancisco Guzmán, Qatar Computing Research Institute
Lluís Padró, Technical University of Catalonia

SIGDAT Liaison
Noah Smith, University of Washington

Local Organizing Committee

Local Co-Chairs
André Martins, Priberam
João Graça, Unbabel Inc.

Local Publicity Chair
Isabel Trancoso, University of Lisbon

Handbook Chair
Fernando Batista, University Institute of Lisbon (ISCTE-IUL)

Website and App Chair
Bruno Martins, University of Lisbon

Student Volunteer Coordinator
Luísa Coheur, University of Lisbon

Local Arrangements Chair
Helena Moniz, Instituto de Engenharia de Sistemas e Computadores - I&D (INESC-ID)

Program Committee

Program Co-Chairs

Chris Callison-Burch, University of Pennsylvania
Jian Su, Institute for Infocomm Research (I2R)

Area Chairs

Computational Psycholinguistics
Vera Demberg, Saarland University

Discourse, Dialogue, and Pragmatics
Kentaro Inui, Tohoku University
Oliver Lemon, Heriot Watt University

Information Extraction
Heng Ji, Rensselaer Polytechnic Institute
Sebastian Riedel, University College London
Jing Jiang, Singapore Management University

Information Retrieval and Question Answering
Zhu Xiaoyan, Tsinghua University
Liu Ting, Harbin Institute of Technology

Language and Vision
Julia Hockenmaier, University of Illinois Urbana Champaign

Machine Translation and Multilinguality
Zhang Min, SooChow University
Lucia Specia, University of Sheffield
Marine Carpuat, University of Maryland

NLP for the Web and Social Media, including Computational Social Science
Alice Oh, KAIST
Brendan O'Connor, University of Massachusetts Amherst

Phonology, Morphology, and Word Segmentation
Greg Kondrak, University of Alberta
Xu Sun, Peking University

Semantics
Marco Baroni, University of Trento
Shiqi Zhao, Baidu
Percy Liang, Stanford University

Sentiment Analysis and Opinion Mining
Ku Lun-Wei, Institute of Information Science, Academia Sinica
He Yulan, Aston University

Spoken Language Processing
Mari Ostendorf, University of Washington

Statistical Models and Machine Learning Methods
Trevor Cohn, University of Melbourne
Jordan Boyd-Graber, University of Colorado

Summarization and Generation
Meg Mitchell, Microsoft Research
Furu Wei, Microsoft Research Asia

Tagging, Chunking, Syntax and Parsing
Shay Cohen, University of Edinburgh
Yue Zhang, Singapore University of Technology and Design
Yusuke Miyao, National Institute of Informatics, Japan

Text Mining and NLP applications
Sophia Ananiadou, University of Manchester

Best Paper Award Committee
Douglas Downey, Northwestern University
Kevin Knight, University of Southern California
Qun Liu, Dublin City University
Miles Osborne, Bloomberg
Mari Ostendorf, University of Washington
Xiaojun Wan, Peking University
Janyce Weibe, University of Pittsburgh

Invited Speaker: Yoshua Bengio

Deep Learning of Semantic Representations

Abstract: The core ingredient of deep learning is the notion of distributed representation. This talk will start by explaining its theoretical advantages, in comparison with non-parametric methods based on counting frequencies of occurrence of observed tuples of values (like with n-grams). The talk will then explain how having multiple levels of representation, i.e., depth, can in principle give another exponential advantage. Neural language models have been extremely successful in recent years but extending their reach from language modeling to machine translation is very appealing because it forces the learned intermediate representations to capture meaning, and we found that the resulting word embeddings are qualitatively different. Recently, we introduced the notion of attention-based encoder-decoder systems, with impressive results on machine translation several language pairs and for mapping an image to a sentence, and these results will conclude the talk.

Biography: Yoshua Bengio received a PhD in Computer Science from McGill University, Canada in 1991. After two post-doctoral years, one at M.I.T. with Michael Jordan and one at AT&T Bell Laboratories with Yann LeCun and Vladimir Vapnik, he became professor at the Department of Computer Science and Operations Research at Université de Montréal. He is the author of two books and more than 200 publications, the most cited being in the areas of deep learning, recurrent neural networks, probabilistic learning algorithms, natural language processing and manifold learning. He is among the most cited Canadian computer scientists and is or has been associate editor of the top journals in machine learning and neural networks. Since '2000 he holds a Canada Research Chair in Statistical Learning Algorithms, since '2006 an NSERC Industrial Chair, since '2005 his is a Senior Fellow of the Canadian Institute for Advanced Research and since 2014 he co-directs its program focused on deep learning. He is on the board of the NIPS foundation and has been program chair and general chair for NIPS. He has co-organized the Learning Workshop for 14 years and co-created the new International Conference on Learning Representations. His current interests are centered around a quest for AI through machine learning, and include fundamental questions on deep learning and representation learning, the geometry of generalization in high-dimensional spaces, manifold learning, biologically inspired learning algorithms, and challenging applications of statistical machine learning.

Invited Speaker: Justin Grimmer

Measuring How Elected Officials and Constituents Communicate

Abstract: This talk will show how elected officials use communication to cultivate support with constituents, how constituents express their views to elected officials, and why biases in both kinds of communication matter for political representation. To demonstrate the bias and its effects, I propose to use novel collections of political texts and new text as data methods. Using the new data and methods, I will show how the incentives of communication contribute to perceptions of an angry public and vitriolic politicians. Among elected officials, the ideologically extreme members of Congress disproportionately participate in policy debates, resulting in political debates that occur between the most extreme members of each party. Among constituents, the most ideologically extreme and angry voters disproportionately contact their member of Congress, creating the impression of a polarized and vitriolic public. The talk will explain how the findings help us to understand how representation occurs in American politics, while also explaining how computational tools can help address questions in the social sciences.

Biography: Justin Grimmer is an associate professor of political science at Stanford University. His research examines how representation occurs in American politics using new statistical methods. His first book Representational Style in Congress: What Legislators Say and Why It Matters (Cambridge University Press, 2013) shows how senators define the type of representation they provide constituents and how this affects constituents' evaluations and was awarded the 2014 Richard Fenno Prize. His second book The Impression of Influence: How Legislator Communication and Government Spending Cultivate a Personal Vote (Princeton University Press, 2014 with Sean J. Westwood and Solomon Messing) demonstrates how legislators ensure they receive credit for government actions. His work has appeared in the American Political Science Review, American Journal of Political Science, Journal of Politics, Political Analysis, Proceedings of the National Academy of Sciences, Regulation and Governance, and Poetics.

Conference Program

Friday, September 18, 2015

18:30–20:00 Welcome Reception

Saturday, September 19, 2015

07:30–18:00 Registration

08:40–10:00 Session P1: Plenary Session

08:40–09:00 *Opening Remarks and Introductory Speeches*
General Chair, Program Co-Chairs and Local Co-Chairs

09:00–10:00 *Invited Talk: Deep Learning of Semantic Representations*
Yoshua Bengio

10:00–10:30 *Coffee break*

10:30–12:10 Session 1A: Semantics 1 (Long + TACL Papers)

10:30–10:55 *Language Understanding for Text-based Games using Deep Reinforcement Learning*
Karthik Narasimhan, Tejas Kulkarni and Regina Barzilay

10:55–11:20 *Distributional vectors encode referential attributes*
Abhijeet Gupta, Gemma Boleda, Marco Baroni and Sebastian Padó

11:20–11:45 *Building a shared world: mapping distributional to model-theoretic semantic spaces*
Aurélie Herbelot and Eva Maria Vecchi

11:45–12:10 *[TACL] Deriving Boolean Structures from Distributional Vectors*
Germán Kruszewski, Denis Paperno and Marco Baroni

Saturday, September 19, 2015 (continued)

10:30–12:10 Session 1B: Machine Translation 1 (Long + TACL Papers)

10:30–10:55 *Dependency Graph-to-String Translation*
Liangyou Li, Andy Way and Qun Liu

10:55–11:20 *Reordering Grammar Induction*
Miloš Stanojević and Khalil Sima'an

11:20–11:45 *Syntax-based Rewriting for Simultaneous Machine Translation*
He He, Alvin Grissom II, John Morgan, Jordan Boyd-Graber and Hal Daumé III

11:45–12:10 *[TACL] Modelling and Optimizing on Syntactic N-Grams for Statistical Machine Translation*
Rico Sennrich

10:30–12:10 Session 1C: NLP for the Web and Social Media, including Computational Social Science (Long Papers)

10:30–10:55 *Identifying Political Sentiment between Nation States with Social Media*
Nathanael Chambers, Victor Bowen, Ethan Genco, Xisen Tian, Eric Young, Ganesh Harihara and Eugene Yang

10:55–11:20 *Open Extraction of Fine-Grained Political Statements*
David Bamman and Noah A. Smith

11:20–11:45 *Using Personal Traits For Brand Preference Prediction*
Chao Yang, Shimei Pan, Jalal Mahmud, Huahai Yang and Padmini Srinivasan

11:45–12:10 *Semantic Annotation for Microblog Topics Using Wikipedia Temporal Information*
Tuan Tran, Nam Khanh Tran, Asmelash Teka Hadgu and Robert Jäschke

10:30–12:10 Session 1D (P1-4): Summarization (Long Paper Posters)

System Combination for Multi-document Summarization
Kai Hong, Mitchell Marcus and Ani Nenkova

Phrase-based Compressive Cross-Language Summarization
Jin-ge Yao, Xiaojun Wan and Jianguo Xiao

Re-evaluating Automatic Summarization with BLEU and 192 Shades of ROUGE
Yvette Graham

Indicative Tweet Generation: An Extractive Summarization Problem?
Priya Sidhaye and Jackie Chi Kit Cheung

Saturday, September 19, 2015 (continued)

10:30–12:10 Session 1D (P5): Language and Vision (Long Paper Posters)

Visual Bilingual Lexicon Induction with Transferred ConvNet Features
Douwe Kiela, Ivan Vulić and Stephen Clark

10:30–12:10 Session 1D (P6-9): Sentiment Analysis and Opinion Mining (Long Paper Posters)

Cross Lingual Sentiment Analysis using Modified BRAE
Sarthak Jain and Shashank Batra

Monotone Submodularity in Opinion Summaries
Jayanth Jayanth, Jayaprakash Sundararaj and Pushpak Bhattacharyya

Joint Prediction for Entity/Event-Level Sentiment Analysis using Probabilistic Soft Logic Models
Lingjia Deng and Janyce Wiebe

Learning to Recognize Affective Polarity in Similes
Ashequl Qadir, Ellen Riloff and Marilyn Walker

10:30–12:10 Session 1E (P1-3): Language and Vision (Short Paper Posters)

Cross-document Event Coreference Resolution based on Cross-media Features
Tongtao Zhang, Hongzhi Li, Heng Ji and Shih-Fu Chang

A Survey of Current Datasets for Vision and Language Research
Francis Ferraro, Nasrin Mostafazadeh, Ting-Hao Huang, Lucy Vanderwende, Jacob Devlin, Michel Galley and Margaret Mitchell

Combining Geometric, Textual and Visual Features for Predicting Prepositions in Image Descriptions
Arnau Ramisa, Josiah Wang, Ying Lu, Emmanuel Dellandrea, Francesc Moreno-Noguer and Robert Gaizauskas

10:30–12:10 Session 1E (P4-16): Statistical Models and Machine Learning Methods for NLP (Short Paper Posters)

On A Strictly Convex IBM Model 1
Andrei Simion, Michael Collins and Cliff Stein

Factorization of Latent Variables in Distributional Semantic Models
Arvid Österlund, David Ödling and Magnus Sahlgren

Non-lexical neural architecture for fine-grained POS Tagging
Matthieu Labeau, Kevin Löser and Alexandre Allauzen

Online Representation Learning in Recurrent Neural Language Models
Marek Rei

A Model of Zero-Shot Learning of Spoken Language Understanding
Majid Yazdani and James Henderson

Modeling Tweet Arrival Times using Log-Gaussian Cox Processes
Michal Lukasik, P. K. Srijith, Trevor Cohn and Kalina Bontcheva

Pre-Computable Multi-Layer Neural Network Language Models
Jacob Devlin, Chris Quirk and Arul Menezes

Birds of a Feather Linked Together: A Discriminative Topic Model using Link-based Priors
Weiwei Yang, Jordan Boyd-Graber and Philip Resnik

Aligning Knowledge and Text Embeddings by Entity Descriptions
Huaping Zhong, Jianwen Zhang, Zhen Wang, Hai Wan and Zheng Chen

An Empirical Analysis of Optimization for Max-Margin NLP
Jonathan K. Kummerfeld, Taylor Berg-Kirkpatrick and Dan Klein

Learning Better Embeddings for Rare Words Using Distributional Representations
Irina Sergienya and Hinrich Schütze

Composing Relationships with Translations
Alberto Garcia-Duran, Antoine Bordes and Nicolas Usunier

Noise or additional information? Leveraging crowdsource annotation item agreement for natural language tasks.
Emily Jamison and Iryna Gurevych

12:10–13:30 ***Lunch***

Saturday, September 19, 2015 (continued)

13:30–15:10 Session 2A: Statistical Modeling and Machine Learning 1 (Long + TACL Papers)

13:30–13:55 *Evaluation methods for unsupervised word embeddings*
Tobias Schnabel, Igor Labutov, David Mimno and Thorsten Joachims

13:55–14:20 *Efficient Methods for Incorporating Knowledge into Topic Models*
Yi Yang, Doug Downey and Jordan Boyd-Graber

14:20–14:45 *Traversing Knowledge Graphs in Vector Space*
Kelvin Guu, John Miller and Percy Liang

14:45–15:10 *[TACL] Improving Topic Models with Latent Feature Word Representations*
Dat Quoc Nguyen, Richard Billingsley, Lan Du and Mark Johnson

13:30–15:10 Session 2B: Tagging, Chunking and Parsing 1 (Long +TACL Papers)

13:30–13:55 *Density-Driven Cross-Lingual Transfer of Dependency Parsers*
Mohammad Sadegh Rasooli and Michael Collins

13:55–14:20 *A Neural Network Model for Low-Resource Universal Dependency Parsing*
Long Duong, Trevor Cohn, Steven Bird and Paul Cook

14:20–14:45 *Improved Transition-based Parsing by Modeling Characters instead of Words with LSTMs*
Miguel Ballesteros, Chris Dyer and Noah A. Smith

14:45–15:10 *[TACL] Approximation-Aware Dependency Parsing by Belief Propagation*
Matthew R. Gormley, Mark Dredze and Jason Eisner

13:30–15:10 Session 2C: Summarization (Long Papers)

13:30–13:55 *Sentence Compression by Deletion with LSTMs*
Katja Filippova, Enrique Alfonseca, Carlos A. Colmenares, Lukasz Kaiser and Oriol Vinyals

13:55–14:20 *An Empirical Comparison Between N-gram and Syntactic Language Models for Word Ordering*
Jiangming Liu and Yue Zhang

14:20–14:45 *A Neural Attention Model for Abstractive Sentence Summarization*
Alexander M. Rush, Sumit Chopra and Jason Weston

14:45–15:10 *Scientific Article Summarization Using Citation-Context and Article's Discourse Structure*
Arman Cohan and Nazli Goharian

13:30–15:10 Session 2D (P1-9): Text Mining and NLP Applications (Long Paper Posters)

Hashtag Recommendation Using Dirichlet Process Mixture Models Incorporating Types of Hashtags
Yeyun Gong, Qi Zhang and Xuanjing Huang

A Graph-based Readability Assessment Method using Word Coupling
Zhiwei Jiang, Gang Sun, Qing Gu, Tao Bai and Daoxu Chen

More Features Are Not Always Better: Evaluating Generalizing Models in Incident Type Classification of Tweets
Axel Schulz, Christian Guckelsberger and Benedikt Schmidt

Flexible Domain Adaptation for Automated Essay Scoring Using Correlated Linear Regression
Peter Phandi, Kian Ming A. Chai and Hwee Tou Ng

Show Me Your Evidence - an Automatic Method for Context Dependent Evidence Detection
Ruty Rinott, Lena Dankin, Carlos Alzate Perez, Mitesh M. Khapra, Ehud Aharoni and Noam Slonim

Spelling Correction of User Search Queries through Statistical Machine Translation
Saša Hasan, Carmen Heger and Saab Mansour

Human Evaluation of Grammatical Error Correction Systems
Roman Grundkiewicz, Marcin Junczys-Dowmunt and Edward Gillian

Learning a Deep Hybrid Model for Semi-Supervised Text Classification
Alexander Ororbia II, C. Lee Giles and David Reitter

Joint Embedding of Query and Ad by Leveraging Implicit Feedback
Sungjin Lee and Yifan Hu

Saturday, September 19, 2015 (continued)

13:30–15:10 Session 2E (P1-11): Information Extraction (Short Paper Posters)

Automatic Extraction of Time Expressions Accross Domains in French Narratives
Mike Donald Tapi Nzali, Xavier Tannier and Aurelie Neveol

Semi-Supervised Bootstrapping of Relationship Extractors with Distributional Semantics
David S. Batista, Bruno Martins and Mário J. Silva

Extraction and generalisation of variables from scientific publications
Erwin Marsi and Pinar Öztürk

Named entity recognition with document-specific KB tag gazetteers
Will Radford, Xavier Carreras and James Henderson

"A Spousal Relation Begins with a Deletion of engage and Ends with an Addition of divorce": Learning State Changing Verbs from Wikipedia Revision History
Derry Tanti Wijaya, Ndapandula Nakashole and Tom Mitchell

Improving Distant Supervision for Information Extraction Using Label Propagation Through Lists
Lidong Bing, Sneha Chaudhari, Richard Wang and William Cohen

An Entity-centric Approach for Overcoming Knowledge Graph Sparsity
Manjunath Hegde and Partha P. Talukdar

Semantic Relation Classification via Convolutional Neural Networks with Simple Negative Sampling
Kun Xu, Yansong Feng, Songfang Huang and Dongyan Zhao

A Baseline Temporal Tagger for all Languages
Jannik Strötgen and Michael Gertz

Named Entity Recognition for Chinese Social Media with Jointly Trained Embeddings
Nanyun Peng and Mark Dredze

Inferring Binary Relation Schemas for Open Information Extraction
Kangqi Luo, Xusheng Luo and Kenny Zhu

13:30–15:10 **Session 2E (P12-16): Information Retrieval and Question Answering (Short Paper Posters)**

LDTM: A Latent Document Type Model for Cumulative Citation Recommendation
Jingang Wang, Dandan Song, Zhiwei Zhang, Lejian Liao, Luo Si and Chin-Yew Lin

Online Sentence Novelty Scoring for Topical Document Streams
Sungjin Lee

Global Thread-level Inference for Comment Classification in Community Question Answering
Shafiq Joty, Alberto Barrón-Cedeño, Giovanni Da San Martino, Simone Filice, Lluís Màrquez, Alessandro Moschitti and Preslav Nakov

Key Concept Identification for Medical Information Retrieval
Jiaping Zheng and Hong Yu

Image-Mediated Learning for Zero-Shot Cross-Lingual Document Retrieval
Ruka Funaki and Hideki Nakayama

15:10–15:40 ***Coffee break***

15:40–17:20 **Session 3A: Sentiment Analysis and Opinion Mining 1 (Long Papers)**

15:40–16:05 *Detecting Risks in the Banking System by Sentiment Analysis*
Clemens Nopp and Allan Hanbury

16:05–16:30 *Sentiment Flow - A General Model of Web Review Argumentation*
Henning Wachsmuth, Johannes Kiesel and Benno Stein

16:30–16:55 *Neural Networks for Open Domain Targeted Sentiment*
Meishan Zhang, Yue Zhang and Duy Tin Vo

16:55–17:20 *Extracting Condition-Opinion Relations Toward Fine-grained Opinion Mining*
Yuki Nakayama and Atsushi Fujii

Saturday, September 19, 2015 (continued)

15:40–17:20 Session 3B: Semantics 2 (Long +TACL Papers)

15:40–16:05 *A large annotated corpus for learning natural language inference*
Samuel R. Bowman, Gabor Angeli, Christopher Potts and Christopher D. Manning

16:05–16:30 *Question-Answer Driven Semantic Role Labeling: Using Natural Language to Annotate Natural Language*
Luheng He, Mike Lewis and Luke Zettlemoyer

16:30–16:55 *[TACL] It's All Fun and Games until Someone Annotates: Video Games with a Purpose for Linguistic Annotation.*
David Jurgens and Roberto Navigli

16:55–17:20 *[TACL] Semantic Proto-Roles*
Drew Reisinger, Rachel Rudinger, Francis Ferraro, Kyle Rawlins and Benjamin Van Durme

15:40–17:20 Session 3C: Information Retrieval and Question Answering (Long Papers)

15:40–16:05 *Name List Only? Target Entity Disambiguation in Short Texts*
Yixin Cao, Juanzi Li, Xiaofei Guo, Shuanhu Bai, Heng Ji and Jie Tang

16:05–16:30 *Biography-Dependent Collaborative Entity Archiving for Slot Filling*
Yu Hong, Xiaobin Wang, Yadong Chen, Jian Wang, Tongtao Zhang and Heng Ji

16:30–16:55 *Stochastic Top-k ListNet*
Tianyi Luo, Dong Wang, Rong Liu and Yiqiao Pan

16:55–17:20 *Exploring Markov Logic Networks for Question Answering*
Tushar Khot, Niranjan Balasubramanian, Eric Gribkoff, Ashish Sabharwal, Peter Clark and Oren Etzioni

15:40–17:20 Session 3D (P1-9): Information Extraction (Long + TACL Paper Posters)

Language and Domain Independent Entity Linking with Quantified Collective Validation
Han Wang, Jin Guang Zheng, Xiaogang Ma, Peter Fox and Heng Ji

Modeling Relation Paths for Representation Learning of Knowledge Bases
Yankai Lin, Zhiyuan Liu, Huanbo Luan, Maosong Sun, Siwei Rao and Song Liu

Corpus-level Fine-grained Entity Typing Using Contextual Information
Yadollah Yaghoobzadeh and Hinrich Schütze

Knowledge Base Unification via Sense Embeddings and Disambiguation
Claudio Delli Bovi, Luis Espinosa Anke and Roberto Navigli

Open-Domain Name Error Detection using a Multi-Task RNN
Hao Cheng, Hao Fang and Mari Ostendorf

Extracting Relations between Non-Standard Entities using Distant Supervision and Imitation Learning
Isabelle Augenstein, Andreas Vlachos and Diana Maynard

Sieve-Based Spatial Relation Extraction with Expanding Parse Trees
Jennifer D'Souza and Vincent Ng

[TACL] Cross-Document Co-Reference Resolution using Sample-Based Clustering with Knowledge Enrichment
Sourav Dutta and Gerhard Weikum

[TACL] Combining Minimally-supervised Methods for Arabic Named Entity Recognition
Maha Althobaiti, Udo Kruschwitz and Massimo Poesio

Saturday, September 19, 2015 (continued)

15:40–17:20 Session 3E (P1-13): Text Mining and NLP Applications (Short Paper Posters)

Mr. Bennet, his coachman, and the Archbishop walk into a bar but only one of them gets recognized: On The Difficulty of Detecting Characters in Literary Texts
Hardik Vala, David Jurgens, Andrew Piper and Derek Ruths

Convolutional Sentence Kernel from Word Embeddings for Short Text Categorization
Jonghoon Kim, Francois Rousseau and Michalis Vazirgiannis

Predicting the Structure of Cooking Recipes
Jermsak Jermsurawong and Nizar Habash

TSDPMM: Incorporating Prior Topic Knowledge into Dirichlet Process Mixture Models for Text Clustering
Linmei Hu, Juanzi Li, Xiaoli Li, Chao Shao and Xuzhong Wang

Sentence Modeling with Gated Recursive Neural Network
Xinchi Chen, Xipeng Qiu, Chenxi Zhu, Shiyu Wu and Xuanjing Huang

Learning Timeline Difference for Text Categorization
Fumiyo Fukumoto and Yoshimi Suzuki

Summarizing Topical Contents from PubMed Documents Using a Thematic Analysis
Sun Kim, Lana Yeganova and W John Wilbur

Recognizing Biographical Sections in Wikipedia
Alessio Palmero Aprosio and Sara Tonelli

Learn to Solve Algebra Word Problems Using Quadratic Programming
Lipu Zhou, Shuaixiang Dai and Liwei Chen

An Unsupervised Method for Discovering Lexical Variations in Roman Urdu Informal Text
Abdul Rafae, Abdul Qayyum, Muhammad Moeenuddin, Asim Karim, Hassan Sajjad and Faisal Kamiran

Component-Enhanced Chinese Character Embeddings
Yanran Li, Wenjie Li, Fei Sun and Sujian Li

Multi-label Text Categorization with Joint Learning Predictions-as-Features Method
Li Li, Houfeng Wang, Xu Sun, Baobao Chang, Shi Zhao and Lei Sha

A Framework for Comparing Groups of Documents
Arun Maiya

Saturday, September 19, 2015 (continued)

Sunday, September 20, 2015

07:30–18:00 Registration

09:00–10:00 Session P2: Plenary Session

Invited Talk: Measuring How Elected Officials and Constituents Communicate
Justin Grimmer

10:00–10:30 ***Coffee break***

10:30–12:10 Session 4A: Information Extraction 1 (Long Papers)

10:30–10:55 *C3EL: A Joint Model for Cross-Document Co-Reference Resolution and Entity Linking*
Sourav Dutta and Gerhard Weikum

10:55–11:20 *Joint Mention Extraction and Classification with Mention Hypergraphs*
Wei Lu and Dan Roth

11:20–11:45 *FINET: Context-Aware Fine-Grained Named Entity Typing*
Luciano Del Corro, Abdalghani Abujabal, Rainer Gemulla and Gerhard Weikum

11:45–12:10 *Joint Entity Recognition and Disambiguation*
Gang Luo, Xiaojiang Huang, Chin-Yew Lin and Zaiqing Nie

10:30–12:10 Session 4B: Statistical Modeling and Machine Learning 2 (Long Papers)

10:30–10:55 *How Much Information Does a Human Translator Add to the Original?*
Barret Zoph, Marjan Ghazvininejad and Kevin Knight

10:55–11:20 *Hierarchical Recurrent Neural Network for Document Modeling*
Rui Lin, Shujie Liu, Muyun Yang, Mu Li, Ming Zhou and Sheng Li

11:20–11:45 *Auto-Sizing Neural Networks: With Applications to n-gram Language Models*
Kenton Murray and David Chiang

11:45–12:10 *Dual Decomposition Inference for Graphical Models over Strings*
Nanyun Peng, Ryan Cotterell and Jason Eisner

Sunday, September 20, 2015 (continued)

10:30–12:10 Session 4C: Discourse (Long +TACL Papers)

10:30–10:55 *Discourse parsing for multi-party chat dialogues*
Stergos Afantenos, Eric Kow, Nicholas Asher and Jérémy Perret

10:55–11:20 *Joint prediction in MST-style discourse parsing for argumentation mining*
Andreas Peldszus and Manfred Stede

11:20–11:45 *[TACL] One Vector is Not Enough: Entity-Augmented Distributed Semantics for Discourse Relations*
Yangfeng Ji and Jacob Eisenstein

11:45–12:10 *[TACL] Latent Structures for Coreference Resolution*
Sebastian Martschat and Michael Strube

10:30–12:10 Session 4D (P1-9): Semantics (Long Paper Posters)

Feature-Rich Two-Stage Logistic Regression for Monolingual Alignment
Md Arafat Sultan, Steven Bethard and Tamara Sumner

Semantic Role Labeling with Neural Network Factors
Nicholas FitzGerald, Oscar Täckström, Kuzman Ganchev and Dipanjan Das

RELLY: Inferring Hypernym Relationships Between Relational Phrases
Adam Grycner, Gerhard Weikum, Jay Pujara, James Foulds and Lise Getoor

Mise en Place: Unsupervised Interpretation of Instructional Recipes
Chloé Kiddon, Ganesa Thandavam Ponnuraj, Luke Zettlemoyer and Yejin Choi

Semantic Framework for Comparison Structures in Natural Language
Omid Bakhshandeh and James Allen

Sarcastic or Not: Word Embeddings to Predict the Literal or Sarcastic Meaning of Words
Debanjan Ghosh, Weiwei Guo and Smaranda Muresan

Incorporating Trustiness and Collective Synonym/Contrastive Evidence into Taxonomy Construction
Tuan Luu Anh, Jung-jae Kim and See Kiong Ng

Learning to Automatically Solve Logic Grid Puzzles
Arindam Mitra and Chitta Baral

Sunday, September 20, 2015 (continued)

10:30–12:10 Session 4E (P1-13): Machine Translation and Multilinguality (Short Paper Posters)

Improving fast_align by Reordering
Chenchen Ding, Masao Utiyama and Eiichiro Sumita

Touch-Based Pre-Post-Editing of Machine Translation Output
Benjamin Marie and Aurélien Max

A Discriminative Training Procedure for Continuous Translation Models
Quoc-Khanh DO, Alexandre Allauzen and François Yvon

System Combination for Machine Translation through Paraphrasing
Wei-Yun Ma and Kathleen McKeown

Hierarchical Incremental Adaptation for Statistical Machine Translation
Joern Wuebker, Spence Green and John DeNero

ReVal: A Simple and Effective Machine Translation Evaluation Metric Based on Recurrent Neural Networks
Rohit Gupta, Constantin Orasan and Josef van Genabith

Investigating Continuous Space Language Models for Machine Translation Quality Estimation
Kashif Shah, Raymond W. M. Ng, Fethi Bougares and Lucia Specia

Supervised Phrase Table Triangulation with Neural Word Embeddings for Low-Resource Languages
Tomer Levinboim and David Chiang

Translation Invariant Word Embeddings
Kejun Huang, Matt Gardner, Evangelos Papalexakis, Christos Faloutsos, Nikos Sidiropoulos, Tom Mitchell, Partha P. Talukdar and Xiao Fu

Hierarchical Phrase-based Stream Decoding
Andrew Finch, Xiaolin Wang, Masao Utiyama and Eiichiro Sumita

Rule Selection with Soft Syntactic Features for String-to-Tree Statistical Machine Translation
Fabienne Braune, Nina Seemann and Alexander Fraser

Motivating Personality-aware Machine Translation
Shachar Mirkin, Scott Nowson, Caroline Brun and Julien Perez

Trans-gram, Fast Cross-lingual Word-embeddings
Jocelyn Coulmance, Jean-Marc Marty, Guillaume Wenzek and Amine Benhalloum

Sunday, September 20, 2015 (continued)

10:30–12:10 Session 4E (P14-16): Computational Psycholinguistics (Short Paper Posters)

The Overall Markedness of Discourse Relations
Lifeng Jin and Marie-Catherine de Marneffe

Experiments in Open Domain Deception Detection
Verónica Pérez-Rosas and Rada Mihalcea

A model of rapid phonotactic generalization
Tal Linzen and Timothy O'Donnell

12:10–12:50 *Lunch*

12:50–13:30 Session P3: SIGDAT business meeting

13:30–15:10 Session 5A: Text Mining and NLP Applications 1 (Long + TACL Papers)

13:30–13:55 *[TACL] Unsupervised Identification of Translationese*
Ella Rabinovich and Shuly Wintner

13:55–14:20 *Automatically Solving Number Word Problems by Semantic Parsing and Reasoning*
Shuming Shi, Yuehui Wang, Chin-Yew Lin, Xiaojiang Liu and Yong Rui

14:20–14:45 *[TACL] Which Step Do I Take First? Troubleshooting with Bayesian Models*
Annie Louis and Mirella Lapata

14:45–15:10 *[TACL] Problems in Current Text Simplification Research: New Data Can Help*
Wei Xu, Chris Callison-Burch and Courtney Napoles

Sunday, September 20, 2015 (continued)

13:30–15:10 Session 5B: Semantics 3 (Long +TACL Papers)

13:30–13:55 *Parsing English into Abstract Meaning Representation Using Syntax-Based Machine Translation*
Michael Pust, Ulf Hermjakob, Kevin Knight, Daniel Marcu and Jonathan May

13:55–14:20 *The Forest Convolutional Network: Compositional Distributional Semantics with a Neural Chart and without Binarization*
Phong Le and Willem Zuidema

14:20–14:45 *Alignment-Based Compositional Semantics for Instruction Following*
Jacob Andreas and Dan Klein

14:45–15:10 *[TACL] Context-aware Frame-Semantic Role Labeling*
Michael Roth and Mirella Lapata

13:30–15:10 Session 5C: Phonology and Word Segmentation (Long Papers)

13:30–13:55 *Do we need bigram alignment models? On the effect of alignment quality on transduction accuracy in G2P*
Steffen Eger

13:55–14:20 *Keyboard Logs as Natural Annotations for Word Segmentation*
Fumihiko Takahasi and Shinsuke Mori

14:20–14:45 *Long Short-Term Memory Neural Networks for Chinese Word Segmentation*
Xinchi Chen, Xipeng Qiu, Chenxi Zhu, Pengfei Liu and Xuanjing Huang

14:45–15:10 *Semi-supervised Chinese Word Segmentation based on Bilingual Information*
Wei Chen and Bo Xu

13:30–15:10 Session 5D (P1-8): Machine Translation and Multilinguality (Long Paper Posters)

Hierarchical Back-off Modeling of Hiero Grammar based on Non-parametric Bayesian Model
Hidetaka Kamigaito, Taro Watanabe, Hiroya Takamura, Manabu Okumura and Eiichiro Sumita

Consistency-Aware Search for Word Alignment
Shiqi Shen, Yang Liu, Maosong Sun and Huanbo Luan

Graph-Based Collective Lexical Selection for Statistical Machine Translation
Jinsong Su, Deyi Xiong, Shujian Huang, Xianpei Han and Junfeng Yao

Bilingual Correspondence Recursive Autoencoder for Statistical Machine Translation
Jinsong Su, Deyi Xiong, Biao Zhang, Yang Liu, Junfeng Yao and Min Zhang

How to Avoid Unwanted Pregnancies: Domain Adaptation using Neural Network Models
Shafiq Joty, Hassan Sajjad, Nadir Durrani, Kamla Al-Mannai, Ahmed Abdelali and Stephan Vogel

Detecting Content-Heavy Sentences: A Cross-Language Case Study
Junyi Jessy Li and Ani Nenkova

Search-Aware Tuning for Hierarchical Phrase-based Decoding
Feifei Zhai, Liang Huang and Kai Zhao

Part-of-speech Taggers for Low-resource Languages using CCA Features
Young-Bum Kim, Benjamin Snyder and Ruhi Sarikaya

Sunday, September 20, 2015 (continued)

13:30–15:10 Session 5E (P1-12): Tagging, Chunking, Sytnax and Parsing (Short Paper Posters)

An Improved Tag Dictionary for Faster Part-of-Speech Tagging
Robert Moore

Improving Arabic Diacritization through Syntactic Analysis
Anas Shahrour, Salam Khalifa and Nizar Habash

Combining Discrete and Continuous Features for Deterministic Transition-based Dependency Parsing
Meishan Zhang and Yue Zhang

Efficient Inner-to-outer Greedy Algorithm for Higher-order Labeled Dependency Parsing
Xuezhe Ma and Eduard Hovy

Online Updating of Word Representations for Part-of-Speech Tagging
Wenpeng Yin, Tobias Schnabel and Hinrich Schütze

Empty Category Detection using Path Features and Distributed Case Frames
Shunsuke Takeno, Masaaki Nagata and Kazuhide Yamamoto

Foreebank: Syntactic Analysis of Customer Support Forums
Rasoul Kaljahi, Jennifer Foster, Johann Roturier, Corentin Ribeyre, Teresa Lynn and Joseph Le Roux

Semi-supervised Dependency Parsing using Bilexical Contextual Features from Auto-Parsed Data
Eliyahu Kiperwasser and Yoav Goldberg

Improved Transition-Based Parsing and Tagging with Neural Networks
Chris Alberti, David Weiss, Greg Coppola and Slav Petrov

Syntactic Parse Fusion
Do Kook Choe, David McClosky and Eugene Charniak

Not All Contexts Are Created Equal: Better Word Representations with Variable Attention
Wang Ling, Yulia Tsvetkov, Silvio Amir, Ramon Fermandez, Chris Dyer, Alan W Black, Isabel Trancoso and Chu-Cheng Lin

An Improved Non-monotonic Transition System for Dependency Parsing
Matthew Honnibal and Mark Johnson

Sunday, September 20, 2015 (continued)

15:10–15:40 ***Coffee break***

15:40–17:20 **Session 6A: Machine Translation 2 (Long Papers)**

15:40–16:05 *Improving Statistical Machine Translation with a Multilingual Paraphrase Database*
Ramtin Mehdizadeh Seraj, Maryam Siahbani and Anoop Sarkar

16:05–16:30 *Learning Semantic Representations for Nonterminals in Hierarchical Phrase-Based Translation*
Xing Wang, Deyi Xiong and Min Zhang

16:30–16:55 *A Comparison between Count and Neural Network Models Based on Joint Translation and Reordering Sequences*
Andreas Guta, Tamer Alkhouli, Jan-Thorsten Peter, Joern Wuebker and Hermann Ney

16:55–17:20 *Effective Approaches to Attention-based Neural Machine Translation*
Thang Luong, Hieu Pham and Christopher D. Manning

15:40–17:20 **Session 6B: Sentiment Analysis and Opinion Mining 2 / Tagging, Chunking and Parsing 2 (Long Papers)**

15:40–16:05 *Document Modeling with Gated Recurrent Neural Network for Sentiment Classification*
Duyu Tang, Bing Qin and Ting Liu

16:05–16:30 *Fine-grained Opinion Mining with Recurrent Neural Networks and Word Embeddings*
Pengfei Liu, Shafiq Joty and Helen Meng

16:30–16:55 *Joint A* CCG Parsing and Semantic Role Labelling*
Mike Lewis, Luheng He and Luke Zettlemoyer

16:55–17:20 *Improving Semantic Parsing with Enriched Synchronous Context-Free Grammar*
Junhui Li, Muhua Zhu, Wei Lu and Guodong Zhou

15:40–17:20 Session 6C: Language and Vision / Information Extraction 2 (Long Papers)

15:40–16:05 *Solving Geometry Problems: Combining Text and Diagram Interpretation*
Minjoon Seo, Hannaneh Hajishirzi, Ali Farhadi, Oren Etzioni and Clint Malcolm

16:05–16:30 *Do You See What I Mean? Visual Resolution of Linguistic Ambiguities*
Yevgeni Berzak, Andrei Barbu, Daniel Harari, Boris Katz and Shimon Ullman

16:30–16:55 *Efficient and Expressive Knowledge Base Completion Using Subgraph Feature Extraction*
Matt Gardner and Tom Mitchell

16:55–17:20 *Representing Text for Joint Embedding of Text and Knowledge Bases*
Kristina Toutanova, Danqi Chen, Patrick Pantel, Hoifung Poon, Pallavi Choudhury and Michael Gamon

15:40–17:20 Session 6D (P1-11): Statistical Models and Machine Learning Methods for NLP (Long Paper Posters)

A Utility Model of Authors in the Scientific Community
Yanchuan Sim, Bryan Routledge and Noah A. Smith

Finding Function in Form: Compositional Character Models for Open Vocabulary Word Representation
Wang Ling, Chris Dyer, Alan W Black, Isabel Trancoso, Ramon Fermandez, Silvio Amir, Luis Marujo and Tiago Luis

Syntax-Aware Multi-Sense Word Embeddings for Deep Compositional Models of Meaning
Jianpeng Cheng and Dimitri Kartsaklis

Conversation Trees: A Grammar Model for Topic Structure in Forums
Annie Louis and Shay B. Cohen

Fast, Flexible Models for Discovering Topic Correlation across Weakly-Related Collections
Jingwei Zhang, Aaron Gerow, Jaan Altosaar, James Evans and Richard Jean So

Molding CNNs for text: non-linear, non-consecutive convolutions
Tao Lei, Regina Barzilay and Tommi Jaakkola

Multi-Perspective Sentence Similarity Modeling with Convolutional Neural Networks
Hua He, Kevin Gimpel and Jimmy Lin

Posterior calibration and exploratory analysis for natural language processing models
Khanh Nguyen and Brendan O'Connor

A Generative Word Embedding Model and its Low Rank Positive Semidefinite Solution
Shaohua Li, Jun Zhu and Chunyan Miao

Reading Documents for Bayesian Online Change Point Detection
Taehoon Kim and Jaesik Choi

15:40–17:20 Session 6E (P1-13): Semantics (Short Paper Posters)

Recognizing Textual Entailment Using Probabilistic Inference
Lei Sha, Sujian Li, Baobao Chang, Zhifang Sui and Tingsong Jiang

Chinese Semantic Role Labeling with Bidirectional Recurrent Neural Networks
Zhen Wang, Tingsong Jiang, Baobao Chang and Zhifang Sui

Unsupervised Negation Focus Identification with Word-Topic Graph Model
Bowei Zou, Guodong Zhou and Qiaoming Zhu

Reverse-engineering Language: A Study on the Semantic Compositionality of German Compounds
Corina Dima

Event Detection and Factuality Assessment with Non-Expert Supervision
Kenton Lee, Yoav Artzi, Yejin Choi and Luke Zettlemoyer

Large-Scale Acquisition of Entailment Pattern Pairs by Exploiting Transitivity
Julien Kloetzer, Kentaro Torisawa, Chikara Hashimoto and Jong-Hoon Oh

Context-Dependent Knowledge Graph Embedding
Yuanfei Luo, Quan Wang, Bin Wang and Li Guo

Learning to Identify the Best Contexts for Knowledge-based WSD
Evgenia Wasserman Pritsker, William Cohen and Einat Minkov

Sunday, September 20, 2015 (continued)

Measuring Prerequisite Relations Among Concepts
Chen Liang, Zhaohui Wu, Wenyi Huang and C. Lee Giles

Adapting Phrase-based Machine Translation to Normalise Medical Terms in Social Media Messages
Nut Limsopatham and Nigel Collier

Script Induction as Language Modeling
Rachel Rudinger, Pushpendre Rastogi, Francis Ferraro and Benjamin Van Durme

Online Learning of Interpretable Word Embeddings
Hongyin Luo, Zhiyuan Liu, Huanbo Luan and Maosong Sun

A Strong Lexical Matching Method for the Machine Comprehension Test
Ellery Smith, Nicola Greco, Matko Bosnjak and Andreas Vlachos

19:00–23:00 Conference Dinner

Monday, September 21, 2015

07:30–18:00 Registration

09:00–10:00 Session P4: Plenary Session

09:00–09:05 *Best Paper Awards*
Chris Callison-Burch and Jian Su

09:05–09:30 *Broad-coverage CCG Semantic Parsing with AMR*
Yoav Artzi, Kenton Lee and Luke Zettlemoyer

09:30–09:55 *Semantically Conditioned LSTM-based Natural Language Generation for Spoken Dialogue Systems*
Tsung-Hsien Wen, Milica Gasic, Nikola Mrkšić, Pei-Hao Su, David Vandyke and Steve Young

09:55–10:05 *A Large Annotated Corpus for Learning Natural Language Inference*
Samuel R. Bowman, Gabor Angeli, Christopher Potts and Christopher D. Manning

10:05–10:30 ***Coffee break***

Monday, September 21, 2015 (continued)

10:30–12:10 Session 7A: Semantics 4 (Long +TACL Papers)

10:30–10:55 *Do Multi-Sense Embeddings Improve Natural Language Understanding?*
Jiwei Li and Dan Jurafsky

10:55–11:20 *Learning Semantic Composition to Detect Non-compositionality of Multiword Expressions*
Majid Yazdani, Meghdad Farahmand and James Henderson

11:20–11:45 *Solving General Arithmetic Word Problems*
Subhro Roy and Dan Roth

11:45–12:10 *[TACL] From Paraphrase Database to Compositional Paraphrase Model and Back*
John Wieting, Mohit Bansal, Kevin Gimpel, Karen Livescu and Dan Roth

10:30–12:10 Session 7B: Information Extraction 3 (Long Papers)

10:30–10:55 *Distant Supervision for Relation Extraction via Piecewise Convolutional Neural Networks*
Daojian Zeng, Kang Liu, Yubo Chen and Jun Zhao

10:55–11:20 *CORE: Context-Aware Open Relation Extraction with Factorization Machines*
Fabio Petroni, Luciano Del Corro and Rainer Gemulla

11:20–11:45 *Improved Relation Extraction with Feature-Rich Compositional Embedding Models*
Matthew R. Gormley, Mo Yu and Mark Dredze

11:45–12:10 *Classifying Relations via Long Short Term Memory Networks along Shortest Dependency Paths*
Yan Xu, Lili Mou, Ge Li, Yunchuan Chen, Hao Peng and Zhi Jin

10:30–12:10 Session 7C: Computational Psycholinguistics / Machine Translation 3 (Long Papers)

10:30–10:55 *A Computational Cognitive Model of Novel Word Generalization*
Aida Nematzadeh, Erin Grant and Suzanne Stevenson

10:55–11:20 *Personality Profiling of Fictional Characters using Sense-Level Links between Lexical Resources*
Lucie Flekova and Iryna Gurevych

11:20–11:45 *Leave-one-out Word Alignment without Garbage Collector Effects*
Xiaolin Wang, Masao Utiyama, Andrew Finch, Taro Watanabe and Eiichiro Sumita

11:45–12:10 *Generalized Agreement for Bidirectional Word Alignment*
Chunyang Liu, Yang Liu, Maosong Sun, Huanbo Luan and Heng Yu

10:30–12:10 Session 7D (P1-6): Word Segmentation, Tagging and Parsing (Long +TACL Paper Posters)

A Transition-based Model for Joint Segmentation, POS-tagging and Normalization
Tao Qian, Yue Zhang, Meishan Zhang, Yafeng Ren and Donghong Ji

Multilingual discriminative lexicalized phrase structure parsing
Benoit Crabbé

Hierarchical Low-Rank Tensors for Multilingual Transfer Parsing
Yuan Zhang and Regina Barzilay

Diversity in Spectral Learning for Natural Language Parsing
Shashi Narayan and Shay B. Cohen

Transition-based Dependency Parsing Using Two Heterogeneous Gated Recursive Neural Networks
Xinchi Chen, Yaqian Zhou, Chenxi Zhu, Xipeng Qiu and Xuanjing Huang

[TACL] A Graph-based Lattice Dependency Parser for Joint Morphological Segmentation and Syntactic Analysis
Wolfgang Seeker and Özlem Çetinoğlu

10:30–12:10 Session 7E (P1-3): Spoken Language Processing (Short Paper Posters)

Turn-taking phenomena in incremental dialogue systems
Hatim Khouzaimi, Romain Laroche and Fabrice Lefevre

Hierarchical Latent Words Language Models for Robust Modeling to Out-Of Domain Tasks
Ryo Masumura, Taichi Asami, Takanobu Oba, Hirokazu Masataki, Sumitaka Sakauchi and Akinori Ito

A Coarse-Grained Model for Optimal Coupling of ASR and SMT Systems for Speech Translation
Gaurav Kumar, Graeme Blackwood, Jan Trmal, Daniel Povey and Sanjeev Khudanpur

10:30–12:10 Session 7E (P4-18): Summarization (Short Paper Posters)

Abstractive Multi-document Summarization with Semantic Information Extraction
Wei Li

Concept-based Summarization using Integer Linear Programming: From Concept Pruning to Multiple Optimal Solutions
Florian Boudin, Hugo Mougard and Benoit Favre

GhostWriter: Using an LSTM for Automatic Rap Lyric Generation
Peter Potash, Alexey Romanov and Anna Rumshisky

Better Summarization Evaluation with Word Embeddings for ROUGE
Jun-Ping Ng and Viktoria Abrecht

Krimping texts for better summarization
Marina Litvak, Mark Last and Natalia Vanetik

From the Virtual to the RealWorld: Referring to Objects in Real-World Spatial Scenes
Dimitra Gkatzia, Verena Rieser, Phil Bartie and William Mackaness

An Unsupervised Bayesian Modelling Approach for Storyline Detection on News Articles
Deyu Zhou, Haiyang Xu and Yulan He

Topical Coherence for Graph-based Extractive Summarization
Daraksha Parveen, Hans-Martin Ramsl and Michael Strube

Monday, September 21, 2015 (continued)

Summarizing Student Responses to Reflection Prompts
Wencan Luo and Diane Litman

Extractive Summarization by Maximizing Semantic Volume
Dani Yogatama, Fei Liu and Noah A. Smith

LCSTS: A Large Scale Chinese Short Text Summarization Dataset
Baotian Hu, Qingcai Chen and Fangze Zhu

Discourse Planning with an N-gram Model of Relations
Or Biran and Kathleen McKeown

Experiments with Generative Models for Dependency Tree Linearization
Richard Futrell and Edward Gibson

Summarization Based on Embedding Distributions
Hayato Kobayashi, Masaki Noguchi and Taichi Yatsuka

Reversibility reconsidered: finite-state factors for efficient probabilistic sampling in parsing and generation
Marc Dymetman, Sriram Venkatapathy and Chunyang Xiao

12:10–13:30 ***Lunch***

13:30–15:15 **Session 8A: Fun and Quirky Topics (Short Papers)**

13:30–13:45 *A quantitative analysis of gender differences in movies using psycholinguistic normatives*
Anil Ramakrishna, Nikolaos Malandrakis, Elizabeth Staruk and Shrikanth Narayanan

13:45–14:00 *EMNLP versus ACL: Analyzing NLP research over time*
Sujatha Das Gollapalli and Xiaoli Li

14:00–14:15 *Answering Elementary Science Questions by Constructing Coherent Scenes using Background Knowledge*
Yang Li and Peter Clark

14:15–14:30 *WikiQA: A Challenge Dataset for Open-Domain Question Answering*
Yi Yang, Wen-tau Yih and Christopher Meek

Monday, September 21, 2015 (continued)

14:30–14:45 *Personalized Machine Translation: Predicting Translational Preferences*
Shachar Mirkin and Jean-Luc Meunier

14:45–15:00 *Talking to the crowd: What do people react to in online discussions?*
Aaron Jaech, Victoria Zayats, Hao Fang, Mari Ostendorf and Hannaneh Hajishirzi

15:00–15:15 *What Your Username Says About You*
Aaron Jaech and Mari Ostendorf

13:30–15:15 Session 8B: Semantics 5 (Short Papers)

13:30–13:45 *Knowledge Base Inference using Bridging Entities*
Bhushan Kotnis, Pradeep Bansal and Partha P. Talukdar

13:45–14:00 *Specializing Word Embeddings for Similarity or Relatedness*
Douwe Kiela, Felix Hill and Stephen Clark

14:00–14:15 *Evaluation of Word Vector Representations by Subspace Alignment*
Yulia Tsvetkov, Manaal Faruqui, Wang Ling, Guillaume Lample and Chris Dyer

14:15–14:30 *Higher-order logical inference with compositional semantics*
Koji Mineshima, Pascual Martínez-Gómez, Yusuke Miyao and Daisuke Bekki

14:30–14:45 *Any-language frame-semantic parsing*
Anders Johannsen, Héctor Martínez Alonso and Anders Søgaard

15:00–15:15 *What's in an Embedding? Analyzing Word Embeddings through Multilingual Evaluation*
Arne Köhn

13:30–15:15 Session 8C: Statistical Modeling, Machine Learning / Machine Translation (Short Papers)

13:30–13:45 *Joint Event Trigger Identification and Event Coreference Resolution with Structured Perceptron*
Jun Araki and Teruko Mitamura

13:45–14:00 *A Joint Dependency Model of Morphological and Syntactic Structure for Statistical Machine Translation*
Rico Sennrich and Barry Haddow

14:00–14:15 *Variable-Length Word Encodings for Neural Translation Models*
Rohan Chitnis and John DeNero

14:15–14:30 *A Binarized Neural Network Joint Model for Machine Translation*
Jingyi Zhang, Masao Utiyama, Eiichiro Sumita, Graham Neubig and Satoshi Nakamura

14:30–14:45 *Bayesian Optimization of Text Representations*
Dani Yogatama, Lingpeng Kong and Noah A. Smith

14:45–15:00 *A Comparative Study on Regularization Strategies for Embedding-based Neural Networks*
Hao Peng, Lili Mou, Ge Li, Yunchuan Chen, Yangyang Lu and Zhi Jin

15:00–15:15 *Efficient Hyper-parameter Optimization for NLP Applications*
Lidan Wang, Minwei Feng, Bowen Zhou, Bing Xiang and Sridhar Mahadevan

13:30–15:15 Session 8D (P1-6): NLP for the Web and Social Media, including Computational Social Science (Long Paper Posters)

Improved Arabic Dialect Classification with Social Media Data
Fei Huang

Exploiting Debate Portals for Semi-Supervised Argumentation Mining in User-Generated Web Discourse
Ivan Habernal and Iryna Gurevych

Confounds and Consequences in Geotagged Twitter Data
Umashanthi Pavalanathan and Jacob Eisenstein

Modeling Reportable Events as Turning Points in Narrative
Jessica Ouyang and Kathleen McKeown

Towards the Extraction of Customer-to-Customer Suggestions from Reviews
Sapna Negi and Paul Buitelaar

Using Content-level Structures for Summarizing Microblog Repost Trees
Jing Li, Wei Gao, Zhongyu Wei, Baolin Peng and Kam-Fai Wong

13:30–15:15 Session 8D (P7-9): Discourse (Long Paper Posters)

Intra-sentential Zero Anaphora Resolution using Subject Sharing Recognition
Ryu Iida, Kentaro Torisawa, Chikara Hashimoto, Jong-Hoon Oh and Julien Kloetzer

Estimation of Discourse Segmentation Labels from Crowd Data
Ziheng Huang, Jialu Zhong and Rebecca J. Passonneau

Comparing Word Representations for Implicit Discourse Relation Classification
Chloé Braud and Pascal Denis

13:30–15:15 Session 8E (P1-9): Discourse (Short Paper Posters)

Better Document-level Sentiment Analysis from RST Discourse Parsing
Parminder Bhatia, Yangfeng Ji and Jacob Eisenstein

Closing the Gap: Domain Adaptation from Explicit to Implicit Discourse Relations
Yangfeng Ji, Gongbo Zhang and Jacob Eisenstein

Wikification of Concept Mentions within Spoken Dialogues Using Domain Constraints from Wikipedia
Seokhwan Kim, Rafael E. Banchs and Haizhou Li

Shallow Convolutional Neural Network for Implicit Discourse Relation Recognition
Biao Zhang, Jinsong Su, Deyi Xiong, Yaojie Lu, Hong Duan and Junfeng Yao

On the Role of Discourse Markers for Discriminating Claims and Premises in Argumentative Discourse

Fatal or not? Finding errors that lead to dialogue breakdowns in chat-oriented dialogue systems
Ryuichiro Higashinaka, Masahiro Mizukami, Kotaro Funakoshi, Masahiro Araki, Hiroshi Tsukahara and Yuka Kobayashi

Learning Word Meanings and Grammar for Describing Everyday Activities in Smart Environments
Muhammad Attamimi, Yuji Ando, Tomoaki Nakamura, Takayuki Nagai, Daichi Mochihashi, Ichiro Kobayashi and Hideki Asoh

Discourse Element Identification in Student Essays based on Global and Local Cohesion
Wei Song, Ruiji Fu, Lizhen Liu and Ting Liu

Adapting Coreference Resolution for Narrative Processing
Quynh Ngoc Thi Do, Steven Bethard and Marie-Francine Moens

13:30–15:15 Session 8E (P10-15): Phonology, Morphology and Word Segmentation (Short Paper Posters)

Joint Lemmatization and Morphological Tagging with Lemming
Thomas Müller, Ryan Cotterell, Alexander Fraser and Hinrich Schütze

Transducer Disambiguation with Sparse Topological Features
Gonzalo Iglesias, Adrià de Gispert and Bill Byrne

Arabic Diacritization with Recurrent Neural Networks
Yonatan Belinkov and James Glass

Automatic Diacritics Restoration for Hungarian
Attila Novák and Borbála Siklósi

Morphological Analysis for Unsegmented Languages using Recurrent Neural Network Language Model
Hajime Morita, Daisuke Kawahara and Sadao Kurohashi

Can Symbol Grounding Improve Low-Level NLP? Word Segmentation as a Case Study
Hirotaka Kameko, Shinsuke Mori and Yoshimasa Tsuruoka

15:15–15:40 ***Coffee break***

Monday, September 21, 2015 (continued)

15:40–17:20 Session 9A: Statistical Modeling and Machine Learning 3 (Long + TACL Papers)

15:40–16:05 *When Are Tree Structures Necessary for Deep Learning of Representations?*
Jiwei Li, Thang Luong, Dan Jurafsky and Eduard Hovy

16:05–16:30 *Discriminative Neural Sentence Modeling by Tree-Based Convolution*
Lili Mou, Hao Peng, Ge Li, Yan Xu, Lu Zhang and Zhi Jin

16:30–16:55 *Multi-Timescale Long Short-Term Memory Neural Network for Modelling Sentences and Documents*
Pengfei Liu, Xipeng Qiu, Xinchi Chen, Shiyu Wu and Xuanjing Huang

16:55–17:20 *[TACL] Learning Structural Kernels for Natural Language Processing*
Daniel Beck, Trevor Cohn, Christian Hardmeier and Lucia Specia

15:40–17:20 Session 9B: Text Mining and NLP Applications 2 (Long Papers)

15:40–16:05 *Verbal and Nonverbal Clues for Real-life Deception Detection*
Verónica Pérez-Rosas, Mohamed Abouelenien, Rada Mihalcea, Yao Xiao, CJ Linton and Mihai Burzo

16:05–16:30 *Social Media Text Classification under Negative Covariate Shift*
Geli Fei and Bing Liu

16:30–16:55 *Co-Training for Topic Classification of Scholarly Data*
Cornelia Caragea, Florin Bulgarov and Rada Mihalcea

16:55–17:20 *Humor Recognition and Humor Anchor Extraction*
Diyi Yang, Alon Lavie, Chris Dyer and Eduard Hovy

Monday, September 21, 2015 (continued)

15:40–17:20 Session 9C: Spoken Language Processing and Language Modeling (Long Papers)

15:40–16:05 *Topic Identification and Discovery on Text and Speech*
Chandler May, Francis Ferraro, Alan McCree, Jonathan Wintrode, Daniel Garcia-Romero and Benjamin Van Durme

16:05–16:30 *A Dynamic Programming Algorithm for Computing N-gram Posteriors from Lattices*
Dogan Can and Shrikanth Narayanan

16:30–16:55 *Bilingual Structured Language Models for Statistical Machine Translation*
Ekaterina Garmash and Christof Monz

16:55–17:20 *Compact, Efficient and Unlimited Capacity: Language Modeling with Compressed Suffix Trees*
Ehsan Shareghi, Matthias Petri, Gholamreza Haffari and Trevor Cohn

15:40–17:20 Session 9D (P1-8): Semantics (Long Paper Posters)

ERSOM: A Structural Ontology Matching Approach Using Automatically Learned Entity Representation
Chuncheng Xiang, Tingsong Jiang, Baobao Chang and Zhifang Sui

A Single Word is not Enough: Ranking Multiword Expressions Using Distributional Semantics
Martin Riedl and Chris Biemann

Syntactic Dependencies and Distributed Word Representations for Analogy Detection and Mining
Likun Qiu, Yue Zhang and Yanan Lu

Navigating the Semantic Horizon using Relative Neighborhood Graphs
Amaru Cuba Gyllensten and Magnus Sahlgren

Multi- and Cross-Modal Semantics Beyond Vision: Grounding in Auditory Perception
Douwe Kiela and Stephen Clark

Automatic recognition of habituals: a three-way classification of clausal aspect
Annemarie Friedrich and Manfred Pinkal

Distributed Representations for Unsupervised Semantic Role Labeling
Kristian Woodsend and Mirella Lapata

A Tableau Prover for Natural Logic and Language
Lasha Abzianidze

15:40–17:20 Session 9E (P1-9): Sentiment Analysis and Opinion Mining (Short Paper Posters)

JEAM: A Novel Model for Cross-Domain Sentiment Classification Based on Emotion Analysis
Kun-Hu Luo, Zhi-Hong Deng, Hongliang Yu and Liang-Chen Wei

PhraseRNN: Phrase Recursive Neural Network for Aspect-based Sentiment Analysis
Thien Hai Nguyen and Kiyoaki Shirai

ASTD: Arabic Sentiment Tweets Dataset
Mahmoud Nabil, Mohamed Aly and Amir Atiya

Adjective Intensity and Sentiment Analysis
Raksha Sharma, Mohit Gupta, Astha Agarwal and Pushpak Bhattacharyya

Abstract

In this paper, we consider the task of learning control policies for text-based games. In these games, all interactions in the virtual world are through text and the underlying state is not observed. The resulting language barrier makes such environments challenging for automatic game players. We employ a deep reinforcement learning framework to jointly learn state representations and action policies using game rewards as feedback. This framework enables us to map text descriptions into vector representations that capture the semantics of the game states. We evaluate our approach on two game worlds, comparing against baselines using bag-of-words and bag-of-bigrams for state representations. Our algorithm outperforms the baselines on both worlds demonstrating the importance of learning expressive representations. [1]

State 1: The old bridge
You are standing very close to the bridge's eastern foundation. If you go east you will be back on solid ground ... The bridge sways in the wind.

Command: **Go east**

State 2: Ruined gatehouse
The old gatehouse is near collapse. Part of its northern wall has already fallen down ... East of the gatehouse leads out to a small open area surrounded by the remains of the castle. There is also a standing archway offering passage to a path along the old southern inner wall.
Exits: Standing archway, castle corner, Bridge over the abyss

Figure 1: Sample gameplay from a Fantasy World. The player with the quest of finding a secret tomb, is currently located on an *old bridge*. She then chooses an action to *go east* that brings her to a *ruined gatehouse* (State 2).

1 Introduction

In this paper, we address the task of learning control policies for text-based strategy games. These games, predecessors to modern graphical ones, still enjoy a large following worldwide.[2] They often involve complex worlds with rich interactions and elaborate textual descriptions of the underlying states (see Figure 1). Players read descriptions of the current world state and respond with natural language commands to take actions. Since the underlying state is not directly observable, the player has to understand the text in order to act, making it challenging for existing AI programs to play these games (DePristo and Zubek, 2001).

In designing an autonomous game player, we have considerable latitude when selecting an adequate state representation to use. The simplest method is to use a bag-of-words representation derived from the text description. However, this scheme disregards the ordering of words and the finer nuances of meaning that evolve from composing words into sentences and paragraphs. For instance, in State 2 in Figure 1, the agent has to understand that going *east* will lead it to the castle whereas moving *south* will take it to the standing archway. An alternative approach is to convert text descriptions to pre-specified representations using annotated training data, commonly used in

Lisbon, Portugal, 17-21 September 2015.

language grounding tasks (Matuszek et al., 2013; Kushman et al., 2014).

In contrast, our goal is to learn useful representations in conjunction with control policies. We adopt a reinforcement learning framework and formulate game sequences as Markov Decision Processes. An agent playing the game aims to maximize rewards that it obtains from the game engine upon the occurrence of certain events. The agent learns a policy in the form of an action-value function $Q(s, a)$ which denotes the long-term merit of an action a in state s.

The action-value function is parametrized using a deep recurrent neural network, trained using the game feedback. The network contains two modules. The first one converts textual descriptions into vector representations that act as proxies for states. This component is implemented using Long Short-Term Memory (LSTM) networks (Hochreiter and Schmidhuber, 1997). The second module of the network scores the actions given the vector representation computed by the first.

We evaluate our model using two Multi-User Dungeon (MUD) games (Curtis, 1992; Amir and Doyle, 2002). The first game is designed to provide a controlled setup for the task, while the second is a publicly available one and contains human generated text descriptions with significant language variability. We compare our algorithm against baselines of a random player and models that use bag-of-words or bag-of-bigrams representations for a state. We demonstrate that our model LSTM-DQN significantly outperforms the baselines in terms of number of completed quests and accumulated rewards. For instance, on a fantasy MUD game, our model learns to complete 96% of the quests, while the bag-of-words model and a random baseline solve only 82% and 5% of the quests, respectively. Moreover, we show that the acquired representation can be reused across games, speeding up learning and leading to faster convergence of Q-values.

2 Related Work

Learning control policies from text is gaining increasing interest in the NLP community. Example applications include interpreting help documentation for software (Branavan et al., 2010), navigating with directions (Vogel and Jurafsky, 2010; Kollar et al., 2010; Artzi and Zettlemoyer, 2013; Matuszek et al., 2013; Andreas and Klein, 2015) and playing computer games (Eisenstein et al., 2009; Branavan et al., 2011a).

Games provide a rich domain for grounded language analysis. Prior work has assumed perfect knowledge of the underlying state of the game to learn policies. Gorniak and Roy (2005) developed a game character that can be controlled by spoken instructions adaptable to the game situation. The grounding of commands to actions is learned from a transcript manually annotated with actions and state attributes. Eisenstein et al. (2009) learn game rules by analyzing a collection of game-related documents and precompiled traces of the game. In contrast to the above work, our model combines text interpretation and strategy learning in a single framework. As a result, textual analysis is guided by the received control feedback, and the learned strategy directly builds on the text interpretation.

Our work closely relates to an automatic game player that utilizes text manuals to learn strategies for Civilization (Branavan et al., 2011a). Similar to our approach, text analysis and control strategies are learned jointly using feedback provided by the game simulation. In their setup, states are fully observable, and the model learns a strategy by combining state/action features and features extracted from text. However, in our application, the state representation is not provided, but has to be inferred from a textual description. Therefore, it is not sufficient to extract features from text to supplement a simulation-based player.

Another related line of work consists of automatic video game players that infer state representations directly from raw pixels (Koutník et al., 2013; Mnih et al., 2015). For instance, Mnih et al. (2015) learn control strategies using convolutional neural networks, trained with a variant of Q-learning (Watkins and Dayan, 1992). While both approaches use deep reinforcement learning for training, our work has important differences. In order to handle the sequential nature of text, we use Long Short-Term Memory networks to automatically learn useful representations for arbitrary text descriptions. Additionally, we show that decomposing the network into a representation layer and an action selector is useful for transferring the learnt representations to new game scenarios.

3 Background

Game Representation We represent a game by the tuple $\langle H, A, T, R, \Psi \rangle$, where H is the set of

all possible game states, $A = \{(a, o)\}$ is the set of all commands (action-object pairs), $T(h' \mid h, a, o)$ is the stochastic transition function between states and $R(h, a, o)$ is the reward function. The game state H is *hidden* from the player, who only receives a varying textual description, produced by a stochastic function $\Psi : H \rightarrow S$. Specifically, the underlying state h in the game engine keeps track of attributes such as the player's location, her health points, time of day, etc. The function Ψ (also part of the game framework) then converts this state into a textual description of the location the player is at or a message indicating low health. We do not assume access to either H or Ψ for our agent during both training and testing phases of our experiments. We denote the space of all possible text descriptions s to be S. Rewards are generated using R and are only given to the player upon completion of in-game quests.

Q-Learning Reinforcement Learning is a commonly used framework for learning control policies in game environments (Silver et al., 2007; Amato and Shani, 2010; Branavan et al., 2011b; Szita, 2012). The game environment can be formulated as a sequence of state transitions (s, a, r, s') of a Markov Decision Process (MDP). The agent takes an action a in state s by consulting a state-action value function $Q(s, a)$, which is a measure of the action's expected long-term reward. Q-Learning (Watkins and Dayan, 1992) is a model-free technique which is used to learn an optimal $Q(s, a)$ for the agent. Starting from a random Q-function, the agent continuously updates its Q-values by playing the game and obtaining rewards. The iterative updates are derived from the Bellman equation (Sutton and Barto, 1998):

$$Q_{i+1}(s, a) = \mathrm{E}[r + \gamma \max_{a'} Q_i(s', a') \mid s, a] \quad (1)$$

where γ is a discount factor for future rewards and the expectation is over all game transitions that involved the agent taking action a in state s.

Using these evolving Q-values, the agent chooses the action with the highest $Q(s, a)$ to maximize its expected future rewards. In practice, the trade-off between exploration and exploitation can be achieved following an ϵ-greedy policy (Sutton and Barto, 1998), where the agent performs a random action with probability ϵ.

Deep Q-Network In large games, it is often impractical to maintain the Q-value for all possible state-action pairs. One solution to this problem is to approximate $Q(s, a)$ using a parametrized function $Q(s, a; \theta)$, which can generalize over states and actions by considering higher-level attributes (Sutton and Barto, 1998; Branavan et al., 2011a). However, creating a good parametrization requires knowledge of the state and action spaces. One way to bypass this feature engineering is to use a Deep Q-Network (DQN) (Mnih et al., 2015). The DQN approximates the Q-value function with a deep neural network to predict $Q(s, a)$ for all possible actions a simultaneously given the current state s. The non-linear function layers of the DQN also enable it to learn better value functions than linear approximators.

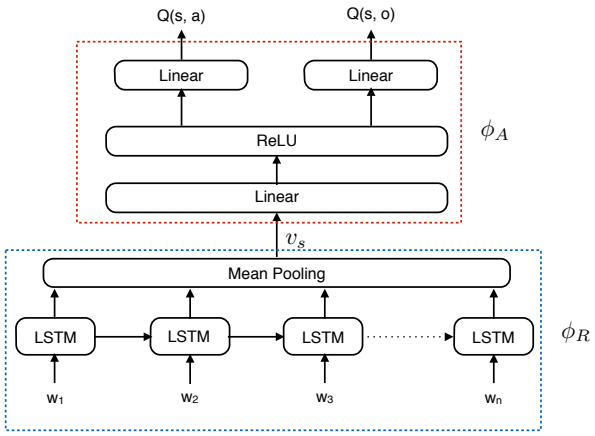

Figure 2: Architecture of LSTM-DQN: The Representation Generator (ϕ_R) (bottom) takes as input a stream of words observed in state s and produces a vector representation v_s, which is fed into the action scorer (ϕ_A) (top) to produce scores for all actions and argument objects.

4 Learning Representations and Control Policies

In this section, we describe our model (DQN) and describe its use in learning good Q-value approximations for games with stochastic textual descriptions. We divide our model into two parts. The first module is a *representation generator* that converts the textual description of the current state into a vector. This vector is then input into the second module which is an *action scorer*. Figure 2 shows the overall architecture of our model. We learn the parameters of both the representation generator and the action scorer jointly, using the in-game reward feedback.

Representation Generator (ϕ_R) The representation generator reads raw text displayed to the agent and converts it to a vector representation v_s. A bag-of-words (BOW) representation is not sufficient to capture higher-order structures of sentences and paragraphs. The need for a better semantic representation of the text is evident from the average performance of this representation in playing MUD-games (as we show in Section 6).

In order to assimilate better representations, we utilize a Long Short-Term Memory network (LSTM) (Hochreiter and Schmidhuber, 1997) as a representation generator. LSTMs are recurrent neural networks with the ability to connect and recognize long-range patterns between words in text. They are more robust than BOW to small variations in word usage and are able to capture underlying semantics of sentences to some extent. In recent work, LSTMs have been used successfully in NLP tasks such as machine translation (Sutskever et al., 2014) and sentiment analysis (Tai et al., 2015) to compose vector representations of sentences from word-level embeddings (Mikolov et al., 2013; Pennington et al., 2014). In our setup, the LSTM network takes in word embeddings w_k from the words in a description s and produces output vectors x_k at each step.

To get the final state representation v_s, we add a *mean pooling* layer which computes the element-wise mean over the output vectors x_k.[3]

$$v_s = \frac{1}{n}\sum_{k=1}^{n} x_k \tag{2}$$

Action Scorer (ϕ_A) The action scorer module produces scores for the set of possible actions given the current state representation. We use a multi-layered neural network for this purpose (see Figure 2). The input to this module is the vector from the representation generator, $v_s = \phi_R(s)$ and the outputs are scores for actions $a \in A$. Scores for all actions are predicted simultaneously, which is computationally more efficient than scoring each state-action pair separately. Thus, by combining the representation generator and action scorer, we can obtain the approximation for the Q-function as $Q(s,a) \approx \phi_A(\phi_R(s))[a]$.

An additional complexity in playing MUD-games is that the actions taken by the player are multi-word natural language *commands* such as *eat apple* or *go east*. Due to computational constraints, in this work we limit ourselves to consider commands to consist of one action (e.g. *eat*) and one argument object (e.g. *apple*). This assumption holds for the majority of the commands in our worlds, with the exception of one class of commands that require two arguments (e.g. *move red-root right*, *move blue-root up*). We consider all possible actions and objects available in the game and predict both for each state using the same network (Figure 2). We consider the Q-value of the entire command (a, o) to be the average of the Q-values of the action a and the object o. For the rest of this section, we only show equations for $Q(s,a)$ but similar ones hold for $Q(s,o)$.

Parameter Learning We learn the parameters θ_R of the representation generator and θ_A of the action scorer using stochastic gradient descent with *RMSprop* (Tieleman and Hinton, 2012). The complete training procedure is shown in Algorithm 1. In each iteration i, we update the parameters to reduce the discrepancy between the predicted value of the current state $Q(s_t, a_t; \theta_i)$ (where $\theta_i = [\theta_R; \theta_A]_i$) and the expected Q-value given the reward r_t and the value of the next state $\max_a Q(s_{t+1}, a; \theta_{i-1})$.

We keep track of the agent's previous experiences in a *memory* $\mathcal{D}$.[4] Instead of performing updates to the Q-value using transitions from the current episode, we sample a random transition $(\hat{s}, \hat{a}, s', r)$ from $\mathcal{D}$. Updating the parameters in this way avoids issues due to strong correlation when using transitions of the same episode (Mnih et al., 2015). Using the sampled transition and (1), we obtain the following loss function to minimize:

$$\mathcal{L}_i(\theta_i) = \mathrm{E}_{\hat{s},\hat{a}}[(y_i - Q(\hat{s}, \hat{a}; \theta_i))^2] \tag{3}$$

where $y_i = \mathrm{E}_{\hat{s},\hat{a}}[r + \gamma \max_{a'} Q(s', a'; \theta_{i-1}) \mid \hat{s}, \hat{a}]$ is the target Q-value with parameters θ_{i-1} fixed from the previous iteration.

The updates on the parameters θ can be performed using the following gradient of $\mathcal{L}_i(\theta_i)$:

$$\nabla_{\theta_i}\mathcal{L}_i(\theta_i) = \mathrm{E}_{\hat{s},\hat{a}}[2(y_i - Q(\hat{s}, \hat{a}; \theta_i))\nabla_{\theta_i} Q(\hat{s}, \hat{a}; \theta_i)]$$

For each epoch of training, the agent plays several episodes of the game, which is restarted after every terminal state.

[3] We also experimented with considering just the output vector of the LSTM after processing the last word. Empirically, we find that mean pooling leads to faster learning, so we use it in all our experiments.

[4] The memory is limited and rewritten in a first-in-first-out (FIFO) fashion.

Algorithm 1 Training Procedure for DQN with prioritized sampling

Initialize experience memory $\mathcal{D}$
Initialize parameters of representation generator (ϕ_R) and action scorer (ϕ_A) randomly
for $episode = 1, M$ **do**
    Initialize game and get start state description s_1
    for $t = 1, T$ **do**
        Convert s_t (text) to representation v_{s_t} using ϕ_R
        if $random() < \epsilon$ **then**
            Select a random action a_t
        else
            Compute $Q(s_t, a)$ for all actions using $\phi_A(v_{s_t})$
            Select $a_t = \text{argmax}\ Q(s_t, a)$
        Execute action a_t and observe reward r_t and new state s_{t+1}
        Set priority $p_t = 1$ if $r_t > 0$, else $p_t = 0$
        Store transition $(s_t, a_t, r_t, s_{t+1}, p_t)$ in $\mathcal{D}$
        Sample random mini batch of transitions $(s_j, a_j, r_j, s_{j+1}, p_j)$ from $\mathcal{D}$, with fraction ρ having $p_j = 1$
        Set $y_j = \begin{cases} r_j & \text{if } s_{j+1} \text{ is terminal} \\ r_j + \gamma \max_{a'} Q(s_{j+1}, a'; \theta) & \text{if } s_{j+1} \text{ is non-terminal} \end{cases}$
        Perform gradient descent step on the loss $\mathcal{L}(\theta) = (y_j - Q(s_j, a_j; \theta))^2$

Mini-batch Sampling In practice, online updates to the parameters θ are performed over a mini batch of state transitions, instead of a single transition. This increases the number of experiences used per step and is also more efficient due to optimized matrix operations.

The simplest method to create these mini-batches from the experience memory $\mathcal{D}$ is to sample uniformly at random. However, certain experiences are more valuable than others for the agent to learn from. For instance, rare transitions that provide positive rewards can be used more often to learn optimal Q-values faster. In our experiments, we consider such positive-reward transitions to have higher *priority* and keep track of them in $\mathcal{D}$. We use *prioritized sampling* (inspired by Moore and Atkeson (1993)) to sample a fraction ρ of transitions from the higher priority pool and a fraction $1 - \rho$ from the rest.

5 Experimental Setup

Game Environment For our game environment, we modify Evennia,[5] an open-source library for building online textual MUD games. Evennia is a Python-based framework that allows one to easily create new games by writing a batch file describing the environment with details of rooms, objects and actions. The game engine keeps track of the game state internally, presenting textual descriptions to the player and receiving text commands from the player. We conduct experiments on two worlds - a smaller *Home world* we created ourselves, and a larger, more complex *Fantasy world* created by Evennia's developers. The motivation behind Home world is to abstract away high-level planning and focus on the language understanding requirements of the game.

Stats	Home World	Fantasy World
Vocabulary size	84	1340
Avg. words / description	10.5	65.21
Max descriptions / room	3	100
# diff. quest descriptions	12	-
State transitions	Deterministic	Stochastic
# states (underlying)	16	≥ 56
Branching factor (# commands / state)	40	222

Table 1: Various statistics of the two game worlds

Table 1 provides statistics of the game worlds. We observe that the Fantasy world is moderately sized with a vocabulary of 1340 words and up to 100 different descriptions for a room. These descriptions were created manually by the game developers. These diverse, engaging descriptions are designed to make it interesting and exciting for human players. Several rooms have many alternative descriptions, invoked randomly on each visit by

[5] http://www.evennia.com/

the player.

Comparatively, the Home world is smaller: it has a very restricted vocabulary of 84 words and the room descriptions are relatively structured. However, both the room descriptions (which are also varied and randomly provided to the agent) and the quest descriptions were adversarially created with negation and conjunction of facts to force an agent to actually understand the state in order to play well. Therefore, this domain provides an interesting challenge for language understanding.

In both worlds, the agent receives a positive reward on completing a quest, and negative rewards for getting into bad situations like falling off a bridge, or losing a battle. We also add small deterministic negative rewards for each non-terminating step. This incentivizes the agent to learn policies that solve quests in fewer steps. The supplementary material has details on the reward structure.

Home World We created *Home world* to mimic the environment of a typical house.[6] The world consists of four rooms - a living room, a bedroom, a kitchen and a garden with connecting pathways. Every room is reachable from every other room. Each room contains a representative object that the agent can interact with. For instance, the kitchen has an *apple* that the player can *eat*. Transitions between the rooms are deterministic. At the start of each game episode, the player is placed in a random room and provided with a randomly selected quest. The text provided to the player contains both the description of her current state and that of the quest. Thus, the player can begin in one of 16 different states (4 rooms $\times$ 4 quests), which adds to the world's complexity.

An example of a quest given to the player in text is *Not you are sleepy now but you are hungry now*. To complete this quest and obtain a reward, the player has to navigate through the house to reach the kitchen and eat the apple (i.e type in the command *eat apple*). More importantly, the player should interpret that the quest does not require her to take a nap in the bedroom. We created such misguiding quests to make it hard for agents to succeed without having an adequate level of language understanding.

[6] An illustration is provided in the supplementary material.

Fantasy World The Fantasy world is considerably more complex and involves quests such as navigating through a broken bridge or finding the secret tomb of an ancient hero. This game also has stochastic transitions in addition to varying state descriptions provided to the player. For instance, there is a possibility of the player falling from the bridge if she lingers too long on it.

Due to the large command space in this game,[7] we make use of cues provided by the game itself to narrow down the set of possible objects to consider in each state. For instance, in the MUD example in Figure 1, the game provides a list of possible exits. If the game does not provide such clues for the current state, we consider all objects in the game.

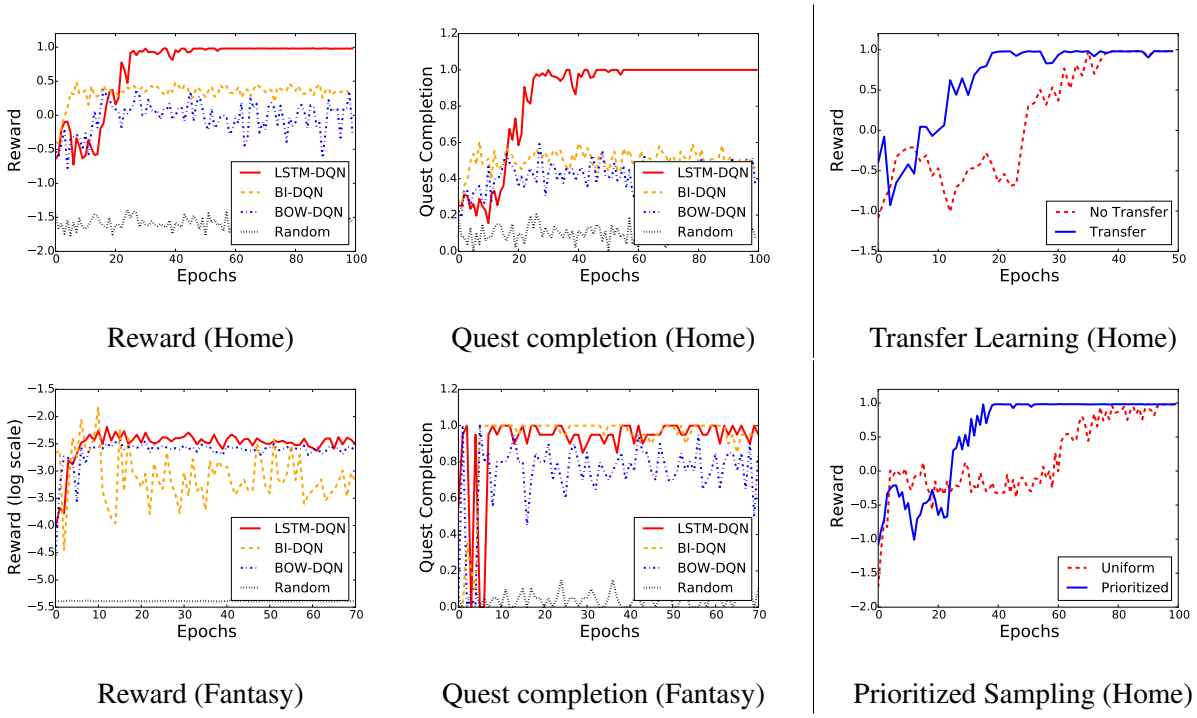
Evaluation We use two metrics for measuring an agent's performance: (1) the cumulative reward obtained per episode averaged over the episodes and (2) the fraction of quests completed by the agent. The evaluation procedure is as follows. In each epoch, we first train the agent on M episodes of T steps each. At the end of this training, we have a testing phase of running M episodes of the game for T steps. We use $M = 50, T = 20$ for the Home world and $M = 20, T = 250$ for the Fantasy world. For all evaluation episodes, we run the agent following an ϵ-greedy policy with $\epsilon = 0.05$, which makes the agent choose the best action according to its Q-values 95% of the time. We report the agent's performance at each epoch.

Baselines We compare our LSTM-DQN model with three baselines. The first is a *Random* agent that chooses both actions and objects uniformly at random from all available choices.[8] The other two are BOW-DQN and BI-DQN, which use a bag-of-words and a bag-of-bigrams representation of the text, respectively, as input to the DQN action scorer. These baselines serve to illustrate the importance of having a good representation layer for the task.

Settings For our DQN models, we used $\mathcal{D} = 100000, \gamma = 0.5$. We use a learning rate of 0.0005 for RMSprop. We anneal the ϵ for ϵ-greedy from 1 to 0.2 over 100000 transitions. A mini-batch gradient update is performed every 4 steps of the gameplay. We roll out the LSTM (over words) for

[7] We consider 222 possible command combinations of 6 actions and 37 object arguments.

[8] In the case of the Fantasy world, the object choices are narrowed down using game clues as described earlier.



Reward (Home) | Quest completion (Home) | Transfer Learning (Home)

Reward (Fantasy) | Quest completion (Fantasy) | Prioritized Sampling (Home)

Figure 3: **Left:** Graphs showing the evolution of average reward and quest completion rate for BOW-DQN, LSTM-DQN and a Random baseline on the Home world (**top**) and Fantasy world (**bottom**). Note that the reward is shown in log scale for the Fantasy world. **Right:** Graphs showing effects of transfer learning and prioritized sampling on the Home world.

a maximum of 30 steps on the Home world and for 100 steps on the Fantasy world. For the prioritized sampling, we used $\rho = 0.25$ for both worlds. We employed a mini-batch size of 64 and word embedding size $d = 20$ in all experiments.

6 Results

Home World Figure 3 illustrates the performance of LSTM-DQN compared to the baselines. We can observe that the Random baseline performs quite poorly, completing only around 10% of quests on average[9] obtaining a low reward of around -1.58. The BOW-DQN model performs significantly better and is able to complete around 46% of the quests, with an average reward of 0.20. The improvement in reward is due to both greater quest success rate and a lower rate of issuing invalid commands (e.g. *eat apple* would be invalid in the bedroom since there is no apple). We notice that both the reward and quest completion graphs of this model are volatile. This is because the model fails to pick out differences between quests like *Not you are hungry now but you are sleepy now* and *Not you are sleepy now but you are hungry now*. The BI-DQN model suffers from the same issue although it performs slightly better than BOW-DQN by completing 48% of quests. In contrast, the LSTM-DQN model does not suffer from this issue and is able to complete 100% of the quests after around 50 epochs of training, achieving close to the optimal reward possible.[10] This demonstrates that having an expressive representation for text is crucial to understanding the game states and choosing intelligent actions.

In addition, we also investigated the impact of using a deep neural network for modeling the action scorer ϕ_A. Figure 4 illustrates the performance of the BOW-DQN and BI-DQN models along with their simpler versions BOW-LIN and BI-LIN, which use a single linear layer for ϕ_A. It can be seen that the DQN models clearly achieve better performance than their linear counterparts, which points to them modeling the control policy better.

Fantasy World We evaluate all the models on the Fantasy world in the same manner as before and report reward, quest completion rates and Q-

[9] Averaged over the last 10 epochs.

[10] Note that since each step incurs a penalty of -0.01, the best reward (on average) a player can get is around 0.98.

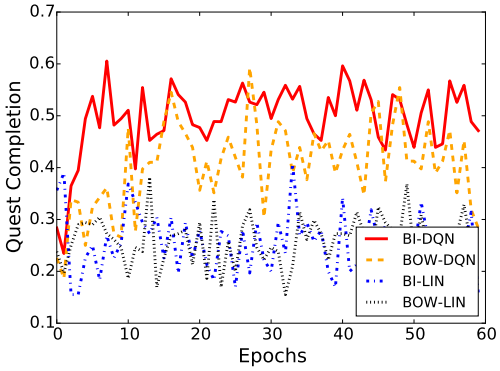


Figure 4: Quest completion rates of DQN vs. Linear models on Home world.

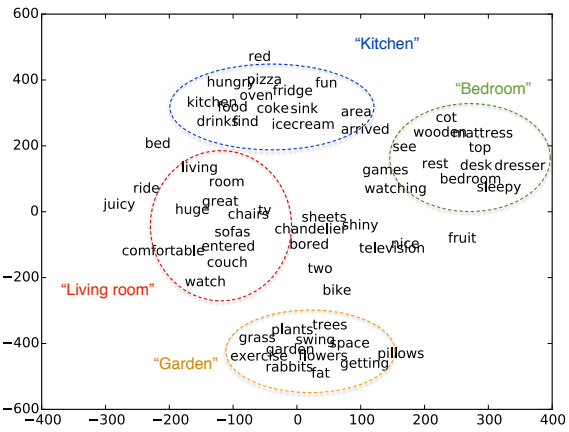

Figure 5: t-SNE visualization of the word embeddings (except stopwords) after training on Home world. The embedding values are initialized randomly.

values. The quest we evaluate on involves crossing the broken bridge (which takes a minimum of five steps), with the possibility of falling off at random (a 5% chance) when the player is on the bridge. The game has an additional quest of reaching a secret tomb. However, this is a complex quest that requires the player to memorize game events and perform high-level planning which are beyond the scope of this current work. Therefore, we focus only on the first quest.

From Figure 3 (bottom), we can see that the Random baseline does poorly in terms of both average per-episode reward[11] and quest completion rates. BOW-DQN converges to a much higher average reward of -12.68 and achieves around 82% quest completion. Again, the BOW-DQN is often confused by varying (10 different) descriptions of the portions of the bridge, which reflects in its erratic performance on the quest. The BI-DQN performs very well on quest completion by finishing 97% of quests. However, this model tends to find sub-optimal solutions and gets an average reward of -26.68, even worse than BOW-DQN. One reason for this is the negative rewards the agent obtains after falling off the bridge. The LSTM-DQN model again performs best, achieving an average reward of -11.33 and completing 96% of quests on average. Though this world does not contain descriptions adversarial to BOW-DQN or BI-DQN, the LSTM-DQN obtains higher average reward by completing the quest in fewer steps and showing more resilience to variations in the state descriptions.

Transfer Learning We would like the representations learnt by ϕ_R to be generic enough and *transferable* to new game worlds. To test this, we created a second Home world with the same rooms, but a completely different map, changing the locations of the rooms and the pathways between them. The main differentiating factor of this world from the original home world lies in the high-level planning required to complete quests.

We initialized the LSTM part of an LSTM-DQN agent with parameters θ_R learnt from the original home world and trained it on the new world.[12] Figure 3 (top right) demonstrates that the agent with transferred parameters is able to learn quicker than an agent starting from scratch initialized with random parameters (*No Transfer*), reaching the optimal policy almost 20 epochs earlier. This indicates that these simulated worlds can be used to learn good representations for language that transfer across worlds.

Prioritized sampling We also investigate the effects of different minibatch sampling procedures on the parameter learning. From Figure 3 (bottom right), we observe that using prioritized sampling significantly speeds up learning, with the agent achieving the optimal policy around 50 epochs faster than using uniform sampling. This shows promise for further research into different schemes of assigning priority to transitions.

Representation Analysis We analyzed the representations learnt by the LSTM-DQN model on the Home world. Figure 5 shows a visualization

[11] Note that the rewards graph is in log scale.

[12] The parameters for the Action Scorer (θ_A) are initialized randomly.

Description	Nearest neighbor
You are halfways out on the unstable bridge. From the castle you hear a distant howling sound, like that of a large dog or other beast.	The bridge slopes precariously where it extends westwards towards the lowest point - the center point of the hang bridge. You clasp the ropes firmly as the bridge sways and creaks under you.
The ruins opens up to the sky in a small open area, lined by columns. ... To the west is the gatehouse and entrance to the castle, whereas southwards the columns make way for a wide open courtyard.	The old gatehouse is near collapse. .... East the gatehouse leads out to a small open area surrounded by the remains of the castle. There is also a standing archway offering passage to a path along the old southern inner wall.

Table 2: Sample descriptions from the Fantasy world and their nearest neighbors (NN) according to their vector representations from the LSTM representation generator. The NNs are often descriptions of the same or similar (nearby) states in the game.

of learnt word embeddings, reduced to two dimensions using t-SNE (Van der Maaten and Hinton, 2008). All the vectors were initialized randomly before training. We can see that semantically similar words appear close together to form coherent subspaces. In fact, we observe four different subspaces, each for one type of room along with its corresponding object(s) and quest words. For instance, food items like *pizza* and rooms like *kitchen* are very close to the word *hungry* which appears in a quest description. This shows that the agent learns to form meaningful associations between the semantics of the quest and the environment. Table 2 shows some examples of descriptions from Fantasy world and their nearest neighbors using cosine similarity between their corresponding vector representations produced by LSTM-DQN. The model is able to correlate descriptions of the same (or similar) underlying states and project them onto nearby points in the representation subspace.

7 Conclusions

We address the task of end-to-end learning of control policies for text-based games. In these games, all interactions in the virtual world are through text and the underlying state is not observed. The resulting language variability makes such environments challenging for automatic game players. We employ a deep reinforcement learning framework to jointly learn state representations and action policies using game rewards as feedback. This framework enables us to map text descriptions into vector representations that capture the semantics of the game states. Our experiments demonstrate the importance of learning good representations of text in order to play these games well. Future directions include tackling high-level planning and strategy learning to improve the performance of intelligent agents.

Acknowledgements

We are grateful to the developers of Evennia, the game framework upon which this work is based. We also thank Nate Kushman, Clement Gehring, Gustavo Goretkin, members of MIT's NLP group and the anonymous EMNLP reviewers for insightful comments and feedback. T. Kulkarni was graciously supported by the Leventhal Fellowship. We would also like to acknowledge MIT's Center for Brains, Minds and Machines (CBMM) for support.

Distributional vectors encode referential attributes

Abstract

Distributional methods have proven to excel at capturing fuzzy, graded aspects of meaning (*Italy* is more similar to *Spain* than to *Germany*). In contrast, it is difficult to extract the values of more specific attributes of word referents from distributional representations, attributes of the kind typically found in structured knowledge bases (*Italy* has *60 million* inhabitants). In this paper, we pursue the hypothesis that distributional vectors also implicitly encode referential attributes.

We show that a standard supervised regression model is in fact sufficient to retrieve such attributes to a reasonable degree of accuracy: When evaluated on the prediction of both categorical and numeric attributes of countries and cities, the model consistently reduces baseline error by 30%, and is not far from the upper bound. Further analysis suggests that our model is able to "objectify" distributional representations for entities, anchoring them more firmly in the external world in measurable ways.

1 Introduction

Distributional models induce vector-based semantic representations of words from their contextual distributions in corpora, exploiting the observation that words with related meanings tend to occur in similar linguistic contexts (Turney and Pantel, 2010; Erk, 2012). Since the approach only requires raw text as input, it can be used to harvest word representations on a very large scale. By encoding the rich knowledge that is present in text, these representations are able to capture many aspects of word meaning. Moreover, approximating semantic similarity by graded geometric distance in a vector space is an effective strategy to address the many linguistic phenomena that are better characterized in gradient rather than discrete terms, such as synonymy, selectional preferences, and semantic priming (Baroni and Lenci, 2010; Erk et al., 2010; Padó and Lapata, 2007, among others).

However, not all aspects of human semantic knowledge are satisfactorily captured in terms of fuzzy relations and graded similarity. In particular, our knowledge of the meaning of words denoting specific entities involves a number of "hard facts" about the referents they denote that are best formalized as attribute-value pairs, of the sort that are stored in manually-curated knowledge bases, such as FreeBase or Wikidata.[1] While distributional vectors can capture the useful fact that, say, *Italy* is in many ways more similar to *Spain* than to *Germany*, as humans we also know (or we can easily look up) a set of objective facts about Italy, such as what is its capital, its area, its official language and GDP, that are difficult to express in the language of vector algebra and geometry.

In this paper, we explore the hypothesis that distributional vectors implicitly encode such attributes of referential entities, which we will call *referential attributes*. We show that a simple supervised algorithm applied to vectors can retrieve them so that they can be expressed in the explicit language of structured knowledge bases. Concretely, we train a logistic regression model to predict the values of both numeric and categorical FreeBase attributes of countries and cities from their distributional vectors. This model makes predictions that are significantly better than an informed baseline, in-between the latter and an upper-bound method. Qualitative analysis of the results points both to the inherent difficulty of correctly retrieving certain classes of attributes, and to some intriguing properties of the conceptual nature of the knowledge encoded in distributional data, that bias their predictions about certain objective attributes of geographic entities.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 12–21,
Lisbon, Portugal, 17-21 September 2015.

We see our experiment as a first step towards integrating conceptual and referential aspects of meaning in distributional semantics, as we further discuss in the conclusion.

2 Method

2.1 Distributional Representations

Mikolov et al.'s (2013) skip-gram model is a state-of-the-art "predictive" distributional semantic model which represents each word in a space of latent dimensions optimized to predict the contexts of the word's occurrences. For our study, we adopt the pre-trained 1,000-dimensional skip-gram model for Named Entities that is available at `https://code.google.com/p/word2vec/` and was produced from a 100-billion token news corpus. We refer to this model as WORD2VEC.

2.2 Referential Representations

As our source of referential attributes, we use FreeBase (see footnote 1), a knowledge base of structured information on a wide range of entities of different semantic types (people, geographical entities, etc.). The information in FreeBase comes from various sources, including Wikipedia and domain-specific databases, plus user content generation and correction. FreeBase currently records at least 2 attributes for over 47 million entities, and it has been used fairly extensively in NLP before (Mintz et al., 2009; Socher et al., 2013a, among others).

For each *entity*, FreeBase contains a list of *attribute-value* tuples (where values can in turn be entities, allowing a graph view of the data that we do not exploit here). Table 1 shows a sample of the attributes that FreeBase records for countries. Note that some attributes are simple (e.g., `date_founded`), while other can be called complex, in the sense that they are attributes of attributes (e.g., `geolocation::latitude`). We use a double-colon notation to refer to complex attributes. The values of all attributes can be either numeric or categorical. The numeric attributes in particular are often strongly correlated, both within attributes types across years (e.g., fertility rate in different years) and across attributes within years (e.g., absolute GDP and GDP per capita in a given year).

We built two datasets for our experiments, one for countries and one for cities, with data automatically extracted from FreeBase.[2] We consider two datasets in order to check that the mapping we seek can be established not just for one, possible hand-picked, type of entities; we leave it to future work to study very different kinds of entities, such as people or institutions.

Attribute	Value
`geolocation::latitude`	52.52
`geolocation::longitude`	13.38
`fertility_rate::1960`	2.37
`fertility_rate::1994`	1.24
`fertility_rate::2010`	1.39
`date_founded`	1871-01-18
`containedBy`	Western Europe
`containedBy`	Europe
`containedBy`	Eurasia
`adjectival_form`	German

Table 1: Sample of numeric and binary FreeBase attributes for *Germany*.

The *Countries* dataset consists of the 260 countries for which we have a distributional vector. Some countries do not exist anymore, like Yugoslavia, but, since this does not impact our method, we keep them in the dataset. The dataset records all simple attributes as well as complex attributes of at most two hops in the FreeBase graph, without manual inspection. We linearly rescale all numeric attributes to [0..1] and translate all categorical attributes into a binary representation by suffixing the original value to the original attribute name. For example, the attribute `member-of::organization` with the value `world_bank` results in a binary attribute `member-of::organization::world_bank` having value 1 for all and only those countries that are members of the World Bank, 0 for the others.[3] Attributes that occur less than 15 times are discarded, since they are either not consistently recorded or rare. This results in a total of 707 numeric and 247 binary attributes. Finally, we partition the data into training, validation, and test set, using a 60-20-20 percent split.

We apply the same process to the *Cities* dataset, which consists of 1645 cities from the intersection of the distributional and FreeBase city lists. In

[2]Both datasets are publicly available at `http://www.ims.uni-stuttgart.de/forschung/ressourcen/korpora/CityCountry.html`.

[3]We considered treating some categorical attributes as multi-valued, but decided against it since the cases in which alternative values are mutually exclusive are rare (e.g., the same country can be `containedBy` multiple entities, cf. Table 1).

this case, we have 211 numeric and 106 binary attributes – the numbers are smaller because countries have a richer representation in FreeBase than cities.

2.3 Attribute Prediction

We do zero-shot learning of full FreeBase attribute-based country/city representations, based on distributional (WORD2VEC) representations. It is zero-shot learning in the sense of Palatucci et al. (2009): We split the datasets at the entity, rather than attribute level, such that at test time our system must predict the full attribute set of countries and cities that were not seen during training at all.

We use logistic regression. In effect, we predict each output variable (FreeBase attribute) with an independent logistic regression model based on a constant set of input features (WORD2VEC distributional dimensions). We call this model DIST2REF. DIST2REF does *not* take advantage of the correlations between the output attributes mentioned in Section 2.2.

The dependent variables are binary as well as numeric FreeBase attributes, and our model does not distinguish between them. For binary attributes, we interpret the value returned by the model as the probability of "success" of a binary Bernoulli trial. In the numeric case, we view the probability returned by the model as directly representing normalized attribute values.

2.4 Experimental Setup

We design the model using the Countries dataset, and apply it to Cities without further tuning to test its robustness. We optimize the parameters with gradient descent, using the Cross Entropy error function. We considered L_2 regularization to address possible overfitting, but experiments on validation set showed that the model performs best without any regularization.

As for baselines, for binary features we predict the majority class (0 or 1), and for numeric features we predict the mean value of the feature in the training set. These are of course strong baselines to beat.

As an upper bound, we train a model that uses the same architecture as described above but uses as input not distributional vectors but the FreeBase attributes themselves. In other words, this model has to learn "only" an identity mapping. This is not trivial, though, for example due to the presence of strong correlations among attributes, in particular the time series attributes (cf. Section 2.2). We call this model REF2REF.

2.5 Evaluation

Since there is no appropriate unified evaluation measure that covers both numeric and binary attributes, we evaluate them separately. For binary attributes, we report the attributes' mean accuracy.

For numeric attributes, we consider attribute prediction a ranking task. As an example, take the `population::2011::number` attribute, and imagine that we only have three countries (Germany: 80M; Spain: 36M; and Netherlands: 17M). If we predict 56M for Spain's population, it is still (correctly) predicted as the second most populous country (rank difference of 0); a prediction of 16M, however, would push Spain to third place (rank difference of 1).

This suggests the use of rank correlation coefficients like Spearman's ρ. However, we want to measure not only how well the model can rank the countries in the test set, but also whether these predictions are consistent with the training set (which makes evaluation both more challenging and more realistic). One way of achieving this goal would be to use ρ on the union of training and test instances, but this could lead to misleadingly high correlation coefficients since this method would include the labels of the training instances in the evaluation.

Consequently, we define our own evaluation measure, following a rationale similar to Frome et al.'s (2013) evaluation of a zero-shot learning scenario. What we evaluate, for each attribute, is the rank of the test countries in the whole country list. Note that this makes our task harder, as there are more confounders: If we only evaluated on the test set, there would be shorter lists and therefore less chances of getting bad rankings. So, concretely, we first define the prediction quality of each attribute, $Q(a)$, as the median of the rank difference between the prediction and the gold standard in a list that includes both training and test countries (we use the median to give less weight to outlier countries). We also normalize the rank difference to obtain a number between zero and one. In a second step, we define the quality of the complete model, the *normalized rank score (NRS)*, as the mean of all attribute quality scores, in parallel to our evaluation on binary attributes.

Let the set of instances I be partitioned into training instances Tr and test instances Ts. Let $a \in A$

Attribute Type	Model	Countries	Cities
Binary (Acc)	Most Frequent Class Baseline	0.86	0.97
	DIST2REF	0.90	0.99
	REF2REF (upper bound)	0.96	1.00
Numeric (NRS)	Mean Value Baseline	0.35	0.35
	DIST2REF	0.22	0.25
	REF2REF (upper bound)	0.14	0.21

Table 2: Results for predicting FreeBase attributes from distributional vectors on the test sets. Both evaluation measures range between 0 and 1. For accuracy, 1 is best. For normalized rank score (NRS), 0 is best. All pairwise differences between models are significant ($p<0.001$, bootstrap resampling).

denote an attribute. We write $p_a(i)$ for the predicted value of attribute a for instance i and $g_a(i)$ for the gold standard value. Finally, let $r(v, S)$ denote the rank of value v in the list resulting when ordering the set S. Now we can define:

$$Q(a) = \frac{1}{||I||} med\{|r(p_a(i), I) - r(g_a(i), I)| - 1 \mid i \in Ts\} \quad (1)$$

$$NRS = \frac{1}{||A||} \sum_{a \in A} Q(a) \quad (2)$$

This measure can be interpreted similarly to Mean Reciprocal Rank (Manning et al., 2008): It has range [0..1], with smaller numbers indicating better ranking: 0.1, for example, means that, on average, the prediction is 10% of the ranks off (e.g., by four countries in a forty-country list).[4]

Note that, when evaluating each instance i, we use gold-standard values for all other instances, so that there the baseline is not hampered by ties.

3 Results

Table 2 shows the results of our experiments on the two test sets. For accuracy 1 is best, but for NRS 0 is best. Recall from Section 2.2 that we perform model selection on the Countries dataset only.

The baseline is relatively high, in particular for the binary attributes, many of which are positive for a small subset of entities only. The amount of skew differs considerably between the two datasets, though. For Countries, the baseline yields an accuracy of 0.86, but it achieves 0.97 on Cities. The increase stems from very sparse categorical City features such as `containedBy`, which includes all levels of administrative divisions – that is, for the US, all counties appear as values and are transformed into sparse binary features (cf. Section 2.2). Of course, the predictions of the baseline are useless, since it always predicts the absence of any features. On numeric features, where the baseline predicts the mean, its performance is 0.35 NRS on both datasets. In other words, its average prediction is off by about one third the length of the ranked list for each attribute.

Recall that the upper bound model, REF2REF, uses FreeBase attributes to predict FreeBase attributes. All it has to learn is that there is one feature in the input that corresponds ideally to the output. This works almost perfectly for binary attributes, with accuracy values of 0.96 (Countries) and 1.00 (Cities). However, its performance on numeric features (with NRS at 0.14 and 0.21, respectively) is not quite perfect. We attribute this to the presence of correlations (cf. Section 2.2).

The model whose performance we are actually interested in, DIST2REF, in which we map from distributional information to FreeBase features, performs with remarkable consistency between these two extremes. In fact, we see a consistent error reduction of around 30% over the baseline, with a similar distance to the upper bound. A significance test with bootstrap resampling (Efron and Tibshirani, 1994) showed that all pairwise comparisons (Baseline vs. DIST2REF, DIST2REF vs. REF2REF) are statistically significant at $p<0.001$.

To rule out that we misinterpret our accuracy-based evaluation for the binary features in the face of a highly skewed class distribution, we also computed precision, recall, and F-Score values. The relative patterns match those of the accuracy-based evaluation well (Countries: baseline F=0.13, DIST2REF F=0.51, REF2REF F=0.77) and indicate that generally precision is higher than recall.

[4] Subtracting 1 in Equation (1) ensures that, when the predicted and gold value of an attribute are adjacent in the ranking, their rank difference is 0, capturing the intuition of rank difference as counting the number of falsely intervening items.

We think that these are overall promising results, given that the FreeBase attributes we predict are fairly fine-grained, and we only use generic distributional information as input.

4 Analysis

We take the overall results just presented to suggest that we are able to learn referential attributes from distributional information to a large extent. In this section we take a closer look at what kind of information we are able to learn, what is beyond the scope of our model, and what are the differences between the entity representations in WORD2VEC and the ones our model produces. All the data concerns the test sets only.

4.1 Attribute Groups

We start with a qualitative analysis of the Countries dataset. Due to the large number of attributes, we sort all individual attributes into *attribute groups* by their base name (i.e. the leftmost component of their name, cf. Section 2.2), which offers an accessible level of granularity for inspection. We obtain 34 numeric and 40 binary attribute groups with median sizes of 8.5 and 2 attributes per group, respectively.

Table 3 shows the attribute groups for both types sorted by quality. For each group, we report average normalized rank score (NRS) and accuracy, respectively, for both DIST2REF and the baseline.

The analysis suggests that there are two main factors that account for the results: (1) The degree to which an attribute is *contextually supported*, that is, to what extent its values can be identified on the basis of the contextual information that is captured in a distributional model, and (2) general properties of the data that affect Machine Learning, most notably data sparseness, possibly also feature value distributions.

Attributes that are contextually supported include for instance those related to socioeconomic development (see below for details); people talk (and so write) about countries being more or less developed, rich, having one or another kind of laws, and this is captured in the abstractions over textual context that distributional models perform. As an extreme example of an attribute that is *not* contextually supported, consider the numeric ISO code of a country (`iso_numeric`), whose values are arbitrary: They do not correspond to facts about the world that are reflected in the way people use language, and so can't be picked up by the distributional model. For this reason, DIST2REF does worse than the baseline.

Note that, in a sufficiently large corpus, we might indeed encounter statements like *The numeric ISO code for Spain is 724*. However, since distributional models represent words as *aggregated* distributions of their contexts, and compute semantic similarity from these context distributions, the contexts that they use need to be generic enough to yield meaningful overlap between concepts (e.g., words). As a result, distributional models cannot easily represent knowledge of the form "the value for property Y of word/concept X is Z".

Fortunately, we find that many FreeBase attributes are contextually supported to a substantial degree, even some seemingly arbitrary ones. An example is calling codes, which we predict very well. They turn out to be correlated with geolocations: 2X calling codes are located in Africa, 3X calling codes in Southern and Eastern Europe and 4X calling codes in Western and Northern Europe (for comparison, ISO codes are assigned in a roughly alphabetical order).

Numeric Attributes. Our best numeric attributes belong to the `geolocation` group (latitude and longitude). We provide a more detailed analysis of these attributes below (Section 4.2). As mentioned above, we also excel at many attributes related to a country's economic and social development (broadly construed), such as GNI, GDP, CO_2 emissions, internet usage (each per capita), or fertility rate. These attributes can be expected to be contextually grounded – e.g., Luxembourg will occur with contexts like "broadband" or "rich" more than India.

Note, however, that the information contained in the vectors is surprisingly subtle: For instance, the fertility rate is a function of both general development status (lower rates in more developed countries) and of specific social factors (higher rates in countries with more support for families, such as France and Finland compared countries with less support, such as Germany or Italy).

Around the middle of the table, we find the absolute versions of the developmental cluster above (GNI in $, real and nominal GDP). Evidently, the absolute versions of these attributes are substantially less contextually supported than the relative versions. This is not surprising: While India and China have high absolute GDPs because they are

Numeric Attributes (Normalized Rank Score: lower is better)					Binary Attributes (Accuracy: higher is better)

Table 3: Results for all attribute groups on the Countries test set, in descending order of performance. DIST2REF, BL: models; **#A**: number of attributes in group; **f(A)**: median number of countries instantiating each attribute in the dataset (260 countries); **!**: attribute group where model performs worse than baseline.

large countries, and for instance Luxembourg has a much smaller one, these numbers are not indicative of the actual conditions in these countries, and therefore also not so clearly correlated with what people write about them. This provides another interesting angle on the difference between distributional and formal knowledge representation. In a formal system, absolute GDP, relative GDP, and population stand in a fixed linear relationship and knowing any two of the three uniquely determines the third – thus, all three attributes have equal status. In our distributional space, their status is clearly different, determined by the conceptual relevance of the different attributes.

Towards the end of the table, we find more attributes related to socioeconomic development, such as `government_percent_debt` and `minimum_wage`. While these should be contextually supported, too, the problem here is factor (2) mentioned above, namely severe data sparsity (see column **f(A)** in Table 3, which lists the median number of datapoints that exhibit each attribute group). The same goes for the remaining attribute groups, for instance `casualties` (describing the

total number of military casualties incurred in history), date_founded and date_dissolved,[5] or climate_avg_rainfall.

Binary Attributes. The binary attributes show a similar picture, albeit somewhat less sharp. We again find contextually unsupported groups, many of them arising from our fully automatic attribute mining from FreeBase (cf. Section 2.2). There are many categorical attributes that store metadata about numeric attributes (such as the currency in the gdp and gni groups) as well as meta-information of FreeBase: exceptions is a specific marker of potentially inconsistent entries about Ghana, and equivalent_instances is a flag concerning links between FreeBase and OpenCyc. Fortunately, almost all contextually unsupported groups are small, with only one or two attributes, and do not have a large impact on the overall performance. We decided not to exclude them from evaluation for robustness' sake, since there is no automatic way to identify contextually unsupported attributes in a new dataset.

We obtain good results on meaningful attributes that are arguably strongly contextually grounded, such as geographical and geopolitical attributes (member_of: membership in international organizations; location on a continent, etc.). However, we fare relatively badly on government-related attributes (form of government, governing officials). While this seems surprising at first glance, the form_of_government attribute in FreeBase makes very fine-grained distinctions: Its values include "unitary state", "presidential system", "parliamentary system" and "republic", which are not mutually exclusive, and misses obvious alternatives like "authoritarian system". It is not surprising that distributional models cannot make such subtle distinction between presidential and parliamentary systems. The attribute governing_official presents a similar case. Other bad attributes are very domain-specific, including athletes, encoding the athletic disciplines that countries participate in (such as swimming, judo, running, etc.), and the data sparsity issue is certainly worse for the binary attributes.

[5]Note that date-based attributes can be contextually supported: We do better on national_anthem_since, for which we have more datapoints, 97.

Model	Countries	Cities
WORD2VEC	-0.36	-0.45
DIST2REF	0.49	0.88

Table 4: Pearson correlation coefficients of model-predicted vs. ground truth distances between countries and cities in the test sets. WORD2VEC correlations are negative because we use cosines.

4.2 Geolocation

To analyze the difference between the distributional representations and the output of our model, we focus on geolocation, our best attribute group.

It has already been shown that geometric distance in distributional space captures, to a certain extent, physical distance between locations in the real world (Louwerse and Zwaan, 2009). Table 4 shows that DIST2REF extracts even more precise distance information from distributional vectors. The table reports the correlation between real and model-predicted distances for countries and cities. Ground-truth *great circle distances* (Kern and Bland, 1948) between items are computed using the FreeBase longitude and latitude values; for DIST2REF we use its predicted latitude and longitude values; for WORD2VEC, the cosines between the corresponding distributional vectors.

We obtain highly significant correlations in all cases ($p<10^{-14}$), but much higher for DIST2REF. For countries, as shown in Table 4, the correlation is -0.36 for WORD2VEC (negative, because cosine is a *similarity* measure), 0.49 for DIST2REF. For cities, WORD2VEC reaches -0.45 correlation, and DIST2REF distances are at 0.88, showing that the method can estimate city positions to a perhaps unexpectedly high degree of accuracy.[6]

This result suggests that we manage to objectify the information in the distributional model, anchoring the entities more firmly in the external world. Indeed, distributional models are known to be subject to conceptual or cultural effects in their distance estimations. For instance, in WORD2VEC German and Spanish cities are much farther away than in the physical world, while cities within Spain and within Germany are predicted to be a bit closer than they actually are. Note that these effects have

[6]The results are confirmed when the analysis is repeated using the Spearman correlation measure: The DIST2REF coefficients are stable, whereas those of WORD2VEC go down to 0.22 (countries) and 0.40 (cities), respectively. The good results for Spearman, as a rank-based measure, indicate that our success is not dominated by outliers.

an actual cognitive basis: Human intuitions about objective physical distance between countries and cities are biased by cognitive, cultural and socio-economic factors, as explored for example in Friedman et al. (2002), who report that Texans locate Canadian cities closer to the US border relative to Mexican cities, despite their proximity to the latter, and that they place Southern US cities further south than they really are.

Interestingly, DIST2REF does also show some cultural effects in its geolocation errors: For example, some Pacific island states with lesser-known identities (e.g., Nauru and French Polynesia) are placed in the Indian Ocean, where we find the perhaps prototypes of beautiful islands, like Seychelles and Mauritius; also, Central American countries (such as Panama, El Salvador, and Nicaragua) move towards their "cultural center of gravity", South America.

However, this kind of cultural bias is much more prominent in the original WORD2VEC distributional representation. The Spain/Germany effect discussed above is not found in the DIST2REF model at all. And while both DIST2REF and WORD2VEC place Mexican and Spanish cities in our test set closer to each other than they actually are, WORD2VEC does so to a much larger extent. In line with our goal to extract referential attributes, thus, we are satisfied to see that DIST2REF manages to minimize this bias and distill the referential part from the distributional representations.

5 Related Work

There is a large literature on exploiting corpus evidence, sometimes through distributional semantic methods, in order to construct and populate structured knowledge bases (KBs) (e.g., Buitelaar and Cimiano (2008) and references therein). This line of work, however, does not attempt to *connect* entity representations extracted from corpora and from KBs, as we do. Moreover, it focuses on harvesting relations between entities or between entities and a limited number of discrete attributes, rather than predicting full-fledged KB representations of specific entities, like we do. Freitas and Curry (2014) and Freitas et al. (2014) embed relational graphs from KBs in a distributional semantic space to support various forms of search and reasoning about the KB. The focus is again on relations between discrete entities, and on exploiting distributional semantics to navigate among them.

Socher et al. (2013a) represent WordNet and FreeBase entities with corpus-based distributional vectors. They train a tensor for each relation of interest to return high scores when combined with the vectors of two entities that hold the intended relation. At test time, the system is used to classify relational tuples as true or false, as well as to predict new entities that hold a certain relationship with a target entity. This is quite close in spirit to what we do, except that, given an *entity1-relation-entity2* tuple, we treat *relation-entity2* as a binary attribute of *entity1*, and we try to induce such attributes on a larger scale (Socher et al. consider seven relations in total). Moreover, we rely on the same architecture to learn discrete features denoting relations with entities and numerical features, to induce full attribute-based descriptions of entities.

Our proposal is only distantly related to methods to embed words tokens and KB entities and relationships in a vector space, e.g., for better relation extraction (see Weston et al. (2013) and references therein). This line of work does not use distributional semantics to induce word vectors, and ignores numerical attributes.

The broader goal of getting at referential information with distributional semantics is shared with Herbelot (2015). However, the specific approach is different, as she constructs vectors for individual entities (literary characters) by contextualizing generic noun vectors with distributional properties of those entities. Finally, we share our methodology with work on mapping between corpus-based word representations and other representational spaces, such as subject-generated concept properties (Johns and Jones, 2012; Hill et al., 2014; Făgărăşan et al., 2015), visual features (Frome et al., 2013; Socher et al., 2013b; Lazaridou et al., 2014) or brain signals (Mitchell et al., 2008; Murphy et al., 2012). In all these settings, the focus is entirely on predicting numerical attributes, whereas we treat both numerical and binary attributes. Rubinstein et al. (2015) use distributional vectors to predict binary conceptual attributes of common nouns, as well as a continuous score measuring saliency of such attributes. Our target features are conceptually very different from those of all these studies.

6 Discussion and Conclusion

We have shown that a simple model can learn to predict, to a reasonable degree of accuracy, ref-

erential attributes of an entity that are typically seen in a knowledge base from the corresponding corpus-based distributional representation. The results suggest that, while distributional semantic vectors can be used "as-is" to capture generic word similarity, with some supervision it is also possible to extract other kinds of information from them, including structured factual statements of the sort encoded in manually-curated knowledge bases. This makes distributional vectors very attractive as general-purpose word meaning representations.

We have also shown that some of the errors in the predictions can be explained on cultural grounds, but that these effects are more pronounced in the input of our model, a standard distributional semantic model, than in its output. In this sense, our model manages to objectify the information that it is provided with. Our analyses also suggest that the main limiting factor in learning referential attributes, apart from good old data sparseness, is the degree to which they are *contextually supported*, that is, to what extent they are expressed with consistent and specific linguistic means in the context of their target words. This determines whether they are actually represented in the distributional model in the first place.

More generally, we see our work as a small step towards the more general goal of bridging the concept-referent gap in distributional semantics. A common noun such as *dog* denotes a *concept*, based on a prototype with fuzzy boundaries, susceptible of metaphorical extensions, and bearing all the other hallmarks of generic conceptual knowledge (Carlson, 2009; Murphy, 2002). These might be adequately captured by the properties of the *dog* vector in distributional semantic space. However, when used in a specific discourse, words and more complex linguistic expressions often denote specific *referents* with fixed, "hard" properties, such as *this dog*, or *Amur*, when used for my neighbor's dog at 3.31pm on May 29th 2015 in Novosibirsk, a 61cm-tall black-and-tan foxhound. Amur is more easily characterized by a set of precise attribute-value pairs than by a vector in a generic conceptual space. Our experiment suggests that distributional vectors encode both generic conceptual knowledge and more precise attributes of specific referents. Of course, while we can use FreeBase and other knowledge bases to gather training data about public-domain entities, such as countries or cities, it is still not clear where we could gather appropriate training data to learn about the specific properties of "private-discourse" referents such as Amur. Moreover, it remains to be seen whether the properties of common named entities, such as countries and cities, that are in a sense "hybrid" between the conceptual and referential domains, also transfer to entities of a more specific and private kind. Finally, it is still not clear how to extend the current approach beyond words and phrases directly denoting an entity (*Amur*) to other kinds of definite descriptions (*this dog*).

Abstract

In this paper, we introduce an approach to automatically map a standard distributional semantic space onto a set-theoretic model. We predict that there is a functional relationship between distributional information and vectorial concept representations in which dimensions are predicates and weights are generalised quantifiers. In order to test our prediction, we learn a model of such relationship over a publicly available dataset of feature norms annotated with natural language quantifiers. Our initial experimental results show that, at least for domain-specific data, we can indeed map between formalisms, and generate high-quality vector representations which encapsulate set overlap information. We further investigate the generation of natural language quantifiers from such vectors.

1 Introduction

In recent years, the complementarity of distributional and formal semantics has become increasingly evident. While distributional semantics (Turney and Pantel, 2010; Clark, 2012; Erk, 2012) has proved very successful in modelling lexical effects such as graded similarity and polysemy, it clearly has difficulties accounting for logical phenomena which are well covered by model-theoretic semantics (Grefenstette, 2013).

A number of proposals have emerged from these considerations, suggesting that an overarching semantics integrating both distributional and formal aspects would be desirable (Coecke et al., 2011; Bernardi et al., 2013; Grefenstette, 2013; Baroni et al., 2014a; Garrette et al., 2013; Beltagy et al., 2013; Lewis and Steedman, 2013). We will use the term 'Formal Distributional Semantics' (FDS) to refer to such proposals. This paper follows this line of work, focusing on one central question: the formalisation of the systematic dependencies between lexical and set-theoretic levels.

Let us consider the following examples.

1. Kim writes books.
2. Kim likes books.

The preferred reading of 1 has a logical form where the object is treated as an existential, while the object in 2 has a generic reading:

- $\exists x^*[book'(x^*) \wedge write'(Kim, x^*)]$
- $GEN\, x[book'(x) \rightarrow like'(Kim, x)]$

with x^* indicating a plurality and GEN the generic quantifier.

It is generally accepted that the appropriate choice of quantifier for an ambiguous bare plural object depends, amongst other things, on the lexical semantics of the verb (e.g. Glasbey (2006)). This type of interaction implies the existence of systematic influences of the lexicon over logic, which could in principle be formalised.

A model of the lexicon/logic interface would be desirable to explain how speakers resolve standard cases of ambiguity like the bare plural in 1 and 2, but more generally, it could be the basis for answering a more fundamental question: how do speakers construct a model of a sentence for which they have no prior perceptual data?

People can make complex inferences about statements without having access to their real-world reference. As an example, consider the sentence *The kouprey is a mammal*. English speakers have no problem ascertaining that if x is a kouprey, x is a mammal (which set-theoretic semantics would express as $\forall x[kouprey'(x) \rightarrow mammal'(x)]$), regardless of whether they have ever encountered a kouprey. The inference is supported by the lexical semantics of *mammal*, which applies a property (being a mammal) to *all* instances of a class. Much more complex inferences are routinely performed by speakers, down to estimating the cardinality of the entities involved in a particular situation. Compare e.g. *The cats are on the sofa* (2 / a few cats?), *I picked pears today* (a few / a few dozen?) and *The protesters were blocking the entire avenue* (hundreds/thousands of protesters?).

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 22–32,
Lisbon, Portugal, 17-21 September 2015.

Understanding how this process works would not only give us an insight into a complex cognitive process, but also make a crucial contribution to NLP tasks relying on inference (e.g. the Recognising Textual Entailment challenge, RTE: Dagan et al. (2009)). Indeed, while systems have successfully been developed to model entailment between quantifiers, ranging from natural logic approaches (MacCartney and Manning, 2008) to distributional semantics solutions (Baroni et al., 2012), they rely on an explicit representation of quantification. That is, they can model the entailment *All koupreys are mammals* $\models$ *This kouprey is a mammal*, but not *Koupreys are mammals* $\models$ *This kouprey is a mammal*.

In this work, we assume the existence of a mapping between language (distributional models) and world (set-theoretic models), or to be more precise, between language and a shared set of beliefs about the world, as negotiated by a group of speakers. To operationalise this mapping, we propose that set-theoretic models, like distributions, can be expressed in terms of vectors – giving us a common representation across formalisms. Using a publicly available dataset of feature norms annotated with quantifiers[1] (Herbelot and Vecchi, 2015), we show that human-like intuitions about the quantification of simple subject/predicate pairs can be induced from standard distributional data.

This paper is structured as follows. §2 reviews related work, focusing in turn on approaches to formal distributional semantics, computational work on quantification, and mapping between semantic spaces. In §3, we describe our dataset. §4 and §5 describe our experiments, reporting correlation against human annotations. We discuss our results in §6 and end with an attempt at generating natural language quantifiers from our mapped vectors (§7).

2 Related Work

2.1 Formal Distributional Semantics

The relation between distributional and formal semantics has been the object of a number of studies in recent years. Proposals for a FDS, i.e. a combination of both formalisms, roughly fall into two groups: a) the fully distributional approaches, which redefine the concepts of formal semantics in distributional terms (Coecke et al., 2011; Bernardi et al., 2013; Grefenstette, 2013; Hermann et al., 2013; Baroni et al., 2014a; Clarke, 2012); b) the hybrid approaches, which try to keep the set-theoretic apparatus for function words and integrate distributions as content words representations (Erk, 2013; Garrette et al., 2013; Beltagy et al., 2013; Lewis and Steedman, 2013). This paper follows the hybrid frameworks in that we fully preserve the principles of set theory and do not attempt to give a distributional interpretation to phenomena traditionally catered for by formal semantics such as quantification or negation.

Our account is also similar to that proposed by Erk (2015). Erk suggests that distributional data influences semantic 'knowledge'[2]: specifically, while a speaker may not know the extension of the word *alligator*, they maintain an information state which models properties of alligators (for instance, that they are animals). This information state is described in terms of probabilistic logic, which accounts for an agent's uncertainty about what the world is like. The probability of a sentence is the summed probability of the possible worlds that make it true. Similarly, we assume a systematic relation between distributional information and world knowledge, expressed set-theoretically. The knowledge representation we derive is not a model proper: it cannot be said to be a description of a world – either the real one or a speaker's set of beliefs (c.f. §4 for more details). But it is a good approximation of the shared intuitions people have about the world, in the way that distributional representations are an averaged representation of how a group of speakers use their language.

2.2 Generalised quantifiers

Computational semantics has traditionally focused on very specific aspects of quantification. There is a large literature on the computational formalisation of quantifiers as automata, starting with Van Benthem (1986). In parallel to this work, much research has been done on drawing inferences from explicitly quantified statements – i.e. statements quantified with determiners such as *some/most/all*, which give information about the set overlap of a subject-predicate pair (Cooper et al., 1996; Alshawi and Crouch, 1992; MacCartney and Manning, 2008). Recent work in this area has even shown that entailment between explicit quantifiers can be modelled distributionally (Baroni et al., 2012). A complementary object of focus, actively pursued in the 1990s, has been inference between generic statements (Bacchus, 1989; Vogel, 1995).

Beside those efforts, computational approaches have been developed to convert arbitrary text into logical forms. The techniques range from completely supervised (Baldwin et al., 2004; Bos, 2008) to lightly supervised (Zettlemoyer and Collins, 2005). Such work has shown that it was possible to automatically give complex formal semantics analyses to large amounts of data. But the formalisation of quantifiers in those systems either remains very much underspecified (e.g. bare plurals are not resolved into either existentials or generics) or relies on some grounded information, for example in the form of a database.

To the best of our knowledge, no existing system is able to universally predict the generalised quantification of noun phrases, including those introduced by the (in)definite singulars *a/the* and definite plurals *the*. The closest attempt is Herbelot (2013), who suggests that

[1] Data available at `http://www.cl.cam.ac.uk/~ah433/mcrae-quantified-majority.txt`

[2] We use the term *knowledge* loosely, to refer to a speaker's beliefs about the world or a state of affairs.

Table 1: Example annotations for concepts.

'model-theoretic vectors' can be built out of distributional vectors supplemented with manually annotated training data. The proposed implementation, however, fails to validate the theory.

Our work follows the intuition that distributions can be translated into set-theoretic equivalents. But it implements the mapping as a systematic linear transformation. Our approach is similar to Gupta et al. (2015), who predict numerical attributes for unseen concepts (countries and cities) from distributional vectors, getting comparably accurate estimates for features such as the GDP or CO_2 emissions of a country. We complement such research by providing a more formal interpretation of the mapping between language and world knowledge. In particular, we offer a) a vectorial representation of set-theoretic models; b) a mechanism for predicting the application of generalised quantifiers to the sets in a model.

2.3 Mapping between Semantic Spaces

The mapping between different semantic modalities or semantic spaces has been explored in various aspects. In cognitive science, research by Riordan and Jones (2011) and Andrews et al. (2009) show that models that map between and integrate perceptual and linguistic information perform better at fitting human semantic intuition. In NLP, Mikolov et al. (2013b) show that a linear mapping between vector spaces of different languages can be learned to infer missing dictionary entries by relying on a small amount of bilingual information. Frome et al. (2013) learn a linear regression to transform vector-based image representations onto vectors representing the same concepts in a linguistic semantic space, and Lazaridou et al. (2014) explore mapping techniques to learn a cross-modal mapping between text and images with promising performance. We follow the basic intuition introduced by these previous studies: a simple linear function can map between semantic spaces, in this case between a linguistic (distributional) semantic space and a model-theoretic space.

3 Annotated datasets

3.1 The quantified McRae norms

The McRae norms (McRae et al., 2005) are a set of feature norms elicited from 725 human participants for 541 concepts covering living and non-living entities (e.g. alligator, chair, accordion). The annotators were given concepts and asked to provide features for them, covering physical, functional and other properties. The result is a set of 7257 concept-feature pairs such as *airplane used-for-passengers* or *bear is-brown*.

In our work, we use the annotation layer produced by Herbelot and Vecchi (2015) for the McRae norms (henceforth QMR): for each concept-feature pair (C, f), the annotation provides a natural language quantifier expressing the ratio of instances of C having the feature f, as elicited by three coders. The quantifiers in use are NO, FEW, SOME, MOST, ALL. Table 1 provides example annotations for concept-feature pairs (reproduced from the original paper). An additional label, KIND, was introduced for usages of the concept as a kind, where quantification does not apply (e.g. *beaver symbol-of-Canada*). A subset of the annotation layer is available for training computational models, corresponding to all instances with a majority label (i.e. those where two or three coders agreed on a label). The reported average weighted Cohen kappa on this data is $\kappa = 0.59$.

In the following, we use a derived gold standard including all 5 quantified classes in QMR (removing the KIND items), with the annotation set to majority opinion (6156 instances). The natural language quantifiers are converted to a numerical format (see §4 for details). Using the numerical data, we can calculate the mean Spearman rank correlation between the three annotators, which comes to 0.63.

3.2 Additional animal data

QMR gives us an average of 11 features per concept. This results in fairly sparse vectors in the model-theoretic semantic space (see §4). In order to remedy data sparsity, we consider the use of additional data in the form of the animal dataset from Herbelot (2013) (henceforth AD). AD[3] is a set of 72 animal concepts with quantification annotations along 54 features. The main differences between QMR and AD are as follows:

- Nature of features: the features in AD are not human elicited norms, but linguistic predicates obtained from a corpus analysis.
- Comprehensiveness of annotation: the 72 concepts were annotated along all 54 features. This ensures the availability of a large number of negatively quantified pairs (e.g. *cat is-fish*).

We manually align the AD concepts and features to the QMR format, changing e.g. *bat* to *bat_(animal)*. The QMR and AD sets have an overlap of 39 concepts and 33 features.

[3]Data available at `http://www.cl.cam.ac.uk/~ah433/material/herbelot_iwcs13_data.txt`.

4 Semantic spaces

We construct two distinct semantic spaces (distributional and model-theoretic), as described below.

4.1 The distributional semantic space

We consider two distributional semantic space architectures which have each shown to have considerable success in a number of semantic tasks. First, we build a co-occurrence based space ($\mathbf{DS}_{cooc}$), in which a word is represented by co-occurrence counts with content words (nouns, verbs, adjectives and adverbs). As a source corpus, we use a concatenation of the ukWaC, a 2009 dump of the English Wikipedia and the BNC[4], which consists of about 2.8 billion tokens. We select the top 10K content words for the contexts, using a bag-of-words approach and counting co-occurrences within a sentence. We then apply positive Pointwise Mutual Information to the raw counts, and reduce the dimensions to 300 through Singular Value Decomposition.[5]

Next we consider the context-predicting vectors ($\mathbf{DS}_{Mikolov}$) available as part of the word2vec[6] project (Mikolov et al., 2013a). We use the publicly available vectors which were trained on a Google News dataset of circa 100 billion tokens. Baroni et al. (2014b) showed that vectors constructed under this architecture outperform the classic count-based approaches across many semantic tasks, and we therefore explore this option as a valid distributional representation of a word's semantics.

4.2 The model-theoretic space

Our 'model-theoretic space' differs in a couple of important respects from traditional formal semantics models. So it may be helpful to first come back to the standard definition of a model, which relies on two components: an ontology and a denotation function (Cann, 1993). The ontology describes a world (which can be a simple situation or 'state of affairs'), with everything that is contained in that world. Ontologies can be represented in various ways, but in this paper, we assume they are formalised in terms of *sets* of entities. The denotation function associates words with their *extensions* in the model, i.e. the sets they refer to. Thanks to the availability of the ontology, it is possible to define a truth function for sentences, which computes whether a particular statement corresponds to the model or not.

In our account, we do not have an *a priori* model of the world: we wish to infer it from our observation of language data. We believe this to be an advantage over traditional formal semantics, which requires full ontological data to be available in order to account for reference and truth conditions, but never spells out how this data comes into being. This however implies that our produced ontology will necessarily be partial: we can only model what can be inferred from language use. This has consequences for the denotation function.

Let's imagine a world with three cats and two horses. In model theory, the word *horse* has an extension in that world which is the set of horses, with a cardinality of two. This can be trivially derived because the world is fully described in the ontology. In our approach, however, it is unlikely we might be able to learn the cardinality of *any* set in *any* world. And in fact, it is clear that 'in real life', speakers do miss this information for many sets (how many horses are there in the world?) Note that we do not in principle reject the possibility to learn cardinalities from distributional data (for an example of this, see Gupta et al. (2015)). We simply remark that this will not always possible, or even desirable from a cognitive point of view. By extension, this means that a model built from distributional data does not support denotation in the standard way, and thus precludes the definition of a truth function: we cannot verify the truth of the sentence *There are 25,957 white horses in the world*. Our 'model-theoretic' space may then be described as an underspecified set-theoretic representation of some shared beliefs about the world.

Our 'ontology' can be defined as follows. To each word w_k in vocabulary $V = w_{1...m}$ corresponds a set w'_k with underspecified cardinality. A number of predicates $p'_{1...n}$ are similarly defined as sets with an unknown number of elements. Our claim is that this very underspecified model can be further specified by learning a function F from distributions to generalised quantifiers. Specifically, $F(\vec{w_k}) = \{Q_1(w'_k, p'_1), Q_2(w'_k, p'_2)...Q_n(w'_k, p'_n)\}$, where $\vec{w_k}$ is the distribution of w_k and $Q_1...Q_n \in \{no, few, some, most, all\}$. That is, F takes a distribution $\vec{w_k}$ and returns a quantifier for each predicate in the model, corresponding to the set overlap between w'_k and $p'_{1...n}$. Note that we focus here on 5 quantifiers only, but as mentioned above, we do not preclude the possibility of learning others (including cardinals in appropriate cases).

$F(\vec{w_k})$ lives in a model-theoretic space which broadly follows the representation suggested by Herbelot (2013). We assume a space with n dimensions $d_1...d_n$ which correspond to predicates $p'_{1...n}$ (e.g. *is fluffy*, *used for transportation*). In that space, $F(\vec{w_k})$ is weighted along the dimension d_m in proportion to the set overlap $w'_k \cap p'_m$.[7] The following shows a toy vector with only four dimensions for the concept *horse*.

a_mammal	1
has_four_legs	0.95
is_brown	0.35
is_scaly	0

[4] `http://wacky.sslmit.unibo.it`, `http://www.natcorp.ox.ac.uk`

[5] All semantic spaces, both distributional and model-theoretic, were built using the DISSECT toolkit (Dinu et al., 2013).

[6] `https://code.google.com/p/word2vec`

[7] In Herbelot (2013), weights are taken to be probabilities, but we prefer to talk of quantifiers, as the notion models our data more directly.

This vector tells us that the set of horses includes the set of mammals (the number of horses that are also mammals divided by the number of horses comes to 1, i.e. *all horses are mammals*), and that the set of horses and the set of things that are scaly are disjoint (*no horse is scaly*). We also learn that a great majority of horses have four legs and that some are brown.

In the following, we experiment with 3 model-theoretic spaces built from the McRae and AD datasets described in §3. As both datasets are annotated with natural language quantifiers rather than cardinality ratios, we convert the annotation into a numerical format, where ALL → 1, MOST → 0.95, SOME → 0.35, FEW → 0.05, and NO → 0. These values correspond to the weights giving the best inter-annotator agreement in Herbelot and Vecchi (2015), when calculating weighted Cohen's kappa on QMR.

In each model-theoretic space, a concept is represented as a vector in which the dimensions are features (*has_buttons, is_green*), and the values of the vectors along each dimension are quantifiers (in numerical format). When a feature does not occur with a concept in QMR, the concept's vector receives a weight of 0 on the corresponding dimension.[8] We define 3 spaces as follows. The McRae-based model-theoretic space (**MT**$_{QMR}$) contains 541 concepts, as described in §3.1. The second space is constructed specifically for the additional animal data from §3.2 (**MT**$_{AD}$). Finally, we merge the two into a single space of 555 unique concepts (**MT**$_{QMR+AD}$).

5 Experiments

5.1 Experimental setup

To map from one semantic representation to another, we learn a function f: **DS** → **MT** that transforms a distributional semantic vector for a concept to its model-theoretic equivalent.

Following previous research showing that similarities amongst word representations can be maintained within linear transformations (Mikolov et al., 2013b; Frome et al., 2013), we learn the mapping as a linear relationship between the distributional representation of a word and its model-theoretic representation. We estimate the coefficients of the function using (multivariate) partial least squares regression (PLSR) as implemented in the R pls package (Mevik and Wehrens, 2007).

We learn a function from the distributional space to each of the model-theoretic spaces (c.f. §4). The distribution of training and test items is outlined in Table 2, expressed as a number of concept vectors. We also include the number of quantified instances in the test set (i.e. the number of actual concept-feature pairs that were explicitly annotated in QMR/AD and that we can thus evaluate – this is a portion of each concept vector in the spaces including QMR data).

Space	*# train vec.*	*# test vec.*	*# dims*	*# test inst.*
MT$_{QMR}$	400	141	2172	1570
MT$_{AD}$	60	12	54	648
MT$_{QMR+AD}$	410	145	2193	1595

Table 2: Distribution of training/test items for each model-theoretic semantic space. We also provide the number of dimensions for each space, and the actual number of concept-feature instances tested on.

5.2 Results

We first consider a preliminary quantitative analysis to better understand the behavior of the transformations, while a more qualitative analysis is provided in §6. The results in Table 3 show the degree to which predicted values for each dimension in a model-theoretic space correlate with the gold annotations, operationalised as the Spearman ρ (rank-order correlation). Wherever appropriate, we also report the mean Spearman correlation between the three human annotators for the particular test set under consideration, showing how much they agreed on their judgements.[9] These figures provide an upper bound performance for the system, i.e. we will consider having reached human performance if the correlation between system and gold standard is in the same range as the agreement between humans. For each mapping tested, Table 3 provides details about the training data used to learn the mapping function and the test data for the respective results. Also for each mapping, results are reported when learned from either the co-occurrence distributional space (DS$_{cooc}$) or the context-predicting distributional space (DS$_{Mikolov}$).

The top section of the table reports results for the QMR and AD dataset taken separately, as well as their concatenation. Performance on the domain-specific AD is very promising, at 0.641 correlation, calculated over 648 test instances. The results when trained on just the QMR features (MT$_{QMR}$) are much lower (0.35 over 1570 test instances), which we put down to the wider variety of concepts in that dataset; we however observe a substantial increase in performance when we train and test over the two datasets (MT$_{QMR+AD}$: 0.569 over 1595 instances).

We investigate whether merging the datasets generally benefits QMR concepts or just the animals (see middle section in Table 3). The result on the MT$_{animals}$ test set, which includes animals from the AD and QMR datasets, shows that this category fares indeed very well, at $\rho = 0.663$. But while augmenting the training data with category-specific datapoints benefits that category, it does not improve the results

[8] No transformations or dimensionality reductions were performed on the MT spaces.

[9] These figures are only available for the QMR dataset, as AD only contains one annotation per subject-predicate pair.

Model-Theoretic		*Distributional*		
train	*test*	DS_{cooc}	$DS_{Mikolov}$	*human*
MT_{QMR}	MT_{QMR}	0.350	0.346	0.624
MT_{AD}	MT_{AD}	**0.641**	0.634	–
MT_{QMR+AD}	MT_{QMR+AD}	0.569	0.523	–
MT_{QMR+AD}	$MT_{animals}$	**0.663**	0.612	–
MT_{QMR+AD}	$MT_{no\text{-}animals}$	0.353	0.341	–
MT_{QMR}	$MT_{QMR^{animals}}$	0.419	0.405	–
MT_{QMR+AD}	$MT_{QMR^{animals}}$	**0.666**	0.600	0.663

Table 3: (Spearman) correlations of mapped dimensions with gold annotations for all test items. The table reports results (ρ) when mapped from a distributional space (DS_{cooc} or $DS_{Mikolov}$) to each MT space, as well as the correlation with human annotations when available. The train/test data for the mappings is specified in Table 2. For further analysis we report the results when tested *only* on animal test items ($animals$), or on all test items *but* animals ($no\text{-}animals$). $MT_{animals}$ contains test items from both AD and the animal section of the McRae norms. See text for more details.

for concepts of other classes (c.f. compare $MT_{animals}$ with $MT_{no\text{-}animals}$).

Finally, we quantify the specific improvement to the QMR animal concepts by comparing the correlation obtained on $MT_{QMR^{animals}}$ (a test set consisting only of QMR animal features) after training on a) the QMR data alone and b) the merged dataset (third section of Table 3). Performance increases from 0.419 to 0.666 on that specific set. This is in line with the inter-annotator agreement (0.663).

To summarise, we find that the best correlations with the gold annotations are seen when we include the animal-only dataset in training (MT_{AD} and MT_{QMR+AD}) and test on just animal concepts (MT_{AD}, $MT_{animals}$ and $MT_{QMR^{animals}}$). As one might expect, category-specific training data yields high performance when tested on the same category. Although this expectation seems intuitive, it is worth noting that our system produces promisingly high correlations, reaching human-performance on a subset of our data. The assumption we can draw from these results is that, given a reasonable amount of training data for a category, we can proficiently generate model-theoretic representations for concept-feature pairs from a distributional space. The empirical question remains whether this can be generalized for all categories in the QMR dataset.

It is important to keep in mind that the MT spaces are not full matrices, meaning that we have 'missing values' for various dimensions when a concept is converted into a vector. For example, the feature has_a_tail is not among the annotated features for *bear* in QMR and has a weight of 0, even though *most* bears have a tail. This is a consequence of the original McRae dataset, rather than the design of our approach. But it follows that in this quantitative analysis, we are not able to confirm the accuracy of the predicted values on dimensions for which we do not have gold annotations. This may also affect the performance of the system by including 'false' 0 weights in the training data. Although this does not affect our reported correlation results – we test the correlations on those values for which we have gold annotations only – it does open the door to a natural next step in the evaluation. In order to judge the performance of the system on the missing gold dimensions, we need a manual analysis to assess the quality of the whole vectors, which goes hand-in-hand with obtaining additional annotations for the missing dimensions. It seems, therefore, that an active learning strategy would allow us to not only evaluate the model-theoretic vectors more fully, but also improve the system by capturing new data.[10]

	% of gold in...
top 5 neighbours	19% (27/145)
top 10 neighbours	29% (42/145)
top 20 neighbours	46% (67/145)

Table 4: Percentage of gold vectors found in the top neighbours of the mapped concepts, shown for the $DS_{cooc} \rightarrow MT_{QMR+AD}$ transformation.

In this analysis, we focused primarily on the comparison between transformations using various truth-theoretic datasets for training and generation. We leave it to further work to extensively compare the effect of varying the type of the distributional space. Our results show, however, that the $Mikolov$ model performs slightly worse than the co-occurrence space ($cooc$), disproving the idea that predictive models always outperform count-based models.

6 Discussion

To further assess the quality of the produced space, we perform a nearest-neighbour analysis of our results to evaluate the coherence of the estimated vectors: for

[10] As suggested by a reviewer, one could also treat the missing entries as latent dimensions and define the loss function on only the known entries. We leave it to future work to test this promising option to resolve the issue of data sparsity.

axe	*hatchet*

Table 5: McRae feature norms for *axe* and *hatchet*

each concept in our test set, we return its nearest neighbours from the gold dataset, as given by the cosine similarity measure, hoping to find that the estimated vector is close to its ideal representation (see Făgărăşan et al. (2015) for a similar evaluation on McRae norms). Results are shown in Table 4. We find that the gold vector is among the top 5 nearest neighbours to the predicted equivalent in nearly 20% of concepts, with the percentage of gold items in the top neighbours improving as we increase the size of the neighbourhood. We perform a more in-depth analysis of the neighbourhoods for each concept to gain a better understanding of their behaviour and quality.

We discover that, in many cases, the mapped vector is close to a similar concept in the gold standard, but not to itself. So for instance, $\overrightarrow{alligator}_{mapped}$ is very close to $\overrightarrow{crocodile}_{gold}$, but not to $\overrightarrow{alligator}_{gold}$. Similar findings are made for *church/cathedral*, *axe/hatchet*, *dishwasher/fridge*, etc. A further investigation show that in the gold standard itself, those pairs are not as close to each other as they should be. Here are some relevant cosine similarities:

$alligator - crocodile$	0.47
$church - cathedral$	0.45
$axe - hatchet$	0.50
$dishwasher - fridge$	0.21

Two reasons can be identified for these comparatively low[11] similarities. First, the McRae norms do not make for a consistent semantic space because a feature that – from an extensional point of view – seems relevant to two concepts may only have been produced by the annotators for one of them. As an example of this, see Table 5, which shows the feature norms for *axe* and *hatchet* after processing (§3). Although the concepts share 4 features, they also differ quite strongly, an *axe* being seen as a weapon with a blade, while the *hatchet* is itself referred to as an axe. Extensionally, of course, there is no reason to think that a hatchet does not have a blade or might not be dangerous, but those features do not appear in the norms for the concept. This results in the two vectors being clearly separated in the set-theoretic space. This means that the distribution of *axe* may well be mapped to a region close to *hatchet*, but thereby ends up separated from the gold *axe* vector.

The second, related issue is that the animal concepts in the McRae norms are annotated along fewer dimensions than in AD. For example, *alligator* – which only appears in the McRae set – has 13 features, while *crocodile* (in both sets) has 70. Given that features which are not mentioned for a concept receive a weight of 0, this also results in very different vectors.

In Table 6, we provide the top weighted features for a small set of concepts. As expected, the animal representations (*bear, housefly*) have higher quality than the other two (*plum, cottage*). But overall, the ranking of dimensions is sensible. We see also that these representations have 'learnt' features for which we do not have values in our gold data – thereby correcting some of the 0 values in the training vectors.

7 Generating natural language quantifiers

In a last experiment, we attempt to map the set-theoretic vectors obtained in §5 back to natural language quantifiers. This last step completes our pipeline, giving us a system that produces quantified statements of the type *All dogs are mammals* or *Some bears are brown* from distributional data.

For each mapped vector $F(\vec{w_k}) = \vec{v_k}$ and a set of dimensions $d_{1...n}$ corresponding to properties $p'_{1...n}$, the value of $\vec{v_k}$ along each dimension is indicative of the proportion of instances of w'_k having the property signalled by the dimension. The smaller the value, the smaller the overlap between the set of instances of w'_k and the set of things having the property. Deriving natural language quantifiers from these values involves setting four thresholds $t_{all}, t_{most}, t_{some}$ and t_{few} so that for instance, if the value of $\vec{v_k}$ along d_m is more than t_{all}, it is the case that *all* instances of $\vec{w_k}$ have property p_m, and similarly for the other quantifiers (*no* has a special status as it is not entailed by any of the other quantifiers under consideration). We set the t-thresholds by a systematic search on a training set (see below).

To evaluate this step, we propose a function that calculates precision while taking into account the two following factors: a) some errors are worse than others: the system shouldn't be overly penalised for classifying a property as MOST rather than ALL, but much more for classifying a gold standard ALL as SOME; b) errors that are conducive to false inferences should be strongly penalised, e.g. generating *all dogs are black* is more serious than *some dogs are mammals*, because the former might lead to incorrect inferences with respect to individual dogs while the latter is true, even though it is pragmatically odd.

[11] Compare with e.g. *ape* - *monkey*, $Sim = 0.97$.

		Gold				
		no	few	some	most	all
Mapped	no	238	66	20	4	2
	few	53	45	30	19	12
	some	6	1	2	3	2
	most	4	6	4	16	56
	all	0	0	0	2	3

Table 8: Confusion matrix for the results of the natural language quantifiers generation.

We set a distance matrix, which we will use for penalising errors. This matrix, shown in Table 7, is basically equivalent to the matrix used by Herbelot and Vecchi (2015) to calculate weighted kappa between annotators, with the difference that all errors involving NO cause incorrect inferences and receive special treatment. Cases where the gold quantifier entails the mapped quantifier (*all cats* $\models$ *some cats*) have positive distances, while cases where the entailment doesn't hold have negative distances. Using the distance matrix, we give a score to each instance in our test data as follows:

$$s = \begin{cases} 1 - d & \text{if } d \geq 0 \\ d & \text{if } d < 0 \end{cases} \quad (1)$$

where d is obtained from the distance matrix.

This has the effect that when the mapped quantifier equals the gold quantifier, the system scores 1; when the mapped value deviates from the gold standard but produces a true sentence (*some dogs are mammals*), the system gets a partial score proportional to the distance between its output and the gold data; when the mapping results in a false sentence (*all dogs are black*), the system is penalised with minus points.

In what follows, we report the average performance of the system as $P = \frac{\sum s_m}{N}$ where s_m is the score assigned to a particular test instance, and N is the number of test instances. We evaluate on the 648 test instances of MT_{AD}, as this is the only dataset containing a fair number of negatively quantified concept-predicate pairs. We perform 5-fold cross-evaluation on this data, using 4 folds to set the t thresholds, and testing on one fold. We obtain an average P of 0.61. Inference is preserved in 73% of cases (also averaged over the 5 folds).

Table 8 shows the confusion matrix for our results. We note that the system classifies NO-quantified instances with good accuracy (72% – most confusions being with FEW). Because of the penalty given to instances that violate proper entailment, the system is conservative and prefers FEW to SOME, as well as MOST to ALL. Table 9 shows randomly selected instances, together with their mapped quantifier and the label from the gold standard.

8 Conclusion

In this paper, we introduced an approach to map from distributional to model-theoretic semantic vectors. Using traditional distributional representations for a concept, we showed that we are able to generate vectorial representations that encapsulate generalised quantifiers.

We found that with a relatively "cheap" linear function – cheap in that it is easy to learn and requires modest training data – we can reproduce the quantifiers in our gold annotation with high correlation, reaching human performance on a domain-specific test set. In future work, we will however explore the effect of more powerful functions to learn the transformations from distributional to model-theoretic spaces.

Our qualitative analysis showed that our predicted model-theoretic vectors sensibly model the concepts under consideration, even for features which do not have gold annotations. This is not only a promising result for our approach, but it provides potential as a next step to this work: expanding our training data with non-zero dimensions in an active learning procedure. We also experimented with generating natural language quantifiers from the mapped vectorial representations, producing 'true' quantified sentences with a 73% accuracy.

We note that our approach gives a systematic way to disambiguate non-explicitly quantified sentences such as generics, opening up new possibilities for improved semantic parsing and recognising entailment. Right now, many parsers give the same broad analysis to *Mosquitoes are insects* and *Mosquitoes carry malaria*, involving an underspecified/generic quantifier. This prevents inferring, for instance, that Mandie the mosquito is definitely an insect but may or may not carry malaria. In contrast, our system would attribute the most plausible quantifiers to those sentences (*all/few*), allowing us to produce correct inferences.

The focus of this paper was concept-predicate pairs out of context. That is, we considered quantified sentences where the restrictor was the entire set denoted by a lexical item. A natural next step is to investigate the quantification of statements involving contextualised subsets. For instance, we should obtain a different quantifier for *taxis are yellow* depending on whether the sentence starts with *In London...* or *In New York...* In future work, we will test our system on such context-specific examples, using contextualised vector representations such as the ones proposed by e.g. Erk and Padó (2008) and Dinu and Lapata (2010).

We conclude by noting again that the set-theoretic models produced in this work differ from formal semantics models in important ways. They do not represent the world *per se*, but rather some shared beliefs about the world, induced from an annotated dataset of feature norms. This calls for a modified version of the standard denotation function and for the replacement of the truth function with a 'plausibility' function, which would indicate how likely a stereotypical speaker might be to agree with a particular sentence. While this would be a fundamental departure from the core philosophy of model theory, we feel that it may be a worthwhile endeavour, allowing us to preserve the immense benefits of the set-theoretic apparatus in a cognitively plausible fashion. Following this aim, we hope to expand the preliminary framework presented here into a more expressive vector-based interpretation of set theory, catering for aspects not covered in this paper (e.g. cardinality, non-intersective modification) and refining our notion of a model, together with its relation to meaning.

Dependency Graph-to-String Translation

Liangyou Li Andy Way Qun Liu

Abstract

Compared to tree grammars, graph grammars have stronger generative capacity over structures. Based on an edge replacement grammar, in this paper we propose to use a synchronous graph-to-string grammar for statistical machine translation. The graph we use is directly converted from a dependency tree by labelling edges. We build our translation model in the log-linear framework with standard features. Large-scale experiments on Chinese–English and German–English tasks show that our model is significantly better than the state-of-the-art hierarchical phrase-based (HPB) model and a recently improved dependency tree-to-string model on BLEU, METEOR and TER scores. Experiments also suggest that our model has better capability to perform long-distance reordering and is more suitable for translating long sentences.

1 Introduction

Compared to trees, which have dominated the field of natural language processing (NLP) for decades, graphs are more general for modelling natural languages. The corresponding grammars for recognizing and producing graphs are more flexible and powerful than tree grammars. However, because of their high complexity, graph grammars have not been widely used in NLP.

Recently, along with progress on graph-based meaning representation, hyperedge replacement grammars (HRG) (Drewes et al., 1997) have been revisited, explored and used for semantic-based machine translation (Jones et al., 2012). However, the translation process is rather complex and the resources it relies on, namely abstract meaning corpora, are limited as well.

As most available syntactic resources and tools are tree-based, in this paper we propose to convert dependency trees, which are usually taken as a kind of shallow semantic representation, to dependency graphs by labelling edges. We then use a synchronous version of edge replacement grammar (ERG) (Section 2), a special case of HRG, to translate these graphs. The resulting translation model has the same order of magnitude in terms of time complexity with the hierarchical phrase-based model (HPB) (Chiang, 2005) under a certain restriction (Section 3).

Compared to dependency tree-to-string models, using ERG for graph-to-string translation brings some benefits (Section 3). Thanks to the stronger generative capacity of the grammar, our model can naturally translate siblings in a tree structure, which are usually treated as non-syntactic phrases and handled by other techniques (Huck et al., 2014; Xie et al., 2014). Furthermore, compared to the known treelet approach (Quirk et al., 2005) and Dep2Str (Xie et al., 2011), our method not only uses treelets but also has a full capacity of reordering.

We define our translation model (Section 4) in the log-linear framework (Och and Ney, 2002). Large-scale experiments (Section 5) on Chinese–English and German–English, two language pairs that have a high degree of syntactic reordering, show that our method significantly improves translation quality over both HPB and Dep2Str, as measured by BLEU (Papineni et al., 2002), TER (Snover et al., 2006) and METEOR (Denkowski and Lavie, 2011). We also find that the rules in our model are more suitable for long-distance reordering and translating long sentences.

2 Edge Replacement Grammar

As a special case of HRG, ERG is also a context-free rewriting grammar to recognize and produce graphs. Following HRG, the graph we use in this

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 33–43,
Lisbon, Portugal, 17-21 September 2015.

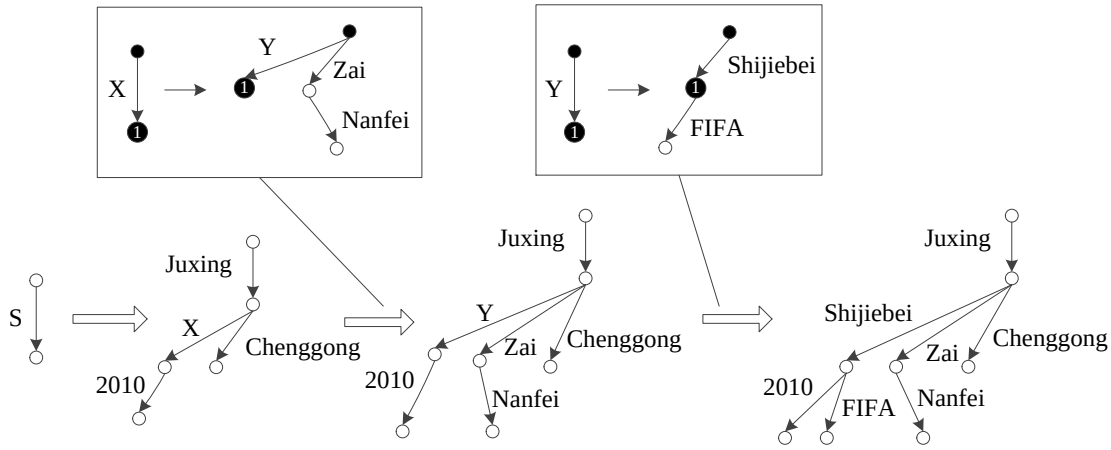

Figure 1: An example of a derivation in an ERG. Dark circles are external nodes.

paper is connected, nodes ordered, acyclic and has edge labels but no node labels (Chiang et al., 2013). We provide some formal definitions on ERG.

Definition 1. A *connected, edge-labeled, ordered graph* is a tuple $H = \langle V, E, \phi \rangle$, where

- V is a finite set of nodes.
- $E \subseteq V^2$ is a finite set of edges.
- $\phi : E \rightarrow C$ assigns a label (drawn from C) to each edge.

In ERG, the elementary unit is a graph fragment, which is also the right-hand side of a production in the grammar. Its definition is as follows.

Definition 2. A *graph fragment* is a tuple $H = \langle V, E, \phi, X \rangle$, where $\langle V, E, \phi \rangle$ is a graph and $X \in (V \cup V^2)$ is a list of distinct nodes. Following Chiang et al. (2013), we call these *external nodes*.

The external nodes indicate how to integrate a graph into another one during a derivation. Different to HRG, ERG limits the number of external nodes to 2 at most to make sure hyperedges do not exist during a derivation. Now we define the ERG.

Definition 3. An *edge replacement grammar* is a tuple $\langle N, T, P, S \rangle$, where

- N and T are disjoint finite sets of nonterminal symbols and terminal symbols, respectively.
- P is a finite set of productions of the form $A \rightarrow R$, where $A \in N$ and R is a graph fragment, where edge-labels are from $N \bigcup T$.
- $S \in N$ is the start symbol.

Figure 1 shows an example of a derivation in an ERG to produce a graph. Starting from the start symbol S, when a rule $(A \rightarrow R)$ is applied to an edge e, the edge is replaced by the graph fragment R. Just like in HRG, the ordering of nodes V_e in e and external nodes X_R in R implies the mapping from V_e to X_R (Chiang et al., 2013).

3 Graph-to-String Grammar

In SMT, we need a synchronous grammar to simultaneously parse an input graph and produce translations. The graph we use in this paper is from a dependency structure which is capable of modelling long-distance relations in a sentence.

3.1 The Grammar

Before defining the synchronous grammar, we firstly define a dependency graph which is a special case of a graph.

Definition 4. A *dependency graph* is a tuple $\langle V, E, \phi, \Delta \rangle$, where $\langle V, E, \phi \rangle$ is a graph and Δ is a restriction: edges are ordered.

A dependency graph is directly derived from a dependency tree by labeling edges with words, as shown in Figure 2. Although in general graph edges are unordered, in Definition 4 we keep word order by ordering edges, because the word order is an important piece of information for translation.

Similar to the graph fragment, a dependency-graph fragment is defined as below.

Definition 5. A *dependency-graph fragment* is a tuple $\langle V, E, \phi, \Delta, X \rangle$, where $\langle V, E, \phi, \Delta \rangle$ is a dependency graph, $X \in (V \cup V^2)$ is a list of external nodes.

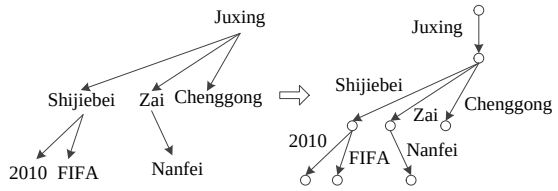

Figure 2: An example of deriving a dependency graph from a dependency tree by labelling edges with words.

In this paper, we define a synchronous ERG over dependency graphs as a dependency graph-to-string grammar, which can be used for MT.

Definition 6. A *dependency graph-to-string grammar* (DGSG) is a tuple $\langle N, T, T', P, S \rangle$, where

- N is a finite set of non-terminal symbols.
- T and T' are finite sets of terminal symbols.
- $S \in N$ is the start symbol.
- P is a finite set of productions of the form $\langle A \rightarrow R, A' \rightarrow R', \sim \rangle$, where $A, A' \in N$, R is a dependency-graph fragment over $N \bigcup T$ and R' is a string over $N \bigcup T'$. $\sim$ is a one-to-one mapping between non-terminal symbols in R and R'.

Figure 3 shows a derivation simultaneously producing a Chinese dependency graph and an English string using a DGSG. Each time a rule is applied, the dependency-graph fragment in the rule replaces an edge in the source graph, and the string in the rule replaces a non-terminal in the target string.

Proposition 1. DGSG has stronger generative capacity over graph-string pairs than both SCFG and synchronous tree substitution grammar (STSG).

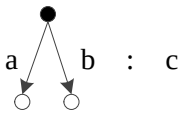
Proof. STSG has stronger generative capacity over structures than SCFG (Chiang, 2012).[1]

Any STSG can easily be converted into a DGSG by labelling edges in tree structures.

[1]The following STSG generates a trivial example of a tree-string pair that no SCFG can generate, as SCFG must always have an equal number of non-terminal symbols.

$$\begin{array}{c} X \\ X \quad | \\ | \ : X \\ \epsilon \quad | \\ \epsilon \end{array}$$

The following DGSG generates a trivial example of a graph-string pair, which no STSG can generate, as the left-head side has no head nodes while STSG always requires one to form a tree.



□

This proof is also verified in Figure 3 where the third rule is used to translate a non-syntactic phrase, which can be a problem for dependency tree-to-string methods. In addition, the second rule translates a treelet and the first rule encodes reordering information inside. All these three aspects are uniformly modeled in our grammar, which makes it more powerful than other methods, such as the treelet approach and the Dep2Str.

3.2 Time Complexity and a Restriction

Given a dependency graph, training and decoding time using DGSG depends on the number of dependency-graph fragments. For example, for a graph where the degree of a node is k, the number of all possible fragments starting from the node is $O(2^k)$. Therefore, the time complexity would be exponential if we consider them all.

It is easy to find that the high complexity of DGSG comes from the free combination of edges. That means that a dependency-graph fragment can cover discontinuous words of an input sentence. However, this is not the convention in the field of SMT.

For efficient training and decoding, we add a restriction to DGSG: each dependency-graph fragment covers a continuous span of the source sentence. This reduces the complexity from exponential time to cubic time.

3.3 Non-terminal Symbols

In this paper we build a dependency graph-to-string model, so we only use one non-terminal symbol X as in HPB on the target side. However, on the source side we define non-terminal symbols over Part-of-Speech (POS) tags, which can be easily obtained as a by-product of dependency parsing.

We define the *head* of a dependency-graph fragment H as a list of edges, the dependency head of each of which is not in this fragment. Then the

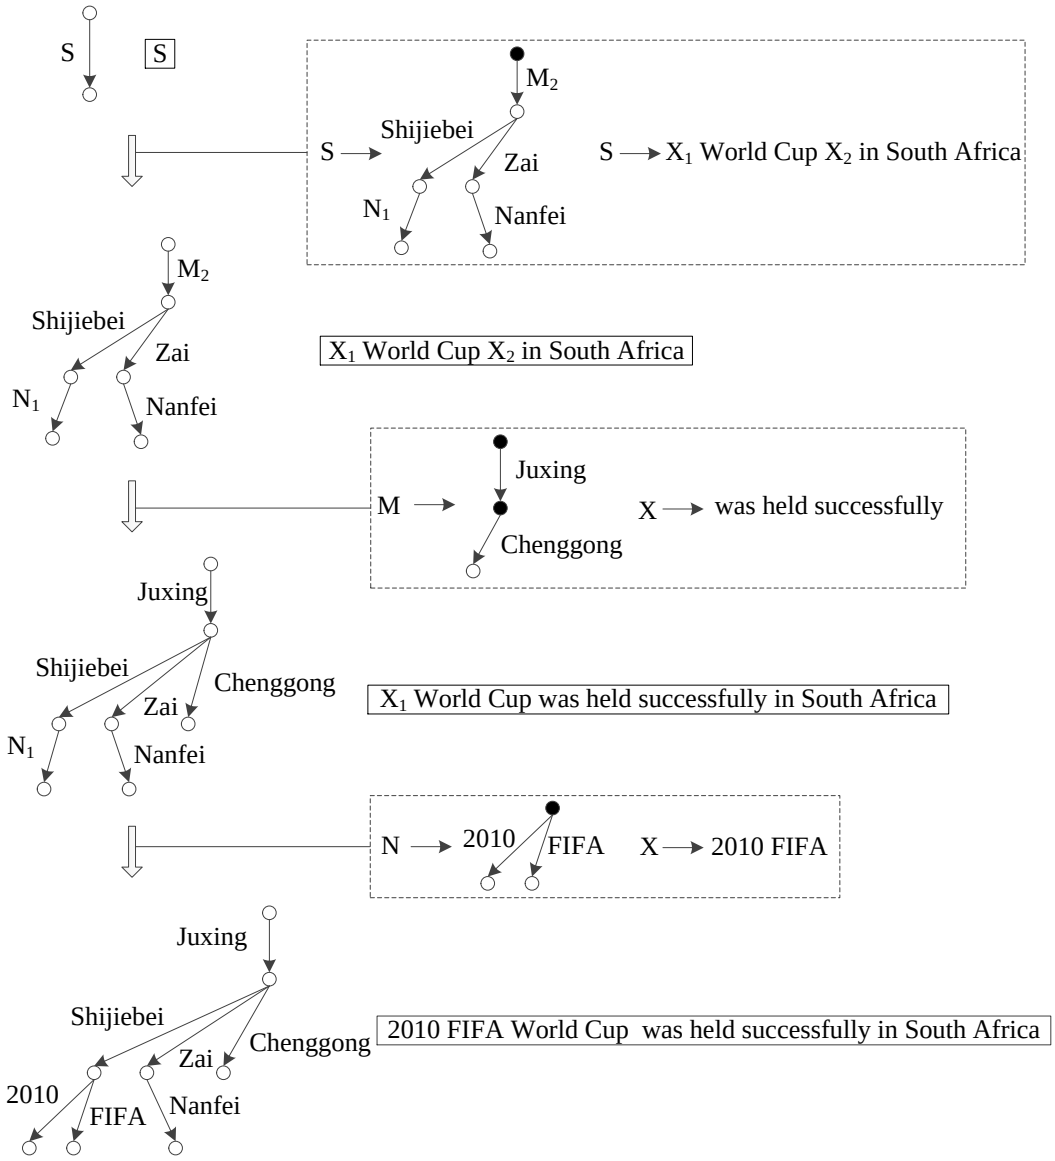


Figure 3: An example of a derivation in dependency graph-to-string grammar to produce a Chinese dependency graph and an English string. Rules are included in dashed rectangles. Target strings are in solid rectangles. External nodes are dark circles. This example is under the restriction in Section 3.2. In addition to the start symbol S, non-terminal symbols for the source side are M and N, while the target side only has one non-terminal X. The index in each non-terminal of a rule indicates the mapping.

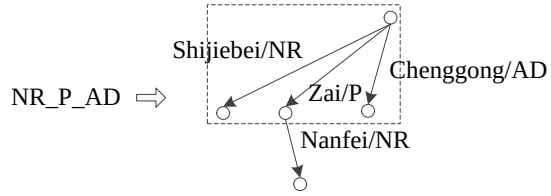

Figure 4: An example inducing a non-terminal symbol (left side) for a dependency-graph fragment (right side). Each edge is labeled by a word associated with its POS tag. The head of this fragment includes three edges which are in the rectangle.

non-terminal symbol for H is defined as the joining of POS tags of its head (Li et al., 2012). Figure 4 shows an example.

3.4 Rule Extraction

As well as the restriction defined in Section 3.2 making the grammar much smaller, it also results in a similar way of extracting rules as in HPB. Inspired by HPB, we define the rule set over *initial pairs*.

Given a word-aligned dependency graph-string pair $P = \langle G, e, \sim \rangle$, let G_i^j stand for the sub-graph (it may not be connected) covering words from position i to position j. Then a rule $\langle G_i^j, e_{i'}^{j'} \rangle$ is an initial pair of P, iff:

1. G_i^j is a dependency-graph fragment. That means it is a connected sub-graph and has at most two external nodes, nodes which connect with nodes outside or are the root.
2. It is consistent with the word alignment $\sim$ (Och and Ney, 2004).

The set of rules from P satisfies the following:

1. If $\langle G_i^j, e_{i'}^{j'} \rangle$ is an initial pair, then
$$\langle N(G_i^j) \rightarrow G_i^j, X \rightarrow e_{i'}^{j'} \rangle$$
is a rule, where $N(G)$ defines the non-terminal symbol for G.
2. If $\langle N(R) \rightarrow R, X \rightarrow R' \rangle$ is a rule of P and $\langle G_i^j, e_{i'}^{j'} \rangle$ is an initial pair such that G_i^j is a sub-graph of R and $R' = r_1 e_{i'}^{j'} r_2$, then
$$\langle N(R) \rightarrow R \backslash G_{i\,k}^j, X \rightarrow r_1 X_k r_2 \rangle$$
is a rule of P, where $\backslash$ means replacing G_i^j in R with an edge labelled with $N(G_i^j)$ and k is a unique index for a pair of non-terminal symbols.

As in HPB, in addition to rules extracted from the parallel corpus, we also use glue rules to combine fragments and translations when no matched rule can be found.

Furthermore, we can use the same rule extraction algorithm as that in HPB, except that we need to check if a span of a source sentence indicates a dependency-graph fragment, in which case we keep the dependency structure and induce a non-terminal for the fragment.

4 Model and Decoding

We define our model in the log-linear framework over a derivation d, as in Equation (1):

$$P(d) \propto \prod_i \phi_i(d)^{\lambda_i} \quad (1)$$

where ϕ_i are features defined on derivations and λ_i are feature weights. In our experiments, we use 9 features:

- translation probabilities $P(s|t)$ and $P(t|s)$, where s is the source graph fragment and t is the target string.
- lexical translation probabilities $P_{lex}(s|t)$ and $P_{lex}(t|s)$.
- language model $lm(e)$ over translation e.
- rule penalty $exp(-1)$.
- word penalty $exp(|e|)$.
- glue penalty $exp(-1)$.
- unknown words penalty $exp(u(g))$, where $u(g)$ is the number of unknown words in a source graph g.

Our decoder is based on the conventional chart parsing CYK algorithm (Kasami, 1965; Younger, 1967; Cocke and Schwartz, 1970). It searches for the best derivation d^* among all possible derivations D, as in Equation (2):

$$d^* = \underset{d \in D}{\operatorname{argmax}} P(d) \quad (2)$$

For each span of an input graph, the decoder checks if it is a dependency-graph fragment. Then

Table 1: Chinese–English (ZH–EN) and German–English (DE–EN) corpora. For the English side of dev and test sets, words counts are averaged across all references.

for each fragment, the decoder finds rules to translate it. The translation of a large span can be obtained by combining translations from its sub-span using rules which have non-terminals. Finally, glue rules are used to make sure that at least one translation is produced.

5 Experiment

We conduct experiments on Chinese–English and German–English translation tasks.

5.1 Datasets

The Chinese–English training corpus is from LDC, including LDC2002E18, LDC2003E07, LDC2003E14, LDC2004T07, the Hansards portion of LDC2004T08 and LDC2005T06. NIST 2002 is taken as a development set to tune weights, and NIST 2004 (MT04) and NIST 2005 (MT05) are two test sets to evaluate systems. Table 1 provides a summary of this corpus. The Stanford Chinese word segmenter (Chang et al., 2008) is used to segment Chinese sentences. The Stanford dependency parser (Chang et al., 2009) parses a Chinese sentence into a projective dependency tree which is then converted to a dependency graph in our model.

The German–English training corpus is from WMT 2014, including Europarl V7 and News Commentary. News-test 2011 is taken as a development set, while News-test 2012 (WMT12) and News-test 2013 (WMT13) are our test sets. Table 1 provides a summary of this corpus. We use mate-tools[2] to perform morphological analysis and parse German sentences (Bohnet, 2010). Then MaltParser[3] converts a parse result into a projective dependency tree (Nivre and Nilsson, 2005).

5.2 Settings

In this paper, we mainly compare our system (**DGST**) with HPB in Moses (Koehn et al., 2007). We implement our model in Moses and take the same settings as Moses HPB in all experiments. In addition, translation results from a recently open-source dependency tree-to-string system, Dep2Str[4] (Li et al., 2014), which is implemented in Moses and improves the dependency-based model in Xie et al. (2011), are also reported. All systems use the same sets of features defined in Section 4.

In all experiments, word alignment is performed by GIZA++ (Och and Ney, 2003) with the heuristic function *grow-diag-final-and*. We use SRILM (Stolcke, 2002) to train a 5-gram language model on the Xinhua portion of the English Gigaword corpus 5th edition with modified Kneser-Ney discounting (Chen and Goodman, 1996). Minimum Error Rate Training (MERT) (Och, 2003) is used to tune weights.

To obtain more reliable results, in each experiment, we run MERT three times and report average scores. These scores are calculated by three widely used automatic metrics in case-insensitive mode: BLEU, METEOR and TER.

5.3 Results

Table 2 shows the scores of all three metrics on all systems. Similar to Li et al. (2014), in our experiments Dep2Str has on average a comparable result with Moses HPB in terms of BLEU and METEOR scores. However, it obtains a significantly higher (i.e. worse) TER score on the Chinese–English task. This may suggest that translations produced by Dep2Str need more post-editing effort (He et al., 2010).

By contrast, on all test sets, measured by all metrics, our system is significantly better than Moses HPB. On the Chinese–English task, our system achieves an average gain of 1.25 (absolute, 3.6% relative) BLEU score and 0.55 (absolute, 1.7% relative) METEOR score while also ob-

taining a reduction of 1.1 (absolute, 1.91% relative) TER score on average.

On the German–English task, our system achieves an average gain of 0.55 (absolute, 2.56% relative) BLEU score and 0.1 (absolute, 0.35% relative) METEOR score and also obtains a reduction of 0.55 (absolute, 0.89% relative) TER score on average.

5.4 Analysis

As shown in Table 2, compared to Moses HPB and Dep2Str, our system achieves higher translation quality as measured by three automatic metrics. In this section, we investigate whether dependency structures bring benefits as expected on long-distance reordering. Table 3 provides the statistics on sentence length of our four test sets.

In both HPB and our model, the length range of a reordering performed on an input sentence is related to the use of glue grammars which bring two benefits during decoding. When no matched rule is found in the models, glue grammars are applied to make sure a translation is produced. In addition, because of the generalization capability of rules, which typically are learned under a length limitation, using them on long sentences could cause translation quality to deteriorate. Therefore, when the length of a phrase is greater than a certain value, glue grammars are also applied. Therefore, our experiment of analysis is based on the length limitation that a rule can cover (max. phrase length) during decoding.

We set this max. phrase length to different values, including 10, 20 (default), 30, 40 and 50. Figure 5 gives the BLEU scores on all test sets. We find that on all different values, our system achieves higher BLEU scores than Moses HPB. In addition, when the max. phrase length becomes larger, Moses HPB shows a declining trend in most cases, especially on the German–English task (WMT12 and WMT13). However, our system is less sensitive to this value. We hypothesize that this is because rules from dependency graphs have better generalization for translating longer phrases and are more suitable for translating long sentences.

5.5 Case Study

On a manual check, we find that translations produced by our system are more fluent than those of both Moses HPB and Dep2Str. Figure 6 gives an example comparing translations produced by three systems on the Chinese–English task.

We first find a case of long-distance relation, i.e. the subject-verb-object (SVO) structure in the source sentence. In this example, this relation implies a long-distance reordering, which moves the translation of the object to the front of its modifiers, as shown in the given reference. Com-

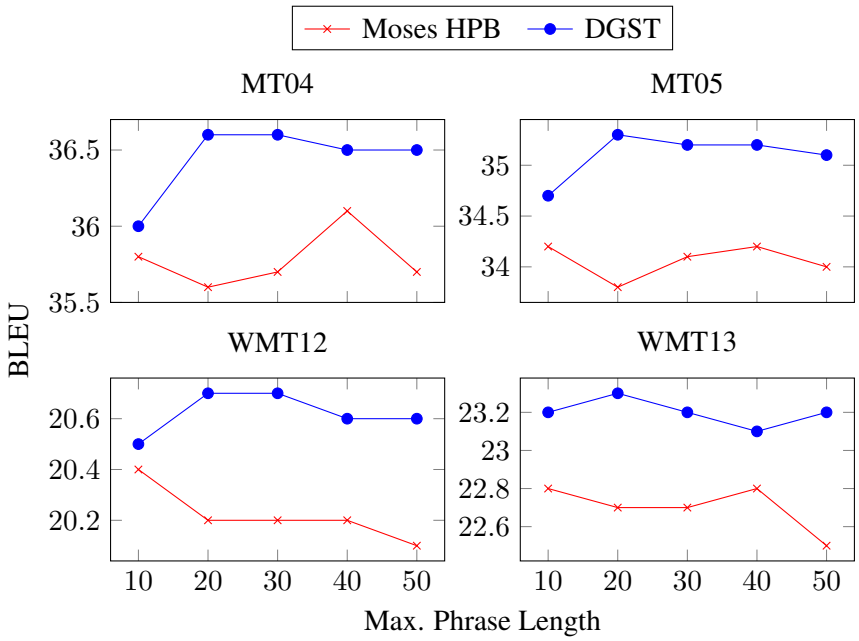

Figure 5: BLEU scores of Moses HPB and DGST (our system) when the length of maximum phrase that a rule can cover during decoding is set to different values.

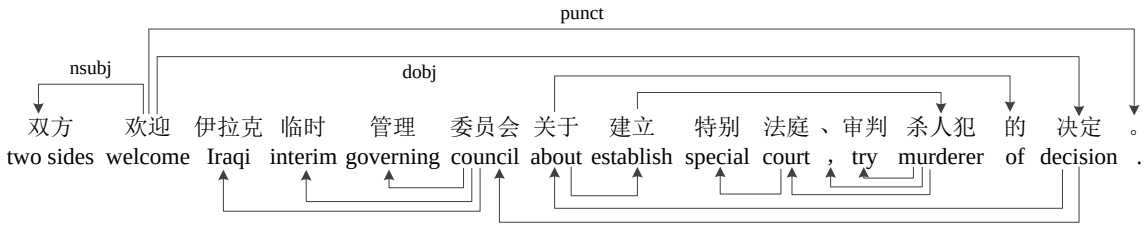

Ref: The two sides welcomed the decision by the Iraqi Interim Governing Council to establish a special court to try the murderers.

HPB: the two sides welcomed the interim iraqi authority on establishing a special court, trial of the murderer.

Dep2Str: the two sides welcomed the decision on the Establishment of a special court, justice murderers of the provisional governing council of iraq.

DGST: the two sides welcomed the decision of the iraqi interim governing council on the establishment of a special court, justice murderers.

Figure 6: An example of comparing translations produced by three systems on the Chinese–English task. The source sentence is parsed into a dependency structure. Each source word is annotated by a corresponding English word (or phrase).

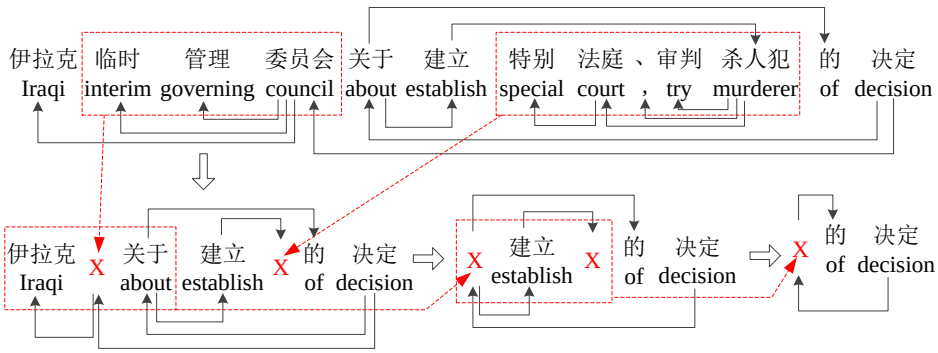

Figure 7: An example of inducing a dependency structure in Figure 6 to ”X 的(of) X” structure in our system by using treelets and non-syntactic phrases. ➪ denotes one or more steps. All non-terminals are simply represented by X.

pared to Moses HPB, both Dep2Str and our system, which rely on dependency structures, are capable of dealing with this. This also suggests that dependency structures are useful for long-distance reordering.

Furthermore, compared to Dep2Str, our system produces a better translation for the "X 的(of) X" expression, which is not explicitly represented in the dependency structure and thus results in a wrong translation in Dep2Str. After looking into the details of the translation process, we find that our system induces the dependency structure to the "X 的(of) X" structure by handling both treelets and non-syntactic phrases. Figure 7 shows the process of this induction.

6 Related Work

Dependency structures have been used in SMT for a few years. Because of its better inter-lingual phrasal cohesion properties (Fox, 2002), it is believed to be beneficial to translation.

Researchers have tried to use dependency structures on both target and source sides. Shen et al. (2010) propose a string-to-dependency model by using dependency fragments of neighbouring words on the target side, which makes the model easier to include a dependency-based language model.

Menezes and Quirk (2005) and Quirk et al. (2005) propose the treelet approach which uses dependency structures on the source side. Xiong et al. (2007) extend this approach by allowing gaps in rules. However, their methods need a separate reordering model to decide the position of translated words (insertion problem). To avoid this problem, Xie et al. (2011) propose to use full head-dependent structures of a dependency tree and build a new dependency-to-string model. However, this model has difficulties in handling non-syntactic phrasal rules and ignores treelets. Meng et al. (2013) and Xie et al. (2014) further augment this model by incorporating constituent phrases and integrating fix/float structures (Shen et al., 2010), respectively, to allow phrasal rules. Li et al. (2014) extend this model by decomposing head-dependent structures into treelets.

Different from these methods, by labelling edges and using the ERG, our model considers the three aspects in a unified way: treelet, reordering and non-syntactic phrase. In addition, the ERG also naturally provides a decision on what kind of treelets and phrases should be used.

7 Conclusion

In this paper, we present a dependency graph-to-string grammar based on a graph grammar, which we call edge replacement grammar. This grammar can simultaneously produce a pair of dependency graph and string. With a restriction of using contiguous edges, our translation model built using this grammar can decode an input dependency graph, which is directly converted from a dependency tree, in cubic time using the CYK algorithm.

Experiments on Chinese–English and German–English tasks show that our model is significantly better than the hierarchical phrase-based model and a recent dependency tree-to-string model (Dep2Str) in Moses. We also find that the rules used in our model are more suitable for long-distance reordering and translating long sentences.

Although experiments show significant improvements over baselines, our model has limitations that can be avenues for future work. The restriction used in this paper reduces the time complexity but at the same time reduces the generative capacity of graph grammars. Without allowing hyperedges or only using at most two external nodes reduces the phrase coverage in our model as well.

Abstract

We present a novel approach for unsupervised induction of a Reordering Grammar using a modified form of permutation trees (Zhang and Gildea, 2007), which we apply to preordering in phrase-based machine translation. Unlike previous approaches, we induce in one step both the hierarchical structure and the transduction function over it from word-aligned parallel corpora. Furthermore, our model (1) handles non-ITG reordering patterns (up to 5-ary branching), (2) is learned from all derivations by treating not only labeling but also bracketing as latent variable, (3) is entirely unlexicalized at the level of reordering rules, and (4) requires no linguistic annotation.

Our model is evaluated both for accuracy in predicting target order, and for its impact on translation quality. We report significant performance gains over phrase reordering, and over two known preordering baselines for English-Japanese.

1 Introduction

Preordering (Collins et al., 2005) aims at permuting the words of a source sentence $\mathbf{s}$ into a new order $\acute{\mathbf{s}}$, hopefully close to a plausible target word order. Preordering is often used to bridge long distance reorderings (e.g., in Japanese- or German-English), before applying phrase-based models (Koehn et al., 2007). Preordering is often broken down into two steps: finding a suitable tree structure, and then finding a transduction function over it. A common approach is to use monolingual syntactic trees and focus on finding a transduction function of the sibling subtrees under the nodes (Lerner and Petrov, 2013; Xia and Mccord, 2004). The (direct correspondence) assumption underlying this approach is that permuting the siblings of nodes in a source syntactic tree can produce a plausible target order. An alternative approach creates reordering rules manually and then learns the right structure for applying these rules (Katz-Brown et al., 2011). Others attempt learning the transduction structure and the transduction function in two separate, consecutive steps (DeNero and Uszkoreit, 2011). Here we address the challenge of learning both the trees and the transduction functions jointly, in one fell swoop, from word-aligned parallel corpora.

Learning both trees and transductions jointly raises two questions. How to obtain suitable trees for the source sentence and how to learn a distribution over random variables specifically aimed at reordering in a hierarchical model? In this work we solve both challenges by using the factorizations of permutations into Permutation Trees (PETs) (Zhang and Gildea, 2007). As we explain next, PETs can be crucial for exposing the hierarchical reordering patterns found in word-alignments.

We obtain permutations in the training data by segmenting every word-aligned source-target pair into *minimal phrase pairs*; the resulting alignment between minimal phrases is written as a permutation (1:1 and onto) on the source side. Every permutation can be factorized into a *forest* of PETs (over the source sentences) which we use as a *latent treebank* for training a Probabilistic Context-Free Grammar (PCFG) tailor made for preordering as we explain next.

Figure 1 shows two alternative PETs for the same permutation over minimal phrases. The nodes have labels (like $P3142$) which stand for local permutations (called prime permutation) over the child nodes; for example, the root label $P3142$ stands for prime permutation $\langle 3, 1, 4, 2\rangle$, which says that the first child of the root becomes 3^{rd} on the target side, the second becomes 1^{st}, the third

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 44–54,
Lisbon, Portugal, 17-21 September 2015.

becomes 4^{th} and the fourth becomes 2^{nd}. The prime permutations are non-factorizable permutations like $\langle 1, 2\rangle$, $\langle 2, 1\rangle$ and $\langle 2, 4, 1, 3\rangle$.

We think PETs are suitable for learning preordering for two reasons. Firstly, PETs specify *exactly* the phrase pairs defined by the permutation. Secondly, every permutation is factorizable into prime permutations only (Albert and Atkinson, 2005). Therefore, PETs expose *maximal* sharing between different permutations in terms of both phrases and their reordering. We expect this to be advantageous for learning hierarchical reordering.

For learning preordering, we first extract an *initial* PCFG from the latent treebank of PETs over the source sentences only. We initialize the nonterminal set of this PCFG to the *prime permutations* decorating the PET nodes. Subsequently we split these coarse labels in the same way as latent variable splitting is learned for treebank parsing (Matsuzaki et al., 2005; Prescher, 2005; Petrov et al., 2006; Saluja et al., 2014). Unlike treebank parsing, however, our training treebank is latent because it consists of a whole forest of PETs per training instance ($\mathbf{s}$).

Learning the splits on a latent treebank of PETs results in a *Reordering PCFG* which we use to parse input source sentences into split-decorated trees, i.e., the labels are the splits of prime permutations. After parsing $\mathbf{s}$, we map the splits back on their initial prime permutations, and then retrieve a reordered version $\acute{\mathbf{s}}$ of $\mathbf{s}$. In this sense, our latent splits are *dedicated to reordering*.

We face two technical difficulties alien to work on latent PCFGs in treebank parsing. Firstly, as mentioned above, permutations may factorize into more than one PET (a forest) leading to a latent training treebank.[1] And secondly, after we parse a source string $\mathbf{s}$, we are interested in $\acute{\mathbf{s}}$, the permuted version of $\mathbf{s}$, not in the best derivation/PET. Exact computation is a known NP-Complete problem (Sima'an, 2002). We solve this by a new Minimum-Bayes Risk decoding approach using Kendall reordering score as loss function, which is an efficient measure over permutations (Birch and Osborne, 2011; Isozaki et al., 2010a).

In summary, this paper contributes:

- A novel latent hierarchical source reordering model working over all derivations of PETs
- A label splitting approach based on PCFGs over minimal phrases as terminals, learned from an ambiguous treebank, where the label splits start out from prime permutations.
- A fast Minimum Bayes Risk decoding over Kendall τ reordering score for selecting $\acute{\mathbf{s}}$.

We report results for extensive experiments on English-Japanese showing that our Reordering PCFG gives substantial improvements when used as preordering for phrase-based models, outperforming two existing baselines for this task.

2 PETs and the Hidden Treebank

We aim at learning a PCFG which we will use for parsing source sentences $\mathbf{s}$ into synchronous trees, from which we can obtain a reordered source version $\acute{\mathbf{s}}$. Since PCFGs are non-synchronous grammars, we will use the nonterminal labels to encode reordering transductions, i.e., this PCFG is implicitly an SCFG. We can do this because $\mathbf{s}$ and $\acute{\mathbf{s}}$ are over the same alphabet.

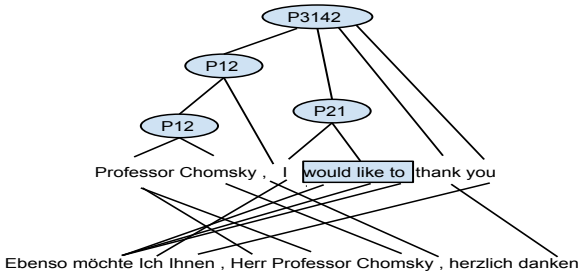
Here, we have access only to a word-aligned parallel corpus, not a treebank. The following steps summarize our approach for acquiring a latent treebank and how it is used for learning a Reordering PCFG:

1. Obtain a permutation over minimal phrases from every word-alignment.
2. Obtain a latent treebank of PETs by factorizing the permutations.
3. Extract a PCFG from the PETs with initial nonterminals taken from the PETs.
4. Learn to split the initial nonterminals and estimate rule probabilities.

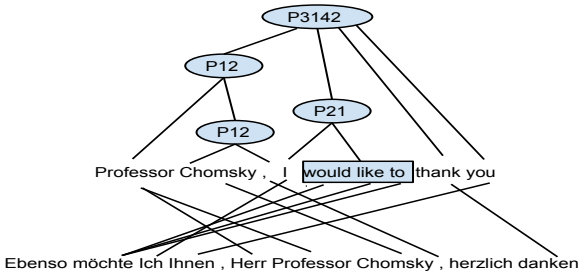
These steps are detailed in the next section, but we will start out with an intuitive exposition of PETs, the latent treebank and the Reordering Grammar.

Figure 1 shows examples of how PETs look like – see (Zhang and Gildea, 2007) for algorithmic details. Here we label the nodes with nonterminals which stand for *prime* permutations from the operators on the PETs. For example, nonterminals $P12$, $P21$ and $P3142$ correspond respectively to reordering transducers $\langle 1, 2\rangle$, $\langle 2, 1\rangle$ and $\langle 3, 1, 4, 2\rangle$. A prime permutation on a source node μ is a transduction dictating how the children of μ are reordered at the target side, e.g., $P21$ inverts the child order. We must stress that any similarity with ITG (Wu, 1997) is restricted to the fact that the straight and inverted operators of ITG are the binary case of prime permutations

[1] All PETs for the same permutation share the same set of prime permutations but differ only in bracketing structure (Zhang and Gildea, 2007).



(a) Canonical PET



(b) Alternative PET

Figure 1: Possible Permutation Trees (PETs) for one sentence pair

in PETs ($P12$ and $P21$). ITGs recognize only the binarizable permutations, which is a major restriction when used on the data: there are many non-binarizable permutations in actual data (Wellington et al., 2006). In contrast, our PETs are obtained by factorizing permutations obtained from the data, i.e., they exactly fit the range of prime permutations in the parallel corpus. In practice we limit them to maximum arity 5.

We can extract PCFG rules from the PETs, e.g., $P21 \rightarrow P12\ P2413$. However, these rules are decorated with too coarse labels. A similar problem was encountered in non-lexicalized monolingual parsing, and one solution was to lexicalize the productions (Collins, 2003) using *head words*. But linguistic heads do not make sense for PETs, so we opt for the alternative approach (Matsuzaki et al., 2005), which splits the nonterminals and softly percolates the splits through the trees gradually fitting them to the training data. Splitting has a shadow side, however, because it leads to combinatorial explosion in grammar size.

Suppose for example node $P21$ could split into $P21_1$ and $P21_2$ and similarly $P2413$ splits into $P2413_1$ and 2413_2. This means that rule $P21 \rightarrow P12\ P2413$ will form eight new rules:

$$P21_1 \rightarrow P12_1\ P2413_1 \quad P21_1 \rightarrow P12_1\ P2413_2$$
$$P21_1 \rightarrow P12_2\ P2413_1 \quad P21_1 \rightarrow P12_2\ P2413_2$$
$$P21_2 \rightarrow P12_1\ P2413_1 \quad P21_2 \rightarrow P12_1\ P2413_2$$
$$P21_2 \rightarrow P12_2\ P2413_1 \quad P21_2 \rightarrow P12_2\ P2413_2$$

Should we want to split each nonterminal into 30 subcategories, then an *n-ary* rule will split into 30^{n+1} new rules, which is prohibitively large. Here we use the "unary trick" as in Figure 2. The superscript on the nonterminals denotes the child position from left to right. For example $P21_1^2$ means that this node is a second child, and the mother nonterminal label is $P21_1$. For the running example rule, this gives the following rules:

$$P21_1 \rightarrow P21_1^1\ P21_1^2 \quad P21_2 \rightarrow P21_2^1\ P21_2^2$$
$$P21_1^1 \rightarrow P12_1 \quad P21_1^2 \rightarrow P2413_1$$
$$P21_1^1 \rightarrow P12_2 \quad P21_1^2 \rightarrow P2413_2$$
$$P21_2^1 \rightarrow P12_1 \quad P21_2^2 \rightarrow P2413_1$$
$$P21_2^1 \rightarrow P12_2 \quad P21_2^2 \rightarrow P2413_2$$

The unary trick leads to substantial reduction in grammar size, e.g., for arity 5 rules and 30 splits we could have had $30^6 = 729000000$ split-rules, but with the unary trick we only have $30{+}30^2{*}5 = 4530$ split rules. The unary trick was used in early lexicalized parsing work (Carroll and Rooth, 1998).[2] This split PCFG constitutes a *latent PCFG* because the splits cannot be read of a treebank. It must be learned from the latent treebank of PETs, as described next.

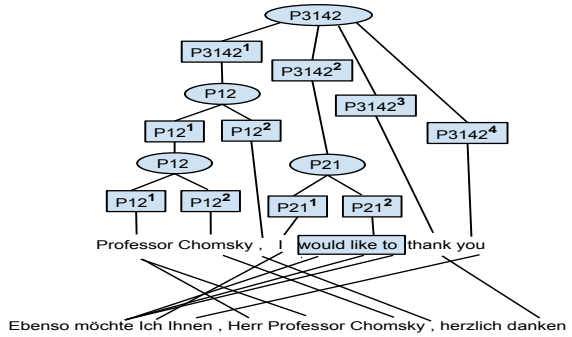


Figure 2: Permutation Tree with unary trick

3 Details of Latent Reordering PCFG

Obtaining permutations Given a source sentence $\mathbf{s}$ and its alignment $\mathbf{a}$ to a target sentence

[2] After applying the unary trick, we add a constraint on splitting: all nonterminals on an n-ary branching rule must be split simultaneously.

$\mathbf{t}$ in the training corpus, we segment $\langle \mathbf{s}, \mathbf{a}, \mathbf{t} \rangle$ into a sequence of *minimal phrases* $\mathbf{s}_m$ (maximal sequence) such that the reordering between these minimal phrases constitutes a permutation π_m. We do not extract non-contiguous or non-minimal phrases because reordering them often involves complicated transductions which could hamper the performance of our learning algorithm.[3]

Unaligned words Next we describe the use of the factorization of permutations into PET forests for training a PCFG model. But first we need to extend the PETs to allow for unaligned words. An unaligned word is joined with a neighboring phrase to the left or the right, depending on the source language properties (e.g., whether the language is head-initial or -final (Chomsky, 1970)). Our experiments use English as source language (head-initial), so the unaligned words are joined to phrases to their right. This modifies a PET by adding a new binary branching node μ (dominating the unaligned word and the phrase it is joined to) which is labeled with a dedicated nonterminal: $P01$ if the unaligned word joins to the right and $P10$ if it joins to the left.

3.1 Probability model

We decompose the permutation π_m into a forest of permutation trees $PEF(\pi_m)$ in $O(n^3)$, following algorithms in (Zhang et al., 2008; Zhang and Gildea, 2007) with trivial modifications. Each PET $\mathbf{\Delta} \in PEF(\pi_m)$ is a different bracketing (differing in binary branching structure only). We consider the bracketing hidden in the latent treebank, and apply unsupervised learning to induce a distribution over possible bracketings. Our probability model starts from the joint probability of a sequence of minimal phrases $\mathbf{s}_m$ and a permutation π_m over it. This demands summing over all PETs $\mathbf{\Delta}$ in the forest $PEF(\pi_m)$, and for every PET also over all its label splits, which are given by the grammar derivations $\mathbf{d}$:

$$P(\mathbf{s}_m, \pi_m) = \sum_{\mathbf{\Delta} \in PEF(\pi_m)} \sum_{\mathbf{d} \in \mathbf{\Delta}} P(\mathbf{d}, \mathbf{s}_m) \qquad (1)$$

The probability of a derivation $\mathbf{d}$ is a product of probabilities of all the rules $\mathbf{r}$ that build it:

$$P(\mathbf{s}_m, \pi_m) = \sum_{\mathbf{\Delta} \in PEF(\pi_m)} \sum_{\mathbf{d} \in \mathbf{\Delta}} \prod_{\mathbf{r} \in \mathbf{d}} P(\mathbf{r}) \qquad (2)$$

[3] Which differs from (Quirk and Menezes, 2006).

As usual, the parameters of this model are the PCFG rule probabilities which are estimated from the latent treebank using EM as explained next.

3.2 Learning Splits on Latent Treebank

For training the latent PCFG over the latent treebank, we resort to EM (Dempster et al., 1977) which estimates PCFG rule probabilities to maximize the likelihood of the parallel corpus instances. Computing expectations for EM is done efficiently using Inside-Outside (Lari and Young, 1990). As in other state splitting models (Matsuzaki et al., 2005), after splitting the non-terminals, we distribute the probability uniformly over the new rules, and we add to each new rule some random noise to break the symmetry. We split the non-terminals only once as in (Matsuzaki et al., 2005) (unlike (Petrov et al., 2006)). For estimating the distribution for unknown words we replace all words that appear ≤ 3 times with the "UNKNOWN" token.

3.3 Inference

We use CKY+ (Chappelier and Rajman, 1998) to parse a source sentence $\mathbf{s}$ into a forest using the learned split PCFG. Unfortunately, computing the most-likely permutation (or alternatively $\acute{\mathbf{s}}$) as in

$$\operatorname*{argmax}_{\pi \in \Pi} \sum_{\mathbf{\Delta} \in PEF(\pi)} \sum_{\mathbf{d} \in \mathbf{\Delta}} P(\mathbf{d}, \pi_m)$$

from a lattice of permutations Π using a PCFG is NP-complete (Sima'an, 2002). Existing techniques, like variational decoding or Minimum-Bayes Risk (MBR), used for minimizing loss over trees as in (Petrov and Klein, 2007), are not directly applicable here. Hence, we opt for minimizing the risk of making an error under a loss function over permutations using the MBR decision rule (Kumar and Byrne, 2004):

$$\hat{\pi} = \operatorname*{argmin}_{\pi} \sum_{\pi_r} Loss(\pi, \pi_r) P(\pi_r) \qquad (3)$$

The loss function we minimize is Kendall τ (Birch and Osborne, 2011; Isozaki et al., 2010a) which is a ratio of wrongly ordered pairs of words (including gapped pairs) to the total number of pairs. We do Monte Carlo sampling of 10000 derivations from the chart of the $\mathbf{s}$ and then find the least risky permutation in terms of this loss. We sample from the true distribution by sampling edges recursively

using their inside probabilities. An empirical distribution over permutations $P(\pi)$ is given by the relative frequency of π in the sample.

With large samples it is hard to efficiently compute expected Kendall τ loss for each sampled hypothesis. For sentence of length k and sample of size n the complexity of a naive algorithm is $O(n^2k^2)$. Computing Kendall τ alone takes $O(k^2)$. We use the fact that Kendall τ decomposes as a linear function over all skip-bigrams b that could be built for any permutation of length k:

$$Kendall(\pi, \pi_r) = \sum_b \frac{1 - \delta(\pi, b)}{\frac{k(k-1)}{2}} \delta(\pi_r, b) \quad (4)$$

Here δ returns 1 if permutation π contains the skip bigram b, otherwise it returns 0. With this decomposition we can use the method from (DeNero et al., 2009) to efficiently compute the MBR hypothesis. Combining Equations 3 and 4 we get:

$$\hat{\pi} = \operatorname*{argmin}_{\pi} \sum_{\pi_r} \sum_b \frac{1 - \delta(\pi, b)}{\frac{k(k-1)}{2}} \delta(\pi_r, b) P(\pi_r) \quad (5)$$

We can move the summation inside and reformulate the expected Kendall τ loss as expectation over the skip-bigrams of the permutation.

$$= \operatorname*{argmin}_{\pi} \sum_b (1 - \delta(\pi, b)) \Big[\textstyle\sum_{\pi_r} \delta(\pi_r, b) P(\pi_r) \Big] \quad (6)$$

$$= \operatorname*{argmin}_{\pi} \sum_b (1 - \delta(\pi, b)) \mathbb{E}_{P(\pi_r)} \delta(\pi_r, b) \quad (7)$$

$$= \operatorname*{argmax}_{\pi} \sum_b \delta(\pi, b) \mathbb{E}_{P(\pi_r)} \delta(\pi_r, b) \quad (8)$$

This means we need to pass through the sampled list only twice: (1) to compute expectations over skip bigrams and (2) to compute expected loss of each sampled permutation. The time complexity is $O(nk^2)$ which is quite fast in practice.

4 Experiments

We conduct experiments with three baselines:

- **Baseline A**: No preordering.
- **Baseline B**: Rule based preordering (Isozaki et al., 2010b), which first obtains an HPSG parse tree using Enju parser [4] and after that swaps the children by moving the syntactic head to the final position to account for different head orientation in English and Japanese.
- **Baseline C**: LADER (Neubig et al., 2012): latent variable preordering that is based on ITG and large-margin training with latent variables. We used LADER in standard settings without any linguistic features (POS tags or syntactic trees).

And we test four variants of our model:

- **RG$_{\text{left}}$** - only canonical left branching PET
- **RG$_{\text{right}}$** - only canonical right branching PET
- **RG$_{\text{ITG-forest}}$** - all PETs that are binary (ITG)
- **RG$_{\text{PET-forest}}$** - all PETs.

We test these models on English-Japanese NTCIR-8 Patent Translation (PATMT) Task. For tuning we use all NTCIR-7 dev sets and for testing the test set from NTCIR-9 from both directions. All used data was tokenized (English with Moses tokenizer and Japanese with KyTea [5]) and filtered for sentences between 4 and 50 words. A subset of this data is used for training the Reordering Grammar, obtained by filtering out sentences that have prime permutations of arity > 5, and for the ITG version arity > 2. Baseline C was trained on 600 sentences because training is prohibitively slow. Table 1 shows the sizes of data used.

corpus	#sents	#words source	#words target
train RG$_{\text{PET}}$	786k	21M	–
train RG$_{\text{ITG}}$	783k	21M	–
train LADER	600	15k	–
train translation	950k	25M	30M
tune translation	2k	55K	66K
test translation	3k	78K	93K

Table 1: Data stats

The Reordering Grammar was trained for 10 iterations of EM on *train RG* data. We use 30 splits for binary non-terminals and 3 for non-binary. Training on this dataset takes 2 days and parsing tuning and testing set without any pruning takes 11 and 18 hours respectively.

4.1 Intrinsic evaluation

We test how well our model predicts gold reorderings before translation by training the alignment model using MGIZA++ [6] on the training corpus and using it to align the test corpus. Gold reorderings for the test corpus are obtained by sorting words by their average target position and (unaligned words follow their right neighboring

[4] http://www.nactem.ac.uk/enju/

[5] http://www.phontron.com/kytea/

[6] http://www.kyloo.net/software/doku.php/mgiza:overview

word). We use Kendall τ score for evaluation (note the difference with Section 3.3 where we defined it as a loss function).

Table 2 shows that our models outperform all baselines on this task. The only strange result here is that rule-based preordering obtains a lower score than no preordering, which might be an artifact of the Enju parser changing the tokenization of its input, so the Kendall τ of this system might not really reflect the real quality of the preordering. All other systems use the same tokenization.

	Kendall τ
$A^{No\ preordering}$	0.7655
$B^{Rule\ based}$	0.7567
C^{LADER}	0.8176
$RG_{\text{left-branching}}$	0.8201
$RG_{\text{right-branching}}$	0.8246
$RG_{\text{ITG-forest}}$	0.823
$RG_{\text{PET-forest}}$	0.8255

Table 2: Reordering prediction

4.2 Extrinsic evaluation in MT

The reordered output of all the mentioned baselines and versions of our model are translated with phrase-based MT system (Koehn et al., 2007) (distortion limit set to 6 with distance based reordering model) that is trained on **gold preordering** of the training data [7] $\acute{\mathbf{s}} - \mathbf{t}$. The only exception is Baseline A which is trained on original $\mathbf{s} - \mathbf{t}$.

We use a 5-gram language model trained with KenLM [8], tune 3 times with kb-mira (Cherry and Foster, 2012) to account for tuner instability and evaluated using Multeval [9] for statistical significance on 3 metrics: BLEU (Papineni et al., 2002), METEOR (Denkowski and Lavie, 2014) and TER (Snover et al., 2006). We additionally report RIBES score (Isozaki et al., 2010a) that concentrates on word order more than other metrics.

Single or all PETs? In Table 3 we see that using *all PETs* during training makes a big impact on performance. Only the *all PETs* variants

[7] Earlier work on preordering applies the preordering model to the training data to obtain a parallel corpus of *guessed* $\acute{\mathbf{s}} - \mathbf{t}$ pairs, which are the word re-aligned and then used for training the back-end MT system (Khalilov and Sima'an, 2011). We skip this, we take the risk of mismatch between the preordering and the back-end system, but this simplifies training and saves a good amount of training time.

[8] http://kheafield.com/code/kenlm/

[9] https://github.com/jhclark/multeval

System	BLEU ↑	METEOR ↑	TER ↓	RIBES ↑
$A^{No\ preord.}$	27.8	48.9	59.2	68.29
$B^{Rule\ based}$	29.6	48.7	59.2	71.12
C^{LADER}	31.1	50.5	56.0	74.29
RG_{left}	31.2^{AB}	50.5^{AB}	56.3^{AB}_{C}	**74.45**
RG_{right}	31.4^{AB}	50.5^{AB}	56.3^{AB}_{C}	**75.29**
$RG_{\text{ITG-forest}}$	$\mathbf{31.6^{ABC}}$	$\mathbf{50.8^{ABC}}$	$\mathbf{55.7^{ABC}}$	**75.29**
$RG_{\text{PET-forest}}$	$\mathbf{32.0^{ABC}}$	$\mathbf{51.0^{ABC}}$	$\mathbf{55.7^{ABC}}$	**75.62**

Table 3: Comparison of different preordering models. Superscripts A, B and C signify if the system is significantly better ($p < 0.05$) than the respective baseline or significantly worse (in which case it is a subscript). Significance tests were not computed for RIBES. Score is bold if the system is significantly better than all the baselines.

($RG_{\text{ITG-forest}}$ and $RG_{\text{PET-forest}}$) significantly outperform all baselines. If we are to choose a *single PET* per training instance, then learning RG from only left-branching PETs (the one usually chosen in other work, e.g. (Saluja et al., 2014)) performs slightly worse than the right-branching PET. This is possibly because English is mostly right-branching. So even though both PETs describe the same reordering, RG_{right} captures reordering over English input better than RG_{left}.

All PETs or binary only? *$RG_{\text{PET-forest}}$ performs significantly better than $RG_{\text{ITG-forest}}$* ($p < 0.05$). Non-ITG reordering operators are predicted rarely (in only 99 sentences of the test set), but they make a difference, because these operators often appear high in the predicted PET. Furthermore, having these operators during training might allow for better fit to the data.

How much reordering is resolved by the Reordering Grammar? Obviously, completely factorizing out the reordering from the translation process is impossible because reordering depends to a certain degree on target lexical choice. To quantify the contribution of Reordering Grammar, we tested decoding with different distortion limit values in the SMT system. We compare the phrase-based (PB) system with distance based cost function for reordering (Koehn et al., 2007) with and without preordering.

Figure 3 shows that Reordering Grammar gives substantial performance improvements at all distortion limits (both BLEU and RIBES). $RG_{\text{PET-forest}}$ is less sensitive to changes in decoder distortion limit than standard PBSMT. The perfor-

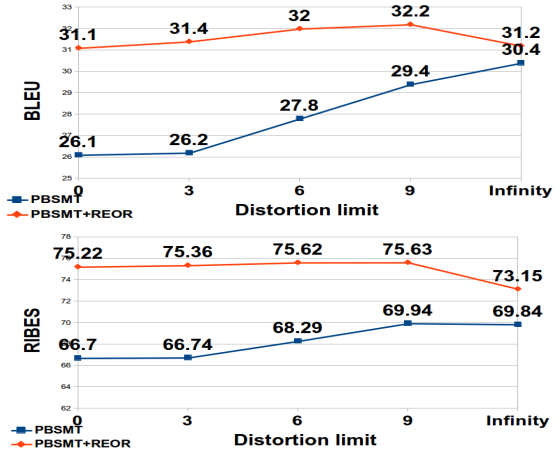

Figure 3: Distortion effect on BLEU and RIBES

mance of $RG_{PET\text{-}forest}$ varies only by 1.1 BLEU points while standard PBSMT by 4.3 BLEU points. Some local reordering in the decoder seems to help $RG_{PET\text{-}forest}$ but **large distortion limits seem to degrade the preordering choice**. This shows also that the improved performance of $RG_{PET\text{-}forest}$ is not only a result of efficiently exploring the full space of permutations, but also a result of improved scoring of permutations.

System	BLEU ↑	METEOR ↑	TER ↓	RIBES ↑
D^{PBMSD}	29.6	50.1	58.0	68.97
E^{Hiero}	32.6	52.1	54.5	74.12
$RG_{PET\text{-}forest}$+MSD	32.4^{D}	51.3^{D}_{E}	55.3^{D}_{E}	**75.72**

Table 4: Comparison to MSD and Hiero

Does the improvement remain for a decoder with MSD reordering model? We compare the $RG_{PET\text{-}forest}$ preordered model against a decoder that uses the strong MSD model (Tillmann, 2004; Koehn et al., 2007). Table 4 shows that using Reordering Grammar as front-end to MSD reordering (full Moses) improves performance by 2.8 BLEU points. The improvement is confirmed by METEOR, TER and RIBES. Our preordering model and MSD are complementary – the Reordering Grammar captures long distance reordering, while MSD possibly does better local reorderings, especially reorderings conditioned on the lexical part of translation units.

Interestingly, the MSD model (BLEU 29.6) improves over distance-based reordering (BLEU 27.8) by (BLEU 1.8), whereas the difference between these systems as back-ends to Reordering Grammar (respectively BLEU 32.4 and 32.0) is far smaller (0.4 BLEU). This suggests that a major share of reorderings can be handled well by preordering without conditioning on target lexical choice. Furthermore, this shows that $RG_{PET\text{-}forest}$ preordering is not very sensitive to the decoder's reordering model.

Comparison to a Hierarchical model (Hiero). Hierarchical preordering is not intended for a hierarchical model as Hiero (Chiang, 2005). Yet, here we compare our preordering system (PB MSD+RG) to Hiero for completeness, while we should keep in mind that Hiero's reordering model has access to much richer training data. We will discuss these differences shortly.

Table 4 shows that the difference in BLEU is not statistically significant, but there is more difference in METEOR and TER. RIBES, which concentrates more on reordering, prefers Reordering Grammar over Hiero. It is somewhat surprising that a preordering model combined with a phrase-based model succeeds to rival Hiero's performance on English-Japanese. Especially when looking at the differences between the two:

1. Reordering Grammar uses only minimal phrases, while Hiero uses composite (longer) phrases which encapsulate internal reorderings, but also non-contiguous phrases.
2. Hiero conditions its reordering on the lexical target side, whereas the Reordering Grammar does not (by definition).
3. Hiero uses a range of features, e.g., a language model, while Reordering Grammar is a mere generative PCFG.

The advantages of Hiero can be brought to bear upon Reordering Grammar by reformulating it as a discriminative model.

Which structure is learned? Figure 4 shows an example PET output showing how our model learns: (1) that the article "the" has no equivalent in Japanese, (2) that verbs go after their object, (3) to use postpositions instead of prepositions, and (4) to correctly group certain syntactic units, e.g. NPs and VPs.

5 Related work

The majority of work on preordering is based on syntactic parse trees, e.g., (Lerner and Petrov, 2013; Khalilov and Sima'an, 2011; Xia and Mccord, 2004). Here we concentrate on work that has common aspects with this work. Neubig et

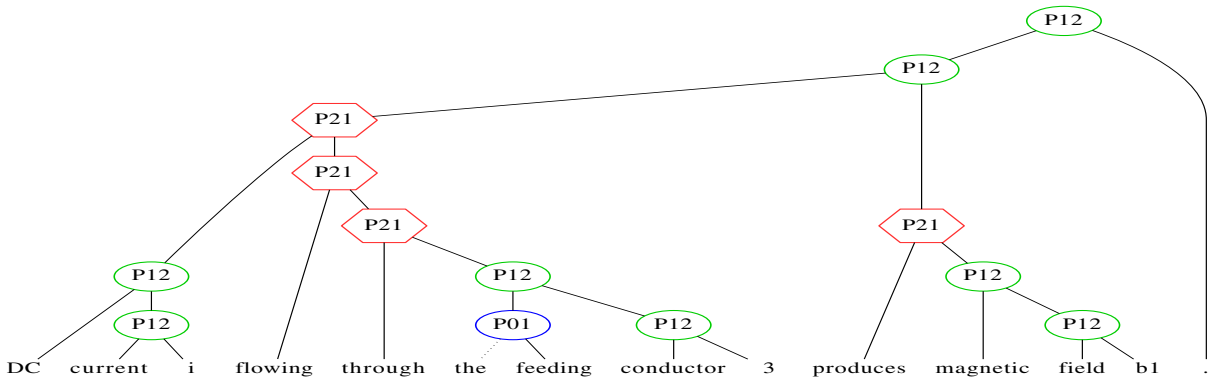

Figure 4: Example parse of English sentence that predicts reordering for English-Japanese

al (2012) trains a latent non-probabilistic discriminative model for preordering as an ITG-like grammar limited to binarizable permutations. Tromble and Eisner (2009) use ITG but do not train the grammar. They only use it to constrain the local search. DeNero and Uszkoreit (2011) present two separate consecutive steps for unsupervised induction of hierarchical structure (ITG) and the induction of a reordering function over it. In contrast, here we learn both the structure and the reordering function simultaneously. Furthermore, at test time, our inference with MBR over a measure of permutation (Kendall) allows exploiting both structure and reordering weights for inference, whereas test-time inference in (DeNero and Uszkoreit, 2011) is also a two step process – the parser forwards to the next stage the best parse.

Dyer and Resnik (2010) treat reordering as a latent variable and try to sum over all derivations that lead not only to the same reordering but also to the same translation. In their work they consider all permutations allowed by a given syntactic tree.

Saers et al (2012) induce synchronous grammar for translation by splitting the non-terminals, but unlike our approach they split generic non-terminals and not operators. Their most expressive grammar covers only binarizable permutations. The decoder that uses this model does not try to sum over many derivations that have the same yield. They do not make independence assumption like our "unary trick" which is probably the reason they do not split more than 8 times. They do not compare their results to any other SMT system and test on a very small dataset.

Saluja et al (2014) attempts inducing a refined Hiero grammar (latent synchronous CFG) from Normalized Decomposition Trees (NDT) (Zhang et al., 2008). While there are similarities with the present work, there are major differences. On the similarity side, NDTs are decomposing alignments in ways similar to PETs, and both Saluja's and our models refine the labels on the nodes of these decompositions. However, there are major differences between the two:

- Our model is completely monolingual and unlexicalized (does not condition its reordering on the translation) in contrast with the Latent SCFG used in (Saluja et al., 2014),
- Our Latent PCFG label splits are defined as refinements of prime permutations, i.e., specifically designed for learning reordering, whereas (Saluja et al., 2014) aims at learning label splitting that helps predicting NDTs from source sentences,
- Our model exploits **all PETs and all derivations**, both during training (latent treebank) and during inferences. In (Saluja et al., 2014) only left branching NDT derivations are used for learning the model.
- The training data used by (Saluja et al., 2014) is about 60 times smaller in number of words than the data used here; the test set of (Saluja et al., 2014) also consists of far shorter sentences where reordering could be less crucial.

A related work with a similar intuition is presented in (Maillette de Buy Wenniger and Sima'an, 2014), where nodes of a tree structure similar to PETs are labeled with reordering patterns obtained by factorizing word alignments into Hierarchical Alignment Trees. These patterns are used for labeling the standard Hiero grammar. Unlike this work, the labels extracted by (Maillette de Buy Wenniger and Sima'an, 2014) are clustered manually into less than a dozen labels without the possibility of fitting the labels to the training data.

6 Conclusion

We present a generative Reordering PCFG model learned from latent treebanks over PETs obtained by factorizing permutations over minimal phrase pairs. Our Reordering PCFG handles non-ITG reordering patterns (up to 5-ary branching) and it works with all PETs that factorize a permutation (rather than a single PET). To the best of our knowledge this is the first time both extensions are shown to improve performance. The empirical results on English-Japanese show that (1) when used for preordering, the Reordering PCFG helps particularly with relieving the phrase-based model from long range reorderings, (2) combined with a state-of-the-art phrase model, Reordering PCFG shows performance not too different from Hiero, supporting the common wisdom of factorizing long range reordering outside the decoder, (3) Reordering PCFG generates derivations that seem to coincide well with linguistically-motivated reordering patterns for English-Japanese. There are various direction we would like to explore, the most obvious of which are integrating the learned reordering with other feature functions in a discriminative setting, and extending the model to deal with non-contiguous minimal phrases.

Abstract

Divergent word order between languages causes delay in simultaneous machine translation. We present a sentence rewriting method that generates more monotonic translations to improve the speed-accuracy tradeoff. We design grammaticality and meaning-preserving syntactic transformation rules that operate on constituent parse trees. We apply the rules to reference translations to make their word order closer to the source language word order. On Japanese-English translation (two languages with substantially different structure), incorporating the rewritten, more monotonic reference translation into a phrase-based machine translation system enables better translations faster than a baseline system that only uses gold reference translations.

1 Introduction

Simultaneous interpretation is challenging because it demands both quality and speed. Conventional **batch** translation waits until the entire sentence is completed before starting to translate. This merely optimizes translation quality and often introduces undesirable lag between the speaker and the audience. Simultaneous interpretation instead requires a tradeoff between quality and speed. A common strategy is to translate independently translatable segments as soon as possible. Various segmentation methods (Fujita et al., 2013; Oda et al., 2014) reduce translation delay; they are limited, however, by the unavoidable word reordering between languages with drastically different word orders. We show an example of Japanese-English translation in Figure 1. Consider the **batch** translation: in English, the verb *change* comes immediately after the subject *We*, whereas in Japanese it comes at the end of the sentence; therefore, to produce an intelligible English sentence, we must translate the object after the final verb is observed, resulting in one large and painfully delayed segment.

To reduce structural discrepancy, we can apply syntactic transformations to make the word order of one language closer to the other. Consider the **monotone** translation in Figure 1. By passivizing the English sentence, we can cache the subject and begin translating before observing the final verb. Furthermore, by using the English possessive, we mimic the order of the Japanese genitive construction. These transformations enable us to divide the input into shorter segments, thus reducing translation delay.

To produce such monotone translations, a straightforward approach is to incorporate interpretation data into the learning of a machine translation (MT) system, because human interpreters use a variety of strategies (Shimizu et al., 2014; Camayd-Freixas, 2011; Tohyama and Matsubara, 2006) to fine-tune the word order. Shimizu et al. (2013) shows that this approach improves the speed-accuracy tradeoff. However, existing parallel simultaneous interpretation corpora (Shimizu et al., 2014; Matsubara et al., 2002; Bendazzoli and Sandrelli, 2005) are often small, and collecting new data is expensive due to the inherent costs of recording and transcribing speeches (Paulik and Waibel, 2010). In addition, due to the intense time pressure during interpretation, human interpretation has the disadvantage of simpler, less precise diction (Camayd-Freixas, 2011; Al-Khanji et al., 2000) compared to human translations done at the translator's leisure, allowing for more introspection and precise word choice.

We aim to address the data scarcity problem and combine translators' lexical precision and interpreters' syntactic flexibility. We propose to **rewrite the reference translation** in a way that uses the original lexicon, obeys standard grammar rules of

the target language, preserves the original semantics, and yields more monotonic translations. We then train the MT system with the rewritten references so that it learns how to produce low-latency translations from the data. A data-driven approach to learning these rewriting rules is hampered by the dearth of parallel data: we have few examples of text that have been both interpreted and translated. Therefore, we design syntactic transformation rules based on linguistic analysis of the source and the target languages. We apply these rules to parsed text and decide whether to accept the rewritten sentence based on the amount of delay reduction. In this work, we focus on Japanese to English translation, because (i) Japanese and English have significantly different word orders (SOV vs. SVO); and consequently, (ii) the syntactic constituents required earlier by an English sentence often come late in the corresponding Japanese sentence.

We evaluate our approach using standard machine translation data (the Reuters newsfeed Japanese-English corpus) in a simultaneous translation setting. Our experimental results show that including the rewritten references into the learning of a phrase-based MT system results in a better speed-accuracy tradeoff against both the original and the rewritten reference translations.

2 The Problem of Delay Reduction

Simultaneous interpretation has two goals: producing good translations *and* producing them promptly. However, most existing parallel corpora and MT systems do not address the issue of **delay** during translation. We explicitly adapt the training data by rewriting rules to reduce delay. We first define translation delay and describe—in general terms—our rewriting rules. In the next section, we describe the rules in more detail.

While we are motivated by real-time interpretation, to simplify our problem, we assume that we have perfect text input. Given this constraint, a typical simultaneous interpretation system (Sridhar et al., 2013; Fujita et al., 2013; Oda et al., 2014) produces partial translations of consecutive segments in the source sentence and concatenates them to produce a complete translation. We define the *translation delay* of a sentence as the average number of tokens the system has to observe between translation of two consecutive segments (denoted by # words/seg).[1] For instance, the minimum delay of 1 word/seg is achieved when we translate immediately upon hearing a word. At test time, when the input is segmented, the delay is the average segment length. During the data preprocessing step of rewriting, we calculate delay from word alignments (Section 4).

Given a reference batch translation x, we apply a set of rewriting rules $\mathcal{R}$ to x to minimize its delay. A rewriting rule $r \in \mathcal{R}$ is a mapping that takes the constituent parse tree of x as input and outputs a modified parse tree, which specifies a rewritten sentence x'. The tree-editing operation includes node deletion, insertion, and swapping, as well as induced changes of word form and node label. A valid transformation rule should rearrange constituents in x to follow the word order of the input sentence as closely as possible, subject to grammatical constraints and preservation of the original meaning.

[1] Ideally, delay should be based on time lapse. However, timestamping is not applicable to typical MT corpus, therefore we approximate it by number of tokens and ignore decoding time.

3 Transformation Rules

We design a variety of syntactic transformation rules for Japanese-English translation motivated by their structural differences. Our rules cover verb, noun, and clause reordering. While we specifically focus on Japanese to English, many rules are broadly applicable to SOV to SVO languages.

3.1 Verb Phrases

The most significant difference between Japanese and English is that the head of a verb phrase comes at the end of Japanese sentences. In English, it occupies one of the initial positions. We now introduce rules that can postpone a head verb.

Passivization and Activization In Japanese, the standard structure of a sentence is $\texttt{NP}_1$ $\texttt{NP}_2$ verb, where case markers following the verb indicate the voice of the sentence. However, in English, we have $\texttt{NP}_1$ verb $\texttt{NP}_2$, where the form of the verb indicates its voice. Changing the voice is particularly useful when $\texttt{NP}_2$ (object in an active-voice sentence and subject in a passive-voice sentence) is long. By reversing positions of verb and $\texttt{NP}_2$, we are not held back by the upcoming verb and can start to translate $\texttt{NP}_2$ immediately. Figure 1 shows an example in which passive voice can help make the target and source word orders more compatible, but it is not the case that passivizing every sentence would be a good idea; sometimes making a passive sentence active makes the word orders more compatible if the objects are relatively short:

O: The talk was **denied** by the boycott group spokesman.
R: The boycott group spokesman **denied** the talk.

Quotative Verbs *Quotative* verbs are verbs that, syntactically and semantically, resemble *said* and often start an independent clause. Such verbs are frequent, especially in news, and can be moved to the end of a sentence:

O: **They announced** that the president will restructure the division.
R: The president will restructure the division, **they announced**.

In addition to quotative verbs, candidates typically include factive (e.g., *know*, *realize*, *observe*), factive-like (e.g., *announce*, *determine*), belief (e.g., *believe*, *think*, *suspect*), and antifactive (e.g., *doubt*, *deny*) verbs. When these verbs are followed by a clause (S or SBAR), we move the verb and its subject to the end of the clause.

While some exploratory work automatically extracts factive verbs, to our knowledge, an exhaustive list does not exist. To obtain a list with reasonable coverage, we exploit the fact that Japanese has an unambiguous quotative particle, *to*, that precedes such verbs.[2] We identify all of the verbs in the Kyoto corpus (Neubig, 2011) marked by the quotative particle and translate them into English. We then use these as our quotative verbs.[3]

3.2 Noun Phrases

Another difference between Japanese and English lies in the order of adjectives and the nouns they modify. We identify two situations where we can take advantage of the flexibility of English grammar to favor sentence structures consistent with positions of nouns in Japanese.

Genitive Reordering In Japanese, genitive constructions always occur in the form of X *no* Y, where Y belongs to X. In English, however, the order may be reversed through the *of* construction. Therefore, we transform constructions $\texttt{NP}_1$ of $\texttt{NP}_2$ to possessives using the apostrophe-s, $\texttt{NP}_2$'(s) $\texttt{NP}_1$ (Figure 1). We use simple heuristics to decide if such a transformation is valid. For example, when X / Y contains proper nouns (e.g., *the City of New York*), numbers (e.g., *seven pounds of sugar*), or pronouns (e.g., *most of them*), changing them to the possessive case is not legal.

***that* Clause** In English, clauses are often modified through a pleonastic pronoun. E.g., *It is* ADJP *to/that* SBAR/S. In Japanese, however, the subject (clause) is usually put at the beginning. To be consistent with the Japanese word order, we move the modified clause to the start of the sentence: *To* S/SBAR *is* ADJP. The rewritten English sentence is still grammatical, although its structure is less frequent in common English usage. For example,

O: **It is important** to remain watchful.
R: To remain watchful **is important**.

[2] We use a morphological analyzer to distinguish between the conjunction and quotative particles. Examples of words marked by this particle include 見られる (*expect*), 言う (*say*), 思われる (*seem*), する (*assume*), 信じる (*believe*) and so on.

[3] We also include the phrase *It looks like*.

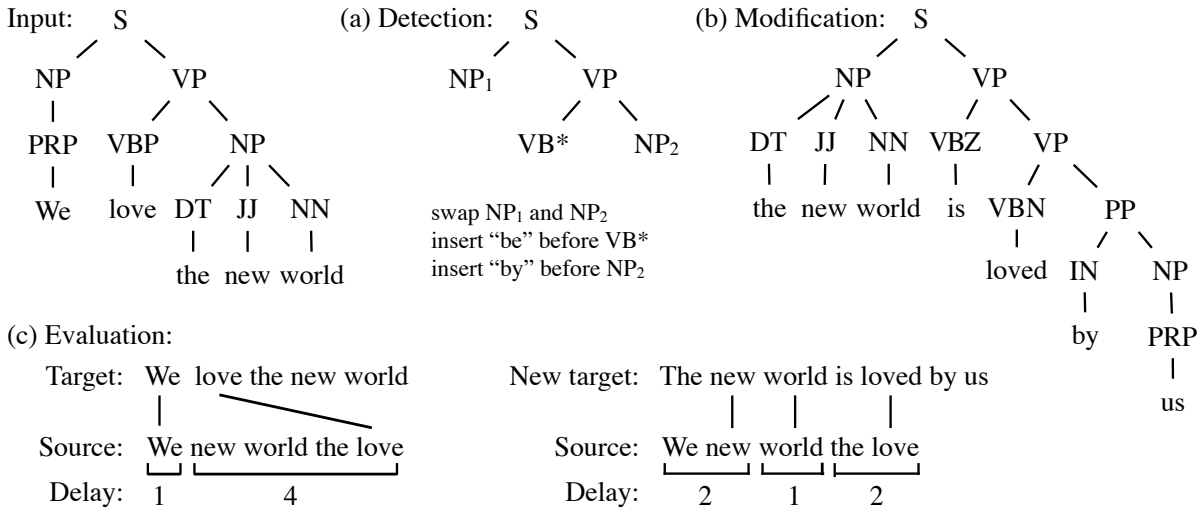

Figure 2: An example of applying the passivization rule to create a translation reference that is more monotonic.

3.3 Conjunction Clause

In Japanese, clausal conjunctions are often marked at the end of the initial clause of a compound sentence. In English, however, the order of clauses is more flexible. We can therefore reduce delay by reordering the English clauses to mirror how they typically appear in Japanese. Below we describe rules reversing the order of clauses connected by these conjunctions:

- Clausal conjunctions: *because (of)*, *in order to*
- Contrastive conjunctions: *despite*, *even though*, *although*
- Conditionals: *(even) if*, *as a result (of)*
- Misc: *according to*

In standard Japanese, such conjunctions include *no de*, *kara*, *de mo* and so on. The sentence often appears in the form of $\texttt{S}_2$ `conj`, $\texttt{S}_1$. In English, however, two common constructions are

> $\texttt{S}_1$ `conj` $\texttt{S}_2$: We should march **because** winter is coming.
> `conj` $\texttt{S}_2$, $\texttt{S}_1$: **Because** winter is coming, we should march.

To follow the Japanese clause order, we adapt the above two constructions to

> $\texttt{S}_2$, `conj'` $\texttt{S}_1$: Winter is coming, **because of this**, we should march.

Here `conj'` represents the original conjunction word appended with simple pronouns/phrases to refer to $\texttt{S}_2$. For example, *because* → *because of this*, *even if* → *even if this is the case*.

4 Sentence Rewriting Process

We now turn our attention to the implementation of the syntactic transformation rules described above. Applying a transformation consists of three steps:

1. **Detection:** Identify nodes in the parse tree for which the transformation is applicable;
2. **Modification:** Transform nodes and labels;
3. **Evaluation:** Compute delay reduction, and decide whether to accept the rewritten sentence.

Figure 2 illustrates the process using passivization as an example. In the detection step, we find the subtree that satisfies the condition of applying a rule. In this case, we look for an `S` node whose children include an `NP` (denoted by $\texttt{NP}_1$), the subject, and a `VP` to its right, such that the `VP` node has a leaf `VB*`, the main verb,[4] followed by another `NP` (denoted by $\texttt{NP}_2$), the object. We allow the parent nodes (`S` and `VP`) to have additional children besides the matched ones. They are not affected during the transformation. In the modification step, we swap the subject node and object node; we add the verb *be* in its correct form by checking the tense of the verb and the form of $\texttt{NP}_2$;[5]and we add the preposition *by* before the subject. The process is executed recursively throughout the parse tree.

[4]The main verb excludes *be* and *have* when it indicates tense (e.g., *have done*).

[5]We use the Nodebox linguistic library (`https://www.nodebox.net/code`) to detect and modify word forms.

Although our rules are designed to minimize long range reordering, there are exceptions.[6] Thus applying a rule does not always reduce delay. In the evaluation step, we compare translation delay before and after applying the rule. We accept a rewritten sentence if its delay is reduced; otherwise, we revert to the input sentence. Since we do not segment sentences during rewriting, we must estimate the delay.

To estimate the delay, we use word alignments. Figure 2c shows the source Japanese sentence in its word-for-word English translation and alignments from the target words to the source words. The first English word, *We*, is aligned to the first Japanese word; it can thus be treated as an independent segment and translated immediately. The second English word, *love*, is aligned to the last Japanese word, which means the system cannot start to translate until four more Japanese words are revealed. This alignment therefore forms a segment with delay of four words/seg. Alignments of the following words come before the source word aligned to *love*; hence, they are already translated in the previous segment and we do not double count their delay. In this example, the delay of the original sentence is 2.5 word/seg; after rewriting, it is reduced to 1.7 word/seg. Therefore, we accept the rewritten sentence. However, when the subject phrase is long and the object phrase is short, a swap may not reduce delay.

We can now formally define the **delay**. Let e_i be the ith target word in the input sentence x and a_i be the maximum index among indices of source words that e_i aligned to. We define the delay of e_i as $d_i = \max(0, a_i - \max_{j<i} a_j)$. The delay of x is then $\sum_{i=1}^{N} d_i/N$, where the sum is over all aligned words except punctuation and stopwords.

Given a set of rules, we need to decide which rules to apply and in what order. Fortunately, our rules have little interaction with each other, and the order of application has a negligible effect. We apply the rules, roughly, sequentially in order of complexity: if the output of current rule is not accepted, the sentence is reverted to the last accepted version.

	Train	Tune	Test
Ja	21.3M	30.2k	23.3k
En-GD	16.8M	23.8k	18.5k
En-RW	16.8M	24.1k	18.7k

Table 1: Number of words in the training, tuning, and test datasets. En-GD and En-RW represent the gold reference set and the rewritten reference set.

5 Experiments

We evaluate our method on the Reuters Japanese-English corpus of news articles (Utiyama and Isahara, 2003). For training the MT system, we also include the EIJIRO dictionary entries and the accompanying example sentences.[7] Statistics of the dataset are shown in Table 1. The rewritten translation is generally slightly longer than the gold translation because our rewriting often involves inserting pronouns (e.g. *it*, *this*) for antecedents.

We use the `TreebankWordTokenizer` from NLTK (Bird et al., 2009) to tokenize English sentences and Kuromoji Japanese morphological analyzer[8] to tokenize Japanese sentences. Our phrase-based MT system is trained by Moses (Koehn et al., 2003) with standard parameters settings. We use GIZA++ (Och and Ney, 2003) for word alignment and k-best batch MIRA (Cherry and Foster, 2012) for tuning. The translation quality is evaluated by BLEU (Papineni et al., 2002) and RIBES (Isozaki et al., 2010).[9] To obtain the parse trees for English sentences, we use the Stanford Parser (Klein and Manning, 2003) and the included English model.

5.1 Quality of Rewritten Translations

After applying the rewriting rules (Section 4), Table 2 shows the percentage of sentences that are candidates and how many rewrites are accepted. The most generalizable rules are passivization and delaying quotative verbs. We rewrite 32.2% of sentences, reducing the delay from 9.9 words/seg to 6.3 words/seg per segment for rewritten sentences and from 7.8 words/seg to 6.7 words/seg overall.

[6] For example, in clause transformation, the Japanese conjunction *moshi*, which is clause initial, may appear at the beginning of a sentence to emphasize conditionals, although its appearance is relatively rare.

[7] Available at `http://eijiro.jp`

[8] Available at `http://www.atilika.org/`

[9] In contrast to BLEU, RIBES is an order-sensitive metric commonly used for translation between Japanese and English.

	verb	voice	noun	conj.
Applicable %	39.9	50.0	26.4	4.8
Accepted %	22.5	24.0	51.2	38.4

Table 2: Percentage of sentences that each rule category can be applied to (Applicable) and the percentage of sentences for which the rule results in a more monotonic sentence (Accepted).

We evaluate the quality of our rewritten sentences from two perspectives: grammaticality and preserved semantics. To examine how close the rewritten sentences are to standard English, we train a 5-gram language model using the English data from the Europarl corpus, consisting of 46 million words, and use it to compute perplexity. Rewriting references increases the perplexity under the language model only slightly: from 332.0 to 335.4. To ensure that rewrites leave meaning unchanged, we use the SEMAFOR semantic role labeler (Das et al., 2014) on the original and modified sentence; for each role-labeled token in the reference sentence, we examine its corresponding role in the rewritten sentence and calculate the average accuracy acrosss all sentences. Even ignoring benign lexical changes—for example, *he* becoming *him* in a passivized sentence—95.5% of the words retain their semantic roles in the rewritten sentences.

Although our rules are conservative to minimize corruption, some errors are unavoidable propagation of parser errors. For example, the sentence *the London Stock Exchange closes at 1230 GMT today* is parsed as:[10]

(S (NP *the London Stock Exchange*)
(VP (VBZ *closes*)
(PP *at 1230*)
(NP *GMT today*)))

GMT today is separated from the PP as an NP and is mistaken as the object. The passive version is then *GMT today is closed at 1230 by the London Stock Exchange*. Such errors could be reduced by skipping nodes with low inside/outside scores given by the parser, or skipping low-frequency patterns. However, we leave this for future work.

5.2 Segmentation

At test time, we use right probability (Fujita et al., 2013, RP) to decide when to start translating a sentence. As we read in the source Japanese sentence, if the input segment matches an entry in the learned phrase table, we query the RP of the Japanese/English phrase pair. A higher RP indicates that the English translation of this Japanese phrase will likely be followed by the translation of the next Japanese phrase. In other words, translation of the two consecutive Japanese phrases is monotonic, thus, we can begin translating immediately. Following (Fujita et al., 2013), if the RP of the current phrase is lower than a fixed threshold, we cache the current phrase and wait for more words from the source sentence; otherwise, we translate all cached phrases. Finally, translations of segments are concatenated to form a complete translation of the input sentence.

5.3 Speed/Accuracy Trade-off

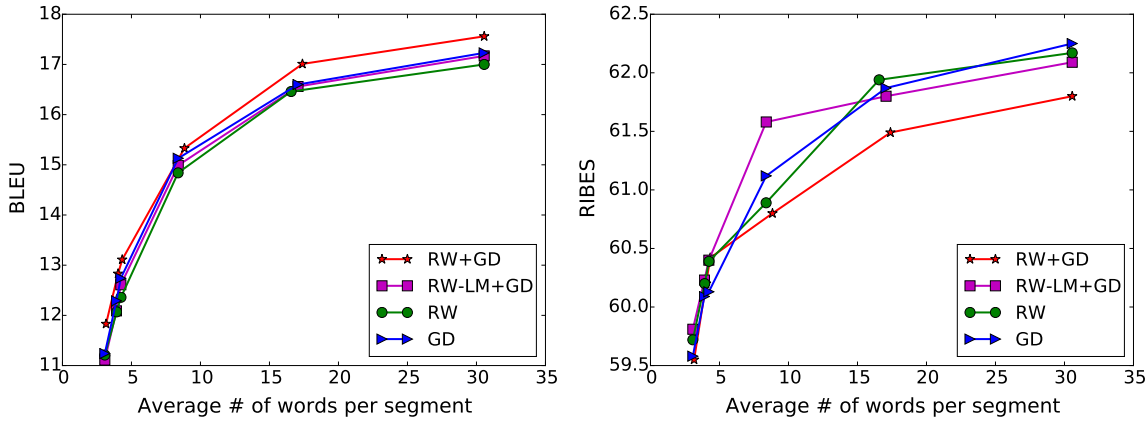
To show the effect of rewritten references, we compare the following MT systems:

- **GD:** only gold reference translations;
- **RW:** only rewritten reference translations;
- **RW+GD:** both gold and the rewritten references; and
- **RW-LM+GD:** using gold reference translations but using the rewritten references for training the LM and for tuning.

For RW+GD and RW-LM+GD, we interpolate the language models of GD and RW. The interpolating weight is tuned with the rewritten sentences. For RW+GD, we combine the translation models (phrase tables and reordering tables) of RW and GD by fill-up combination (Bisazza et al., 2011), where all entries in the tables of RW are preserved and entries from the tables of GD are added if new.

Increasing the RP threshold increases interpretation delay but improves the quality of the translation. We set the RP threshold at 0.0, 0.2, 0.4, 0.8 and finally 1.0 (equivalent to batch translation). Figure 3 shows the BLEU/RIBES scores vs. the number of words per segement as we increase the threshold. Rewritten sentences alone do not significantly improve over the baseline. We suspect this is because the transformation rules sometimes generate ungrammatical sentences due to parsing errors, which impairs learning. However, combining RW and GD results in a better speed-accuracy tradeoff: the RW+GD curve completely dominates other curves in Figure 3a, 3c. Thus, using more monotone translations improves simultaneous machine translation, and because RW-LM+GD is about

[10] For simplicity we show the shallow parse only.



(a) BLEU w.r.t. gold ref

(b) RIBES w.r.t. gold ref

(c) BLEU w.r.t. rewritten ref

(d) RIBES w.r.t. rewritten ref

Figure 3: Speed/accuracy tradeoff curves: BLEU (left) / RIBES (right) versus translation delay (average number of words per segment).

the same as GD, the major improvement likely comes from the translation model from rewritten sentences.

The right two plots recapitulate the evaluation with the RIBES metric. This result is less clear, as MT systems are optimized for BLEU and RIBES penalizes word reordering, making it difficult to compare systems that intentionally change word order. Nevertheless, RW is comparable to GD on gold references and superior to the baseline on rewritten references.

5.4 Effect on Verbs

Rewriting training data not only creates lower latency simultaneous translations, but it also improves *batch* translation. One reason is that SOV to SVO translation often drops the verb because of long range reordering. (We see this for Japanese here, but this is also true for German.) Similar word orders in the source and target results in less reordering and improves phrase-based MT (Collins et al., 2005; Xu et al., 2009). Table 3 shows the number of verbs in the translations of the test sentences produced by GD, RW, RW+GD, as well as the number in the gold reference translation. Both RW and RW+GD produce more verbs (a statistically significant result), although RW+GD captures the most verbs.

	Translation			
	GD	RW	RW+GD	Gold ref
# of verbs	1971	2050	**2224**	2731

Table 3: Number of verbs in the test set translation produced by different models and the gold reference translation. Boldface indicates the number is significantly larger than others (excluding the gold ref) according to two-sample t-tests with $p < 0.001$.

Ref	**he also said** that the real dangers for the euro lay in the potential for divergences in the domestic policy needs among the various participating nations of the single currency.
GD	**he** also for the euro, is a real danger to launch a single currency in many different countries and domestic policies on the need for the possibility of a difference.
RW	**he** also for the euro is a real danger to launch a single currency in many different countries and domestic policies to the needs of the possibility of a difference, **he said**.

Table 4: Example of translation produced by GD and RW.

5.5 Error Analysis

Table 4 compares translations by GD and RW. RW correctly puts the verb *said* at the end, while GD drops the final verb. However, RW still produces *he* at the beginning (also the first word in the Japanese source sentence). This is because our current segmentation strategy do not preserve words for *later* translation—a note-taking strategy used by human interpreters.

6 Related Work

Previous approaches to simultaneous machine translation have employed explicit interpretation strategies for coping with delay. Two major approaches are segmentation and prediction.

Most segmentation strategies are based on heuristics, such as pauses in speech (Fügen et al., 2007; Bangalore et al., 2009), comma prediction (Sridhar et al., 2013) and phrase reordering probability (Fujita et al., 2013). Learning-based methods have also been proposed. Oda et al. (2014) find segmentations that maximize the BLEU score of the final concatenated translation by dynamic programming. Grissom II et al. (2014) formulate simultaneous translation as a sequential decision making problem and uses reinforcement learning to decide when to translate. One limitation of these methods is that when learning with standard batch MT corpus, their gain can be restricted by natural word reordering between the source and the target sentences, as explained in Section 1.

In an SOV-SVO context, methods to predict unseen words are proposed to alleviate the above restriction. Matsubara et al. (1999) predict the English verb in the target sentence and integrates it syntactically. Grissom II et al. (2014) predict the final verb in the source sentence and decide when to use the predicted verb with reinforcement learning. Nevertheless, unless the predictor considers contextual and background information, which human interpreters often rely on for prediction (Hönig, 1997; Camayd-Freixas, 2011), such a prediction task is inherently hard.

Unlike previous approaches to simultaneous translation, we directly adapt the training data and transform a translated sentence to an "interpreted" one. We can, therefore, take advantage of the abundance of parallel batch-translated corpora for training a simultaneous MT system. In addition, as a data preprocessing step, our approach is orthogonal to the others, with which it can be easily combined.

This work is also related to preprocessing reordering approaches (Xu et al., 2009; Collins et al., 2005; Galley and Manning, 2008; Hoshino et al., 2013; Hoshino et al., 2014) in batch MT for language pairs with substantially different word orders. However, our problem is different in several ways. First, while the approaches resemble each other, our motivation is to reduce translation delay. Second, they reorder the source sentence, which is nontrivial and time-consuming when the sentence is incrementally revealed. Third, rewriting the target sentence requires the output to be grammatical (for it to be used as reference translation), which is not a concern when rewriting source sentences.

7 Conclusion

Training MT systems with more monotonic (interpretation-like) sentences improves the speed-accuracy tradeoff for simultaneous machine translation. By designing syntactic transformations and rewriting batch translations into more monotonic translations, we reduce the translation delay. MT systems trained on the rewritten reference translations learn interpretation strategies implicitly from the data.

Our rewrites are based on linguistic knowledge and inspired by techniques used by human interpreters. They cover a wide range of reordering phenomena between Japanese and English, and more generally, between SOV and SVO languages. A natural extension is to automatically extract such rules from parallel corpora. While there exist approaches that extract syntactic tree transformation rules automatically, one of the difficulties is that most parallel corpora is dominated by lexical paraphrasing instead of syntactic paraphrasing.

Abstract

This paper describes an approach to large-scale modeling of sentiment analysis for the social sciences. The goal is to model relations between nation states through social media. Many cross-disciplinary applications of NLP involve making predictions (such as predicting political elections), but this paper instead focuses on a model that is applicable to broader analysis. Do citizens express opinions in line with their home country's formal relations? When opinions diverge over time, what is the cause and can social media serve to detect these changes? We describe several learning algorithms to study how the populace of a country discusses foreign nations on Twitter, ranging from state-of-the-art contextual sentiment analysis to some required practical learners that filter irrelevant tweets. We evaluate on standard sentiment evaluations, but we also show strong correlations with two public opinion polls and current international alliance relationships. We conclude with some political science use cases.

1 Introduction

The volume of text available on social media provides a new opportunity for public policy and political science. Specifically in the area of international relations, advances in natural language understanding and sentiment analysis may offer new insights into the sentiment of one nation toward another. This paper processes 17 months of Twitter data to identify discussions about sovereign states, and it aggregates opinions toward these states from foreign nations. We present a novel application of contextual sentiment with this task, and identify several semi-supervised learning algorithms that are needed to address the reference resolution challenge inherent to country names. We present intrinsic evaluations of our learners on labeled datasets as well as four extrinsic political science evaluations that show strong alignment with our large-scale sentiment extraction.

An open question for international policy makers is the extent to which public opinion drives decision making. How do military conflicts affect a neutral nation's relationship? Does public opinion shift toward a country after a formal alliance is created, or must popular opinion shift first? These questions are difficult to address due to the lack of measurable data. While polling data can be collected, collection beyond a handful of countries is cost prohibitive. This paper hypothesizes that sentiment analysis can be used as a proxy to track international relations between nation states. We describe the largest attempt (over 2 billion tweets) to measure nation state sentiment across hundreds of country pairs.

The core challenge to measuring public opinion between countries is an accurate algorithm to judge the sentiment of a text toward another nation. Unlike traditional sentiment analysis, the general sentiment of the text is not adequate. Let the following serve as an example.

> *I miss **Pakistan**. I am in full sad mode right about now.* @RachOrange (California)

This tweet is a *positive* example from the USA toward Pakistan. However, a typical sentiment classifier misclassifies this as negative because *miss* and *sad* express sadness. A *contextual* sentiment classification is needed to identify that the predicate *miss* is positive toward its argument. Several

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 65–75,
Lisbon, Portugal, 17-21 September 2015.

recent competitions included contextual classification tasks, and this paper builds on the best of those algorithms for a unique nation-nation sentiment classifier. We describe a multi-classifier model that aggregates tweets into counts of positive and negative sentiment from one country toward another. Several unique filters are required to resolve textual references toward country names.

We first present standard NLP sentiment experiments that show the classifiers achieve good performance on individual tweets. To evaluate the complete nation-nation system, we present four novel evaluations, including two public opinion polls. Correlation with the polls is high at $\rho = .8$, and our nation-nation sentiment is 84% accurate with NATO and EU relations. We then discuss the implications for both NLP as a technical science and political science as a social science.

2 Previous Work

Sentiment analysis is a large field applicable to many genres. This paper focuses on social media and contextual polarity, so we only address the closest work in those areas. For a broader perspective, several survey papers are available (Pang and Lee, 2008; Tang et al., 2009; Liu and Zhang, 2012; Tsytsarau and Palpanas, 2012).

Several sources for microblogs have been used to measure a large population's mood and opinion. O'Connor et al. (2010) used Twitter data to compute a ratio of positive and negative words to measure consumer confidence and presidential approval. Kramer (2010) counted lexicon words on Facebook for a general 'happiness' measure, and Thelwall (2011) built a general sentiment model on MySpace user comments. These are early general sentiment algorithms for social media.

Other microblog research focused on finding noisy training data with distant supervision. Many of these algorithms use emoticons as semantic indicators of polarity. For instance, a tweet that contains a sad face likely contains a negative polarity (Read, 2005; Go et al., 2009; Bifet and Frank, 2010; Pak and Paroubek, 2010; Davidov et al., 2010; Kouloumpis et al., 2011). In a similar vein, hashtags can serve as noisy labels (Davidov et al., 2010; Kouloumpis et al., 2011). Our bootstrap learner is similar in its selection of seed tokens.

Supervised learning for *contextual* polarity has received more attention recently. Jiang et al. (2011) is an early approach. Work on product reviews sought the sentiment toward particular product features. These systems used rule based models based on parts of speech and surface features (Nasukawa and Yi, 2003; Hu and Liu, 2004; Ding and Liu, 2007). Most notably, recent Semeval competitions addressed contextual polarity (Nakov et al., 2013; Rosenthal et al., 2014). The top performing systems learned their own lexicons custom to the domain (Mohammad et al., 2013; Zhu et al., 2014). Our proposed system includes many of their features, but several fail to help on nation-nation sentiment.

Early approaches to *topic detection* on social media were straightforward, selecting a keyword (e.g., "Obama") to represent the topic (e.g., "US President") and retrieving tweets containing the word (O'Connor et al., 2010; Tumasjan et al., 2010; Tan et al., 2011). These systems classify the polarity of *the entire tweet*, but ignore the question of polarity toward the particular topic. This paper focuses on identifying tweets with nation mentions, and identifying the sentiment toward the mention, not the overall sentiment of the text.

Event detection on Twitter is also relevant (Sakaki et al., 2010; Becker et al., 2011). In fact, O'Connor et al. (2013) modeled events to detect international relations, but our goal is to model long term relation trends, not isolated events.

Large-scale computational studies of social media are relatively new to the international relations community. Barbera and Rivero (2014) is a notable example for election analysis. Some studied online discussion about Palestine (Lynch, 2014) and the role of Twitter in the Arab Spring (Howard et al., 2011; Howard, 2013). However, they simply counted the volume of tweets containing keywords. This paper applies a deeper NLP analysis and we show that frequency alone fails at detecting nation-nation relations.

Most relevant to this paper is a study of Arabic tweets into anti-American sentiment. Jamal et al. (2015) used a supervised sentiment classifier on Arabic tweets to measure sentiment toward the USA. Our paper differs by taking a broader view. We investigate with state-of-the-art sentiment algorithms, and we we study practical problems that arise within when measuring nation-nation sentiment across *all* country pairs. To our knowledge, this paper is the largest computational approach (17 months with 2 billion tweets) to measuring international relations on social media.

3 Microblog Datasets

The main dataset for this study is 17 months of tweets obtained through the keyword Twitter API that mention one of 187 unique countries. The dataset spans from Sep. 3, 2013 to Jan 10, 2015 with 3-5 million tweets per day. Each tweet includes the profile location and geolocation data (if available) of the user who posted the tweet. Collection was not limited to a specific location in order to retrieve samples from across the world. This dataset is used in all political science experiments (Sections 6.2 and 6.3).

A smaller labeled dataset is used for supervised classification. We randomly sampled the data to create a dataset of 4250 tweets. The authors initially labeled each tweet with one of four sentiment labels: *positive*, *negative*, *objective*, or *irrelevant*. Text was only labeled as positive if it is positive toward the nation's mention. Text that contains a nation's mention, but does not contain sentiment toward the mention is labeled *objective*. Text with a mention that is *not* referent to a physical country is labeled *irrelevant* despite presence of sentiment. This irrelevant distinction is a departure from sentiment competitions. A second labeling added a fifth label to the *irrelevant* tweets to split off *dining* topics.

Usernames (e.g., @*user*) and URLs are replaced with placeholder tokens. Multiple whitespace characters are condensed and the text is split on it. Punctuation attached to tokens is removed (but saved) and used in later punctuation features. Punctuation is not treated as separate tokens in the n-gram features. We prepend occurrences of "not" to their subsequent tokens, merging the two into a new token (e.g., "not happy" becomes "not-happy"). Once the raw text of the tweet is tokenized as above, non-English tweets are filtered out. English filtering is performed by LingPipe[1]. We manually evaluated this filter and found it 86.2% accurate over 400 tweets. Accuracy is lost due to slang and the short nature of the text.

4 Classifying Nation-Nation Sentiment

Given a tweet containing a country's name, our goal is to identify the sentiment of the text toward that nation. Unlike most work on contextual polarity, this requires reference resolution of the target phrase (e.g., the country name). Previous Semeval competitions evaluate the sentiment of a text toward a phrase, but the semantics of the phrase is largely ignored. For instance, the following example would make an excellent Semeval test item, but its classification is irrelevant to the goal of measuring nation sentiment:

> *My daughter and I have been to Angelo's several times when in Little **Italy**. Love love it!*

The author is obviously positively inclined toward Little Italy, however, Little Italy does not refer to the country of Italy. We found that most tweets referring to dining or visiting foreign-themed restaurants are not relevant to determining nation to nation sentiment. It became necessary to research new classifiers that perform basic reference resolution.

4.1 Reference Resolution: Irrelevant Detection

This paper defines reference resolution in the traditional linguistic sense: determine the real-world referent of a text mention. Most NLP tasks use coreference resolution: determine the text antecedent of a text mention. This paper requires reference resolution because the target phrase often does not refer to an actual geolocated country. After collecting months of tweets that include country name mentions, data analysis revealed several types of these non-references. We treat reference resolution as a classification problem. Below are a variety of supervised and semi-supervised learners that identify different types of errant country references, and ultimately serve to filter out these irrelevant tweets.

4.1.1 Dining Classifier

One of our early observations was that mentions of nations are often in the context of eating and dining, as evidenced here:

> *This is the first **turkey** sandwich I've had in awhile... It's great **turkey**.*

> *Taste of **China** For chinese food lover's. For more info Please visit*

This class of tweet is problematic to our study of international politics. While microblogs about dining can contain heavy emotion, a link to the writer's opinion about the foreign nation itself is ambiguous. We thus filter out dining text through supervised classification. Using the labeled dataset in Section 3, we annotated a *dine* label for all dining tweets. Tweets without a *dine*

[1] *alias-i.com/lingpipe/#lingpipe*

	Dine	Rel
All unigrams in text	✓	✓
1-3grams that include the country	✓	✓
Bigram and Trigram country pattern	✓	✓
Four Square app pattern		✓
Named Entity 2-3grams w/ country		✓
Emoticon happy or sad		✓
Ending text punctuation		✓
Binary: contains exclamation point		✓

Table 1: Dining and Relevant features.

label are considered *not-dine*. We ran a logistic regression for two labels, *dine* and *not-dine*. Text features are shown in Table 1.

4.1.2 Irrelevancy Classifier

Beyond dining, a broader class of irrelevant tweets refer to non-nation entities. These microblogs contain country names, but the mentions do not reference the physical country. The following examples illustrate this class of *irrelevant* tweets (nation tokens in bold):

> *Yesterday was chilly out and now today's going to be 80. New **England** weather is so bipolar I hate it so much*

> *Bank Of **America** Upgrades ConocoPhillips On More Favorable Outlook*

Several types of irrelevancy can be found, but the most common is a non-nation geolocation like *New England*. Proper nouns like *Bank of America* are frequent as well. A named entity recognizer (NER) identified some of these, but we ultimately turned to supervised classification for better accuracy (space constraints prevent discussion of NER performance). We trained a logistic regression classifier on the **relevant** tweets in the Section 3 dataset, and mapped all other labels to **irrelevant**. Features used are shown in Table 1.

4.1.3 Bootstrap Learner

After filtering non-referent tweets, we observed that many *positive* and *negative* tweets reference countries in the context of sporting events and music/concerts. These are correctly labeled **relevant** by the above binary classifiers (and possibly annotated as positive or negative), but the topic (sports or music) does not contain a strong semantic connection to the author's actual opinion about the country. A couple of sport examples are given here:

> *@SpecialKBrook Wow - the Brittish judge scored the fight a draw - lucky **England**'s fighters are better than their judges.*

> ***Congo** LFC now someone give me that goalie's jersey :p*

The sport topic has a less diverse vocabulary than other topics. We hypothesized that a bootstrap learning framework (Riloff and Jones, 1999) could quickly learn its unique language without the need for supervised learning. Beginning with a short list of sport keywords (*football, basketball, baseball, cricket, soccer, golf, hockey, rugby, game, vs*), we ran two iterations of a bootstrapped learner. The first step retrieves tweets containing one of the keywords. The second counts token occurrences in this set and computes pointwise mutual information (PMI) scores for each unigram by comparing with the unigram counts over the entire corpus. The learner processed ˜190 million tweets (a couple months of data). The PMI scores from this process then form the basis of a simple topic classifier.

A tweet is classified as a topic (e.g., sports) if its average token PMI score is above a learned threshold for that topic:

$$score_T(text) = \frac{1}{N} \sum_{w \in text} pmi_T(w) \qquad (1)$$

where N is the number of tokens in the text and $T \in \{sports, concerts\}$. The text is classified as in topic if $score_T(text) > \lambda_t$. The threshold λ_T was determined by visual inspection of a held out 1000 tweets to maximize accuracy. The initial seed words and λ_T thresholds for each topic are given here:

Seed Words	λ
football, basketball, baseball, cricket, soccer, golf, hockey, rugby, game, vs	0.08
concert, music, album, song, playlist, stage, drum	0.15

4.2 Contextual Sentiment Analysis

The above classifiers identify *relevant* tweets with *references* to geolocated nations. Approximately 21% are filtered out, leaving 79% for the remaining component of this paper: contextual sentiment analysis. Contextual sentiment analysis focuses on the disposition of text toward a word or phrase (in this case, a country's name). Most data-driven approaches rely on labeled corpora to drive the learning process, and this paper is no different.

Assigning polarity to a word/phrase requires features that capture the surrounding context. The following tweets are examples of context with strong polarity toward the country in bold.

*RT @ChrissyCostanza: Happiest girl ever. I LOVE YOU **SINGAPORE***

*there's no **Singapore** Got Talent cus the only talent we have is stomping complaining & staring*

Singapore is the target country here. The first tweet is overtly positive toward it, but the second requires a more subtle interpretation. The negative context is toward *us*, referencing the people of the Singapore anaphor. It seems reasonable to infer that they are negative toward the country as a whole, but a deeper reasoning is required to make the connection. These difficult decisions require a wide-range of lexical features. We build on the top performing features from contextual polarity systems in Semeval 2013 and 2014 (Mohammad et al., 2013; Zhu et al., 2014). We used the following set of features to capture these different contexts:

Token Features: All unigrams and bigrams.

Target Patterns: This feature creates patterns from n-grams that include the target word. The target is replaced with a variable to capture generalized patterns. For instance, "to France last" becomes "to X last". Bigram and trigram patterns are created.

Punctuation: End of sentence punctuation and punctuation attached to target words. Prefix and postfix punctuation are separate features.

Emoticons: Two binary features for the presence/absence of smiley and sad face emoticons.

Hand-Built Dictionary: Two binary features, *postivemood* and *negativemood*, indicate if a token appears in a sentiment lexicon's positive or negative list. We use Bing Liu's Opinion Lexicon[2].

Nation-Nation Learned Dictionary: Following the success of Zhu et al. (2014), we learn a mood dictionary from our domain-specific nation dataset. We count unigrams (bigrams did not improve performance) in one year of unfiltered tweets with nation mentions that contain an emoticon. Using these counts, each unigram computes its PMI scores toward happy and sad contexts. We construct features based on these PMI scores: (1) the highest happy PMI score of all unigrams in a tweet, (2) the highest sad PMI score, (3) the number of positive tokens, (4) the number of negative tokens, and (5) the sum of the token PMI differences between happy-sad.

[2] *http://www.cs.uic.edu/~liub/FBS/sentiment-analysis.html*

General Learned Dictionary: We computed the same features as in the above learned dictionary, but instead counted tokens in all tweets of the general emoticon corpus of Go et al. (2009).

The contextual sentiment learner is trained on the labeled dataset (Section 3). Only tweets with *positive*, *negative*, or *objective* labels are included (irrelevant and dining are ignored). Stanford's CoreNLP (nlp.stanford.edu/software) is used to train a MaxEnt classifier with its default settings.

5 Nation to Nation Pipeline

The complete system to determine the nation-nation sentiment of a tweet consists of 3 steps: (1) identify the country origin of the tweet, (2) filter out tweets without references to geolocated nations and filter out irrelevant topics, and (3) identify the sentiment toward the country. We processed 17 months of tweets (Section 3).

The first step identifies the origin of the tweet with either its GPS coordinates or the profile location of the Twitter user. Profile locations are mapped to countries with an exhaustive list of country names, major cities, and patterns that match US city/states (e.g., *Pensacola,FL* maps to *USA*). Non-english tweets are removed with lingpipe. The second step filters non-referent, irrelevant, dining, and concert tweets with the classifiers from Section 4.1 (about 21% of tweets at this stage). The final step is the contextual sentiment classifier (Section 4.2). Tweets that make it through receive 1 of 3 possible labels: positive, negative, objective.

The aggregate counts of the three labels are collected for each day. This was around 1.2 million nation labels per day over 17 months. The counts are used for evaluation in the experiments.

6 Experiments

Our goal is to first prove the accuracy of our sentiment classifiers, then show the broader pipeline's correlation with known nation-nation politics.We thus conducted three types of experiments. The first is an intrinsic evaluation of the classifiers with common frameworks from the NLP community. The second is an extrinsic evaluation from multiple political science datasets. The third is a set of use case proposals for application of this analysis.

Dining Classifier

Label	P	R	F1
dining	.76	.48	.59
not-dining	.96	.99	.98
Baseline Accuracy		93.1%	
Accuracy		95.3%	

Irrelevant Classifier

Label	Prec	Recall	F1
irrelevant	.84	.90	.87
relevant	.84	.75	.80
Baseline Accuracy		58.7%	
Accuracy		84.0%	

Sentiment Classifier

Label	Prec	Recall	F1
positive	.64	.47	.54
negative	.60	.33	.43
objective	.71	.87	.78
Baseline Accuracy		59.0%	
Accuracy		68.7%	

Table 2: Classifier performance. Precision/Recall is calculated for each label separately. Accuracy is over all labels: # correct/total.

6.1 Classifier Experiments

The dining, irrelevant, and sentiment classifiers are supervised systems trained on a labeled dataset of 4,250 tweets. We split the dataset into training, dev, and test sets. The dev set contains 200 tweets, the test set has 750 tweets, and the training set size varied based on the available labels. The features in this paper were developed solely on the training and dev datasets. Reported results are on the unseen test set of 750 tweets. The bootstrapped classifiers for sports and concerts were learned without labeled data, so we ran the sports and concerts classifiers on an unseen portion of our data, and manually evaluated the first 200 tweets that were labeled by each classifier.

Precision and recall are calculated individually for each class label: $P = \#correct/\#guessed$ and $R = \#correct/\#gold$. Where $\#guessed$ is how many times the classifier predicted the target label, and $\#gold$ is how many times the target label appears in the dataset. Accuracy is also shown, calculated as a single score over all labels together: $Accuracy = \#correct/N$. The first table in Table 2 shows the dining classifier's performance. The majority class baseline is high at 93% because only 7% of the data is about dining. The classifier achieves a 29% decrease in accuracy error (2% absolute increase). The second table shows the more general irrelevant classifier. The majority class baseline is much lower than dining at 58.7%. Many tweets that contain a country name are not relevant nor references to the geolocated country itself. Our trained classifier does well on this task achieving 84% accuracy, a 26% absolute increase over baseline. It is 84% precise with 90% recall on detecting irrelevant tweets. The third table in Table 2 shows sentiment classifier results. Accuracy is almost 10% absolute above the majority class.

Finally, the bootstrapped classifiers perform at 98% accuracy for sports and 90% for concerts.

Positive/Negative Ratios

Target	Ratio	Target	Ratio
US to Canada	11.9	US to Ireland	3.2
US to Italy	10.8	US to Spain	3.0
US to Japan	7.7	US to France	2.7
US to Australia	3.5	US to Jordan	2.1
US to UK	3.5	US to Mexico	1.9

Table 3: Positive/Negative ratios for the US toward its top 10 frequently mentioned nations.

6.2 Nation-Nation Sentiment Experiments

Nation opinions are represented as directed edges: each edge (X,Y) represents the opinion of nation X toward nation Y. The weight of an edge is the ratio of positive to negative counts:

$$R(X,Y) = C(X,Y,positive)/C(X,Y,negative)$$

where C(X,Y,L) is the number of tweets by nation X users about nation Y with sentiment L. Only tweets that make it through the Nation to Nation Pipeline of Section 5 receive sentiment labels. If a nation pair (X,Y) was observed less than 1000 times, it is not included in the evaluations. We provide experiments later to evaluate this cutoff's affect.

The dataset (Section 3) spans 17 months from 2013-2015. All tweets are classified or filtered out, and R(X,Y) is computed for all pairs. Table 3 shows the top 10 nation pair ratios (with over 500k tweets between them) for the U.S.

We present four formal evaluations to answer the central question of this paper: can sentiment from social media be used to help approximate international opinions? The first two experiments use public opinion polls of national sentiment toward other nations. The third uses military conflicts as a proxy for *negative* relations, and the fourth uses current formal alliances as a proxy for *positive* relations. None of these can provide a complete picture of the connection between popular sentiment and international relations, but the four together provide a strong case that sentiment contains a useful signal.

Correlation: Public Opinion Polls

Human Poll	Sentiment	Freq. Baseline
Germany	Canada	China
Canada	Japan	Israel
UK	EU	USA
Japan	France	Russia
France	UK	India
EU	Brazil	Japan
Brazil	USA	Canada
USA	India	UK
China	South Africa	Pakistan
South Korea	South Korea	France
South Africa	Germany	Iran
India	Russia	Brazil
Russia	China	Germany
Israel	Israel	North Korea
North Korea	North Korea	South Korea
Pakistan	Iran	South Africa
Iran	Pakistan	EU
Correlation	**0.80**	**-0.06**

Table 4: Polling Data: ranking of a nation's "positive contribution" to the world, compared to automatically identified nation-nation sentiment.

Each year, GlobeScan/PIPA releases polling data of 16 nations in a ranked ordering based on how 26,000 people view their "positive contribution" to the world[3]. This poll helps to determine whether or not this paper's sentiment pipeline matches human polling. We created our own ranking by assigning a world score to each nation n: the average sentiment ratio of all other nations toward n. Since the polling data also ranks the EU, we average the EU member nation world scores for an EU world score. Table 4 shows the PIPA poll (**Human Poll**) and our world ranking (**Sentiment**). Using Spearman's rank correlation coefficient to measure agreement, our ranking is strongly correlated at $\rho = 0.8$ (perfect is 1.0). The main mistake in our ranking is Germany. We also compare against a **Frequency Baseline** to eliminate the possibility that it's simply a matter of topic popularity. Poll rankings could simply be correlated with who people choose to discuss, or vice versa. The frequency baseline is the average number of twitter mentions per nation (i.e., the most discussed). This baseline shows no correlation at $\rho = -.06$.

We then evaluated against a US-centric polling agency, Gallup. They asked Americans to rate other nations as 'favorable' or 'unfavorable' in a 2014 poll[4]. The result is a ranking of favorability. In contrast to the PIPA poll which evaluates many nations looking in, Gallup evaluates a single nation looking out. Space constraints prevent us from visually showing the US ranking, but again the sentiment ratios have a strong correlation at $\rho = .81$. The frequency baseline is $\rho = .23$. The nation-nation sentiment extraction strongly correlates with both world views (PIPA) and US-specific views (Gallup).

The third evaluation uses a political science dataset from the Correlates of War Project, the **Militarized Interstate Disputes v4.01** (MID) (Ghosn et al., 2004). This dataset is used in the field of international relations, listing conflicts since 1816. We limit the evaluation to conflicts after 1990 to keep relations current. The dataset ends at 2001, so while not a completely current evaluation, it stands as a proxy for negative relations. Each conflict in MID is labeled with a conflict severity. We convert severity labels between nations to a pair score MID(X,Y):

$$MID(X,Y) = \sum_{d \in Disputes(X,Y)} score(d) \quad (2)$$

where Disputes(X,Y) is the set of conflicts between the two nations X and Y, and score(d) is a severity score for the type of dispute d. *War* is -5, *use of force* is -4, *displays of force* is -3, *threatening use of force* is -2, and *no militarized action* is -1. We take the sum of severity scores and save all nation pairs (X,Y) such that $MID(X,Y) < -10$. This score indicates multiple conflicts and are thus considered as nations with true negative relations.

We then compare our sentiment ratios R(X,Y) against these gold negative pairs. Each continuous R(X,Y) is discretized into sentiment categories for ease of comparison. Since the mean across all R(X,Y) is 1.25, we consider an interval around 1.25 as neutral and create positive and negative labels above and below that neutral center:

$$ratiolabel(Z) = \begin{cases} positive, & \text{if } Z \geq 2.4 \\ slightpos, & \text{if } 2.4 > Z \geq 1.4 \\ neutral, & \text{if } 1.4 > Z \geq 1.1 \\ slightneg, & \text{if } 1.1 > Z \geq 0.8 \\ negative, & \text{if } 0.8 > Z \end{cases}$$

The bottom table in Table 5 shows the number of nation pairs that align with the negative labels of the MID dataset. Only pairs that have at least 1000 tweets are evaluated. Of the resulting 90 pairs, 61 are correctly identified by our system as negative or slight negative for an **accuracy of 68%**. 19 *positive* pairs are incorrectly aligned with *MID-negative*. Error analysis shows that many incorrect

Positive: Formal Alliances

	Pos	SlPos	N	SlNeg	Neg
# Nation Pairs	**341**	**65**	22	**26**	**28**

Negative: Military Disputes

	Pos	SlPos	N	SlNeg	Neg
MID-Negative	**12**	**7**	10	**15**	**46**

Table 5: Top: The number of NATO/EU nation pairs with automatic sentiment labels. Bottom: The number of pairs with military disputes (MID dataset) and automatic sentiment labels.

labels are between nations with a smaller Twitter presence, so performance likely suffers due to lack of data. For robustness testing, we shifted the thresholds that discretize the nation ratios and MID scores into postive and negative categories. The accuracy result shows little change. We also reran the experiment with a higher cutoff of 10,000 instead of 1,000. The negative disputes **accuracy increases from 68% to 81%**, but the recall obviously drops as less countries are included. This suggests the sentiment ratios might be used on a sliding confidence scale based on frequency of mention.

To evaluate positive relations, we use current alliances as a fourth evaluation. NATO and the EU are the main global alliances with elements of mutual defense. We do not include trade-only alliances as trade is not always an indication of allegiance and approval (Russia and Ukraine is a current example of this disparity). This evaluation considers pairs of nations within NATO and within the EU as gold positive relations. We compare our sentiment ratios to these pairs in the top of Table 5. This evaluation is broader than the conflict evaluation because NATO and EU nations have more of a Twitter presence. Of the 482 country pairs, our positive/slightpos accuracy is **84.2%**.

6.3 Application Experiments

We now briefly discuss how these positive results for nation-nation sentiment relates to political science analysis.

One core area of study is how national sentiment shifts over time, *and why*. Computing R(X,Y) on a bi-weekly basis, Figure 1 graphs the sentiment ratio from the USA toward India and Israel. The timeline shows significant favorability toward India during their extended election season, but afterward the opinion is similar to before the election. In contrast, the 2014 Israel-Gaza conflict shows a very different effect. US opinion of Israel is initially steady (slightly positive) until the conflict causes a large dip. Unlike India's spike, *US opinion stays depressed* even after the conflict concludes. It appears to have only risen to 'normal' levels months later. We do note that the water is slightly muddied because our algorithm may not distinguish well between sentiment toward the war, Israel itself, or even sympathy toward casualties. However, it's clear that nation-nation sentiment is captured, and future work is needed to identify finer grained sentiment as needed.

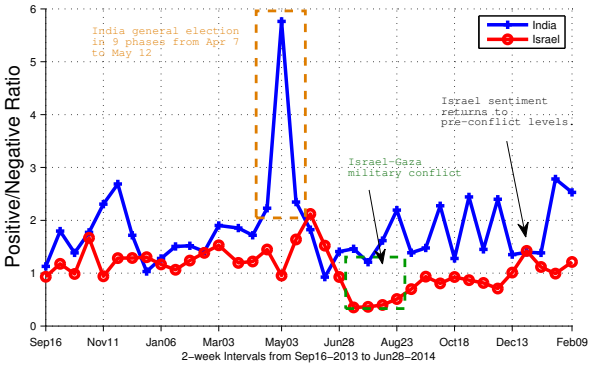

Figure 1: USA opinion of India/Israel over 2-week intervals from Sep-2013 to Feb-2015.

Another application is inter-alliance relations. For instance, Table 6 shows how NATO member nations view *other* alliances. The table shows the average of all R(X,Y) edges for each nation within an alliance to a nation in the other. According to our ratios, NATO countries have stark differences between how they view themselves versus how they view African Union/Arab League nations. Further, our pipeline enables analysis of outside nations looking in. For instance, the nations with the most positive view of the EU are Uruguay, Lithuania (EU member), Belarus, Moldova, and Slovakia (EU member). Almost all (not Uruguay) are eastern european nations. Moldova is currently seeking EU membership and Belarus had closer ties until recently. Our results might point to potential future alliances. Future work is needed to explore this implied connection.

Finally, the R(X,Y) ratios can also represent a nation's *opinion profile*. Represent each nation X by a vector of its R(X,Y) ratios. This represents its entire international view based on social me-

Inter-Alliance Opinion Ratios

Source	Target	Average R(X,Y)
NATO	African Union	0.45
NATO	Arab League	0.48
NATO	European Union	1.51
NATO	NATO	1.55

MID Accuracy with Filters

Filters	Correct	Incorrect	Acc.
Dining+Sports	61	29	**68%**
Sports only	61	37	**62%**
None	56	51	**52%**

Table 7: Filtering effects on the MID results.

dia sentiment. Space prohibits more detail, but we clustered opinion profiles with k-means (k=12) and cosine similarity. Typical alliances, such as European and African clusters, are learned.

6.4 Ablation Tests

The sentiment pipeline includes two practical filters to remove tweets about **dining** and **sports**. We added these during training and developement solely based on our interpretation and analysis of the data. We did not evaluate on the test datasets until the very end. Table 7 shows results from the MID evaluation with the dining and sports filters removed in sequence.

The number of correctly identified negative nation pairs is mostly unchanged, but the number of incorrect decisions increases dramatically. This occurs because a greater number of tweets make it through the pipeline. Further, this shows that the filters effectively remove tweets that cause misclassification errors.

7 Discussion

This work is an important first step toward automatic means to broadly detect international relations from social media. We use sentiment analysis as a proxy for extracting at least one aspect of the large set of factors involved in such relations. This paper is the largest application of sentiment analysis across a diverse set of nation-nation pairs (hundreds of country pairs over 17 months), and we showed that this sentiment is strongly correlated ($\rho = 0.8$) with two independent public opinion polls. These correlations more importantly suggest that we are not simply identifying a binary positive or negative relation, but that the *relative sentiment scores* are useful. The failure of frequency baselines on this ranking further suggests that this is not a side effect of topic frequency.

One argument against using public opinion polls for an evaluation is that the same people who are polled by PIPA might be the same people who tend to voice opinions on Twitter. The Twitter dataset is not independent from the polls, so the strong correlation we found could simply be a matter of sampling the same population. This is not possible to know, but whether or not it is the case, this paper's pipeline could be quite valuable in automating expensive and time consuming human polls.

The results that focused on positive sentiment (polls and alliances) are quite high. Negative sentiment revealed a lower 68% accuracy on the MID dataset, but it is due to the fact that nation-nation conflicts often occur between smaller nations that are not represented well on Twitter. Requiring a higher observed count improves accuracy to 81%.

While we are cautious not to make broad claims about discovering international relations on Twitter, we are encouraged by the experimental alignment with current alliances and historical conflict data. The sentiment timeline for Israel and India (Figure 1) is also intriguing. Tracking nation relations over a longer time period presents an opportunity for future study. This continual tracking of sentiment is one of the most obvious benefits of an automated approach.

Finally, an interactive world map is available to browse this paper's data at *www.usna.edu/Users/cs/nchamber/nations*. Each nation can be selected to visually color the map with its positive/negative lens, and timelines showing sentiment shifts between nations are visible. All code, data, and results are also available on this page. We hope this work encourages even further connections between NLP and political science.

Abstract

Text data has recently been used as evidence in estimating the political ideologies of individuals, including political elites and social media users. While inferences about people are often the intrinsic quantity of interest, we draw inspiration from open information extraction to identify a new task: inferring the political import of propositions like OBAMA IS A SOCIALIST. We present several models that exploit the structure that exists between people and the assertions they make to learn latent positions of people and propositions at the same time, and we evaluate them on a novel dataset of propositions judged on a political spectrum.

1 Introduction

Over the past few years, much work has focussed on inferring political preferences of people from their behavior, both in unsupervised and supervised settings. Classical ideal point models (Poole and Rosenthal, 1985; Martin and Quinn, 2002) estimate the political ideologies of legislators through their observed voting behavior, possibly paired with the textual content of bills (Gerrish and Blei, 2012) and debate text (Nguyen et al., 2015); other unsupervised models estimate ideologies of politicians from their speeches alone (Sim et al., 2013). Twitter users have also been modeled in a similar framework, using their observed following behavior of political elites as evidence to be explained (Barberá, 2015). Supervised models, likewise, have not only been used for assessing the political stance of sentences (Iyyer et al., 2014) but are also very popular for predicting the holistic ideologies of everyday users on Twitter (Rao et al., 2010; Pennacchiotti and Popescu, 2011; Al Zamal et al., 2012; Cohen and Ruths, 2013; Volkova et al., 2014), Facebook (Bond and Messing, 2015) and blogs (Jiang and Argamon, 2008), where training data is relatively easy to obtain—either from user self-declarations, political following behavior, or third-party categorizations.

Aside from their intrinsic value, estimates of users' political ideologies have been useful for quantifying the orientation of news media sources (Park et al., 2011; Zhou et al., 2011). We consider in this work a different task: estimating the political import of propositions like OBAMA IS A SOCIALIST.

In focusing on propositional statements, we draw on a parallel, but largely independent, strand of research in open information extraction. IE systems, from early slot-filling models with predetermined ontologies (Hobbs et al., 1993) to the large-scale open-vocabulary systems in use today (Fader et al., 2011; Mitchell et al., 2015) have worked toward learning type-level propositional information from text, such as BARACK OBAMA IS PRESIDENT. To a large extent, the ability to learn these facts from text is dependent on having data sources that are either relatively factual in their presentation (e.g., news articles and Wikipedia) or are sufficiently diverse to average over conflicting opinions (e.g., broad, random samples of the web).

Many of the propositional statements that individuals make online are, of course, not objective descriptions of reality at all, but rather reflect their own beliefs, opinions and other private mental states (Wiebe et al., 2005). While much work has investigated methods for establishing the truth content of individual sentences — whether from the perspective of veridicality (de Marneffe et al., 2012), fact assessment (Nakashole and Mitchell, 2014), or subjectivity analysis (Wiebe et al., 2003; Wilson, 2008) — the structure that exists between users and their assertions gives us an opportunity to situate them both in the same political space: in this work we operate at the level of subject-

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 76–85,
Lisbon, Portugal, 17-21 September 2015.

predicate propositions, and present models that capture not only the variation in what subjects (e.g., OBAMA, ABORTION, GUN CONTROL) that individual communities are more likely to discuss, but also the variation in what predicates different communities assert of the same subject (e.g., GLOBAL WARMING IS A HOAX vs. IS A FACT). The contributions of this work are as follows:

- We present a new evaluation dataset of 766 propositions judged according to their positions in a political spectrum.
- We present and evaluate several models for estimating the ideal points of subject-predicate propositions, and find that unsupervised methods perform best (on sufficiently partisan data).

2 Task and Data

The task that we propose in this work is assessing the political import of type-level propositions; on average, are liberals or conservatives more likely to claim that GLOBAL WARMING IS A HOAX? To support this task, we create a benchmark of political propositions, extracted from politically partisan data, paired with human judgments (details in §2.3). We define a **proposition** to be a tuple comprised of a subject and predicate, each consisting of one or more words, such as ⟨global warming, *is a hoax*⟩.[1] We adopt an open vocabulary approach where each unique predicate defines a unary relation.

2.1 Data

In order to extract propositions that are likely to be political in nature and exhibit variability according to ideology, we collect data from a politically volatile source: comments on partisan blogs.

We draw data from NPR,[2] Mother Jones[3] and Politico[4], all listed by Pew Research (Mitchell et al., 2014) as news sources most trusted by those with consistently liberal views; Breitbart,[5] most trusted by those with consistently conservative views; and the Daily Caller,[6] Young Conservatives[7] and the Independent Journal Review,[8] all popular among conservatives (Kaufman, 2014). All data comes from articles published between 2012–2015 and is centered on the US political landscape.

Source	Articles	Posts	Tokens	Users
Politico	10,305	9.8M	348.4M	173,519
Breitbart	46,068	8.8M	336.4M	165,607
Daily Caller	46,114	5.4M	240.4M	228,696
Mother Jones	16,830	1.9M	119.2M	138,995
NPR	14993	1.6M	82.6M	62,600
IJ Review	3,396	278K	13.1M	51,589
Young Cons.	4,948	222K	10.6M	34,434
Total	142,654	28.0M	1.15B	621,231

Table 1: Data.

We gather comments using the Disqus API;[9] as a comment hosting service, Disqus allows users to post to different blogs using a single identity. Table 1 lists the total number of articles, user comments, unique users and tokens extracted from each blog source. In total, we extract 28 million comments (1.2 billion tokens) posted by 621,231 unique users.[10]

2.2 Extracting Propositions

The blog comments in table 1 provide raw data from which to mine propositional assertions. In order to extract structured ⟨subject, *predicate*⟩ propositions from text, we first parse all comments using the collapsed dependencies (de Marneffe and Manning, 2008) of the Stanford parser (Manning et al., 2014), and identify all subjects as those that hold an `nsubj` or `nsubjpass` relation to their head. In order to balance the tradeoff between generality and specificity in the representation of assertions, we extract three representations of each predicate.

1. Exact strings, which capture verbatim the specific nuance of the assertion. This includes all subjects paired with their heads and all descendants of that head. Tense and number are preserved.

   Example: ⟨Reagan, *gave amnesty to 3 million undocumented immigrants*⟩

2. Reduced syntactic tuples, which provide a level of abstraction by lemmatizing word forms and including only specific syntactic relationships. This includes propositions de-

[1] We use these typographical conventions throughout: Subjects are in sans serif, predicates in *italics*.

[10] While terms of service prohibit our release of this data, we will make available tools to allow others to collect similar data from Disqus for these blogs.

fined as nominal subjects paired with their heads and children of that head that are negators, modal auxiliaries (*can, may, might, shall, could, would*), particles and direct objects. All word forms are lemmatized, removing tense information on verbs and number on nouns.

Example: ⟨Reagan, *give amnesty*⟩

3. Subject-verb tuples, which provide a more general layer of abstraction by only encoding the relationship between a subject and its main action. In this case, a proposition is defined as the nominal subject and its lemmatized head.

Example: ⟨Reagan, *give*⟩

The human benchmark defined in §2.3 below considers only verbatim predicates, while all models proposed in §3 and all baselines in §4 include the union of all three representations as data.

Here, syntactic structure not only provides information in the representation of propositions, but also allows us to define criteria by which to exclude predicates — since we are looking to extract propositions that are directly asserted by an author of a blog comment (and not second-order reporting), we exclude all propositions dominated by an attitude predicate (*Republicans think that Obama should be impeached*) and all those contained within a conditional clause (*If Obama were impeached...*). We also exclude all assertions drawn from questions (i.e., sentences containing a question mark) and all assertions extracted from quoted text (i.e., surrounded by quotation marks).

In total, from all 28 million comments across all seven blogs, we extract all propositions defined by the criteria above, yielding a total of 61 million propositions (45 million unique).

2.3 Human Benchmark

From all propositions with a verbatim predicate extracted from the entire dataset, we rank the most frequent subjects and manually filter out non-content terms (like *that*, *one*, *someone*, *anyone*, etc.) to yield a set of 138 target topics, the most frequent of which are *obama*, *democrats*, *bush*, *hillary*, and *america*.

For each proposition containing one of these topics as its subject and mentioned by at least 5 different people across all blogs, we randomly sampled 1,000 in proportion to their frequency of use (so that sentences that appear more frequently in the data are more likely to be sampled); the sentences selected in this random way contain a variety of politically charged viewpoints. We then presented them to workers on Amazon Mechanical Turk for judgments on the extent to which they reflect a US liberal vs. conservative political worldview.

For each sentence, we paid 7 annotators in the United States to a.) confirm that the extracted sentence was a well-formed assertion and b.) to rate "the most likely political belief of the person who would say it" on a five-point scale: very conservative/Republican (-2), slightly conservative/Republican (-1), neutral (0), slightly liberal/Democrat (1), and very liberal/Democrat (2).

We keep all sentences that at least six annotators have marked as meaningful (those excluded by this criterion include sentence fragments like *bush wasn't* and those that are difficult to understand without context, such as *romney is obama*) and where the standard deviation of the responses is under 1 (which excludes sentences with flat distributions such as *government does nothing well* and those with bimodal distributions, such as *christie is done*). After this quality control, we average the responses to create a dataset of 766 propositions paired with their political judgments. Table 2 presents a random sample of annotations from this dataset.

proposition	mean	s.d.
obama lied and people died	-2.000	0.000
gay marriage is not a civil right	-1.857	0.350
obama can't be trusted	-1.714	0.452
hillary lied	-0.857	0.990
hillary won't run	-0.714	0.452
bush was just as bad	0.857	0.639
obama would win	1.429	0.495
rand paul is a phony	1.429	0.495
abortion is not murder	1.571	0.495
hillary will win in 2016	1.857	0.350

Table 2: Random sample of AMT annotations.

3 Models

The models we introduce to assess the political import of propositions are based on two fundamental ideas. First, users' latent political preferences, while unobserved, can provide an organizing principle for inference about propositions in an unsupervised setting. Second, by decoupling the variation in *subjects* discussed by different communities (e.g., liberals may talk more

about global warming while conservatives may talk more about gun rights) from variation in what statements are *predicated* of those subjects (e.g., liberals may assert that ⟨global warming, *is a fact*⟩ while conservatives may be more likely to assert that it *is a hoax*), we are able to have a more flexible and interpretable parameterization of observed textual behavior that allows us to directly measure both.

We present two models below: one that represents users and propositions as real-valued points, and another that represents each as categorical variables. For both models, the input is a set of users paired with a list of ⟨subject, *predicate*⟩ tuples they author; the variables of interest we seek are representations of those users, subjects, and predicates that explain the coupling between users and propositions we see.

3.1 Additive Model

The first model we present (fig. 1) represents each user, subject, and predicate as a real-valued point in K-dimensional space. In the experiments that follow, we consider the simple case where $K = 1$ but present the model in more general terms below.

In this model, we parameterize the generative probability of a subject (like Obama) as used by an individual u as the exponentiated sum of a background log frequency of that subject in the corpus overall (m_{sbj}) and K additive effects, normalized over the space of S possible subjects, as a real-valued analogue to the SAGE model of Eisenstein et al. (2011). While the background term controls the overall frequency of a subject in the corpus, $\beta \in \mathbb{R}^{K \times S}$ mediates the relative increase or decrease in probability of a subject for each latent dimension. Intuitively, when both $\eta_{u,k}$ and $\beta_{k,sbj}$ (for a given user u, dimension k, and subject sbj) are the same sign (either both positive or both negative), the probability of that subject under that user increases; when they differ, it decreases. $\beta_{\cdot,sbj}$ is a K-dimensional representation of subject sbj, and $\eta_{u,\cdot}$ is a K-dimensional representation of user u.

$$P(sbj \mid u, \eta, \beta, m_{sbj}) = \frac{\exp\left(m_{sbj} + \sum_{k=1}^{K} \eta_{u,k}\beta_{k,sbj}\right)}{\sum_{sbj'} \exp\left(m_{sbj'} + \sum_{k=1}^{K} \eta_{u,k}\beta_{k,sbj'}\right)} \quad (1)$$

Likewise, we parameterize the generative probability of a predicate (conditioned on a subject) in the same way; for S subjects, each of which contains (up to) P predicates, $\psi \in \mathbb{R}^{S \times K \times P}$ captures the relative increase or decrease in probability for a given predicate conditioned on its subject, relative to its background frequency in the corpus overall, $m_{pred|sbj}$.

$$P(pred \mid sbj, u, \eta, \psi, m_{pred|sbj}) = \frac{\exp\left(m_{pred|sbj} + \sum_{k=1}^{K} \eta_{u,k}\psi_{sbj,k,pred}\right)}{\sum_{pred'} \exp\left(m_{pred'|sbj} + \sum_{k=1}^{K} \eta_{u,k}\psi_{sbj,k,pred'}\right)} \quad (2)$$

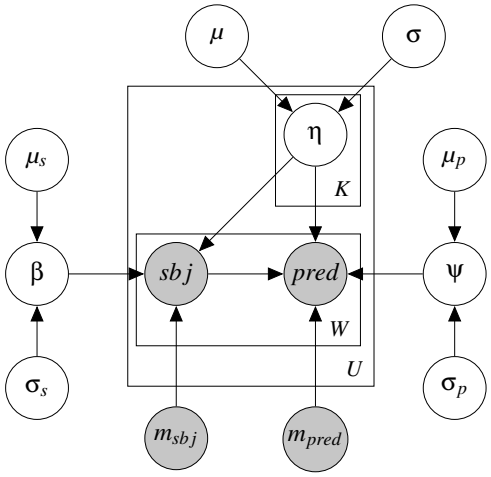

Figure 1: Additive model with decoupled subjects and predicates. η contains a K-dimensional representation of each user; β captures the variation in observed subjects, and ψ captures the variation in predicates for a fixed subject.

The full generative story for this model runs as follows. For a vocabulary of subjects of size S, where each subject s has P predicates:

- For each dimension k, draw subject coefficients $\beta_k \in \mathbb{R}^S \sim \text{Norm}(\mu_s, \sigma_s \mathbf{I})$
- For each subject s:
  - For each dimension k, draw subject-specific predicate coefficients $\psi_{s,k} \in \mathbb{R}^P \sim \text{Norm}(\mu_p, \sigma_p \mathbf{I})$
- For each user u:
  - Draw user representation $\eta \in \mathbb{R}^K \sim \text{Norm}(\mu, \sigma \mathbf{I})$
  - For each proposition $\langle sbj, pred \rangle$ made by u:
    - Draw sbj according to eq. 1
    - Draw $pred$ according to eq. 2

The unobserved quantities of interest in this model are η, β and ψ. In the experiments reported

below, we set the prior distributions on η, β and ψ to be standard normals ($\mu = 0, \sigma = 1$) and perform maximum *a posteriori* inference with respect to η, β and ψ in turn for a total of 25 iterations.

While β and ψ provide scores for the political import of subjects and of predicates conditioned on fixed subjects, respectively, we can recover a single ideological score for both a subject and its predicate by adding their effects together. In the evaluation given in §5, let the PREDICATE SCORE for $\langle$subject, *predicate*$\rangle$ be that given by $\psi_{\text{subject},\cdot,\textit{predicate}}$, and let the PROPOSITION SCORE be $\beta_{\cdot,\text{subject}} + \psi_{\text{subject},\cdot,\textit{predicate}}$.

3.2 Single Membership Model

While the additive model above represents each user and proposition as a real-valued point in K-dimensional space, we can also represent those values as categorical variables in an unsupervised naïve Bayes parameterization; in this case, a user is not defined as a mixture of different effects, but rather belongs to a single unique community. The generative story for this model (shown in fig. 2) is as follows:

- Draw population distribution over categories $\theta \sim \text{Dir}(\alpha)$
- For each category k, draw distribution over subjects $\phi_k \sim \text{Dir}(\gamma)$
- For each category k and subject s:
  - Draw distribution over subject-specific predicates $\xi_{k,s} \sim \text{Dir}(\gamma_s)$
- For each user u:
  - Draw user type index $z \sim \text{Cat}(\theta)$
  - For each proposition $\langle sbj, pred\rangle$ made by u:
    - Draw subject $sbj \sim \text{Cat}(\phi_z)$
    - Draw predicate $pred \sim \text{Cat}(\xi_{z,sbj})$

We set $K = 2$ in an attempt to recover a distinction between liberal and conservative users. For the experiments reported below, we run inference using collapsed Gibbs sampling (Griffiths and Steyvers, 2004) for 100 iterations, performing hyperparameter optimization on α, γ and γ_s (all asymmetric) every 10 using the fixed-point method of Minka (2003).

In order to compare the subject-specific predicate distributions across categories, we first calculate the posterior predictive distribution by taking a single sample of all latent variables z to estimate

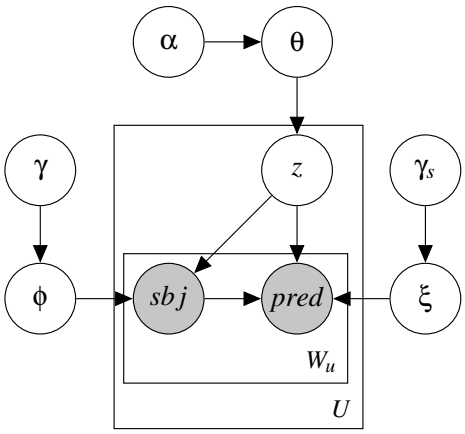

Figure 2: Single membership model with decoupled subjects and predicates. z is the latent category identity of a user (e.g., liberal or conservative); ϕ is a distribution over subjects for each category; and ξ is a distribution of predicates given subject s.

the following (Asuncion et al., 2009):

$$\hat{\zeta}_{z,v} = \frac{\mathbf{c}(z, v) + \gamma_v}{\sum_{v'} \mathbf{c}(z, v') + \gamma_{v'}} \tag{3}$$

Where $\hat{\zeta}_{z,v}$ is the vth element of the zth multinomial being estimated, $\mathbf{c}(z, v)$ is the count of element v associated with category z and γ_v is the associated Dirichlet hyperparameter for that element. Given this smoothed distribution, for each proposition we assign it a real valued score, the log-likelihood ratio between its value in these two distributions. In the evaluation that follows, let the PREDICATE SCORE for a given $\langle$subject, *predicate*$\rangle$ under this model be:

$$\log \left(\frac{\hat{\xi}_{0,\text{subject},\textit{predicate}}}{\hat{\xi}_{1,\text{subject},\textit{predicate}}} \right) \tag{4}$$

Let the PROPOSITION SCORE be:

$$\log \left(\frac{\hat{\phi}_{0,\text{subject}} \times \hat{\xi}_{0,\text{subject},\textit{predicate}}}{\hat{\phi}_{1,\text{subject}} \times \hat{\xi}_{1,\text{subject},\textit{predicate}}} \right) \tag{5}$$

4 Comparison

The two models described in §3 are unsupervised methods for estimating the latent political positions of users along with propositional assertions. We compare with three other models, a mixture of unsupervised, supervised, and semi-supervised methods. Unlike our models, these were not designed for the task described in §2.

4.1 Principal Component Analysis

To compare against another purely unsupervised model, we evaluate against principal component analysis (PCA), a latent linear model that minimizes the average reconstruction error between an original data matrix $\mathbf{X} \in \mathbb{R}^{n \times p}$ and a low-dimensional approximation $\mathbf{Z}\mathbf{W}^\top$, where $\mathbf{Z} \in \mathbb{R}^{n \times K}$ can be thought of as a K-dimensional latent representation of the input and $\mathbf{W} \in \mathbb{R}^{p \times K}$ contains the eigenvectors of the K largest eigenvalues of the covariance matrix $\mathbf{X}\mathbf{X}^\top$, providing a K-dimensional representation for each feature. We perform PCA with $K = 1$ on two representations of our data: a.) **counts**, where the input data matrix contains the counts for each proposition for each user, and b.) **frequencies**, where we normalize those counts for each user to unit length. While the input data is sparse, we must center each column to have a 0 mean (resulting in a dense matrix) and perform PCA through a singular value decomposition of that column-centered data using the method of Halko (2011); in using SVD for PCA, the right singular vectors correspond to the principal directions; from these we directly read off a $K = 1$ dimensional score for each proposition in our data.

4.2 ℓ_2-Regularized Logistic Regression

While unsupervised methods potentially allow us to learn interesting structure in data, they are often eclipsed in prediction tasks by the addition of any form of supervision. While purely supervised models give more control over the exact decision boundary being learned, they can suffer by learning from a much smaller training set than unsupervised methods have access to. To evaluate this tradeoff, we compare against a supervised model trained using naturally occurring data – users who self-declare themselves in their profiles to be *liberal*, *conservative*, *democrat*, or *republican*. We randomly sampled 150 users who self-identify as liberals and 150 who identify as conservatives. We do not expect these users to be a truly random sample of the population — those who self-declare their political affiliation are more likely to engage with political content differently from those who do not (Sandvig, 2015; Hargittai, 2015) — but is a method that has been used for political prediction tasks in the past (Cohen and Ruths, 2013).

We build a predictive model using two classes of features: a.) binary indicators of the most frequent 25,000 unigrams and multiword expressions[11] in the corpus overall; and b.) features derived from user posting activity to the seven blogs shown in table 1 (binary indicators of the blogs posted to, and the identity of the most frequent blog). In a tenfold cross-validation (using ℓ_2-regularized logistic regression), this classifier attains an accuracy rate of 76.7% (with a standard error of ± 1.7 across the ten folds).

In order to establish real-valued scores for propositions, we follow the same method as for the single membership model described above, using the log likelihood ratio of the probability of the proposition under each condition, where that probability is given as the count of the proposition among users classified as (e.g.) liberals (plus some small smoothing factor) divided by the total number of propositions used by them overall.

$$score(prop) = \log \frac{P(prop \mid z = conservative)}{P(prop \mid z = liberal)} \tag{6}$$

4.3 Co-Training

Since the features we use for the supervised model provide two roughly independent views of the data, we also evaluate against the semi-supervised method of co-training (Blum and Mitchell, 1998). Here, we train two different logistic regression classifiers, each with access to only the unigrams and multiword expressions employed by the user (h_{words}) or to binary indicators of the blogs posted to and the identity of the most frequent blog (h_{blogs}). For ten iterations, we pick a random sample U' of 1,000 data points from the full dataset U and classify each using the two classifiers; each classifier then adds up to 100 of the highest-confidence predictions to the training set, retaining the class distribution balance of the initial training set; after training, the final predictive probability for an item is the product of the two trained classifiers. In a tenfold cross-validation, co-training yielded a slightly higher (but not statistically significant) accuracy over pure supervision (77.0% ± 1.8). We calculate scores for propositions in the same way as for the fully supervised case above.

5 Evaluation

For the experiments that follow, we limit the input data available to all models to only those propo-

[11] Multiword expressions were found using the method of Justeson and Katz (1995).

sitions whose subject falls within the evaluation benchmark; and include only propositions used by at least five different users, and only users who make at least five different assertions, yielding a total dataset of 40,803 users and 1.9 million propositions (81,728 unique), containing the union of all three kinds of extracted propositions from §2.2.

Each of the automatic methods that we discuss above assigns a real-valued score to propositions like OBAMA IS A SOCIALIST. Our goal in evaluation is to judge how well those model scores recover those assigned by humans in our benchmark. Since each method may make different assumptions about the distribution of scores (and normalizing them may be sensitive to outliers), we do not attempt to model them directly, but rather use two nonparametric tests: Spearman's rank correlation coefficient and cluster purity.

Spearman's rank correlation coefficient. The set of scores in the human benchmark and as output by a model each defines a ranked list of propositions; Spearman's rank correlation coefficient (ρ) is a nonparametric test of the Pearson correlation coefficient measured over the ranks of items in two lists (rather than their values). We use the absolute value of ρ to compare the degree to which the ranked propositions of two lists are linearly correlated; a perfect correlation would have $\rho = 1.0$; no correlation would have $\rho = 0.0$.

Purity. While Spearman's rank correlation coefficient gives us a nonparametric estimate of the degree to which the exact order of two sequences are the same, we can also soften the exact ordering assumption and evaluate the degree to which a ranked proposition falls on the correct side of the political continuum (i.e., not considering whether OBAMA IS A SOCIALIST is more or less conservative than OBAMA IS A DICTATOR but rather that it is more conservative than liberal). For each ranked list, we form two clusters of propositions, split at the midpoint: all scores below the midpoint define one cluster, and all scores above or equal define a second. For $N = 766$ propositions, given gold clusters $\mathcal{G} = \{g_1, g_2\}$ and model clusters $\mathcal{C}_n = \{c_1, c_2\}$ (each containing 383 propositions), we calculate purity as the average overlap for the best alignment between the two gold clusters and their model counterparts.[12]

$$\text{Purity} = \frac{1}{N}\left(\max_j |g_1 \cap c_j| + \max_j |g_2 \cap c_j|\right) \tag{7}$$

A perfect purity score (in which all items from each cluster in $\mathcal{C}$ are matched to the same cluster in $\mathcal{G}$) is 1.0; given that all clusters are identically sized (being defined as the set falling on each half of a midpoint), a random assignment would yield a score of 0.50 in expectation.

Model	Purity	Spearman's ρ
Additive (PROP.)	0.757 $\pm$0.020	0.648 $\pm$0.017
Single mem. (PROP.)	0.754 $\pm$0.019	0.628 $\pm$0.017
Single mem. (PRED.)	0.702 $\pm$0.018	0.555 $\pm$0.015
Additive (PRED.)	0.705 $\pm$0.018	0.490 $\pm$0.013
Co-training	0.695 $\pm$0.018	0.450 $\pm$0.013
LR	0.619 $\pm$0.016	0.278 $\pm$0.010
PCA (frequency)	0.518 $\pm$0.014	0.098 $\pm$0.009
PCA (counts)	0.514 $\pm$0.014	0.066 $\pm$0.008

Table 3: Evaluation. Higher is better.

Table 3 presents the results of this evaluation. For both of the models described in §3, we present results for scoring a proposition like OBAMA IS A SOCIALIST based only on the conditional predicate score (PRED.) and on a score that includes variation in the subject as well (PROP.). Since both models are fit using approximate inference with a non-convex objective function, we run five models with different random initializations and present the average across all five.

We estimate confidence intervals using the block jackknife (Quenouille, 1956; Efron and Stein, 1981), calculating purity and Spearman's ρ over 76 resampled subsets of the full 766 elements, each leaving out 10.[13] For both metrics, the two best performing models show statistically significant improvement over all other models, but are not significantly different from each other.

We draw two messages from these results:

For heavily partisan data, unsupervised methods are sufficient. In drawing on comments on politically partisan blogs, we are able to match human judgments of the political import of propositions quite well (both of the unsupervised models

[12] In this case, with two clusters on each side, the best alignment in maximal in that $g_{n,i} \rightarrow c_{n,j} \Rightarrow g_{n,\neg i} \rightarrow c_{n,\neg j}$.

[13] As a clustering metric, purity has no closed-form expression for confidence sets, and since its evaluation requires its elements to be unique (in order to be matched across clusters), we cannot use common resampling-with-replacement techniques such as the bootstrap (Efron, 1979).

described in §3 outperform their supervised and semi-supervised counterparts by a large margin), which suggests that the easiest structure to find in this particular data is the affiliation of users with their political ideologies. Both unsupervised models are able to exploit the natural structure without being constrained by a small amount of training data that may be more biased (e.g., in its class balance) than helpful. The two generative models also widely outperform PCA, which may reflect a mismatch between its underlying assumptions and the textual data we observe; PCA treats data sparsity as structural zeros (not simply missing data) and so must model not only the variation that exists between users, but also the variation that exists in their frequency of use; other latent component models may be a better fit for this kind of data.

Joint information is important. For both models, including information about the full joint probability of a subject and predicate together yields substantial improvements for both purity and the Spearman correlation coefficient compared to scores calculated from variation in the conditional predicate alone. While we might have considered variation in the predicate to be sufficient in distinguishing between political parties, we see that this is simply not the case; variation in the subject may help anchor propositions in the spectrum relative to each other.

6 Convergent Validity

The primary quantity of interest that we are trying to estimate in the models described above is the political position of an *assertion*; a user's latent political affiliation is only a helpful auxiliary variable in reaching this goal. We can, however, also measure the correlation of those variables themselves with other variables of interest, such as users' self-declarations of political affiliation and audience participation on the different blogs. Both provide measures of convergent validity that confirm the distinction being made in our models is indeed one of political ideology.

6.1 Correlation with Self-declarations

One form of data not exploited by the unsupervised models described above are users' self-declarations; we omit these above in order to make the models as general as possible (requiring only text and not metadata), but they can provide an independent measure of the distinctions our unsupervised models are learning. (The supervised baselines in contrast are able to draw on this profile information for training data.)

Approximately 12% of the users in the data input to our models (4,718 of 40,804) have affiliated self-declared profile information; the most frequent of these include *retired*, *businessman*, *student*, and *patriot*. For all of these users, we regress binary indicators of the top 25,000 unigrams in their profiles against the MAP estimate of their political affiliation in the single-membership model. Across all 5 folds, the features with the highest predictive weights for one class were *patriot*, *conservative*, *obama*, and *god* while the highest predictive weights for the other are *progressive*, *voter*, *liberal*, and *science*.

6.2 Estimating Media Audience

We can also use users' latent political ideologies to estimate the overall ideological makeup of a blog's active audience. If we assign each post to our estimate of the political ideology of its author, we find that Mother Jones has the highest fraction of comments by estimated liberals at 80.4%, while Breitbart has the highest percentage of comments by conservatives (79.5%).

Blog	% Liberal by post
Mother Jones	80.4%
NPR	67.4%
Politico	51.6%
Young Conservatives	38.0%
Daily Caller	28.4%
IJ Review	28.0%
Breitbart	20.5%

Table 4: Media audience.

This broadly accords with Mitchell et al. (2014), which finds that among the blogs in our dataset, consistently liberal respondents trust NPR and Mother Jones most, while consistent conservatives trust Breitbart most and NPR and Mother Jones the least.

7 Conclusion

We introduce the task of estimating the political import of propositions such as OBAMA IS A SOCIALIST; while much work in open information extraction has focused on learning facts such as OBAMA IS PRESIDENT from text, we are able to exploit structure in the users and communities who make such assertions in order to align them all

within the same political space. Given sufficiently partisan data (here, comments on political blogs), we find that the unsupervised generative models presented here are able to outperform other models, including those given access to supervision.

One natural downstream application of this work is fine-grained opinion polling; while existing work has leveraged social media data on Twitter for uncovering correlations with consumer confidence, political polls (O'Connor et al., 2010), and flu trends (Paul and Dredze, 2011), our work points the way toward identifying fine-grained, interpretable propositions in public discourse and estimating latent aspects (such as political affiliation) of the communities who assert them. Data and code to support this work can be found at `http://people.ischool.berkeley.edu/~dbamman/emnlp2015/`.

Abstract

In this paper, we present a comprehensive study of the relationship between an individual's personal traits and his/her brand preferences. In our analysis, we included a large number of character traits such as personality, personal values and individual needs. These trait features were obtained from both a psychometric survey and automated social media analytics. We also included an extensive set of brand names from diverse product categories. From this analysis, we want to shed some light on (1) whether it is possible to use personal traits to infer an individual's brand preferences (2) whether the trait features automatically inferred from social media are good proxies for the ground truth character traits in brand preference prediction.

1 Introduction

Brand preference analysis is an important topic in marketing. To induce a desired brand choice, a marketer must understand the main factors that influence a consumer's brand preferences. This task is not easy since many factors may play a role in determining one's brand preferences such as a consumer's individual characteristics and preferences as well as the properties of a brand (e.g., its perceived quality). Among consumer related factors, demographics such as age, gender and income have been studied extensively in marketing research (Evans, 1959; Elliott, 1994; Lin, 2002). In this study, we focus on analyzing a set of consumer characteristics, which have received less attention but with these features, potentially we can build more precise and more accurate brand preference prediction models. Especially, we focus on three types of personal traits: *personality*, *personal values*, and *individual needs*. *Personality* is a combination of characteristics or qualities that form an individual's distinctive character; *Personal values* reflect what are important to different individuals and what motivate them in their decision making. Moreover, all people have certain *needs* that they want to satisfy. Thus, analyzing a comprehensive set of personal traits may help us understand the way we react to a particular brand.

Previously, the relationship between personal traits and brand preference/purchase decisions has drawn limited interest in marketing research due to the difficulty in obtaining consumer traits on a large scale. Among these efforts, Westfall found that differences exist between the personalities of the owners of convertible cars and those of standard & compact cars (Westfall, 1962). Similarly, the congruence of personal and brand personality was suggested to be a predictor of consumers' brand preferences (Jamal and Goode, 2001; Dikcius et al., 2013). However, Shank & Langmeyer found personal traits less useful in building a strategic marketing tool (Shank and Langmeyer, 1994).

Given limited and sometimes conflicting results in previous research, in this study, we want to systematically investigate the relationship between a comprehensive set of personal traits and brand preferences. Specifically, we want to shed some light on (1) whether it is possible to use personal traits to predict consumer's brand preferences? (2) whether it is feasible to use automatically inferred personal traits to build brand preference prediction systems that are scalable?

Our study offers several significant contributions to the field of brand preference analysis:

1. It is the first study that includes a comprehensive set of personal traits in brand preference analysis. Our current investigation includes *personality* (5 general categories and 30 sub-

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 86–96,
Lisbon, Portugal, 17-21 September 2015.

facets), *personal values* (5 dimensions) and *individual needs* (12 dimensions). In contrast, previous work typically only included a small number of personal traits (e.g., just 5 personality traits in (Hirsh et al., 2012)).

2. It is the first study that uses personal traits obtained from both psychometric evaluation and social media analytics. The traits scores derived from psychometric tests are more accurate, which allow us to focus on the relationship between personal traits and brand preferences without the distractions from the mistakes introduced by an automated trait inference system. However, since psychometric tests require users to answer a large number of survey questions, without sufficient incentives, it is difficult to perform psychometric evaluation for a large number of people. In contrast, automatically derived trait features based on social media analytics require no user effort, and can be applied to millions of social media users.

3. Our study involves diverse brand categories such as luxury car brands, retail brands, fast food brands, and household product brands (e.g., shampoo brands). With this data, we can investigate whether the relationship between personal traits and brand preferences varies across multiple product categories.

Since the current study focuses on a comprehensive set of consumer characteristics and preferences which does not include many important brand properties such as perceived quality, risk, price and market presence, the main goal of our investigation is not to build a highly accurate brand preference prediction system. Instead, we want to first establish the feasibility of using derived trait features in building large-scale brand preference prediction systems. In the following, we first summarize some prior work, then describe the details of our experiments.

2 Related Work

Predicting brand preference is a hard problem. A large number of factors may influence customers' choices. Table 1 summarizes the factors that have been explored in previous research. Due to the scope, so far, there isn't any prior investigation that is capable of incorporating all the factors in a single model. Our study is one of the most comprehensive analyses so far. We not only investigate the influence of a large number of personal traits but also combine them with other known consumer-related features such as demographics and personal interests. We however have not included any brand-related properties such as perceived quality, risk and market presence because we do not have access to these data.

Consumer Oriented Features	Demographic characteristics (Evans, 1959; Koponen, 1960; Elliott, 1994; Lin, 2002) including Age, Education, Gender, Family dimensions, Marital Status, Ethnic group, Geographic location, Social Class, Community
	Attitude (Bass and Talarzyk, 1972; Haley and Case, 1979), Personalities (Westfall, 1962; Shank and Langmeyer, 1994; Myszkowski and Storme, 2012), Needs (Evans, 1959), Trust (Chaudhuri and Holbrook, 2001), Customer Satisfaction (Bryant and Cha, 1996; Mittal and Kamakura, 2001; Olsen, 2002), Brand loyalty (Olsen, 2002), Group Influences (Witt and Bruce, 1972), Consumers' memory (Hutchinson et al., 1994), Aspirations (Truong et al., 2010), Purchase history (Dong and Stewart, 2012), Mental Accounting (Thaler, 1985), Involvement (Celsi and Olson, 1988), Social Influence (Wood and Hayes, 2012)
Brand-Related Factors	Price, Market presence, Market response in (Papadopoulos et al., 1990), Promotion (Graeff, 1996), Brand name (Zinkhan and Martin Jr, 1987; Klink, 2001), Quality (Dickerson, 1982; Olsen, 2002), Service quality, Equity, Value in (Hellier et al., 2003), Country of origin (Han and Terpstra, 1988; Tse and Gorn, 1993), Product image (Westfall, 1962), Brand personality (Aaker, 1997), Pioneering advantages (Carpenter and Nakamoto, 1989), Recallability (Costley and Brucks, 1992), Communication (advertising) (Nicholls et al., 2011; Liu and Tang, 2011), Social environment (Witt and Bruce, 1972), Perceived risk (Peter and Ryan, 1976; Campbell and Goodstein, 2001), Product attributes (Semeijn et al., 2004), Product visibility (Sutton and Riesz, 1979)

Table 1: Features explored in previous studies

In recent social media studies, Wang et al. utilized customer reviews to predict coffee brand satisfaction (Wang et al., 2013). Also, there is a large-body of work trying to predict brand preferences based on one's social media posts. Most of these work, however is performed in the context of sentiment analysis. In sentiment analysis, the main focus was to infer the sentiment associated with a post that mentions a particular brand/product. For example, Kim et al. collected 600,000 tweets that contain smartphone-related keywords and then performed sentiment analysis to infer whether a user's attitude toward a particular mobile phone is positive or negative (Kim et al., 2012). Similarly, Mostafa analyzed the sentiment associated with 3,500+ tweets, which showed a generally positive consumer sentiment towards several famous brands (Mostafa, 2013). In contrast, our trait-based analysis is more general since it does not require users to explicitly express their opinions about a specific brand. For example, to infer whether an individual likes BMW or not, with sentiment analysis, a user has to ex-

plicitly express his opinion towards BMW (e.g. Driving BMW is exciting!). In contrast, with our system, if we know that he likes to seek excitement (excitement, a needs dimension) and enjoys luxury products (Hedonism, a values dimension), we can guess he may like BMW although he has never explicitly mentioned BMW in his social media posts before. This difference is important since among the millions of products on social media, only a small number of products have been explicitly rated/mentioned by a particular user.

In summary, brand preferences may be influenced by many consumer and brand-related factors. Previous research has not paid sufficient attention to the influence of personal traits. In addition, most previous studies used psychometric surveys which are impractical in mass marketing since it is unlikely that a large number of customers would take the time to answer lengthy survey questions. In this study, we focus on investigating the feasibility of using automatically inferred personal traits in large-scale brand preference prediction. Next, we describe the dataset we collected to support this study.

3 Data Collection

To investigate how personal traits are related to an individual's brand preferences, we collected two datasets. In the first dataset, in addition to brand preferences, we also used standard psychometric tests to obtain clean and accurate personal trait measures. With this dataset, we can build and evaluate brand preference prediction models that use accurate personal traits. In contrast, the second dataset is used to build and evaluate brand preference prediction models that use trait features automatically inferred from social media. By comparing the models built from both datasets, we can answer questions such as: (1) whether personal traits are useful in predicting brand preferences (2) whether the traits automatically inferred from social media are useful in predicting brand preferences.

To collect these datasets, we designed two Amazon Mechanical Turk (MTurk) [1] tasks. All the MTurk participants are from the US since people outside the US may be unfamiliar with some of the brands. In the following, we describe the details of each MTurk task.

[1] http://mturk.com/

Category	Brand
Beverage (2)	Coca-Cola, Pepsi
Luxury Car (3)	BMW, Cadillac, Lexus
Fast Food (4)	Chipotle, McDonald's, Panera Bread (PB) , Subway
Retail (4)	Kohl's, Macy's, Nordstrom, Target
Shampoo (4)	Head & Shoulders (HS), Herbal Essences (HE), Pantene, Suave
Smart Phone (5)	HTC, iPhone, Samsung, SONY, Nokia

Table 2: Selected brand categories and brands

3.1 Task 1: PTBP Survey

To collect the first dataset, we conducted a Personal Traits & Brand Preferences (PTBP) survey. Our trait survey includes five parts designed to measure three types of personal traits: *personality*, *values* and *needs* plus demographics and personal interests. Specifically, since the Big-Five model of personality is the most popular model of personality traits among personality psychologists, we adopted a standard survey for Big 5 personality. Here to limit the time MTurkers need to spend on the survey, instead of the full 300-item personality test, we used the shorter 50-item IPIP survey (Goldberg, 1993) which will score a user along 5 general personality dimensions: openness, conscientiousness, extraversion, agreeableness and neuroticism. However, with the shorter survey, we can not obtain the scores for 30 additional personality facets. Similarly, we used the standard 21-item PVQ survey to obtain the *values* defined in Schwartz's theory of basic values (Schwartz, 2003). We also used the 35-item BNS survey to obtain the *needs* defined in Ford's needs model (Ford, 2005; Yang and Li, 2013). In addition, we also included survey questions about a user's demographics (e.g., gender, age, marital status, education and income) and personal interests (e.g,, automobile, sports, movies, travel) since they were used in some previous studies on brand preference (Pennacchiotti and Gurumurthy, 2011; Lin, 2002). Finally for each user, we collected her preferences for 22 brands in six categories. We have chosen well-known brands from diverse groups ranging from mobile phones to retail stores and fast food restaurants. The brands within each category are often competitors. For each brand in each category, we asked users to rate their preferences using a 5-point scale: *Love, Like, Neutral, Dislike* and *Hate*. A user can choose "n/a" if she has no knowledge of a particular brand. In total, we have collected the data from 1,207 MTurkers. To ensure the quality of the data collected from MTurk, we also included several validation ques-

tions. The validation questions are pairs of questions that are paraphrases of each other. If the answers to a pair of validation questions are significantly different, the user data are excluded from our analysis. Our final dataset has 1,017 valid responses. Table 2 lists all the brands used in our study. All the measures used in our PTBP survey are listed in Table 3.

Question Category	Features
Personalities (5)	Big-five personalities: Agreeableness, Conscientiousness, Extraversion, Neuroticism, Openness
Values (5)	Conservation, Hedonism, Openness to change, Self Enhancement, Self Transcendence
Needs (12)	Challenge, Closeness, Curiosity, Excitement, Harmony, Ideal, Liberty, Love, Practicality, Self-expression, Stability, Structure
Topics of Interest (20)	Politics, Business, Technology, Science, Health, Sports, Education, Books, Dance, Movie, Music, Television, Theater, Video games, Automobiles, Dining wine, Fashion style, Home garden, International news, US news
Location (2)	City, State
Demographics (6)	Gender, Age, Marital status, Have children, Education status, Income
Brand Preferences (22)	Ratings for all the 22 brands

Table 3: PTBP Survey Feature Summary

3.2 Task 2: TAE Survey

The data collected in the Text Analytics Evaluation (TAE) survey are used to study the correlation between the trait features inferred from a person's social media posts (e.g., tweets) and his brand preferences. Before the TAE survey, the participants were first asked to verify whether they had a Twitter account, if so, provide us their Twitter IDs. The users also agreed that we could access their tweets after the survey. Since our automated trait inference system relies on linguistic cues derived from a person's Twitter posts, to ensure we can have a stable and reliable reading of one's personal traits from his tweets, only active Twitter users with over 50 tweets (excluding retweets) can participate this survey. Since the majority of MTurkers are not active Twitter users, to increase the size of our data, in addition to MTurk, we also directly invited random Twitter users to participate in our TAE survey.

In addition to Twitter IDs, we also asked participants to provide their preferences for the same 22 brands as those used in the PTBP survey. Similarly, to filter out data by people who do not follow instructions, we also added two validation questions. In total, in the TAE survey, we have collected data from 659 participants, out of which 608 are valid. (550 valid ones are from MTurk, and 109 are from direct Twitter invitation).

3.3 Data Preparation

To obtain the trait scores for each user based on his answers in the PTBP survey, we first computed the raw trait scores based on the original survey guidelines. Since different surveys used different scales, we normalized the trait scores by using their rank percentile (e.g., top 1%, top 5%). As a result, all the normalized personal trait scores are between 0 and 1.

Moreover, for each of the 20 topics of interest, we created a binary variable, indicating whether a participant is interested in a specific topic. In addition, each demographics feature such as age, education, income, was first mapped to an integer and then normalized into a number between 0 and 1.

To derive the trait scores for a user in the TAE survey, we crawled all the tweets in his Twitter account. Since personal traits are inferred from the text authored by a user, we discarded all the retweets. Due to the restrictions of the Twitter API, we can only crawl a maximum of 3,200 tweets for each user[2].

Recent research in psycholinguistics has shown it is possible to automatically infer personal traits from one's linguistic footprints such as tweets and blogs (Yarkoni, 2010; Chen et al., 2014; Yang and Li, 2013). Here, we used a similar approach. Specifically, given input text authored by a user (e.g., tweets), our system computed the word counts of different psychologically-meaningful word categories defined in the Linguistic Inquiry and Word Count (LIWC) dictionary (Pennebaker et al., 2001). The LIWC counts were then used to build prediction models to correlate one's word usage with his ground truth personal traits obtained via a prior psychometric survey. Then the built models were used to automatically infer a user's personal traits. Based on a preliminary evaluation with 250 participants, more than 80 percent of them, scores for traits that were inferred for all three models correlated significantly with survey-based scores ($p<0.05$ and correlation coefficient between 0.05 and 0.8). Specifically, scores that were derived by our system correlated with survey-based scores for 80.8% of participants' $\widehat{\text{Big}}$ Five scores ($p<0.05$ and correlation coefficients between 0.05 and 0.75), for 86.6% of participants'

[2]https://dev.twitter.com

Needs scores ($p<0.05$ and correlation coefficient between 0.05 and 0.8), and for 98.21% of participants' *Values* scores ($p<0.05$ and correlation coefficients between 0.05 and 0.55). Moreover, the participants also rated on a five-point scale how well each derived characteristic matched their perceptions of themselves, and their ratings suggest that the inferred characteristics largely matched their self-perceptions. Specifically, means of all ratings were above 3 ("somewhat") out of 5 ("perfect"): 3.4 (with a std. of 1.14) for *Big Five*, 3.39 (with a std. of 1.34) for *Needs*, and 3.13 (with a std. of 1.17) for *Values*.

In addition to personal traits, we also included topics of interest in the TAE dataset. They were automatically inferred from tweets using Latent Dirichlet Allocation (LDA) (Blei et al., 2003). Since we need a large Twitter dataset to mine a list of general topics of interest, our current tweet collection is not sufficient. Therefore, we use a separate and much larger Twitter dataset from 10,000 randomly selected Twitter users. For each user, we crawled his tweets and then aggregated them into a big document, one for each Twitter user. As a result, we have 10,000 documents in our dataset. We then built an LDA topic model using this dataset. From the LDA inference results, we can infer a user's topics of interest. Basically, for a given user u, LDA outputs a per user topic distribution Θ_u, which is a T-dimensional vector where T is the number of topics. The value $\theta_{u,i}$ is an indication of how likely Topic i is mentioned in user u's tweets. The higher $\theta_{u,i}$ is, the more likely that user u is interested in topic i. Table 4 shows some of the topics automatically learned by LDA.

Manually Labeled Name	**Top 10 Topic keywords**
Mobile phone	google app apple data mobile iphone web android tech windows
Alcohol	drinking beer wine vegas earned badge tonight ale bar ipa
Travel	travel hotel cruise ttot trip family great world tips top
Driving	slow drive traffic lane car north south blvd lanes crash
Game	game app ipad video ve games gameinsight free android xbox

Table 4: Selected topics and top words from LDA

As a summary, table 5 shows all the features from the TAE survey, including those automatically inferred from tweets. For *personality*, following the same procedure defined in (Yarkoni, 2010), in addition to the Big five personality dimensions, our system is able to automatically extract 30 additional personality facets for the TAE dataset.

Question Category	**Features**
Survey Features	
Twitter ID	
Brand Preference	for 22 Brands
Derived Features	
Personalities (35)	Big-five personalities plus their sub-facets automatically inferred from tweets (Yarkoni, 2010)
Values (5)	Same as those in Table 3 but inferred from tweets
Needs (12)	Same as those in Table 3 but inferred from tweets
Topics of Interest (50)	Automatically inferred using a topic model
Location (2)	City, State inferred from IP address
Twitter Metadata (5)	Number of tweets, Number of followers, Number of friends, Favorite count, Listed count
Online Behavior (31)	Avg. number of tweets posted in each of the 7 days in a week, and each of the 24 hours in a day.

Table 5: TAE survey feature summary

In the following section, we explain two analyses we performed on these datasets.

4 Experiment 1

The main objective of this analysis is twofold: (1) to understand why people like or dislike a brand. (2) to build a computational model that automatically differentiates people who have *positive*, *negative*, or *neutral* opinions about a brand.

4.1 Definition and Statistics

For each brand in this study, we define people who have *positive* opinions as those who gave a *love* or *like* rating in their brand preference surveys. Similarly, people who have *negative* opinions are those who gave a *hate* or *dislike* rating. People who gave a *neutral* rating are in the *neutral* category. Table 6 shows the number of instances in each of the three categories for each brand.

4.2 Classification

In this experiment, we want to investigate whether it is possible to differentiate people who have (*Positive*, *Negative*, or *Neutral*) opinions towards different brands. For each brand, we built three-way classifiers using different classification algorithms including AdaBoost (Freund and Schapire, 1996), Decision Tree (C4.5) (Quinlan, 1993), Logistic Regression, Naive Bayes, Random Forest (Breiman, 2001), and SVM (Platt, 1999). In addition, for SVM, we have tested different kernels including polynomial kernel, pearson VII function-based universal kernel (Üstün et al., 2006), and the radial basis function kernel. They are all implemented in the Weka machine learning toolkit (Hall

Brands	PTBP Survey			TAE Survey		
	Positive	Negative	Neutral	Positive	Negative	Neutral
Coca-Cola	519	190	115	363	73	67
Pepsi	360	315	153	261	132	110
BMW	382	85	113	280	34	183

Nokia	161	266	215	126	94	263

Table 6: Number of instances in each category

et al., 2009). Since our current goal is not to build the best brand preference prediction system, but to show the feasibility of building brand preference prediction systems that are scalable to millions of users, we ran all our classifiers using the default parameter settings from Weka (E.g. for Random Forest, we used 10 trees. The umber of features was set to log2(number of all features)+1.). We expect in the future, by optimizing model parameters, we can further improve the prediction power of each model.

The baseline classifiers classify every data instance into the majority class. Among all the classifiers we tested, we found that overall Naive Bayes has the best performance on both the PTBP and the TAE datasets. In the following, we report the average F-scores and AUC across 22 different brands using Naive Bayes with 10-fold cross validations. We created models that use all the user features and also those that use only trait features. Table 7 shows the results.

Best Classifier	PTBP		TAE	
	F	AUC	F	AUC
All features	0.483	0.569	0.501	0.547
Traits only	0.475	0.556	0.502	0.528
Baseline	0.396	0.493	0.444	0.490

Table 7: 3-Way Classification Results

Overall, all the classifiers performed significantly better than the baselines ($p<0.05$). Moreover, the models using all the features performed similarly to those using only trait features. The differences are not statistically significant. In addition, comparing the models trained on the PTBP data with those on the TAE dataset, their performances are very similar, although the exact numbers are not directly comparable since they are from two different datasets.

To break down the results by product category, in Table 8, we list the per-brand classification results using only the trait features. The numbers in the parentheses show the F-score percentage increase from the baselines. In general, models with trait features did much better than the baselines on both datasets. But their effectiveness varied from one brand to another. For example, the trait features were very effective in predicting user preferences for *Cadillac* (50.8% increase on the PTBP dataset and 68.5% increase on the TAE dataset). In contrast, there was barely any improvement for *Target*. After inspecting the data, it seems this may be caused by the distribution of the data. For instance, the Target TAE data was very skewed. There were 430 people who had positive opinions about Target versus 18 people who had negative opinions. Since the baseline predicts "all people like Target", which resulted in a pretty high F-score (0.781), any further improvement over this baseline became more difficult.

Brand	PTBP			TAE		
	BL F	Best F	↑%	BL F	Best F	↑%
Coca-Cola	0.487	0.503	3.3%	0.605	0.605	0.0%
Pepsi	0.263	0.427	62.4%	0.355	0.416	17.2%
BMW	0.522	0.562	7.7%	0.406	0.499	22.9%
Cadillac	0.266	0.401	50.8%	0.282	0.474	68.1%
Lexus	0.505	0.531	5.2%	0.346	0.5	44.5%
Chipotle	0.564	0.59	4.6%	0.513	0.53	3.3%
McDonald's	0.291	0.42	44.3%	0.371	0.459	23.7%
PB	0.513	0.528	2.9%	0.539	0.58	7.6%
Subway	0.501	0.525	4.8%	0.618	0.623	0.8%
Kohl's	0.368	0.466	26.6%	0.441	0.506	14.7%
Macy's	0.288	0.465	61.5%	0.342	0.5	46.2%
Nordstrom	0.207	0.421	103.4%	0.381	0.467	22.6%
Target	0.668	0.67	0.3%	0.781	0.781	0.0%
HS	0.253	0.399	57.7%	0.337	0.454	34.7%
HE	0.397	0.43	8.3%	0.371	0.494	33.2%
Pantene	0.363	0.452	24.5%	0.368	0.51	38.6%
Suave	0.307	0.375	22.2%	0.309	0.434	40.5%
HTC	0.337	0.411	22.0%	0.361	0.455	26.0%
iPhone	0.432	0.501	16.0%	0.54	0.557	3.2%
Samsung	0.673	0.673	0.0%	0.561	0.574	2.3%
SONY	0.258	0.407	57.8%	0.561	0.575	2.5%
Nokia	0.243	0.397	63.4%	0.384	0.432	12.5%

Table 8: Classification Results By Brand

In summary, for the task of differentiating people who have *positive*, *negative*, or *neutral* opinions towards different brands, automatically inferred traits can be a good proxy for the clean data derived from psychometric surveys. Models based on the trait features inferred from social media can perform similarly to those using a much larger set of clean features. This result is encouraging since

it implies that it is possible to build large-scale brand preference prediction systems that do not require costly psychometric surveys.

4.3 Top Features

In this study, we want to find out what are the most significant features that can be used to differentiate a brand's likers from dislikers. The feature selection was conducted using logistic regression in SPSS[3]. Due to the page limit, we cannot list all the significant features for all the 22 brands. Here we only show the most important features in predicting people who like and dislike luxury car brands based on the PTBP dataset (Table 9). Based on the regression analysis, all the features are significantly associated with brand preferences ($p < 0.05$). In this table, personal trait features are highlighted and followed by their types: P (*Personalities*), V (*Values*), and N (*Needs*). "+" or "-" means the features contribute positively or negatively to the model. As shown in the table, more than half of all the top features are trait features. For example, the No. one trait feature to differentiate BMW likers from dislikers is *ideal*, a trait associated with people who have a desire for perfection. For Cadillac, the top trait is *hedonism*, which is often associated with people who pursue pleasure and sensuous gratification in life. For Lexus, the most useful feature is *self-expression*, a trait often associated with people who have a desire to assert their own identifies. Other interesting findings include that females are less likely to be a fan of a luxury car brand than males. This is true across all three luxury car brands.

BMW		***Cadillac***		***Lexus***	
ideal (N)	+	have children(no)	-	sports	+
love (N)	+	television	+	**self expression (N)**	+
conscientiousness (P)	+	**hedonism (V)**	+	television	+
gender(female)	-	home garden	-	**self enhancement (V)**	+
us news	+	gender(female)	-	fashion style	+
health	+	**conservation (V)**	+	theater	-
hedonism (V)	-	**self enhancement (V)**	-	**agreeableness (P)**	+
challenge (N)	-	science	+	**openness to change (V)**	-
conservation (V)	-	**love (N)**	-	**curiosity (N)**	+
self enhancement (V)	+	theater	-	gender(female)	-

Table 9: Top 10 features for predicting opinions toward cars

5 Experiment 2

In the previous section, we demonstrated that given a particular brand such as Pepsi, it is possible to automatically differentiate the people who have positive, negative or neutral opinions. In this section, we try to answer a different question: given a list of competing brands in the same product category, can we automatically rank a user's preferences of these brands? For example, given popular beverage brands such as Pepsi and Coca-Cola, can we automatically predict whether a person will like Pepsi or Coca-Cola more?

5.1 Average Rank for Each Brand

For each user, we rank all the brands in each product category based on his preferences in the survey (e.g., 1 means most preferred brand). We aggregate the ranks from all the users and show the overall brand preference ranks for both datasets. As shown in table 10, the overall brand preference ranks for the PTBP and TAE surveys are highly correlated. Half of the product categories have exact the same preference ranks for all the products; The other half has only one slightly mis-matched rank in each product category. This suggests that the population participated in the PTBP and TAE survey has very similar brand preference distributions. In the future, it maybe interesting to investigate how this rank is related to different brands' market share.

	PTBP	**TAE**
Beverage	1. Coca-cola 2. Pepsi	1. Coca-cola 2. Pepsi
Car	1. BMW 2. Lexus 3. Cadillac	1. BMW 2. Lexus 3. Cadillac
Fast Food	1. Chipotle 2. Panera Bread 3. Subway 4. McDonald's	1. Panera Bread 2. Chipotle 3. Subway 4. McDonald's
Retail	1. Target 2. Macy's 3. Kohl's 4. Nordstrom	1. Target 2. Kohl's 3. Macy's 4. Nordstrom
Shampoo	1. Herbal Essences 2. Pantene 3. Suave 4. Head & Shoulders	1. Herbal Essences 2. Pantene 3. Head & Shoulders 4. Suave
Smart Phone	1. Samsung 2. iPhone 3. HTC 4. Nokia 5. SONY	1. Samsung 2. iPhone 3. HTC 4. Nokia 5. SONY

Table 10: Overall preference rank

5.2 Rank Correlation

To predict the rank of a product in each category, we trained a multi-class classifier to estimate how likely a user will like a brand. For example, for smart phone brands, since we have four competing brands, we train a 4-way classifier to estimate the likelihood a person likes iPhone, HTC, Nokia and Sony. We then output the preference rank based on the estimated likelihood. Higher likelihood means a stronger preference. We also built

[3]http://www-01.ibm.com/software/analytics/spss/

two types of models, one used all the user features, the other used traits only. We applied them to both the PTBP and the TAE datasets.

Since our model and the ground truth both produce a ranked list for each product category, here we used rank correlation analysis to evaluate the quality of the predicted ranks. For each user and each product category, we computed the Spearman's rank correlation coefficient ρ. If the coefficient ρ is 1, there is a perfect positive correlation between the predict rank and the ground truth (i.e. both produce identical ranks). If ρ is -1, there is a perfect negative correlation between the predicted rank and the ground truth (i.e., the rank predicted by the system is exactly the opposite of the ground truth). If ρ is 0 , then the predicted rank and the ground truth are randomly related. For each product category, we report the average ρ across all the users.

	PTBP		TAE	
	All Features	**Traits Only**	**All Features**	**Traits Only**
Brand	**avg. ρ**	**avg. ρ**	**avg. ρ**	**avg. ρ**
Beverage	0.264	0.301	0.234	0.372
Car	0.322	0.345	0.461	0.447
Fast Food	0.359	0.326	0.328	0.292
Retail	0.326	0.341	0.553	0.505
Shampoo	0.187	0.116	0.284	0.258
Smart Phone	0.414	0.403	0.497	0.545
All Avg.	0.312	0.305	0.393	0.403

Table 11: Evaluating predicted ranks

We use the overall rank data in Table 10 as our baseline. Specifically, for each product category, the baseline always ranks all its brands based on the average ranks defined in Table 10. For each user and each product category, we compute the ρ between the user's ground truth rank in the survey and the rank produced by the baseline. We compute the average ρ across all the users and all the product categories to represent the baseline performance. For the PTBP data, the average ρ for the baseline is 0.193. For the TAE data, the average ρ is 0.060.

There are several main findings from these results. First, for all the product categories, the predicted ranks are all significantly and positively correlated with the ground truth ($p < 0.05$). Also, our models perform significantly better than the non-personalized ranks produced by the baseline. This result is important because it shows that there is a stable and statistically significant agreement between the predicted ranks and the ground truth and the personalized models with additional trait features perform significantly better than the non-personalized baseline system (on PTBP, the average ρ of the model with personal traits is 0.305 versus 0.193 of the baseline. It is 0.403 versus 0.060 on the TAE dataset). Second, the performance on the TAE dataset is better than that on the PTBP dataset (e.g., the average ρ is 0.403 on TAE versus 0.305 on PTBP when only trait features were used). This may be due to the fact that in the TAE dataset, in addition to the Big 5 personality features, we also automatically extracted 30 personality sub-facets from tweets using the procedure described in (Yarkoni, 2010). These finer-grained personality features are not available in the PTBP dataset. This result is encouraging since it suggests that using automatically inferred traits can predict brand preferences as well as if not better than the clean trait features that can be obtained only through costly psychometric evaluations. Finally, for our models, since the overall correlation coefficients ρ are between 0.3 and 0.4, the strength of these correlations is moderate. Thus, it may not be sufficient to build an accurate brand preference prediction system with only user features. Other features especially brand-related features as well as features that capture the compatibility of a brand and a user are needed.

5.3 Top Features

We used multinomial logistic regression to find the most significant predicting features for each brand category. We show the feature ranks by significance for survey data in Table 12 and 13. Almost all of the top 10 features for each brand are significantly correlated with the ranks. Again, the personal traits features are highlighted and followed by their types: P (Personalities), V (Values), and N (Needs).

6 Conclusion and Future Direction

In this paper, we present a comprehensive analysis of the relationship between personal traits and brand preferences. Our study includes a large number of personal traits including personality, personal values and individual needs. We collect two datasets: one contains clean user features obtained from psychometric surveys; The other includes noisy users features derived automatically from social media posts. We investigate the influence of personal traits in two scenarios: (1) in differentiating people who have *positive*, *negative*, or *neutral* opinion about a brand, (2) in ranking

Table 13: Top 10 features for predicting rank correlation (TAE)

a user's preference of competing brands within a product category. Our findings demonstrated that it is possible to use personal traits in predicting a user's brand preferences. Moreover, we have also shown that automatically inferred user features are good proxies for the clean trait features that can be acquired only from costly psychometric surveys. This work may have significant impact on the field of brand preference analysis since this suggests that it is possible for businesses to build scalable marketing tools to identify and target potential customers on social media.

Brand preference prediction is a hard problem. So far, we have focused primarily on user features. To further improve the prediction accuracy, in the future, we will extend our current study by incorporating new features such as the properties of a brand as well social influence from people in one's social network.

Abstract

Trending topics in microblogs such as Twitter are valuable resources to understand social aspects of real-world events. To enable deep analyses of such trends, semantic annotation is an effective approach; yet the problem of annotating microblog trending topics is largely unexplored by the research community. In this work, we tackle the problem of mapping trending Twitter topics to entities from Wikipedia. We propose a novel model that complements traditional text-based approaches by rewarding entities that exhibit a high temporal correlation with topics during their burst time period. By exploiting temporal information from the Wikipedia edit history and page view logs, we have improved the annotation performance by 17-28%, as compared to the competitive baselines.

1 Introduction

With the proliferation of microblogging and its wide influence on how information is shared and digested, the studying of microblog sites has gained interest in recent NLP research. Several approaches have been proposed to enable a deep understanding of information on Twitter. An emerging approach is to use semantic annotation techniques, for instance by mapping Twitter information snippets to canonical entities in a knowledge base or to Wikipedia (Meij et al., 2012; Guo et al., 2013), or by revisiting NLP tasks in the Twitter domain (Owoputi et al., 2013; Ritter et al., 2011). Much of the existing work focuses on annotating a single Twitter message (tweet). However, information in Twitter is rarely digested in isolation, but rather in a collective manner, with the adoption of special mechanisms such as hashtags. When put together, the unprecedentedly massive adoption of a hashtag within a short time period can lead to bursts and often reflect trending social attention. Understanding the meaning of trending hashtags offers a valuable opportunity for various applications and studies, such as viral marketing, social behavior analysis, recommendation, etc. Unfortunately, the task of hashtag annotation has been largely unexplored so far.

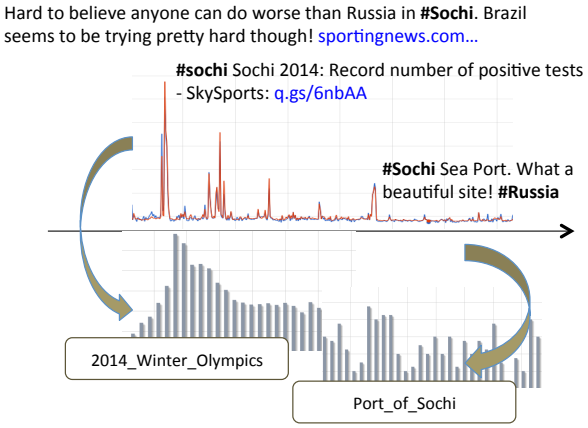

Figure 1: Example of trending hashtag annotation. During the *2014 Winter Olympics*, the hashtag '#sochi' had a different meaning.

In this paper, we study the problem of annotating trending hashtags on Twitter by entities derived from Wikipedia. Instead of establishing a static semantic connection between hashtags and entities, we are interested in *dynamically* linking the hashtags to entities that are closest to the underlying topics during burst time periods of the hashtags. For instance, while '#sochi' refers to a city in Russia, during February 2014, the hashtag was used to report the *2014 Winter Olympics* (cf. Figure 1). Hence, it should be linked more to Wikipedia pages related to the event than to the location.

Compared to traditional domains of text (e.g., news articles), annotating hashtags poses additional challenges. Hashtags' surface forms are

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 97–106,
Lisbon, Portugal, 17-21 September 2015.

very ad-hoc, as they are chosen not in favor of the text quality, but by the dynamics in attention of the large crowd. In addition, the evolution of the semantics of hashtags (e.g., in the case of '#sochi') makes them more ambiguous. Furthermore, a hashtag can encode multiple topics at once. For example, in March 2014, '#oscar' refers to the *86th Academy Awards*, but at the same time also to the *Trial of Oscar Pistorius*. Sometimes, it is difficult even for humans to understand a trending hashtag without knowledge about what was happening with the related entities in the real world.

In this work, we propose a novel solution to these challenges by leveraging temporal knowledge about entity dynamics derived from Wikipedia. We hypothesize that a trending hashtag is associated with an increase in public attention to certain entities, and this can also be observed on Wikipedia. As in Figure 1, we can identify *2014 Winter Olympics* as a prominent entity for '#sochi' during February 2014, by observing the change of user attention to the entity, for instance via the page view statistics of Wikipedia articles. We exploit both Wikipedia edits and page views for annotation. We also propose a novel learning method, inspired by the information spreading nature of social media such as Twitter, to suggest the optimal annotations without the need for human labeling. In summary:

- We are the first to combine the Wikipedia edit history and page view statistics to overcome the temporal ambiguity of Twitter hashtags.
- We propose a novel and efficient learning algorithm based on influence maximization to automatically annotate hashtags. The idea is generalizable to other social media sites that have a similar information spreading nature.
- We conduct thorough experiments on a real-world dataset and show that our system can outperform competitive baselines by 17-28%.

2 Related Work

Entity Linking in Microblogs The task of semantic annotation in microblogs has been recently tackled by different methods, which can be divided into two classes, i.e., content-based and graph-based methods. While the content-based methods (Meij et al., 2012; Guo et al., 2013; Fang and Chang, 2014) consider tweets independently, the graph-based methods (Cassidy et al., 2012; Liu et al., 2013) use all related tweets (e.g., posted by a user) together. However, most of them focus on entity mentions in tweets. In contrast, we take into account hashtags which reflect the topics discussed in tweets, and leverage external resources from Wikipedia (in particular, the edit history and page view logs) for semantic annotation.

Analysis of Twitter Hashtags In an attempt to understand the user interest dynamics on Twitter, a rich body of work analyzes the temporal patterns of popular hashtags (Lehmann et al., 2012; Naaman et al., 2011; Tsur and Rappoport, 2012). Few works have paid attention to the semantics of hashtags, i.e., to the underlying topics conveyed in the corresponding tweets. Recently, Bansal et al. (2015) attempt to segment a hashtag and link each of its tokens to a Wikipedia page. However, the authors only aim to retrieve entities directly mentioned within a hashtag, which are very few in practice. The external information derived from the tweets is largely ignored. In contrast, we exploit both context information from the microblog and Wikipedia resources.

Event Mining Using Wikipedia Recently some works exploit Wikipedia for detecting and analyzing events on Twitter (Osborne et al., 2012; Tolomei et al., 2013; Tran et al., 2014). However, most of the existing studies focus on the statistical signals of Wikipedia (such as the edit or page view volumes). We are the first to combine the content of the Wikipedia edit history and the magnitude of page views to handle trending topics on Twitter.

3 Framework

Preliminaries We refer to an *entity* (denoted by e) as any object described by a Wikipedia article (ignoring disambiguation, lists, and redirect pages). The number of times an entity's article has been requested is called the *entity view count*. The text content of the article is denoted by $C(e)$. In this work, we choose to study hashtags at the daily level, i.e., from the timestamps of tweets we only consider their creation day. A hashtag is called *trending* at a time point (a day) if the number of tweets where it appears is significantly higher than that on other days. There are many ways to detect such trendings. (Lappas et al., 2009; Lehmann et al., 2012). Each trending hashtag has one or multiple *burst time periods*, surrounding the trend-

ing day, where the users' interest in the underlying topic remains stronger than in other periods. We denote with $T(h)$ (or T for short) one hashtag burst time period, and with $D_T(h)$ the set of tweets containing the hashtag h created during T.

Task Definition Given a trending hashtag h and the burst time period T of h, identify the top-k most prominent entities to describe h during T.

It is worth noting that not all trending hashtags are mapable to Wikipedia entities, as the coverage of topics in Wikipedia is much lower than on Twitter. This is also the limitation of systems relying on Wikipedia such as entity disambiguation, which can only disambiguate popular entities and not the ones in the long tail. In this study, we focus on the precision and the popular trending hashtags, and leave the improvement of recall to future work.

Overview We approach the task in three steps. The first step is to identify all entity candidates by checking surface forms of the constituent tweets of the hashtag. In the second step, we compute different similarities between each candidate and the hashtag, based on different types of contexts, which are derived from either side (Wikipedia or Twitter). Finally, we learn a unified ranking function for each (hashtag, entity) pair and choose the top-k entities with the highest scores. The ranking function is learned through an unsupervised model and needs no human-defined labels.

3.1 Entity Linking

The most obvious resource to identify candidate entities for a hashtag is via its tweets. We follow common approaches that use a lexicon to match each textual phrase in a tweet to a potential entity set (Shen et al., 2013; Fang and Chang, 2014). Our lexicon is constructed from Wikipedia page titles, hyperlink anchors, redirects, and disambiguation pages, which are mapped to the corresponding entities. As for the tweet phrases, we extract all n-grams ($n \leq 5$) from the input tweets within T. We apply the longest-match heuristic (Meij et al., 2012): We start with the longest n-grams and stop as soon as the entity set is found, otherwise we continue with the smaller constituent n-grams.

Candidate Set Expansion While the lexicon-based linking works well for single tweets, applying it on the hashtag level has subtle implications. Processing a huge amount of text, especially during a hashtag burst time period, incurs expensive computational costs. Therefore, to guarantee a good recall in this step while still maintaining feasible computation, we apply entity linking only on a random sample of the complete tweet set. Then, for each candidate entity e, we include all entities whose Wikipedia article is linked with the article of e by an outgoing or incoming link.

3.2 Measuring Entity–Hashtag Similarities

To rank the entity by prominence, we measure the similarity between each candidate entity and the hashtag. We study three types of similarities:

Mention Similarity This measure relies on the explicit mentions of entities in tweets. It assumes that entities directly linked from more prominent anchors are more relevant to the hashtag. It is estimated using both statistics from Wikipedia and tweet phrases, and turns out to be surprisingly effective in practice (Fang and Chang, 2014).

Context Similarity For entities that are not directly linked to mentions (the mention similarity is zero) we exploit external resources instead. Their prominence is perceived by users via external sources, such as web pages linked from tweets, or entity home pages or Wikipedia pages. By exploiting the content of entities from these external sources, we can complement the explicit similarity metrics based on mentions.

Temporal Similarity The two measures above rely on the textual representation and are degraded by the linguistic difference between the two platforms. To overcome this drawback, we incorporate the temporal dynamics of hashtags and entities, which serve as a proxy to the change of user interests towards the underlying topics (Ciglan and Nørvåg, 2010). We employ the correlation between the times series of hashtag adoption and the entity view as the third similarity measure.

3.3 Ranking Entity Prominence

While each similarity measure captures one evidence of the entity prominence, we need to unify all scores to obtain a global ranking function. In this work, we propose to combine the individual similarities using a linear function:

$$f(e,h) = \alpha f_m(e,h) + \beta f_c(e,h) + \gamma f_t(e,h) \quad (1)$$

where α, β, γ are model weights and f_m, f_c, f_t are the similarity measures based on mentions, context, and temporal information, respectively, be-

tween the entity e and the hashtag h. We further constrain that $\alpha + \beta + \gamma = 1$, so that the ranking scores of entities are normalized between 0 and 1, and that our learning algorithm is more tractable. The algorithm, which automatically learns the parameters without the need of human-labeled data, is explained in detail in Section 5.

4 Similarity Measures

We now discuss in detail how the similarity measures between hashtags and entities are computed.

4.1 Link-based Mention Similarity

The similarity of an entity with one individual mention in a tweet can be interpreted as the probabilistic prior in mapping the mention to the entity via the lexicon. One common way to estimate the entity prior exploits the anchor statistics from Wikipedia links, and has been proven to work well in different domains of text. We follow this approach and define $LP(e|m) = \frac{|l_m(e)|}{\sum_{m'}|l_{m'}(e)|}$ as the link prior of the entity e given a mention m, where $l_m(e)$ is the set of links with anchor m that point to e. The mention similarity f_m is measured as the aggregation of link priors of the entity e over all mentions in all tweets with the hashtag h:

$$f_m(e,h) = \sum_m (LP(e|m) \cdot q(m)) \quad (2)$$

where $q(m)$ is the frequency of the mention m over all mentions of e in all tweets of h.

4.1.1 Context Similarity

To compute f_c, we first construct the contexts for hashtags and entities. The context of a hashtag is built by extracting all words from its tweets. We tokenize and parse the tweets' part-of-speech tags (Owoputi et al., 2013), and remove words of Twitter-specific tags (e.g., @-mentions, URLs, emoticons, etc.). Hashtags are normalized using the word breaking method by Wang et al. (2011).

The textual context of an entity is extracted from its Wikipedia article. One subtle aspect is that the articles are not created at once, but are incrementally updated over time in accordance with changing information about entities. Texts added in the same time period of a trending hashtag contribute more to the context similarity between the entity and the hashtag. Based on this observation, we use the Wikipedia revision history – an archive of all revisions of Wikipedia articles – to calculate the entity context. We collect the revisions of articles during the time period T, plus one day to acknowledge possible time lags. We compute the difference between two consecutive revisions, and extract only the added text snippets. These snippets are accumulated to form the *temporal context* of an entity e during T, denoted by $C_T(e)$. The distribution of a word w for the entity e is estimated by a mixture between the probability of generating w from the temporal context and from the general context $C(e)$ of the entity:

$$\hat{P}(w|e) = \lambda \hat{P}(w|M_{C_T(e)}) + (1-\lambda)\hat{P}(w|M_{C(e)})$$

where $M_{C_T(e)}$ and $M_{C(e)}$ are the language models of e based on $C_T(e)$ and $C(e)$, respectively. The probability $\hat{P}(w|M_{C(e)})$ can be regarded as corresponding to the background model, while $\hat{P}(w|M_{C_T(e)})$ corresponds to the foreground model in traditional language modeling settings. Here we use a simple maximum likelihood estimation to estimate these probabilities: $\hat{P}(w|M_{C(e)}) = \frac{tf_{w,c}}{|C(e)|}$ and $\hat{P}(w|M_{C_T(e)}) = \frac{tf_{w,c_T}}{|C_T(e)|}$, where $tf_{w,c}$ and tf_{w,c_T} are the term frequencies of w in the two text sources of $C(e)$ and $C_T(e)$, respectively, and $|C(e)|$ and $|C_T(e)|$ are the lengths of the two texts, respectively. We use the same estimation for tweets: $\hat{P}(w|h) = \frac{tf_{w,D(h)}}{|D(h)|}$, where $D(h)$ is the concatenated text of all tweets of h in T. We use and normalize the Kullback-Leibler divergence to compare the distributions over all words appearing both in the Wikipedia contexts and the tweets:

$$KL(e \parallel h) = \sum_w \hat{P}(w|e) \cdot \frac{\hat{P}(w|e)}{\hat{P}(w|h)}$$
$$f_c(e,h) = e^{-KL(e \parallel h)} \quad (3)$$

4.1.2 Temporal Similarity

The third similarity, f_t, is computed using temporal signals from both sources – Twitter and Wikipedia. For the hashtags, we build the time series based on the volume of tweets adopting the hashtag h on each day in T: $TS_h = [n_1, n_2, \ldots, n_{|T|}]$. Similarly for the entities, we build the time series of view counts for the entity e in T: $TS_e = [v_1, v_2, \ldots, v_{|T|}]$. A time series similarity metric is then used to compute f_t. Several metrics can be used, however most of them suffer from the time lag and scaling discrepancy, or incur expensive computational costs (Radinsky et al., 2011). In this work, we employ a simple yet

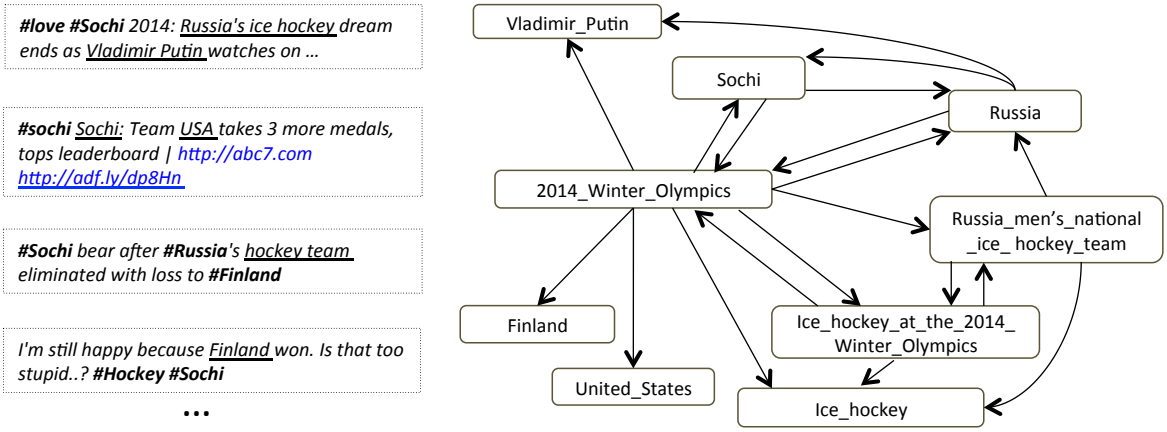

Figure 2: Excerpt of tweets about ice hockey results in the *2014 Winter Olympics* (left), and the observed linking process between time-aligned revisions of candidate Wikipedia entities (right). Links come more from prominent entities to marginal ones to provide background, or more context for the topics. Thus, starting from prominent entities, we can reach more entities in the graph of candidate entities

effective metric that is agnostic to the scaling and time lag of time series (Yang and Leskovec, 2011). It measures the distance between two time series by finding optimal shifting and scaling parameters to match the shape of two time series:

$$f_t(e,h) = \min_{q,\delta} \frac{\|TS_h - \delta d_q(TS_e)\|}{\|TS_h\|} \quad (4)$$

where $d_q(TS_e)$ is the time series derived from TS_e by shifting q time units, and $\|\cdot\|$ is the L_2 norm. It has been proven that Equation 4 has a closed-form solution for δ given fixed q, thus we can design an efficient gradient-based optimization algorithm to compute f_t (Yang and Leskovec, 2011).

5 Entity Prominence Ranking

5.1 Ranking Framework

To unify the individual similarities into one global metric (Equation 1), we need a guiding premise of what manifest the prominence of an entity to a hashtag. Such a premise can be instructed through manual assessment (Meij et al., 2012; Guo et al., 2013), but it requires human-labeled data and is biased from evaluator to evaluator. Other heuristics assume that entities close to the main topic of a text are also coherent to each other (Ratinov et al., 2011; Liu et al., 2013). Based on this, state-of-the-art methods in traditional disambiguation estimate entity prominence by optimizing the overall coherence of the entities' semantic relatedness. However, this coherence does not hold for topics in hashtags: Entities reported in a big topic such as the Olympics vary greatly with different sub-events. They are not always coherent to each other, as they are largely dependent on the users' diverse attention to each sub-event. This heterogeneity of hashtags calls for a different premise, abandoning the idea of coherence.

Influence Maximization (IM) We propose a new approach to find entities for a hashtag. We use an observed behavioral pattern in creating Wikipedia pages for guiding our approach to entity prominence: Wikipedia articles of entities that are prominent for a topic are quickly created or updated,[1] and subsequently enriched with links to related entities. This linking process signals the dynamics of editor attention and exposure to the event (Keegan et al., 2011). We argue that the process does not, or to a much lesser degree, happen to more marginal entities or to very general entities. As illustrated in Figure 2, the entities closer to the 2014 Olympics get more updates in the revisions of their Wikipedia articles, with subsequent links pointing to articles of more distant entities. The direction of the links influences the shifting attention of users (Keegan et al., 2011) as they follow the structure of articles in Wikipedia.

We assume that, similar to Wikipedia, the entity prominence also influences how users are exposed and spread the hashtag on Twitter. In particular, the initial spreading of a trending hashtag involves more entities in the focus of the topic. Subsequent exposure and spreading of the hashtag then include other related entities (e.g., discussing background or providing context), driven by interests in different parts of the topic. Based on this assumption,

[1] Osborne et al. (2012) suggested a time lag of 3 hours.

we propose to gauge the entity prominence as its potential in *maximizing the information spreading* within all entities present in the tweets of the hashtag. In other words, the problem of ranking the most prominent entities becomes identifying the set of entities that lead to the largest number of entities in the candidate set. This problem is known in social network research as *influence maximization* (Kempe et al., 2003).

Iterative Influence-Prominence Learning (IPL) IM itself is an NP-hard problem (Kempe et al., 2003). Therefore, we propose an approximation framework, which can *jointly* learn the influence scores of the entity and the entity prominence together. The framework (called IPL) contains several iterations, each consisting of two steps: (1) Pick up a model and use it to compute the entity influence score. (2) Based on the influence scores, update the entity prominence. In the sequel we detail our learning framework.

5.2 Entity Graph

Influence Graph To compute the entity influence scores, we first construct the entity *influence graph* as follows. For each hashtag h, we construct a directed graph $G_h = (E_h, V_h)$, where the nodes $E_h \subseteq E$ consist of all candidate entities (cf. Section 3.1), and an edge $(e_i, e_j) \in V_h$ indicates that there is a link from e_j's Wikipedia article to e_i's. Note that edges of the influence graph are inversed in direction to links in Wikipedia, as such a link gives an "influence endorsement" from the destination entity to the source entity.

Entity Relatedness In this work, we assume that an entity endorses more of its influence score to highly related entities than to lower related ones. We use a popular entity relatedness measure suggested by Milne and Witten (2008):

$$MW(e_1, e_2) = 1 - \frac{\log(\max(|I_1|,|I_2|) - \log(|I_1 \cap I_2|))}{\log(|E|) - \log(\min(|I_1|,|I_2|))}$$

where I_1 and I_2 are sets of entities having links to e_1 and e_2, respectively, and E is the set of all entities in Wikipedia. The influence transition from e_i to e_j is defined as the normalized value:

$$b_{i,j} = \frac{MW(e_i, e_j)}{\sum_{(e_i,e_k) \in V} MW(e_i, e_k)} \quad (5)$$

Influence Score Let $\mathbf{r}_h$ be the influence score vector of entities in G_h. We can estimate $\mathbf{r}_h$ efficiently using random walk models, similarly to the baseline method suggested by Liu et al. (2014):

$$\mathbf{r_h} \coloneqq \tau \mathbf{B} \mathbf{r_h} + (1 - \tau)\mathbf{s_h} \quad (6)$$

where $\mathbf{B}$ is the influence transition matrix, $\mathbf{s_h}$ are the initial influence scores that are based on the entity prominence model (Step 1 of IPL), and τ is the damping factor.

Algorithm 1: Entity Influence-Prominence Learning

Input : $h, T, D_T(h), \mathbf{B}, k$, learning rate μ, threshold ϵ
Output: ω, top-k most prominent entities.

Initialize: $\omega \coloneqq \omega^{(0)}$
Calculate $\mathbf{f}_m, \mathbf{f}_c, \mathbf{f}_t, \mathbf{f}_\omega \coloneqq \mathbf{f}_{\omega^{(0)}}$ using Eqs. 1, 2, 3, 4
while *true* **do**
  $\hat{\mathbf{f}}_\omega \coloneqq$ normalize $\mathbf{f}_\omega$
  Set $\mathbf{s_h} \coloneqq \hat{\mathbf{f}}_\omega$, calculate $\mathbf{r_h}$ using Eq. 6
  Sort $\mathbf{r_h}$, get the top-k entities $E(h,k)$
  if $\sum_{e \in E(h,k)} L(f(e,h), r(e,h)) < \epsilon$ **then**
    Stop
  end
  $\omega \coloneqq \omega - \mu \sum_{e \in E(h,k)} \nabla L(f(e,h), r(e,h))$
end
return $\omega, E(h,k)$

5.3 Learning Algorithm

Now we detail the IPL algorithm. The objective is to learn the model $\omega = (\alpha, \beta, \gamma)$ of the global function (Equation 1). The general idea is that we find an optimal ω such that the average error with respect to the top influencing entities is minimized

$$\omega = \arg\min \sum_{E(h,k)} L(f(e,h), r(e,h))$$

where $r(e,h)$ is the influence score of e and h, $E(h,k)$ is the set of top-k entities with highest $r(e,h)$, and L is the squared error loss function, $L(x,y) = \frac{(x-y)^2}{2}$.

The main steps are depicted in Algorithm 1. We start with an initial guess for ω, and compute the similarities for the candidate entities. Here $\mathbf{f}_m$, $\mathbf{f}_c$, $\mathbf{f}_t$, and $\mathbf{f}_\omega$ represent the similarity score vectors. We use matrix multiplication to calculate the similarities efficiently. In each iteration, we first normalize $\mathbf{f}_\omega$ such that the entity scores sum up to 1. A random walk is performed to calculate the influence score $\mathbf{r_h}$. Then we update ω using a batch gradient descent method on the top-k influencer entities. To derive the gradient of the loss function L, we first remark that our random walk Equation 6 is similar to context-sensitive PageRank (Haveliwala, 2002). Using the linearity property (Fogaras et al., 2005),

Total Tweets	500,551,041
Trending Hashtags	2,444
Test Hashtags	30
Test Tweets	352,394
Distinct Mentions	145,941
Test (Entity, Hashtag) pairs	6,965
Candidates per Hashtag (avg.)	50
Extended Candidates (avg.)	182

Table 1: Statistics of the dataset.

we can express $r(e,h)$ as the linear function of influence scores obtained by initializing with the individual similarities f_m, f_c, and f_t instead of f_ω. The derivative thus can be written as:

$$\nabla L(f(e,h), r(e,h)) = \alpha(r_m(e,h) - f_m(e,h)) + \beta(r_c(e,h) - f_c(e,h)) + \gamma(r_t(e,h) - f_t(e,h))$$

where $r_m(e,h), r_c(e,h), r_t(e,h)$ are the components of the three vector solutions of Equation 6, each having $\mathbf{s_h}$ replaced by $\mathbf{f}_m$, $\mathbf{f}_c$, $\mathbf{f}_t$ respectively.

Since both $\mathbf{B}$ and $\hat{\mathbf{f}_\omega}$ are normalized such that their column sums are equal to 1, Equation 6 is convergent (Haveliwala, 2002). Also, as discussed above, $\mathbf{r_h}$ is a linear combination of factors that are independent of ω, hence L is a convex function, and the batch gradient descent is also guaranteed to converge. In practice, we can utilize several indexing techniques to significantly speed up the similarity and influence scores calculation.

6 Experiments and Results

6.1 Setup

Dataset There is no standard benchmark for our problem, since available datasets on microblog annotation (such as the Microposts challenge (Basave et al., 2014)) do not have global statistics, so we cannot identify the trending hashtags. Therefore, we created our own dataset. We used the Twitter API to collect from the public stream a sample of $500,551,041$ tweets from January to April 2014. We removed hashtags that were adopted by less than 500 users, having no letters, or having characters repeated more than 4 times (e.g., '#oooommgg'). We identified trending hashtags by computing the daily time series of hashtag tweet counts, and removing those of which the time series' variance score is less than 900. To identify the hashtag burst time period T, we compute the *outlier fraction* (Lehmann et al., 2012) for each hashtag h and day t: $p_t(h) = \frac{|n_t - n_b|}{\max(n_b, n_{\min})}$, where n_t is the number of tweets containing h, n_b is the median value of n_t over all points in a 2-month time window centered on t, and $n_{\min} = 10$ is the threshold to filter low activity hashtags. The hashtag is skipped if its highest outlier fraction score is less than 15. Finally, we define the *burst time period* of a trending hashtag as the time window of size w, centered at day t_0 with the highest $p_{t_0}(h)$.

For the Wikipedia datasets we process the dump from 3rd May 2014, so as to cover all events in the Twitter dataset. We have developed Hedera (Tran and Nguyen, 2014), a scalable tool for processing the Wikipedia revision history dataset based on Map-Reduce paradigm. In addition, we download the Wikipedia page view dataset that stores how many times a Wikipedia article was requested on an hourly level. We process the dataset for the four months of our study and use Hedera to accumulate all view counts of redirects to the actual articles.

Sampling From the trending hashtags, we sample 30 distinct hashtags for evaluation. Since our study focuses on trending hashtags that are mapable to entities in Wikipedia, the sampling must cover a sufficient number of "popular" topics that are seen in Wikipedia, and at the same time cover rare topics in the long tail. To do this, we apply several heuristics in the sampling. First, we only consider hashtags where the lexicon-based linking (Section 3.1) results in at least 20 different entities. Second, we randomly choose hashtags to cover different types of topics (long-running events, breaking events, endogenous hashtags). Instead of inspecting all hashtags in our corpus, we follow Lehmann et al. (2012) and calculate the fraction of tweets published before, during and after the peak. The hashtags are then clustered in this 3-dimensional vector space. Each cluster suggests a group of hashtags with a distinct semantics (Lehmann et al., 2012). We then pick up hashtags randomly from each cluster, resulting in 200 hashtags in total. From this rough sample, three inspectors carefully checked the tweets and chose 30 hashtags where the meanings and hashtag types were certain to the knowledge of the inspectors.

Parameter Settings We initialize the similarity weights to $\frac{1}{3}$, the damping factor to $\tau = 0.85$, and the weight for the language model to $\lambda = 0.9$. The learning rate μ is empirically fixed to $\mu = 0.003$.

	Tagme	Wikiminer	Meij	Kauri	M	C	T	IPL
P@5	0.284	0.253	0.500	0.305	0.453	0.263	0.474	**0.642**
P@15	0.253	0.147	**0.670**	0.319	0.312	0.245	0.378	0.495
MAP	0.148	0.096	0.375	0.162	0.211	0.140	0.291	**0.439**

Table 2: Experimental results on the sampled trending hashtags.

Baseline We compare IPL with other entity annotation methods. Our first group of baselines includes entity linking systems in domains of general text, Wikiminer (Milne and Witten, 2008), and short text, Tagme (Ferragina and Scaiella, 2012). For each method, we use the default parameter settings, apply them for the individual tweets, and take the average of the annotation confidence scores as the prominence ranking function. The second group of baselines includes systems specifically designed for microblogs. For the content-based methods, we compare against Meij et al. (2012), which uses a supervised method to rank entities with respect to tweets. We train the model using the same training data as in the original paper. For the graph-based method, we compare against KAURI (Shen et al., 2013), a method which uses user interest propagation to optimize the entity linking scores. To tune the parameters, we pick up four hashtags from different clusters, randomly sample 50 tweets for each, and manually annotate the tweets. For all baselines, we obtained the implementation from the authors. The exception is Meij method, where we implemented ourselves, but we clarified with the authors via emails on several settings. In addition, we also compare three variants of our method, using only local functions for entity ranking (referred to as M, C, and T for *mention*, *context*, and *time*, respectively).

Evaluation In total, there are $6,965$ entity-hashtag pairs returned by all systems. We employ five volunteers to evaluate the pairs in the range from 0 to 2, where 0 means the entity is noisy or obviously unrelated, 2 means the entity is strongly tied to the topic of the hashtag, and 1 means that although the entity and hashtag might share some common contexts, they are not involved in a direct relationship (for instance, the entity is a too general concept such as *Ice hockey*, as in the case illustrated in Figure 2). The annotators were advised to use search engines, the Twitter search box or Wikipedia archives whenever applicable to get more background on the stories. Inter-annotator agreement under Fleiss score is 0.625.

6.2 Results and Discussion

Table 2 shows the performance comparison of the methods using the standard metrics for a ranking system (precision at 5 and 15 and MAP at 15). In general, all baselines perform worse than reported in the literature, confirming the higher complexity of the hashtag annotation task as compared to traditional tasks. Interestingly enough, using our local similarities already produces better results than Tagme and Wikiminer. The local model f_m significantly outperforms both the baselines in all metrics. Combining the similarities improves the performance even more significantly.[2] Compared to the baselines, IPL improves the performance by 17-28%. The time similarity achieves the highest result compared to other content-based mention and context similarities. This supports our assumption that lexical matching is not always the best strategy to link entities in tweets. The time series-based metric incurs lower cost than others, yet it produces a considerably good performance. Context similarity based on Wikipedia edits does not yield much improvement. This can be explained in two ways. First, information in Wikipedia is largely biased to popular entities, it fails to capture many entities in the long tail. Second, language models are dependent on direct word representations, which are different between Twitter and Wikipedia. This is another advantage of non-content measures such as f_t.

For the second group of baselines (Kauri and Meij), we also observe the reduction in precision, especially for Kauri. This is because the method relies on the coherence of user interests within a group of tweets to be able to perform well, which does not hold in the context of hashtags. One astonishing result is that Meij performs better than IPL in terms of P@15. However, it performs worse in terms of MAP and P@5, suggesting that most of the correctly identified entities are ranked lower in the list. This is reasonable, as Meij attempts to optimize (with human supervision effort) the se-

[2] All significance tests are done against both Tagme and Wikiminer, with a p-value < 0.01.

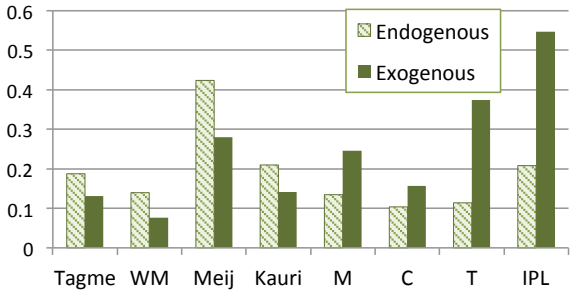

Figure 3: Performance of the methods for different types of trending hashtags.

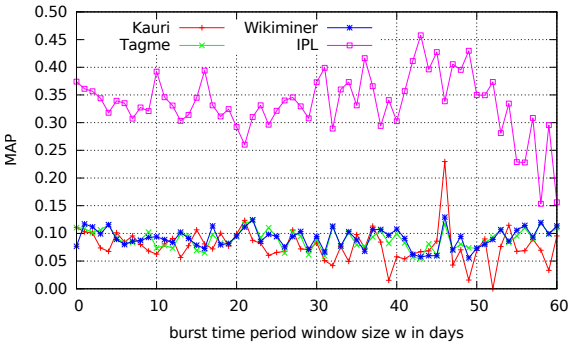

Figure 4: IPL compared to other baselines on different sizes of the burst time window T.

mantic agreement between entities and information found in the tweets, instead of ranking their prominence as in our work. To investigate this case further, we re-examined the hashtags and divided them by their semantics, as to whether the hashtags are spurious trends of memes inside social media (*endogenous*, e.g., "#stopasian2014"), or whether they reflect external events (*exogenous*, e.g., "#mh370"). The performance of the methods in terms of MAP scores is shown in Figure 3. It can be clearly seen that entity linking methods perform well in the endogenous group, but then deteriorate in the exogenous group. The explanation is that for endogenous hashtags, the topical consonance between tweets is very low, thus most of the assessments become just verifying general concepts (such as locations) In this case, topical annotation is trumped by conceptual annotation. However, whenever the hashtag evolves into a meaningful topic, a deeper annotation method will produce a significant improvement, as seen in Figure 3.

Finally, we study the impact of the burst time period on the annotation quality. For this, we expand the window size w (cf. Section 6.1) and examine how different methods perform. The result is depicted in Figure 4. It is obvious that within the window of 2 months (where the hashtag time series is constructed and a trending time is identified), our method is stable and always outperforms the baselines by a large margin. Even when the trending hashtag has been saturated, hence introduced more noise, our method is still able to identify the prominent entities with high quality.

7 Conclusion and Future Work

In this work, we address the new problem of topically annotating a trending hashtag using Wikipedia entities, which has many important applications in social media analysis. We study Wikipedia temporal resources and find that using efficient time series-based measures can complement content-based methods well in the domain of Twitter. We propose use similarity measures to model both the local mention-based, as well as the global context- and time-based prominence of entities. We propose a novel strategy of topical annotation of texts using and influence maximization approach and design an efficient learning algorithm to automatically unify the similarities without the need of human involvement. The experiments show that our method outperforms significantly the established baselines.

As future work, we aim to improve the efficiency of our entire workflow, such that the annotation can become an end-to-end service. We also aim to improve the context similarity between entities and the topic, for example by using a deeper distributional semantics-based method, instead of language models as in our current work. In addition, we plan to extend the annotation framework to other types of trending topics, by including the type of out-of-knowledge entities. Finally, we are investigating how to apply more advanced influence maximization methods. We believe that influence maximization has a great potential in NLP research, beyond the scope of annotation for microblogging topics.

Acknowledgments

This work was funded by the European Commission in the FP7 project ForgetIT (600826) and the ERC advanced grant ALEXANDRIA (339233), and by the German Federal Ministry of Education and Research for the project "Gute Arbeit" (01UG1249C). We thank the reviewers for the fruitful discussion and Claudia Niederee from L3S for suggestions on improving Section 5.

System Combination for Multi-document Summarization

Abstract

We present a novel framework of system combination for multi-document summarization. For each input set (input), we generate candidate summaries by combining whole sentences from the summaries generated by different systems. We show that the oracle among these candidates is much better than the summaries that we have combined. We then present a supervised model to select among the candidates. The model relies on a rich set of features that capture content importance from different perspectives. Our model performs better than the systems that we combined based on manual and automatic evaluations. We also achieve very competitive performance on six DUC/TAC datasets, comparable to the state-of-the-art on most datasets.

1 Introduction

Recent work shows that state-of-the-art summarization systems generate very different summaries, despite the fact that they have similar performance (Hong et al., 2014). This suggests that combining summaries from different systems might be helpful in improving content quality.

A handful of papers have studied system combination for summarization. Based on the ranks of the input sentences assigned by different systems (i.e., *basic systems*), methods have been proposed to re-rank these sentences (Wang and Li, 2012; Pei et al., 2012). However, these methods require the basic systems to assign importance scores to all input sentences. Thapar et al. (2006) combine the summaries from different systems, based on a graph-based measure that computes summary-input or summary-summary similarity. However, their method does not show an advantage over the basic systems. In summary, few prior papers have successfully generating better summaries by combining the summaries from different systems (i.e., *basic summaries*).

This paper focuses on *practical system combination*, where we combine the summaries generated by four portable unsupervised systems. We choose these systems, because: First, these systems are either off-the-shelf or easy-to-implement. Second, even though many systems have been proposed for multi-document summarization, the output of them are often available only on one dataset or even unavailable. Third, compared to more sophisticated supervised methods (Kulesza and Taskar, 2012; Cao et al., 2015a), simple unsupervised methods perform unexpectedly well. Many of them achieved the state-of-the-art performance when they were proposed (Erkan and Radev, 2004; Gillick et al., 2009) and still serve as competitive baselines (Hong et al., 2014).

After the summarizers have been chosen, we present a two-step pipeline that combines the basic summaries. In the first step, we generate combined candidate summaries (Section 4). We investigate two methods to do this: one uses entire basic summaries directly, the other combines these summaries on the sentence level. We show that the latter method has a much higher oracle performance. The second step includes a new supervised model that selects among the candidate summaries (Section 5).

Our contributions are:

- We show that by combining summaries on the sentence level, the best possible (oracle) performance is very high.
- In the second step of our pipeline, we propose a supervised model that includes a rich set of new features. These features capture content importance from different

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 107–117,
Lisbon, Portugal, 17-21 September 2015.

perspectives, based on different sources. We verify the effectiveness of these features.

- Our method outperforms the basic systems and several competitive baselines. Our model achieves competitive performance on six DUC/TAC datasets, which is on par with the state-of-the-art on most of these datasets.

- Our method can be used to combine summaries generated by any systems.

2 Related Work

System combination has enjoyed great success in many domains, such as automatic speech recognition (Fiscus, 1997; Mangu et al., 2000), machine translation (Frederking and Nirenburg, 1994; Bangalore et al., 2001) and parsing (Henderson and Brill, 1999; Sagae and Lavie, 2006). However, only a handful of papers have leveraged this idea for summarization. Mohamed and Rajasekaran (2005) present a method that relies on a document graph (DG), which includes concepts connected by relations. This method selects among the outputs of the basic systems, based on their overlaps with the input in terms of DG. Thapar et al. (2006) propose to iteratively include sentences, based on the overlap of DG between the current sentence and (1) the original input, or (2) the basic summaries. However, in both papers, the machine summaries are not compared against human references. Rather, their evaluations compare the summaries to the input based on the overlap of DG. Moreover, even when evaluated in this way, the combined system does not show an advantage over the best basic system.

System combination in summarization has also been regarded as rank aggregation, where the combined system re-ranks the input sentences based on the ranks of those sentences assigned by the basic systems. Wang and Li (2012) propose an unsupervised method to minimize the distance of the final ranking compared to the initial rankings. Pei et al. (2012) propose a supervised method which handles an issue in Wang and Li (2012) that all basic systems are regarded as equally important. Even though both methods show advantages over the basic systems, they have two limitations. Most importantly, only summarizers that assign importance scores to each sentence can be used as the input summarizers. Second, only the sentence scores (ranks) from the basic systems and system identity information is utilized during the re-ranking process. The signal from the original input is ignored. Our method handles these limitations.

Our method derives an overall informativeness score for each candidate summary, then selects the one with the highest score. This is related to the growing body of research in global optimization, which selects the most informative subset of sentences towards a global objective (McDonald, 2007; Gillick et al., 2009; Aker et al., 2010). Some work uses integer linear programming to find the exact solution (Gillick et al., 2009; Li et al., 2015), other work employs supervised methods to optimize the ROUGE scores of a summary (Lin and Bilmes, 2011; Kulesza and Taskar, 2012). Here we use the ROUGE scores of the candidate summaries as labels while training our model.

In our work, we propose novel features that encode the content quality of the entire summary. Though prior work has extensively investigated features that are indicative of important words (Yih et al., 2007; Hong and Nenkova, 2014) or sentences (Litvak et al., 2010; Ouyang et al., 2011), little work has focused on designing global features defined over the summary. Indeed, even for the papers that employ supervised methods to conduct global inference, the features are defined on the sentence level (Aker et al., 2010; Kulesza and Taskar, 2012). The most closely related papers are the ones that investigated automatic evaluation of summarization without human references (Louis and Nenkova, 2009; Saggion et al., 2010), where the effectiveness of several summary-input similarity metrics are examined. In our work, we propose a wide range of features. These features are derived not only based on the input, but also based on the basic summaries and the summary-input pairs from the New York Times (NYT) corpus (Sandhaus, 2008).

3 Data and Evaluation

We conduct a large scale experiment on six datasets from the Document Understanding Conference (DUC) and the Text Analysis Conference (TAC). The tasks include generic (DUC 2001–2004) and query-focused (TAC 2008, 2009) multi-document summarization. We evaluate on the task of generating 100-word summaries.

We use ROUGE (Lin, 2004) for automatic

evaluation, which compares the machine summaries to the human references. We report ROUGE-1 (unigram recall) and ROUGE-2 (bigram recall), with stemming and stopwords included.[1] Among automatic evaluation metrics, ROUGE-1 (R-1) can predict that one system performs significantly better than the other with the highest recall (Rankel et al., 2013). ROUGE-2 (R-2) provides the best agreement with manual evaluations (Owczarzak et al., 2012). R-1 and R-2 are the most widely used metrics in summarization literature.

4 Generating Candidate Summaries

We first introduce the four basic unsupervised systems, then describe our approach of generating candidate summaries. The four systems all perform extractive summarization, which directly selects *sentences* from the input. Among these systems, ICSISumm achieves the highest ROUGE-2 in the TAC 2008, 2009 workshops.[2] The other systems are often used as competitive baselines; we implement these ourselves. Table 1 shows their performances. The word overlap between summaries generated by these systems is low, which indicates high diversity.

The basic systems are used for both generic and query-focused summarization. For the latter task, we filter out the sentences that have no overlap with the query in terms of content words for the systems that we implemented.

4.1 Four Basic Unsupervised Systems

ICSISumm: This system (Gillick et al., 2009) optimizes the coverage of bigrams weighted by their document frequency within the input using Integer Linear Programming (ILP). Even though this problem is NP-hard, a standard ILP solver can find the exact solution fairly quickly in this case.

Greedy-KL: This system aims to minimize the Kullback-Leibler (KL) divergence between the word probability distribution of the summary and that of the input. Because finding the summary with the smallest KL divergence is intractable, we employ a greedy method that iteratively selects an additional sentence that minimizes the KL divergence (Haghighi and Vanderwende, 2009).

ProbSum: This system (Nenkova et al., 2006) scores a sentence by taking the average of word probabilities over the words in the sentence, with stopwords assigned zero weights. Compared to Nenkova et al. (2006), we slightly change the way of handling redundancy: we iteratively include a sentence into the summary if its cosine similarity with any sentence in the summary does not exceed 0.5.[3]

LLRSum: This system (Conroy et al., 2006) employs a log-likelihood ratio (LLR) test to select *topic words* of an input (Lin and Hovy, 2000). The LLR test compares the distribution of words in the input to a large background corpus. Similar to Conroy et al. (2006), we consider words as topic words if their χ-square statistic derived by LLR exceeds 10. The sentence importance score is equal to the number of topic words divided by the number of words in the sentence. Redundancy is handled in the same way as in ProbSum.

4.2 Generating Candidate Summaries

4.2.1 Selecting a Full Summary

There does not exist a system that always outperforms the others for all problems. Based on this fact, we directly use the summary outputs (i.e., basic summaries) as the candidate summaries.

4.2.2 Sentence Level Combination

Different systems provide different pieces of the correct answer. Based on this fact, the combined summary should include sentences that appear in the summaries produced by different systems. Here we exhaustively enumerate sentences so that to form the candidate summaries. A similar approach has been used to generate candidate summaries for single-document summarization (Ceylan et al., 2010).

Let $D = s_1, \ldots, s_n$ denote the sequence of unique sentences that appear in the basic summaries. We enumerate all subsequences $A_i = s_{i_1}, \ldots, s_{i_k}$ of D in lexicographical order. A_i can be used as a candidate summary iff $\sum_{j=1}^{k} l(s_{i_j}) \geq L$ and $\sum_{j=1}^{k-1} l(s_{i_j}) < L$, where $l(s)$ is the number of words in s and L is the predefined summary length. Table 2 shows the average number of (unique) sentences and summaries that are generated per input.

DUC 02	21.1	17.6	12048	710832
DUC 03	19.3	15.4	3448	103440
DUC 04	19.5	15.6	3270	163500
TAC 08	18.5	14.8	2436	107184
TAC 09	18.0	13.7	1328	63744

Table 2: Average number of sentences (# sents), unique sentences (# unique), candidate summaries per input (# summaries) and the total number of candidate summaries for each dataset (# total).

Note that we consider the order of sentences in A_i (generated from D) as a relatively unimportant factor. Though two summaries with the same set of sentences can have different ROUGE scores due to the truncation of the last sentence, because the majority of content covered is still the same, the difference in ROUGE score is relatively small. In order to generate other possible summaries, one needs to swap the last sentence. However, the total number of summaries per dataset is already huge (see Table 2). Therefore, we do not generate other candidate summaries, because it would cost much more additional space, while the difference in content is relatively small.

4.2.3 Comparison of the Oracle Systems

We examine the upper bounds of the two methods described in Section 4.2.1 and Section 4.2.2. For the first method, we design two oracle systems that pick the basic summary with the highest ROUGE-1 (R-1) and ROUGE-2 (R-2) (denoted as SumOracle R-1 and SumOracle R-2). For the second method, we design two oracle systems that pick the best summary in terms of R-1 and R-2 among the summary candidates (denoted as SentOracle R-1 and SentOracle R-2). As shown in Table 1, the advantage of the first two oracles over ICSISumm is limited: on average $0.021/0.006$ and $0.013/0.011$ (R-1/R-2). However, the advantage of the latter oracles over ICSISumm is much larger: on average $0.060/0.022$ and $0.039/0.034$ (R-1/R-2). Clearly, system combination is more promising if we combine the basic summaries at the sentence level. Therefore, we adopt the latter method to generate candidate summaries.

5 Features

We introduce the features used in our model that selects among the candidate summaries. Traditionally in summarization, features are derived based on the input (denoted as I). In our work, we propose a class of novel features that compares the candidate summary to the set of the basic summaries (denoted as H), where H can be regarded as a *hyper-summary* of I. This excels in the way that it takes advantage of the consensus between systems. Moreover, we propose system identity features, which capture the fact that content from a better system should have a higher chance to be selected.

Our model includes classical indicators of content importance (e.g., frequency, locations) and novel features that have been recently proposed for other tasks. For example, we design features that estimate the intrinsic importance of words from a large corpus (Hong and Nenkova, 2014). We also include features that compute the information density of the first sentence that each word appears in (Yang and Nenkova, 2014). These features are specifically tailored for our task (see Section 5.2).

We classify our features into summary level, word level and system identity features. Note that we do not consider stopwords and do not perform stemming. There are 360 features in our model.

5.1 Summary Level Features

Summary level features directly encode the informativeness of the entire summary. Some of them are initially proposed in Louis and Nenkova (2013) that evaluates the summary content without human models. Different from them, the features in our work use not only I, but also H as the "*input*" (except for the redundancy features). "*Input*" refers to I or H in the rest of Section 5.

Distributional Similarity: These features compute the distributional similarity (divergence) between the n-gram ($n = 1, 2$) probability distribution of the summary and that of the *input* (I or H). Good summaries tend to have high similarity and low divergence. We use three measures: Kullback-Leibler (KL) divergence, Jenson-Shannon (JS) divergence and cosine similarity.

Let P and Q denote the n-gram distribution of the summary and that of the *input* respectively. Let $p_\lambda(w)$ be the probability of n-gram w in distribution λ. The KL divergence $KL(P \parallel Q)$ and the JS divergence $JS(P \parallel Q)$ are defined as:

$$KL(P \parallel Q) = \sum_w p_P(w) \cdot \log \frac{p_P(w)}{p_Q(w)} \quad (1)$$

$$JS(P \parallel Q) = \frac{1}{2} KL(P \parallel A) + \frac{1}{2} KL(Q \parallel A) \quad (2)$$

where A is the average of P and Q. Noticing that KL divergence is not symmetric, both $KL(P \parallel Q)$ and $KL(Q \parallel P)$ are computed. In particular, smoothing is performed while computing $KL(Q \parallel P)$, where we use the same setting as in Louis and Nenkova (2013).

Topic words: Good summaries tend to include more topic words (TWs). We derive TWs using the method described in the LLRSum system in Section 4.1. For each summary S, we compute: (1) the ratio of the words that are TWs to all words in S; (2) the recall of TWs in S.

Sentence location: Sentences that appear at the beginning of an article are likely to be more critical. Greedy-based summarizers (ProbSum, LLRSum, GreedyKL) also select important sentences first. To capture these intuitions, we set features over the sentences in a summary (S) based on their locations. There are features that indicate whether a sentence in S has appeared as the first sentence in the *input*. We also set features to indicate the normalized position of a sentence in the documents of an *input*: by assigning 1 to the first sentence, 0 to the last sentence. When one sentence appears multiple times, the earliest position is used. Features are then set on the summary level, which equal to the mean of their corresponding features on the sentence level over all sentences in the summary S.

Redundancy: Redundancy correlates negatively with content quality (Pitler et al., 2010). To indicate redundancy, we compute the maximum and average cosine similarity of all pairs of sentences in the summaries. Summaries with higher redundancy are expected to score higher.

5.2 Word Level Features

Better summaries should include words or phrases that are of higher importance. Hence, we design features to encode the overall importance of unigrams and bigrams in a summary. We first generate features for the n-grams ($n = 1, 2$) in a summary S, then generate the feature vector $\mathbf{v_S}$ for S. The procedure is as follows:

Let t denote the unigram or bigram in a summary. For each t that includes content words, we form $\mathbf{v_t}$, where each component of $\mathbf{v_t}$ is an importance indicator of t. If t does not include any content words, we set $\mathbf{v_t} = \mathbf{0}$. Let S' denote the unique n-grams in S and let L denote the summary length. We compute two feature vectors: $\mathbf{v_{S_1}} = (\sum_{t \in S} \mathbf{v_t})/L$ and $\mathbf{v_{S_2}} = (\sum_{t \in S'} \mathbf{v_t})/L$, which are the coverage of n-grams by word token and word type, normalized by summary length. Finally, $\mathbf{v_S}$ is formed by concatenating $\mathbf{v_{S_1}}$ and $\mathbf{v_{S_2}}$ for unigrams and bigrams.

Below we describe the features in $\mathbf{v_t}$. Similar to Section 5.1, the features are computed based on both I and H. We also derive features based on summary-article pairs from the NYT corpus.

Frequency related features: For each n-gram t, we compute its probability, TF*IDF[4], document frequency (DF) and χ-square statistic from LLR test. Another feature is set to be equal to DF normalized by the number of input documents. A binary feature is set to determine whether DF is at least three, inspired by the observation that document specific words should not be regarded as informative (Mason and Charniak, 2011).

It has been shown that unimportant words of an input should not be considered while scoring the summary (Gupta et al., 2007; Mason and Charniak, 2011). The features below are designed

[4]IDF is computed using the news articles between year 2004 and 2007 of the New York Times corpus.

capture this. Let the binary function $b(t)$ denote whether or not t includes topic words (which approximate whether or not t is important), features are set to be equal to the product of the DF related features and $b(t)$.

Word locations: The words that appear close to the beginning of I or H are likely to be important. Here for each n-gram token, we compute its normalized locations in the documents. Then for each n-gram type t, we compute its *first*, *average*, *last* and *average first* location across its occurrences in all documents of an *input*. Features are also set to determine whether t has appeared in the first sentence and the number of times t appears in the first sentences of an *input*.

Information density of the first sentence: The first sentence of an article can be either informative or entertaining. Clearly, the words that appear in an informative first sentence should be assigned higher importance scores. To capture this, we compute the importance score (called information density in Yang and Nenkova (2014)) of the first sentence, that is defined as the number of TWs divided by the number of words in the sentence. For each t, we compute the maximal and average of importance scores over all first sentences that t appears in.

Global word importance: Some words are globally important (e.g., "war", "death") or unimportant (e.g., "Mr.", "a.m.") to humans, independent of a particular input. Hong and Nenkova (2014) proposed a class of methods to estimate the global importance of words, based on the change of word probabilities between the summary-article pairs from the NYT corpus. The importance are used as features for identifying words that are used in human summaries. Here we replicate the features used in that work, except that we perform more careful pre-processings. This class of features are set only for unigrams.

5.3 System Identity Features

For each basic system A_i, we compute the sentence and n-gram overlap between S and the summary from A_i (S_{A_i}). We hypothesize that the quality (i.e., ROUGE score) of a summary is positively (negatively) correlated to the overlap between this summary and a good (bad) basic summary of the same input. We design six sentence and two word overlap features for each system, which leads to a total of 32 features.

Sentence overlap: Let D_0, D_{A_i} denote the set of sentences in S and S_{A_i}, respectively. For each system A_i, we set a feature $|D_0 \bigcap D_{A_i}|/|D_0|$. We further consider sentence lengths. Let $l(D)$ denote the total length of sentences in set D, we set a feature $l(D_0 \bigcap D_{A_i})/l(D_0)$ for each system A_i. Lastly, we compute the binary version of $|D_0 \bigcap D_{A_i}|/|D_0|$.

Furthermore, we exclude the sentences that appear in multiple basic summaries from D_0, then compute the three features above for the new D_0. System identity features might be more helpful in selecting among the sentences that are generated by only one of the systems.

N-gram overlap: We compute the fraction of n-gram (n = $1, 2$) tokens in S that appears in S_{A_i}. The n-grams consisting of solely stopwords are removed before computation.

6 Baseline Approaches

We present three summary combination methods that are used as baselines:

Voting: We select sentences according to the total number of times that they appear in all basic summaries, from large to small. When there are ties, we randomly pick an unselected sentence. The procedure is repeated 100 times and the mean ROUGE score is reported.

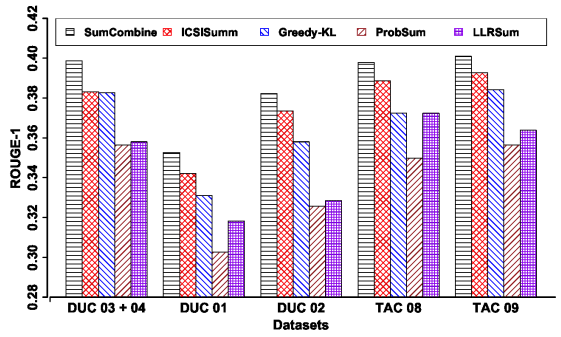
Summarization from Summaries: We directly run ICSISumm and Greedy-KL over the summaries from the basic systems.

Jensen-Shannon (JS) Divergence: We select among the pool of candidate summaries. The summary with the smallest JS divergence between the summary and (1) the input (JS-I), or (2) the hyper-summaries (JS-H) is selected. Summary-input JS divergence is the best metric to identify a better summarizer without human references (Louis and Nenkova, 2009).

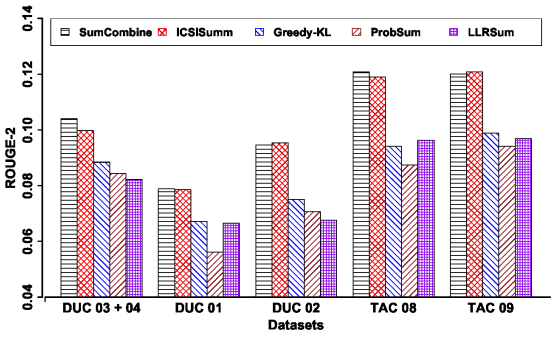
7 Experiments and Results

7.1 Experiment Settings

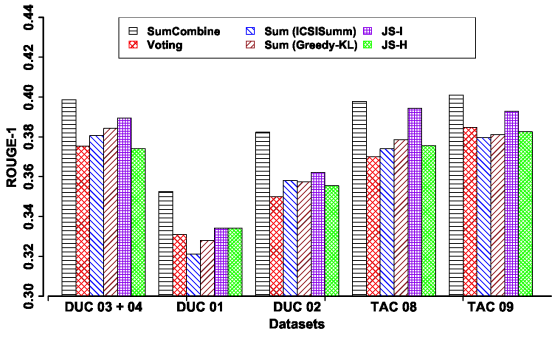
We use the DUC 03, 04 datasets as training and development sets. The candidate summaries of these two sets are used as training instances. There are 80 input sets; each input includes an average of 3336 candidate summaries. During development, we perform four-fold cross-validation. The DUC 01, 02 and TAC 08, 09 datasets are used as the held-out test sets. We use two-sided Wilcoxon test to compare the performance between two systems.



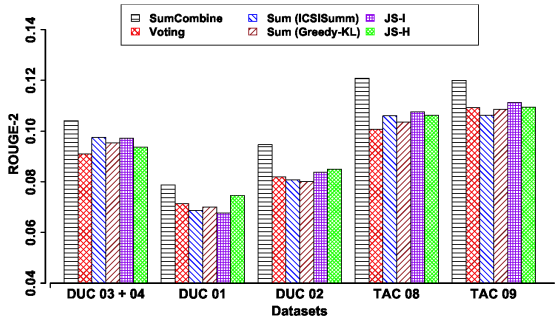
(a) ROUGE-1 of the proposed and the basic systems



(b) ROUGE-2 of the proposed and the basic systems



(c) ROUGE-1 of the proposed and baseline approaches



(d) ROUGE-2 of the proposed and baseline approaches

Figure 1: ROUGE scores of different systems on the DUC 2001–2004 and TAC 2008, 2009 datasets

We choose ROUGE-1 (R-1) as training labels, as it outperforms using ROUGE-2 (R-2) as labels (see Table 3). We suspect that the advantage of R-1 is because it has higher sensitivity in capturing the differences in content between summaries.[5]

In order to find a better learning method, we have experimented with support vector regression (SVR) (Drucker et al., 1997)[6] and SVM-Rank (Joachims, 1999).[7] SVR has been used for estimating sentence (Ouyang et al., 2011) or document (Aker et al., 2010) importance in summarization. SVM-Rank has been used for ranking summaries according to their linguistic qualities (Pitler et al., 2010). In SVM-Rank, only the relative ranks between training instances of an input are considered while learning the model. Our experiment shows that SVR outperforms SVM-Rank (see Table 3). This means that it is useful to compare the summaries across different input sets and leverage the actual ROUGE scores.

Settings	R-1	R-2
SVR + R-1	0.3986	0.1040
SVR + R-2	0.3890	0.1023
SVMRank + R-1	0.3932	0.0996
SVMRank + R-2	0.3854	0.0982

Table 3: Performance on the development set with different models and training labels.

7.2 Comparing with the Basic Systems and the Baseline Methods

We evaluate our model on the development set and the test sets. As shown in Figure 1 (a) and Table 4, our model performs consistently better than all basic systems on R-1. It performs similar to ICSISumm and better than the other basic systems on R-2 (see Figure 1 (b) and Table 4).

Apart from automatic evaluation, we also manually evaluate the summaries using the Pyramid method (Nenkova et al., 2007). This method solicits annotators to score a summary based on its coverage of summary content units, which are identified from human references. Here we evaluate the Pyramid scores of four systems: our system, two best basic systems and the oracle

[5]Recent methods that performs global optimization for summarization mostly use R-1 while training (Lin and Bilmes, 2011; Kulesza and Taskar, 2012; Sipos et al., 2012).

[6]We use the SVR model in SVMLight (Joachims, 1999) with linear kernel and default parameter settings when trained on R-1. When trained on R-2, we tune ϵ in loss function on the developmenet set, because the default setting assigns the same value to all data points.

[7]We use the SVM-Rank toolkit (Joachims, 2006) with default parameter settings.

Dataset	System	R-1	R-2
DUC 03	ICSISumm	0.3813	0.1028
	SumCombine	**0.3959**	0.1018
DUC 04	ICSISumm	0.3841	0.0978
	SumCombine	**0.3995**	**0.1048**
	DPP	0.3979	0.0962
	RegSum	0.3857	0.0975
DUC 01	ICSISumm	0.3421	0.0785
	SumCombine	0.3526†	0.0788
	R2N2_ILP	0.3691	0.0787
	PriorSum	0.3598	0.0789
DUC 02	ICSISumm	0.3733	0.0954
	SumCombine	**0.3823**	0.0946
	R2N2_ILP	0.3796	0.0888
	PriorSum	0.3663	0.0897
	ClusterCMRW	0.3855	0.0865
TAC 08	ICSISumm	0.3880	0.1186
	SumCombine	0.3978	0.1208
	Li et al. (2013)	n/a	0.1235
	A & M (2013)	n/a	0.1230
	Li et al. (2015)	n/a	0.1184
TAC 09	ICSISumm	0.3931	0.1211
	SumCombine	0.4009†	0.1200
	Li et al. (2015)	n/a	0.1277

Table 4: Performance comparison on six DUC and TAC datasets. **Bold** indicates statistical significant compared to ICSISumm ($p < 0.05$). † indicates the difference is close to significant compared to ICSISumm ($0.05 \leq p < 0.1$).

on the TAC 08 dataset. Our model (Combine) outperforms ICSISumm and Greedy-KL by 0.019 and 0.090, respectively (see Table 5).

	Oracle	Combine	ICSISumm	KL
Pyr. score	0.626	0.549	0.530	0.459

Table 5: The Pyramid score on the TAC 08 data.

Figure 1 (c), (d) compare our model with the baseline approaches proposed in Section 6. The baselines that only consider the consensus between different systems perform poorly (voting, summarization on summaries, JS-H). JS-I has the best ROUGE-1 among baselines, while it is still much inferior to our model. Therefore, effective system combination appears to be difficult using methods based on a single indicator.

7.3 Comparing with the State-of-the-art

Table 4 compares our model (SumCombine) with the state-of-the-art systems. On the DUC 03 and 04 data, ICSISumm is among one of the best systems. SumCombine performs significantly better compared to it on R-1. We also achieve a better performance compared to the other top performing extractive systems (DPP (Kulesza and Taskar, 2012), RegSum (Hong and Nenkova, 2014)) on the DUC 04 data.

On the DUC 01 and 02 data, the top performing systems we find are R2N2_ILP (Cao et al., 2015a) and PriorSum (Cao et al., 2015b); both of them utilize neural networks. Comparing to these two, SumCombine achieves a lower performance on the DUC 01 data and a higher performance on the DUC 02 data. It also has a slightly lower R-1 and a higher R-2 compared to ClusterCMRW (Wan and Yang, 2008), a graph-based system that achieves the highest R-1 on the DUC 02 data. On the TAC 08 data, the top performing systems (Li et al., 2013; Almeida and Martins, 2013) achieve the state-of-the-art performance by sentence compression. Our model performs extractive summarization, but still has similar R-2 compared to theirs.[8] On the TAC 09 data, the best system uses a supervised method that weighs bigrams in the ILP framework by leveraging external resources (Li et al., 2015). This system is better than ours on the TAC 09 data and is inferior to ours on the TAC 08 data.

Overall, our combination model achieves very competitive performance, comparable to the state-of-the-art on multiple benchmarks.

At last, we compare SumCombine to SSA (Pei et al., 2012) and WCS (Wang and Li, 2012), the models that perform system combination by rank aggregation. The systems are evaluated on the DUC 04 data. In order to compare with these two papers, we truncate our summaries to 665 bytes and report F_1-score. Pei et al. (2012) report the performance on 10 randomly selected input sets. In order to have the same size of training data with them, we conduct five-fold cross-validation.

System	R-1	R-2	R-SU4
SumCombine	0.3943	0.1015	0.1411
SSA (Pei et al., 2012)	0.3977	0.0953	0.1394
WCS (Wang and Li, 2012)	0.3987	0.0961	0.1353

Table 6: Comparison with other combination methods on the DUC 04 dataset.

As shown in Table 6, SumCombine performs better than SSA and WCS on R-2 and R-SU4, but not on R-1. It is worth noting that these three

[8]These papers report ROUGE-SU4 (R-SU4) (measures skip bigram with maximum gap of 4) instead of R-1. Our model has very similar R-SU4 (-0.0002/$+0.0007$) compared to them.

Table 7: Performance after ablating features (row 2–7) or using a single class of features (row 8–12). **Bold** and † represent statistical significant ($p < 0.05$) and close to significant ($0.05 \leq p < 0.1$) compared to using all features (two-sided Wilcoxon test).

systems cannot be directly compared, because different basic systems are used. In fact, compared to SumCombine, SSA and WCS achieve larger improvements over the basic systems that are used. This might be because ranker aggregation is a better strategy, or because combining weaker systems is easier to result in large improvements.

7.4 Effects of Features

We conduct two experiments to examine the effectiveness of features (see Table 7). First, we remove one class of feature at a time from the full feature set. Second, we show the performance of a single feature class. Apart from reporting the performance on the development and the test sets, we also show the macro average performance across the five sets.[9] This helps to understand the contribution of different features in general.

Summary level, word level and system identity features are all useful, with ablating them leads to an average of 0.0031 to 0.0041 decrease on R-1. Ablating summary and word level features can lead to a significant decrease in performance on some sets. If we use a single set of features, then the summary and word level features turn out to be more useful than the system identity features.

The word and summary level features compute the content importance based on three sources: the input, the basic summaries (hyper-sum) and the New York Times corpus (global). We ablate the features derived from these three sources respectively. The input-based features are the most important; removing them leads to a very large decrease in performance, especially on R-1. The features derived from the basic summaries are also effective; even though removing them only lead to a small decrease in performance, we can observe the decrease on all five sets. Ablating global indicators leads to an average decrease of about 0.002 on R-1 and R-2.

Interestingly, for the same feature class, the effectiveness vary to a great extent across different datasets. For example, ablating word level features decreases the R-2 significantly on the DUC 01 data, but increases the R-2 on the TAC 09 data. However, by looking at the average performance, it becomes clear that it is necessary to use all features. The features computed based on the input are identified as the most important.

8 Conclusion

In this paper, we present a pipeline that combines the summaries from four portable unsupervised summarizers. We show that system combination is very promising in improving content quality. We propose a supervised model to select among the candidate summaries. Experiments show that our model performs better than the systems that are combined, which is comparable to the state-of-the-art on multiple benchmarks.

Abstract

The task of cross-language document summarization is to create a summary in a target language from documents in a different source language. Previous methods only involve direct extraction of automatically translated sentences from the original documents. Inspired by phrase-based machine translation, we propose a phrase-based model to simultaneously perform sentence scoring, extraction and compression. We design a greedy algorithm to approximately optimize the score function. Experimental results show that our methods outperform the state-of-the-art extractive systems while maintaining similar grammatical quality.

1 Introduction

The task of cross-language summarization is to produce a summary in a target language from documents written in a different source language. This task is particularly useful for readers to quickly get the main idea of documents written in a source language that they are not familiar with. Following Wan (2011), we focus on English-to-Chinese summarization in this work.

The simplest and the most straightforward way to perform cross-language summarization is pipelining general summarization and machine translation. Such systems either translate all the documents before running generic summarization algorithms on the translated documents, or summarize from the original documents and then only translate the produced summary into the target language. Wan (2011) show that such pipelining approaches are inferior to methods that utilize information from both sides. In that work, the author proposes graph-based models and achieves fair amount of improvement. However, to the best of our knowledge, no previous work of this task tries to focus on summarization beyond pure sentence extraction.

On the other hand, cross-language summarization can be seen as a special kind of machine translation: translating the original documents into a brief summary in a different language. Inspired by phrase-based machine translation models (Koehn et al., 2003), we propose a phrase-based scoring scheme for cross-language summarization in this work.

Since our framework is based on phrases, we are not limited to produce extractive summaries. We can use the scoring scheme to perform joint sentence selection and compression. Unlike typical sentence compression methods, our proposed algorithm does not require additional syntactic preprocessing such as part-of-speech tagging or syntactic parsing. We only utilize information from translated texts with phrase alignments. The scoring function consists of a submodular term of compressed sentences and a bounded distortion penalty term. We design a greedy procedure to efficiently get approximate solutions.

For experimental evaluation, we use the DUC2001 dataset with manually translated reference Chinese summaries. Results based on the ROUGE metrics show the effectiveness of our proposed methods. We also conduct manual evaluation and the results suggest that the linguistic quality of produced summaries is not decreased by too much, compared with extractive counterparts. In some cases, the grammatical smoothness can even be improved by compression.

The contributions of this paper include:

- Utilizing the phrase alignment information, we design a scoring scheme for the cross-language document summarization task.
- We design an efficient greedy algorithm to generate summaries. The greedy algorithm is

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 118–127,
Lisbon, Portugal, 17-21 September 2015.

partially submodular and has a provable constant approximation factor to the optimal solution up to a small constant.

- We achieve state-of-the-art results using the extractive counterpart of our compressive summarization framework. Performance in terms of ROUGE metrics can be significantly improved when simultaneously performing extraction and compression.

2 Background

Document summarization can be treated as a special kind of translation process: translating from a bunch of related source documents to a short target summary. This analogy also holds for cross-language document summarization, with the only difference that the languages of source documents and the target summary are different.

Our design of sentence scoring function for cross-language document summarization purpose is inspired by phrase-based machine translation models. Here we briefly describe the general idea of phrase-based translation. One may refer to Koehn (2009) for more detailed description.

2.1 Phrase-based Machine Translation

Phrase-based machine translation models are currently giving state-of-the-art translations for many pairs of languages and dominating modern statistical machine translation. Classical word-based IBM models cannot capture local contextual information and local reordering very well. Phrase-based translation models operate on lexical entries with more than one word on the source language and the target language. The allowance of multi-word expressions is believed to be the main reason for the improvements that phrase-based models give. Note that these multi-word expressions, typically addressed as phrases in machine translation literature, are essentially continuous n-grams and do not need to be linguistically integrate and meaningful constituents.

Define y as a phrase-based derivation, or more precisely a finite sequence of phrases $p_1, p_2, \ldots, p_L$. For any derivation y we use $e(y)$ to refer to the target-side translation text defined by y. This translation is derived by concatenating the strings $e(p_1), e(p_2), \ldots, e(p_L)$. The scoring scheme for a phrase-based derivation y from the source sentence to the target sentence $e(y)$ is:

$$\begin{aligned} f(y) &= \sum_{k=1}^{L} g(p_k) + LM(e(y)) \\ &\quad + \sum_{k=1}^{L-1} \eta |start(p_{k+1}) - 1 - end(p_k)| \end{aligned}$$

where $LM(\cdot)$ is the target-side language model score, $g(\cdot)$ is the score function of phrases, $\eta < 0$ is the distortion parameter for penalizing the distance between neighboring phrases in the derivation. Note that the phrases addressed here are typically continuous n-grams and need not to be grammatical linguistic phrasal units. Later we will directly use phrases provided by modern machine translation systems.

Searching for the best translation under this score definition is difficult in general. Thus approximate decoding algorithms such as beam search should be applied. Meanwhile, several constraints should be satisfied during the decoding process. The most important one is to set a constant limit of the distortion term $|start(p_{k+1}) - 1 - end(p_k)| \leq \delta$ to exhibit derivations with distant phrase translations.

3 Phrase-based Cross-Language Summarization

Inspired by the general idea of phrase-based machine translation, we describe our proposed phrase-based model for cross-language summarization in this section.

3.1 Phrase-based Sentence Scoring

In the context of cross-language summarization, here we assume that we can also have phrases in both source and target languages along with phrase alignments between the two sides. For summarization purposes, we may wish to select sentences containing more important phrases. Then it is plausible to measure the scores of these aligned phrases via importance weighing.

Inspired by phrase-based translation models, we can assign phrase-based scores to sentences from the translated documents for summarization purposes. We define our scoring function for each sentence s as:

$$\begin{aligned} F(s) &= \sum_{p \in s} d_0 g(p) + bg(s) \\ &\quad + \eta \, dist(y(s)) \end{aligned}$$

Here in the first term $g(\cdot)$ is the score of phrase p, which can be simply set to document frequency. The phrase score is penalized with a constant damping factor d_0 to decay scores for repeated phrases. The second term $bg(s)$ is the bigram score of sentence s. It is used here to simulate the effect of language models in phrase-based translation models. Denoting $y(s)$ as the phrase-based derivation (as mentioned earlier in the previous section) of sentence s, the last distortion term $dist(y(s)) = \sum_{k=1}^{L} |start(p_{k+1}) - 1 - end(p_k)|$ is exactly the same as the distortion penalty term in phrase-based translation models. This term can be used as a reflection of complexity of the translation. All the above terms can be derived from bilingual sentence pairs with phrase alignments.

Meanwhile, we may also wish to exclude unimportant phrases and badly translated phrases. Our definition can also be used to guide sentence compression by trying to remove redundant phrase.

Based on the definition over sentences, we define our summary scoring measure over a summary S:

$$F(S) = \sum_{p \in S} \sum_{i=1}^{count(p,S)} d^{i-1} g(p) + \sum_{s \in S} bg(s) + \eta \sum_{s \in S} dist(y(s))$$

where d is a predefined constant damping factor to penalize repeated occurrences of the same phrases, $count(p, S)$ is the number of occurrences in the summary S for phrase p. All other terms are inherited from the sentence score definition.

In the next section we describe our framework to efficiently utilize this scoring function for cross-language summarization.

3.2 A Greedy Algorithm for Compressed Sentence Selection

Utilizing the phrase-based score definition of sentences, we can use greedy algorithms to simultaneously perform sentence selection and sentence compression. Assuming that we have a predefined budget B (e.g. total number of Chinese characters allowed) to restrict the total length of a generated summary. We use $C(S)$ to denote the cost of a summary S, measured by the number of Chinese characters contained in total. The greedy algorithm we will use for our compressive summarization is listed in Algorithm 1.

Algorithm 1 A greedy algorithm for phrase-based summarization

1: $S \leftarrow \emptyset$
2: $i \leftarrow 1$
3: $single\_best = \text{argmax}_{s \in U, C(\{s\}) \leq B} F(\{s\})$
4: **while** $U \neq \emptyset$ **do**
5: $\quad s_i = \text{argmax}_{s \in U} \frac{F(S_{i-1} \cup \{s\}) - F(S_{i-1})}{C(\{s\})^r}$
6: $\quad$ **if** $C(S_{i-1} \cup \{s\}) \leq B$ **then**
7: $\quad\quad S_i \leftarrow S_{i-1} \cup \{s\}$
8: $\quad\quad i \leftarrow i + 1$
9: $\quad$ **end if**
10: $\quad U \leftarrow U \setminus \{s_i\}$
11: **end while**
12: **return** $S^* = \text{argmax}_{S \in \{single\_best, S_i\}} F(S)$

The space U denotes the set of all possible compressed sentences. In each iteration, the algorithm tries to find the compressed sentence with maximum gain-cost ratio (Line 5, where we will follow previous work to set $r = 1$), and merge it to the summary set at the current iteration (denoted as S_i). The target is to find the compression with maximum gain-cost ratio. This will be discussed in the next section. Note that the algorithm is also naturally applicable to extractive summarization. For extractive summarization, Line 5 corresponds to direct calculations of sentence scores based on our proposed phrase-based function and U will denote all full sentences from the original translated documents.

The outline of this algorithm is very similar to the greedy algorithm used by Morita et al. (2013) for subtree extraction, except that in our context the increase of cost function when adding a sentence is exactly the cost of that sentence.

When the distortion term is ignored ($\eta = 0$), the scoring function is clearly submodular [1] (Lin and Bilmes, 2010) in terms of the set of compressed sentences, since the score now only consists of functional gains of phrases along with bigrams of a compressed sentence. Morita et al. (2013) have proved that when $r = 1$, this greedy algorithm will achieve a constant approximation factor $\frac{1}{2}(1 - e^{-1})$ to the optimal solution. Note that this only gives us the worst case guarantee. What we can achieve in practice is usually far better.

On the other hand, setting $\eta < 0$ will not affect

[1] A set function $F : 2^U \rightarrow \mathbb{R}$ defined over subsets of a universe set U is said to be *submodular* iff it satisfies the *diminishing returns* property: $\forall S \subseteq T \subseteq U \setminus u$, we have $F(S \cup \{u\}) - F(S) \geq F(T \cup \{u\}) - F(T)$.

the performance guarantee too much. Intuitively this is because in most phrase-based translation models a distortion limit constraint $|start(p_{k+1}) - 1 - end(p_k)| \leq \delta$ will be applied on distortion terms, while performing sentence compression can never increase distortion. The main conclusion is formulated as:

Theorem 1. *If Algorithm 1 outputs S^{greedy} while the optimal solution is OPT, we have*

$$F(S^{greedy}) \geq \frac{1}{2}(1 - e^{-1})F(OPT) + \frac{1}{2}\eta\gamma.$$

Here $\gamma > 0$ is a constant controlled by distortion difference between sentences, which is relatively small in practice compared with phrase scores. $\eta < 0$ is the distortion parameter. Note that when η is set to be 0, the scoring function is submodular and then we recover the $\frac{1}{2}(1 - e^{-1})$ approximation factor as studied by Morita et al. (2013). We leave the proof of Theorem 1 to supplementary materials due to space limit. The submodularity term in the score plays an important role in the proof.

3.3 Finding the Maximum Density Compression

In Algorithm 1, the most important part is the greedy selection process (Line 5). The greedy selection criteria here is to maximize the gain-cost ratio. For compressive summarization, we are trying to compress each unselected sentence s to $\tilde{s}$, aiming at maximizing the gain-cost ratio, where the gain corresponds to

$$\begin{aligned} & F(S_{i-1} \cup \{s\}) - F(S_{i-1}) \\ = & \sum_{p \in s} \sum_{i=1}^{count(p,S)} d^{i-1} g(p) + bg(s) + \eta dist(s), \end{aligned}$$

and then add the compressed sentence $\tilde{s}$ with maximum gain-cost ratio to the summary. We will also address the compression process for each sentence as finding the maximum density compression. The whole framework forms a joint selection and compression process.

In our phrase-based scoring for sentences, although there exist no apparent optimal substructure available for exact dynamic programming due to nonlocal distortion penalty, we can have a tractable approximate procedure since the search space is only defined by local decisions on whether a phrase should be kept or dropped.

Our compression process for each sentence s is displayed in Algorithm 2. It gradually expands the set of phrases to be kept in the final compression, from the initial set of large density phrases (Line 4, assuming that phrases with large scores and small costs will always be kept), we can recover the compression with maximum density. The function $dist(\cdot, \cdot)$ is the unit distortion penalty defined as $dist(a, b) = |start(b) - 1 - end(a)|$. We define $p.score$ to be the sum of damped phrase score for phrase p, i.e. $p.score = \sum_{i=1}^{count(p,S_{i-1})} d^{i-1} g(p)$, when the current partial summary is S_{i-1}. Therefore during each iteration of the greedy selection process, the compression procedure will also be affected by sentences that have already been included. Define $p.cost$ as the number of words p contains.

Algorithm 2 A growing algorithm for finding the maximum density compressed sentence

```
1: function GET_MAX_DENSITY_COMPRESSION(s, S_{i-1})
2:     queue Q ← ∅, kept ← ∅
3:     for each phrase p in s.phrases do
4:         if p.score/p.cost > 1 then
5:             kept ← kept ∪{p}
6:             Q.enqueue(p)
7:         end if
8:     end for
9:     while Q ≠ ∅ do
10:        p ← Q.deque()
11:        ppv ← p.previous_phrase, pnx ← p.next_phrase
12:        if (ppv.score+bg(ppv,p)+ηdist(ppv,p)) / (ppv.cost+p.cost) > 1 then
13:            Q.enqueue(ppv), kept ← kept ∪{ppv}
14:        end if
15:        if (pnx.score+bg(pnx,p)+ηdist(p,pnx)) / (p.cost+pnx.cost) > 1 then
16:            Q.enqueue(pnx), kept ← kept ∪{pnx}
17:        end if
18:    end while
19: return s̃ = kept, ratio = (F(S_{i-1}∪{s̃}) − F(S_{i-1})) / s̃.cost
20: end function
```

Empirically we find this procedure gives almost the same results with exhaustive search while maintaining efficiency. Assuming that sentence length is no more than L, then the asymptotic complexity of Algorithm 2 will be $O(L)$ since the algorithm requires two passes of all phrases. Therefore the whole framework requires $O(kNL)$ time for a document cluster containing N sentences in total to generate a summary with k sentences.

In the final compressed sentence we just leave the selected phrases continuously as they are, relying on bigram scores to ensure local smoothness. The task is after all a summarization task, where bigram scores play a role of not only controlling grammaticality but keeping main information of

the original documents.

Later we will see that this compression process will not hurt grammatical fluency of translated sentences in general. In many cases it may even improve fluency by deleting redundant parentheses or removing incorrectly reordered (unimportant) phrases.

4 Experiments

4.1 Data

Currently there are not so many available datasets for our particular setting of the cross-language summarization task. Hence we only evaluate our method on the same dataset used by Wan (2011). The dataset is created by manually translating the reference summaries into Chinese from the original DUC 2001 dataset in English. We will refer to this dataset as the DUC 2001 dataset in this paper. There are 30 English document sets in the DUC 2001 dataset for multi-document summarization. Each set contains several documents related to the same topic. Three generic reference English summaries are provided by NIST annotators for each document set. All these English summaries have been translated to Chinese by native Chinese annotators.

All the English sentences in the original documents have been automatically translated into Chinese using Google Translate. We also collect the phrase alignment information from the responses of Google Translate (stored in JSON format) along with the translated texts. We use the Stanford Chinese Word Segmenter [2] for Chinese word segmentation.

The parameters in the algorithms are simply set to be $r = 1, d = 0.5, \eta = -0.5$.

4.2 Evaluation

We will report the performance of our compressive solution, denoted as PBCS (for Phrase-Based Compressive Summarization), with comparisons of the following systems:

- **PBES:** The acronym comes from Phrase-Based Extractive Summarization. It is the extractive counterpart of our solution without calling Algorithm 2.
- **Baseline (EN):** This baseline relies on merely the English-side information for English sentence ranking in the original documents. The scoring function is designed to be document frequencies of English bigrams, which is similar to the second term in our proposed sentence scoring function in Section 3.1 and is submodular. [3] The extracted English summary is finally automatically translated into the corresponding Chinese summary. This is also known as the summary translation scheme.
- **Baseline (CN):** This baseline relies on merely the Chinese-side information for Chinese sentence ranking. The scoring function is similarly defined by document frequency of Chinese bigrams. The Chinese summary sentences are then directly extracted from the translated Chinese documents. This is also known as the document translation scheme.
- **CoRank:** We reimplement the graph-based CoRank algorithm, which gives the state-of-the-art performance on the same DUC 2001 dataset for comparison.
- **Baseline (ENcomp):** This is a compressive baseline where the extracted English sentences in Baseline (EN) will be compressed before being translated to Chinese. The compression process follows from an integer linear program as described by Clarke and Lapata (2008). This baseline gives strong performance as we have found on English DUC 2001 dataset as well as other monolingual datasets.

We experiment with two kinds of summary budgets for comparative study. The first one is limiting the summary length to be no more than five sentences. The second one is limiting the total number of Chinese characters of each produced summary to be no more than 300. They will be addressed as Sentence Budgeting and Character Budgeting in the experimental results respectively.

Similar to traditional summarization tasks, we use the ROUGE metrics for automatic evaluation of all systems in comparison. The ROUGE metrics measure summary quality by counting overlapping word units (e.g. n-grams) between the candidate summary and the reference summary. Following previous work in the same

[2] http://nlp.stanford.edu/software/segmenter.shtml

[3] In our experiments this method gives similar performance compared with graph-based pipelining baselines implemented in previous work.

task, we report the following ROUGE F-measure scores: ROUGE-1 (unigrams), ROUGE-2 (bigrams), ROUGE-W (weighted longest common subsequence; weight=1.2), ROUGE-L (longest common subsequences), and ROUGE-SU4 (skip bigrams with a maximum distance of 4). Here we investigate two kinds of ROUGE metrics for Chinese: ROUGE metrics based on words (after Chinese word segmentation) and ROUGE metrics based on singleton Chinese characters. The latter metrics will not suffer from the problem of word segmentation inconsistency.

To compare our method with extractive baselines in terms of information loss and grammatical quality, we also ask three native Chinese students as annotators to carry out manual evaluation. The aspects considered during evaluation include Grammaticality (GR), Non-Redundancy (NR), Referential Clarity (RC), Topical Focus (TF) and Structural Coherence (SC). Each aspect is rated with scores from 1 (poor) to 5 (good) [4]. This evaluation is performed on the same random sample of 10 document sets from the DUC 2001 dataset. One group of the gold-standard summaries is left out for evaluation of human-level performance. The other two groups are shown to the annotators, giving them a sense of topics talked about in the document sets.

4.3 Results and Discussion

Table 1 and Table 2 display the ROUGE results for our proposed methods and the baseline methods, including both word-based and character-based evaluation. We also conduct pairwise t-test and find that almost all the differences between PBCS and other systems are statistically significant with $p \ll 0.01$ [5] except for the ROUGE-W metric.

We have the same observations with previous work on the inferiority of using information from only one-side, while using Chinese-side information only is more beneficial than English-side only. The CoRank algorithm utilizes both sides of information together and achieves significantly better performance over Baseline(EN) and Baseline(CN). Our compressive system outperforms the CoRank algorithm [6] in all metrics.

Also our system overperforms the compressive pipelining system (Baseline(ENcomp)) as well. Note that the latter only considers information from the source language side. Meanwhile sentence compression may sometimes causes worse translations compared with translating the full original sentence.

For manual evaluation, the average score and standard deviation for each metric is displayed in Table 3. From the comparison between compressive summarization and the extractive version, there exist slight improvements of non-redundancy. This exactly matches what we can expect from sentence compression that keeps only important part and drop redundancy. We also observe certain amount of improvements on referential clarity. This may be a result of deletions of some phrases containing pronouns, such as *he said*. Most of such phrases are semantically unimportant and will be dropped during the process of finding the maximum density compression.

Despite not directly using syntactic information, our compressive summaries do not suffer too much loss of grammaticality. This suggest that bigrams can be treated as good indicators of local grammatical smoothness. We reckon that sentences describing the same events may partially share descriptive bigram patterns, thus sentences selected by the algorithm will consist of mostly important patterns that appear repeatedly in the original document cluster. Only those words that are neither semantically important nor syntactically pivotal will be deleted.

Figure 1 lists the summaries for the first document set D04 in the DUC 2001 dataset produced by the proposed compressive system. The Chinese side sentences have been split with spaces according to phrase alignment results. Phrases that have been compressed are grayed out. We also include original English sentences for reference, with deletions according to word alignments from the Chinese sentences. We can observe that our compressive system tries to compress sentences by removing relatively unimportant phrases. The effect of translation errors (e.g. the word *watch* in *on storm watch* has been incorrectly translated in the example) can also be reduced since those incorrectly translated words will be dropped for having low information gains. In some cases the gram-

[4] Fractional numbers are allowed for cases where the annotators feel uncertain about.

[5] The significance level holds after Bonferroni adjustment, for the purpose of multiple testing.

[6] There exists ignorable difference between the results of our reimplemented version of CoRank and those reported by Wan (2011). We believe that this comes from different machine translation results output by Google Translate.

matical fluency can even be improved from sentence compression, as redundant parentheses may sometimes be removed. We leave the output summaries from all systems for the same document set to supplementary materials.

In our experiments, we also study the influence of relevant parameter settings. Figure 2a depicts the variation of ROUGE-2 F-measure when changing the damping factor d from different values in $\{1, 2^{-1}, 3^{-1}, 4^{-1}, 5^{-1}\}$, while $\eta = -0.5$ being fixed. We can see that under proper range the value of d does not effect the result for too much. No damping or too much damping will severely decrease the performance. Figure 2b shows the performance change under different settings of the distortion parameter η taking values from $\{0, -0.2, -0.5, -1, -3\}$, while fixing $d = 0.5$. The results suggest that, for our purposes of summarization, the difference of considering distortion penalty or not is obvious. At certain level, the effect brought by different values distortion parameter becomes stable.

We also empirically study the effect of approximation. The compressive summarization framework proposed in this paper can be trivially cast into an integer linear program (ILP), with the number of variables being too large to make the problem tractable [7]. In this experiment, we use

[7] By casting decisions on whether to select a certain phrase or bigram as binary variables, with additional linear constraints on phrase/bigram selection consistency, we get an ILP with essentially the same objective function and a linear budget constraint. This is conceptually equivalent to solving

凯特 女士 硬朗 ， 紧急服务 在佛罗里达州 的 戴德 县， 承担了 风暴 的冲击 主任 估计， 安德鲁 已经 造成 150亿 美元 到 200亿 美元 的损害 （ 75亿 英镑 ， 100亿 英镑 ） 。

Figure 1: Example compressive summary

lp_solve package [8] as the ILP solver to obtain an exact solution on the first document cluster (D04) in DUC 2001 dataset. In Figure 2c, we depict the objective value achieved by ILP as exact solution, comparing with results from sentences which are gradually selected and compressed by our greedy algorithm. We can see that the approximation is close.

5 Related Work

The task focused in this paper is cross-language document summarization. Several pilot studies have investigated this task. Before Wan (2011)'s work that explicitly utilizes bilingual information in a graph-based framework, earlier methods often use information only from one language (de Chalendar et al., 2005; Pingali et al., 2007; Orasan and Chiorean, 2008; Litvak et al., 2010).

This work is closely related to greedy algorithms for budgeted submodular maximization. Many studies have formalized text summarization tasks as submodular maximization problems (Lin and Bilmes, 2010; Lin and Bilmes, 2011; Morita et al., 2013). A more recent work (Dasgupta et al., 2013) discussed the problem of maximizing a function with a submodular part and a non-submodular dispersion term, which may appear to be closer to our scoring functions.

In recent years, some research has made progress beyond extractive summarization, especially in the context of compressive summarization. Zajic et al. (2006) tries a pipeline strategy with heuristics to generate multiple candidate compressions and extract from this compressed sentences. Berg-Kirkpatrick et al. (2011) create linear models of weights learned by structural SVMs for different components and tried to jointly formulate sentence selection and syntax tree trimming in integer linear programs. Woodsend and Lapata (2012) propose quasi tree substitution grammars for multiple rewriting operations. All these methods involve integer linear programming solvers to generate compressed summaries, which is time-consuming for multi-document summarization tasks. Almeida and Martins (2013) form the compressive summarization problem in a more efficient dual decomposition framework. Models for sentence compression and extractive summarization are trained by multi-task learning techniques. Wang et al. (2013) explore different types of compression on constituent parse trees for query-focused summarization. Li et al. (2013) propose a guided sentence compression model with ILP-based summary sentence selection. Their following work (Li et al., 2014) incorporate various constraints on constituent parse trees to improve the linguistic quality of the compressed sentences. In these studies, the best-performing systems require supervised learning for different subtasks. More recent work tries to formulate document summarization tasks as optimization problems and use their solutions to guide sentence compression(Li et al., 2015; Yao et al., 2015). Bing et al. (2015) employ integer linear programming for conducting phrase selection and merging simultaneously to form compressed sentences after phrase extraction.

6 Conclusion and Future Work

In this paper we propose a phrase-based framework for the task of cross-language document summarization. The proposed scoring scheme can be naturally operated on compressive summarization. We use efficient greedy procedure to approximately optimize the scoring function. Experimental results show improvements of our compressive solution over state-of-the-art systems. Even though we do not explicitly use any syntactic information, the generated summaries of our system do not lose much grammaticality and fluency.

The scoring function in our framework is in-

the original maximization problem with pruned brute-force enumeration and therefore exactly optimal but too costly.

(a) Effect of damping factor d (b) Effect of distortion parameter η (c) Comparison with exact solution

Figure 2: Experimental analysis

spired by earlier phrase-based machine translation models. Our next step is to try more fine-grained scoring schemes using similar techniques from modern approaches of statistical machine translation. To further improve grammaticality of generated summaries, we may try to sacrifice the time efficiency for a little bit and use syntactic information provided by syntactic parsers.

Our framework currently uses only the single best translation. It will be more powerful to integrate machine translation and summarization, utilizing multiple possible translations.

Currently many successful statistical machine translation systems are phrase-based with alignment information provided and we utilize this fact in this work. It is interesting to explore how will the performance be affected if we are only provided with parallel sentences and then alignments can only be derived using an independent aligner.

Re-evaluating Automatic Summarization with BLEU and 192 Shades of ROUGE

Abstract

We provide an analysis of current evaluation methodologies applied to summarization metrics and identify the following areas of concern: (1) movement away from evaluation by correlation with human assessment; (2) omission of important components of human assessment from evaluations, in addition to large numbers of metric variants; (3) absence of methods of significance testing improvements over a baseline. We outline an evaluation methodology that overcomes all such challenges, providing the first method of significance testing suitable for evaluation of summarization metrics. Our evaluation reveals for the first time which metric variants significantly outperform others, optimal metric variants distinct from current recommended best variants, as well as machine translation metric BLEU to have performance on-par with ROUGE for the purpose of evaluation of summarization systems. We subsequently replicate a recent large-scale evaluation that relied on, what we now know to be, suboptimal ROUGE variants revealing distinct conclusions about the relative performance of state-of-the-art summarization systems.

1 Introduction

Automatic metrics of summarization evaluation have their origins in machine translation (MT), with ROUGE (Lin and Hovy, 2003), the first and still most widely used automatic summarization metric, comprising an adaption of the BLEU score (Papineni et al., 2002). Automatic evaluation in MT and summarization have much in common, as both involve the automatic comparison of system-generated texts with one or more human-generated reference texts, contrasting either *system-output translations* or *peer summaries* with *human reference translations* or *model summaries*, depending on the task. In both MT and summarization evaluation, any newly proposed automatic metric must be assessed by the degree to which it provides a good substitute of human assessment, and although there are obvious parallels between evaluation of *systems* in the two areas, when it comes to evaluation of *metrics*, summarization has diverged considerably from methodologies applied to evaluation of metrics in MT.

Since the inception of BLEU, evaluation of automatic metrics in MT has been by correlation with human assessment. In contrast in summarization, over the years since the introduction of ROUGE, summarization evaluation has seen a variety of different methodologies applied to evaluation of its metrics. Evaluation of summarization metrics has included, for example, the ability of a metric/significance test combination to distinguish between sets of human and system-generated summaries (Rankel et al., 2011), or by accuracy of conclusions drawn from metrics when combined with a particular significance test, Wilcoxon rank-sum (Owczarzak et al., 2012).

Besides moving away from well-established methods such as correlation with human judgment, previous summarization metric evaluations have been additionally limited by inclusion of only a small proportion of possible metrics and variants. For example, although the most commonly used metric ROUGE has a very large number of possible variants, it is common to include only a small range of those in evaluations. This has the

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 128–137,
Lisbon, Portugal, 17-21 September 2015.

obvious disadvantage that superior variants may exist but remain unidentified due to their omission.

Despite such limitations, however, subsequent evaluations of state-of-the-art summarization systems operate under the assumption that recommended ROUGE variants are optimal and rely on this assumption to draw conclusions about the relative performance of systems (Hong et al., 2014). This forces us to raise some important questions. Firstly, to what degree was the divergence away from evaluation methodologies still applied to MT metrics today well-founded? For example, were the original methodology, by correlation with human assessment, to be applied, would a distinct variant of ROUGE emerge as superior and subsequently lead to distinct system rankings? Secondly, were *all variants* of ROUGE to be included in evaluations, would a variant originally omitted from the evaluation emerge as superior and lead to further differences in summarization system rankings? Furthermore, although methods of statistical significance testing are commonly applied to evaluation of summarization *systems*, attempts to identify significant differences in performance of *metrics* are extremely rare, and when they have been applied unfortunately have not used an appropriate test.

This motivates our review of past and current methodologies applied to the evaluation of summarization metrics. Since MT evaluation in general has its own imperfections, we do not attempt to indiscriminately impose all MT evaluation methodologies on summarization, but specifically revisit evaluation methodologies applied to one particular area of summarization, evaluation of metrics. Correlations with human assessment reveal an extremely wide range in performance among variants, highlighting the importance of an optimal choice of ROUGE variant in system evaluations. Since distinct variants of ROUGE achieve significantly stronger correlation with human assessment than previous recommended best variants, we subsequently replicate a recent evaluation of state-of-the-art summarization systems revealing distinct conclusions about the relative performance of systems. In addition, we include in the evaluation of metrics, an evaluation of BLEU for the purpose of summarization evaluation, and contrary to common belief, precision-based BLEU is on-par with recall-based ROUGE for evaluation of summarization systems.

2 Related Work

When ROUGE (Lin and Hovy, 2003) was first proposed, the methodology applied to its evaluation, in one respect, was similar to that applied to metrics in MT, as ROUGE variants were evaluated by correlation with a form of human assessment. Where the evaluation methodology diverged from MT, however, was with respect to the precise representation of human assessment that was employed. In MT evaluation of metrics, although experimentation has taken place with regards to methods of elicitation of assessments from human judges (Callison-Burch et al., 2008), human assessment is always aimed to encapsulate the overall quality of translations. In contrast in summarization, metrics are evaluated by the degree to which metric scores correlate with *human coverage scores* for summaries, a recall-based formulation of the number of peer summary units that a human assessor believed had the same meaning as model summaries. Substitution of overall quality assessments with a recall-based manual metric, unfortunately has the potential to introduce bias into the evaluation of metrics in favor of recall-based formulations.

One dimension of summary quality omitted from human coverage scores is, for example, the order in which the units of a summary are arranged within the summary. Despite unit order quite likely being something of importance to a human assessor, assessment of metrics by correlation with human coverage scores does not in any respect take into account the order in which the units of a summary appear, and evaluation by human coverage scores alone means that a summary with its units scrambled or even reversed in theory receives precisely the same metric score as the original. Given current evaluation methodologies for assessment of metrics, a metric that scores two such summaries *differently* would be unfairly penalized for it. Furthermore, when the *linguistic quality* of summaries has been assessed in parallel with annotations used to compute human coverage scores, it has been shown that the two dimensions of quality do not correlate with one another (no significant correlation) (Pitler et al., 2010), providing evidence that coverage scores alone do not fully represent human judgment of the overall quality of summaries.

Subsequent summarization metric evaluations depart from correlation with human judgment fur-

ther by evaluating metrics according to the ability of a metric/significance test combination to identify a significant difference between the quality of human and system-generated summaries (Rankel et al., 2011). Unfortunately, the evaluation of metrics with respect to how well they distinguish between *high-quality human summaries* and *all system-generated summaries*, does not provide insight into the task of metrics, to score *better quality system-generated summaries* higher than *worse quality system-generated summaries*, however. This is in contrast to evaluation of MT metrics by correlation with human judgment, where metrics *only* receive credit for their ability to appropriately score system-output documents relative to other system-output documents. Since differences in quality levels between pairs of system-generated summaries are likely to be far smaller than differences in system and human-generated summaries, the methodology unfortunately sets too low a bar for summarization metrics to meet.

Furthermore, the approach to metric evaluation unfortunately does not work in the long-term, as the performance of summarization systems improves and approaches or achieves the quality of a human, a metric that accurately identifies this achievement would be unfairly penalized for it. Separate from the evaluation of metrics, Rankel et al. (2011) make the highly important recommendation of *paired* tests for identification of significant differences in performance of summarization systems. Since data used in the evaluation of summarization systems is not independent, paired tests are more appropriate and more powerful.

Owczarzak et al. (2012) diverge further from correlation with human judgment for evaluation of metrics by assessing the accuracy of metrics to identify significant differences between pairs of systems when combined with a significance test. Although the approach to evaluation of metrics provides insight into the accuracy of conclusions drawn from metric/test combinations, the evaluation is limited by inclusion of only six variants of ROUGE, fewer than 4% of possible ROUGE variants. Despite such limitations, however, subsequent evaluations relied on recommended ROUGE variants to rank state-of-the-art systems (Hong et al., 2014).

Although methods of identifying significant differences in performance are commonly applied to the evaluation of *systems* in summarization, the application of significance tests to the evaluation of summarization *metrics* is extremely rare, and when attempts have been made, unfortunately appropriate tests have not been applied. Computation of confidence intervals for individual correlation with human coverage scores, for example, unfortunately does not provide insight into whether or not a *difference* in correlation with human coverage scores is significant.

3 Summarization Metric Evaluation

When large-scale human evaluation of summarization systems takes place, human evaluation commonly takes the form of annotation of whether or not system-generated summary units express the meaning of model summary units, annotations subsequently used to compute *human coverage scores*. In addition, an evaluation of the *linguistic quality* of summaries is commonly carried out. As described in Section 2, when used for the evaluation of metrics, linguistic quality is commonly omitted, however, with metrics only assessed by the degree to which they correlate with human coverage scores. In contrast, we include all available human assessment data for evaluating metrics.

3.1 Combining Quality and Coverage

In DUC-2004 (Over et al., 2007), human annotations used to compute summary *coverage* are carried out by identification of matching peer units (PUs), the units in a peer summary that express content of the corresponding model summary. In addition, an overall coverage estimate (E) is provided by the human annotator, the proportion of the corresponding model summary or collective model units (MUs) expressed overall by a given peer summary. Human coverage scores (CS) are computed by combining Matching PUs with coverage estimates as follows:

$$\text{CS} = \frac{|Matching\ PUs| \cdot E}{|MUs|} \qquad (1)$$

In addition to annotations used to compute human coverage scores, human assessors were asked to rate the *linguistic quality* of summaries under 7 different criteria, providing ratings from A to E, with A denoting highest and E least quality rating.

Figure 1 is a scatter-plot of human coverage scores and corresponding linguistic quality scores

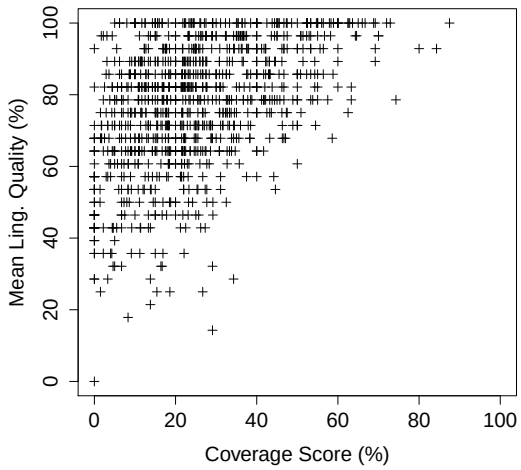

Figure 1: Scatter-plot of mean linguistic quality and coverage scores for human assessments of summaries in DUC-2004

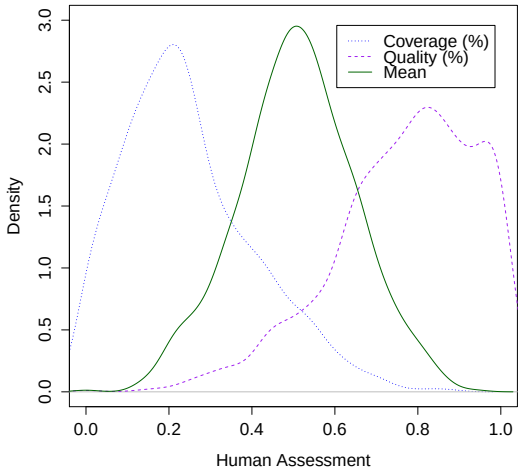

Figure 2: Combining linguistic quality and coverage scores provided by human assessors in DUC-2004

for all human-assessed summaries from DUC-2004, where, for the purpose of comparison, each of the 7 linguistic quality ratings are converted to a corresponding percentage quality (A= 100%; B= 75%; C= 50%; D= 25%; E= 0%). The location of all points almost exclusively within the upper left corner of the plot in Figure 1 indicates that the linguistic quality of almost all summaries reaches at least as high a level as its corresponding coverage score. This follows the intuition that a summary is unlikely to obtain high coverage without sufficient linguistic quality, while the same cannot be said for the converse, that a high level of linguistic quality necessarily leads to high coverage. More importantly, however, linguistic quality scores provide an additional dimension of human assessment, allowing greater discriminatory power between the quality of summaries than was possible with coverage scores alone.

Figure 2 includes linguistic quality and coverage score distributions from DUC-2004 human evaluation, where each distribution is skewed in opposing directions, in addition to the distribution of the average of the two scores for summaries.

For the purpose of metric evaluation, we combine human coverage and linguistic quality scores using the average of the two scores, and use this as a gold standard human score for evaluation of metrics:

$$\text{Human Assessment Score} = \frac{CS+MLQ}{2}$$

3.2 ROUGE

ROUGE includes a large number of distinct variants, including eight choices of n-gram counting method (ROUGE-1; 2; 3; 4; S4; SU4; W; L), binary settings such as word-stemming of summaries and an option to remove or retain stop-words. Additional configurations include the use of precision, recall or f-score to compute individual summary scores. Finally, options for computation of the overall score for a system is by computation of the mean or median of that system's summary score distribution. In total, therefore, when employing ROUGE for the evaluation of summarization systems, there are 192 (8 x 2 x 2 x 3 x 2) possible system-level variants to choose from.

The fact that final overall ROUGE scores for systems are comprised of the mean or median of ROUGE scores of individual summaries, is, again, a divergence from MT evaluation, as n-gram counts used to compute BLEU scores are computed at the document as opposed to sentence-level. However, in this respect, ROUGE has a distinct advantage over BLEU, as the fact that ROUGE comprises the mean or median score of individual summary scores makes possible the application of standard methods of significance testing differences in system-level ROUGE scores, while BLEU is restricted to the application of randomized methods (Koehn, 2004; Graham et al., 2014). For this purpose, differences in median ROUGE

scores can be tested for statistical significance using, for example, Wilcoxon signed-rank test, while paired t-test can be applied to difference of mean ROUGE scores for systems.

3.3 Metric Evaluation by Pearson's r

Moses (Koehn et al., 2007) multi-bleu[1] was used to compute BLEU (Papineni et al., 2002) scores for summaries and prepare4rouge[2] applied to summaries before running ROUGE (Lin and Hovy, 2003). Table 1 shows the Pearson correlation of each variant of ROUGE with human assessment, in addition to BLEU's correlation with the same human assessment of summaries from DUC-2004. Somewhat surprisingly, BLEU MT evaluation metric achieves strongest correlation with human assessment overall, $r = 0.797$, with performance of ROUGE variants ranging from $r = 0.786$, just below that of BLEU, to as low as $r = 0.293$. For many pairs of metrics, differences in correlation with human judgment are small, however, and prior to concluding superiority in performance of one metric over another, significance tests should be applied.

4 Metric Significance Testing

In MT, recent work has identified the suitability of Williams significance test (Williams, 1959) for evaluation of automatic MT metrics (Graham and Baldwin, 2014; Graham et al., 2015; Graham, 2015), and, for similar reasons, Williams test is suited to significance testing differences in performance of competing summarization metrics which we detail further below. Williams test has additionally been used in evaluation of systems that automatically assess spoken and written language quality (Yannakoudakis et al., 2011; Yannakoudakis and Briscoe, 2012; Evanini et al., 2013).

Evaluation of a given summarization metric, M_{new}, by Pearson correlation takes the form of quantifying the correlation, $r(M_{new}, H)$, that exists between metric scores for systems and corresponding human assessment scores, and contrasting this correlation with the correlation for some baseline metric, $r(M_{base}, H)$.

One approach to testing for significance that may seem reasonable is to apply a significance test separately to the correlation of each metric with human assessment, with the hope that the new metric will achieve a significant correlation where the baseline metric does not. The reasoning here is flawed however: the fact that one correlation is significantly higher than zero ($r(M_{new}, H)$) and that of another is not, does not necessarily mean that the *difference* between the two correlations is significant. Instead, a specific test should be applied to the difference in correlations. For this same reason, confidence intervals for individual correlations with human assessment are also not useful.

If samples that data are drawn from are independent, and differences in correlations are computed on independent data sets, the Fisher r to z transformation is applied to test for significant differences in correlations. Data used for the evaluation of summarization metrics are not independent, as evaluations comprise three sets of scores for precisely the same set of summaries (corresponding to variables X_1, X_2 and X_3 below), and subsequently three correlations: $r(M_{base}, H)$, $r(M_{new}, H)$ and $r(M_{new}, M_{base})$. If $r(M_{base}, H)$ and $r(M_{new}, H)$ are both > 0, then the third correlation, between metric scores themselves, $r(M_{base}, M_{new})$, must also be > 0. The strength of this correlation, directly between scores of pairs of summarization metrics, should be taken into account using a significance test of the difference in correlation between $r(M_{base}, H)$ and $r(M_{new}, H)$.

Williams test [3] (Williams, 1959) evaluates the significance of a difference in dependent correlations (Steiger, 1980). It is formulated as follows as a test of whether the population correlation between X_1 and X_3 equals the population correlation between X_2 and X_3:

$$t(n-3) = \frac{(r_{13} - r_{23})\sqrt{(n-1)(1+r_{12})}}{\sqrt{2K\frac{(n-1)}{(n-3)} + \frac{(r_{23}+r_{13})^2}{4}(1-r_{12})^3}},$$

where r_{ij} is the correlation between X_i and X_j, n is the size of the population, and:

$$K = 1 - {r_{12}}^2 - {r_{13}}^2 - {r_{23}}^2 + 2r_{12}r_{13}r_{23}$$

Since the power of Williams test increases when the third correlation, $r(M_{base}, M_{new})$, between metric scores is stronger, metrics should not be ranked by the number of competing metrics they

Table 1: Pearson correlation (r) of BLEU and 192 variants of ROUGE (R-*) with human assessment in DUC-2004, with (Y) and without (N) stemming, with (Y) and without (N) removal of stop words (RSW), aggregated at the summary level using precision (P), recall (R) or f-score (F), aggregated at the system level by average (A) or median (M) summary score, correlations marked with • signify a metric/variant whose correlation with human assessment is not significantly weaker than that of any other metric/variant (an optimal variant) according to pairwise Williams significance tests, variants employed in Hong et al. (2014) are in bold.

outperform, as a metric that happens to correlate strongly with a higher number of competing metrics in a given competition would be at an unfair advantage. This increased power also means, somewhat counter-intuitively, it can happen for a pair of competing metrics for which the correlation between metric scores is strong, that a small difference in competing correlations with human assessment is significant, while, for a different pair of metrics with a larger difference in correlation, the difference is not significant, because $r(M_{base}, M_{new})$ is weak. For example, in Table 1 the difference in correlation with human assessment of BLEU and that of median ROUGE-L precision with stemming and stop-words retained, 0.141 (0.797 − 0.656), is not significant, while the smaller difference in correlation with human assessment between correlations of BLEU and average ROUGE-3 recall with stemming and stop-words removed, 0.067 (0.797 − 0.73) is significant, since scores of the latter pair of metrics correlate with one another with more strength.

As part of this research, we have made available an open-source implementation of statistical tests for evaluation of summarization metrics, at `https://github.com/ygraham/nlp-williams`.

4.1 Significance Test Results

In Table 1, • identifies variants of ROUGE not significantly outperformed by any other variant. Figure 3 shows pairwise Williams significance test outcomes for BLEU, the top ten ROUGE variants, as well as current recommended ROUGE variants (Owczarzak et al. (2012)) used to compare systems in Hong et al. (2014). Current recommended best variants of ROUGE are shown to be *significantly outperformed* by several other ROUGE variants.

Although BLEU achieves strongest correlation with human assessment overall, Figure 3 reveals the difference between BLEU's correlation with human assessment and that of the best-performing ROUGE variant as *not statistically significant*, and since ROUGE holds the distinct advantage over BLEU of facilitating standard methods of significance testing differences in scores for systems, for this reason alone we recommend the use of the best-performing ROUGE variant over BLEU, average ROUGE-2 precision with stemming and stop-words removed.

Table 2 shows proportions of optimal ROUGE

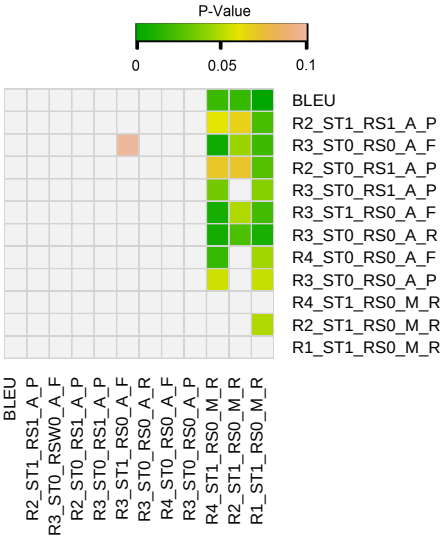

Figure 3: Pairwise significance test outcomes for BLEU, best-performing ROUGE (rows 2-9), and ROUGE applied in Hong et al. (2014) (bottom 3 rows), with (ST1) and without (ST0) stemming, with (RS1) and without (RS0) removal of stop words, for average (A) or median (M) ROUGE precision (P), recall (R) or f-score (F), colored cells denote significant win for row i metric over column j metric with Williams test.

variants that can be attributed to each of ROUGE's configuration options. Contrary to prior belief, the vast majority of optimal ROUGE variants are precision-based, showing that the assumption that recall-based metrics are superior for evaluation of summarization systems to be inaccurate, and a likely presence of bias in favor of recall-based metrics in evaluations by correlation with human coverage scores alone. Furthermore, since there exists a vast number of possible formulations that could potentially be applied to evaluation of summaries that are neither purely precision nor recall-based, evaluation methodologies should avoid reliance on assumptions that either precision or recall is superior and instead base conclusions on empirical evidence where possible.

5 Summarization System Evaluation

Since we have established that the variants of ROUGE used to rank state-of-the-art and baseline summarization systems in Hong et al. (2014) have significantly weaker correlations with human assessment than several other ROUGE variants, this motivates our replication of the evaluation. We evaluate systems using the variant of ROUGE that

Table 3: Summarization systems originally included in Hong et al. (2014) evaluated with the best-performing ROUGE variant (Best): average ROUGE-2 precision with stemming and stop words removed; and evaluated with original suboptimal variant (median ROUGE-2 recall with stemming and without removal of stop-words)

achieves strongest correlation with human assessment, average ROUGE-2 precision with stemming and stop-words removed.

Table 3 shows ROUGE scores for summarization systems originally presented in Hong et al. (2014). System rankings diverge considerably from those of the original evaluation. Notably, the system now taking first place had originally ranked in fourth position.

Since the best variant of ROUGE is based on average ROUGE scores as opposed to median ROUGE scores, a difference of means significance test is appropriate provided the normality assumption of score distributions for systems is not violated. In addition, since data used to evaluate systems are not independent, *paired* tests are also appropriate (Rankel et al., 2011). ROUGE score distributions for systems were tested for normality using the Shapiro-Wilk test (Royston, 1982) where score distributions for none of the included systems were shown to be significantly non-normal.

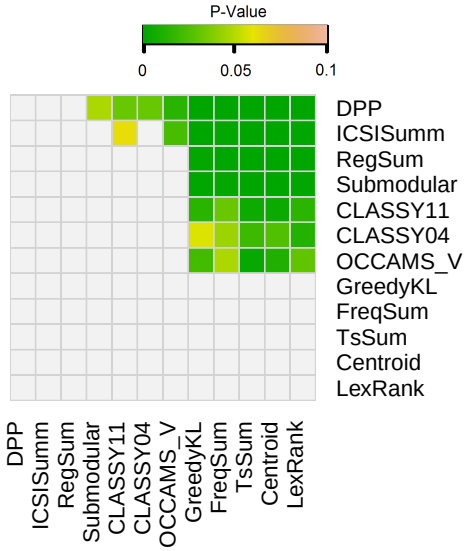

Figure 4: Summarization system pairwise significance test outcomes (paired t-test) for state-of-the-art (top 7 rows) and baseline systems (bottom 5 rows) of Hong et al. (2014) evaluated with best-performing ROUGE variant: average ROUGE-2 precision with stemming and stop words removed, colored cells denote a significant greater mean score for row i system over column j system according to paired t-test.

Figure 4 shows outcomes of paired t-tests for summary score distributions of each pair of systems, revealing three summarization systems not significantly outperformed by any other as DPP, ICSISUMM and REGSUM. In addition, as expected, all state-of-the-art systems significantly outperform all baseline systems.

6 Human Assessment Combinations

In order to evaluate metrics by correlation with human assessment, it is necessary to obtain a single human evaluation score per system. For example, in the evaluation of metrics in Section 3, we combined linguistic quality and coverage into a single score using the mean of the two scores. Other combinations are of course possible, but without any additional human evaluation data, it is challenging to identify the combination that best rep-

Metric	Stem.	RSW	Ave/Med	P/R/F	Mean	Geometric Mean	Harmonic Mean	Coverage Only	Ling. Qual. Only

ROUGE-2	N	N	M	R	0.689	0.828	0.884•	0.901•	0.508

Table 4: Correlation of top-ten metric variants for each alternate combination of linguistic quality and coverage, • denotes a metric not significantly outperformed by any other under that particular human evaluation combination, highest correlations highlighted in bold font.

resents an overall human assessment for a given summary. One possibility would be to search for optimal weights for combining quality and coverage, but there is a risk with this approach that we will not find the most representative combination but simply the combination that best describes the metrics.

An additional variation of human assessment scores is by combining coverage and quality with a variant of the arithmetic mean, such as the harmonic or geometric mean. Table 4 shows correlations of BLEU and the top ten performing variants of ROUGE when evaluated against the arithmetic (mean), harmonic and geometric mean of quality and coverage scores for summaries. In addition, Table 4 includes correlations of metric scores with coverage alone, as well as linguistic quality scores alone to provide additional insight, although linguistic quality scores alone do not provide a sufficient evaluation of metrics – since it is possible to generate summaries with perfect linguistic quality without inclusion of any relevant content whatsoever.

BLEU MT metric achieves highest correlation across all human evaluation combinations and highest again when evaluated against human coverage scores alone, and BLEU's brevity penalty, that like recall penalizes a system for too short output, is a probable cause of the metric overcoming the recall-based bias of an evaluation based on coverage scores alone. In addition, our recommended variant, ave. ROUGE-2 prec. with stemming and stop words removed is not significantly outperformed by BLEU or any other variant of ROUGE for any of the three combined mean human assessment scores.

7 Conclusions

An analysis of evaluation of summarization metrics was provided with an evaluation of BLEU and 192 variants of ROUGE. Detail of the first suitable summarization metric significance test, Williams test, was provided. Results reveal superior variants of metrics distinct from previously best recommendations. Replication of a recent evaluation of state-of-the-art summarization systems also revealed contrasting conclusions about the relative performance of systems. In addition, BLEU achieves strongest correlation with human assessment overall, but does not significantly outperform the best-performing ROUGE variant.

Indicative Tweet Generation: An Extractive Summarization Problem?

Abstract

Social media such as Twitter have become an important method of communication, with potential opportunities for NLG to facilitate the generation of social media content. We focus on the generation of *indicative tweets* that contain a link to an external web page. While it is natural and tempting to view the linked web page as the source text from which the tweet is generated in an extractive summarization setting, it is unclear to what extent actual indicative tweets behave like extractive summaries. We collect a corpus of indicative tweets with their associated articles and investigate to what extent they can be derived from the articles using extractive methods. We also consider the impact of the formality and genre of the article. Our results demonstrate the limits of viewing indicative tweet generation as extractive summarization, and point to the need for the development of a methodology for tweet generation that is sensitive to genre-specific issues.

1 Introduction

With the rise in popularity of social media, message broadcasting sites such as Twitter and other microblogging services have become an important means of communication, with an estimated 500 million tweets being written every day[1]. In addition to individual users, various organizations and public figures such as newspapers, government officials and entertainers have established themselves on social media in order to disseminate information or promote their products.

While there has been recent progress in the development of Twitter-specific POS taggers, parsers, and other tweet understanding tools (Owoputi et al., 2013; Kong et al., 2014), there has been little work on methods for generating tweets, despite the utility this would have for users and organizations.

In this paper, we study the generation of the particular class of tweets that contain a link to an external web page that is composed primarily of text. Given the short length of a tweet, the presence of a URL in the tweet is a strong signal that the tweet is functioning to help Twitter users decide whether to read the full article. This class of tweets, which we call *indicative tweets*, represents a large subset of tweets overall, constituting more than half of the tweets in our data set. Indicative tweets would appear to be the easiest to handle using current methods in text summarization, because there is a clear source of input from which a tweet could be generated. In effect, the tweet would be acting as an indicative summary of the article it is being linked to, and it would seem that existing methods in summarization can be applied. It should be noted that a tweet being indicative does not preclude it from also providing a critical evaluation of the linked article.

There has in fact been some work along these lines, within the framework of extractive summarization. Lofi and Krestel (2012) describe a system to generate tweets from local government records through keyphrase extraction. Lloret and Palomar (2013) compares various extractive summarization algorithms applied on Twitter data to generate tweets from documents.

Lofi and Krestel do not provide a formal evaluation of their model, while Lloret and Palomar compared overlap between system-generated and user-generated tweets using ROUGE (Lin, 2004). Unfortunately, they also show that there is little correlation between ROUGE scores and the perceived quality of the tweets when rated by human users for indicativeness and interest. More scrutiny is

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 138–147,
Lisbon, Portugal, 17-21 September 2015.

required to determine whether the wholesale adoption of methods and evaluation schemes from extractive summarization is justified.

Beyond issues of evaluation measures, it is also unclear whether extraction is the strategy employed by human tweeters. One of the original motivations behind extractive summarization was the observation that human summary writers tended to extract snippets of key phrases from the source text (Mani, 2001). And while it may be true that an automatic tweet generation system need not necessarily follow the same approach to writing as human tweeters, it is still necessary to know what proportion of tweets could be accounted for in an extractive summarization paradigm.

With indicative tweets, an additional issue arises in that the genre of the source text is not constrained; for example it may be a news article or an informal blog post. This may be vastly different from the desired formality of tweet itself, and thus, a genre-appropriate extract may not be available.

We begin to address the above issues through a study that examines to what extent tweet generation can be viewed as an extractive summarization problem. We extracted a dataset of indicative tweets containing a link to an external article, including the documents linked to by the tweets. We used this data and applied unigram, bigram and LCS (longest common subsequence) matching techniques inspired by ROUGE to determine what proportion of tweets can be found in the linked article. Even with the permissive unigram match measure, we find that well under half of the tweet can be found in the linked article. We also use stylistic analysis on the articles to examine the role that genre differences between the source text and the target tweet play, and find that it is easier to extract tweets from more formal articles than less formal ones.

Our results point to the need for the development of a methodology for indicative tweet generation, rather than to expropriate the extractive summarization paradigm that was developed mostly on news text. Such a methodology will ideally be sensitive to stylistic factors as well as the underlying intent of the tweet.

2 Background and Related Work

There have been studies on a number of different issues related to Twitter data, including classifying tweets and sentiment analysis of tweets. Ghosh et al. (2011) classified the retweeting activity of users based on time intervals between retweets of a single user and frequency of retweets from unique users. 'Retweet' here means the occurrence of the same URL in a different tweet. The study was able to classify the retweeting as automatic or robotic retweeting, campaigns, news, blogs and so on, based on the time-interval and user-frequency distributions. In another study, Chen et al. (2012) were able to extract sentiment expressions from a corpus of tweets including both formal words and informal slang that bear sentiment.

Other studies using Twitter data include O'Connor et al. (2010), who use topic summarization for a given search for better browsing. Chakrabarti and Punera (2011) generate an event summary by learning about the event using a Hidden Markov Model over the tweets describing it. Wang et al. (2014) generate a coherent event summary by treating summarization as an optimization problem for topic cohesion. Inouye and Kalita (2011) compare multiple summarization techniques to generate a summary of multi-post blogs on Twitter. Wei and Gao (2014) use tweets to help in generating better summaries of news articles.

As described in Section 1, we analyze tweet generation using measures inspired by extractive summarization evaluation. There has been one study comparing different text summarization techniques for tweet generation by Lloret and Palomar (2013). Summarization systems were used to generate sentences lesser than 140 characters in length by summarizing documents, which could then be taken to be tweets. The system-generated tweets were evaluated using ROUGE measures (Lin, 2004). The ROUGE-1, ROUGE-2 and ROUGE-L measures were used, and a human-written reference tweet was taken to be the gold standard.

The limits of extractive summarization have been studied by He et al. (2000). They compare user preferences for various types of summaries of an audio-visual presentation. They demonstrate that the most preferred method of summarization is highlights and notes provided by the author, rather than transcripts or slides from the presentation. Conroy et al. (2006) computed an oracle ROUGE score to investigate the same issue of the limits of extraction for news text.

These studies show that extractive summarization algorithms may not generate good quality summaries despite giving high ROUGE evaluation scores. Cheung and Penn (2013) show that for the news genre, extractive summarization systems that are optimized for centrality—that is, getting the core parts of the text into the summary—cannot perform well when compared to model summaries, since the model summaries are abstracted from the document to a large extent.

3 Data Extraction and Preprocessing

3.1 Using Twitter for Data Extraction

As mentioned earlier, there have been numerous studies that used data from the public Twitter feeds. However, none of the datasets in those studies focused on tweets and related articles linked to these tweets. The dataset of Lloret and Palomar (2013) is an exception, as it contains tweets and the news articles they link to, but it only contains 200 English tweet-article pairs. Wei and Gao (2014) also constructed a dataset that contains both tweets and articles linked through them, but this data only deals with news text, and does not contain the variety of topics we wanted in the data. We therefore chose to build our own dataset. This section describes extraction, cleaning and other preprocessing of the data.

3.2 Extracting Data

Data was extracted from Twitter using the Twitter REST API using 51 search terms, or hashtags. These hashtags were chosen from a range of topics including pop culture, international summit meetings discussing political issues, lawsuits and trials, social issues and health care issues. All these hashtags were trending (being tweeted about at a high rate) at the time of extraction of the data. To get a broader sample, the data was extracted over the course of 15 days in November, 2014, which gave us multiple news stories to choose from for the search terms. The search terms were chosen so that there would be broad representation in terms of various stylistic properties of text like formality, subjectivity, etc. For example, searches related to politics would be more formal, while those related to films would be informal, and would also have a lot more opinion pieces about them. A few examples of the search terms and their distribution in genre are shown in Table 1.

We extracted about 30,000 tweets, of which more than half, or around 16,000, contained URLs to an external news article, photo on photo sharing sites, or video.

Politics	Science & Technology
#apec2014	#rosetta
#G20	#lollipop
#oscarpistorius	#mangalayan
Events	Films and Pop culture
#haiyan	#TaylorSwift
#memorialday	#theforceawakens
#ottawashootings	#johnoliver
International	Sports
#berlinwall	#ausvssa
#ebola	#playingitmyway
#erdogan	#nycmarathon

Table 1: Examples of the hashtags used for extraction, grouped into various categories.

The data from the tweets was cleaned by removing the tweets that were not in English as well as the retweets; i.e., re-publications of a tweet by a different user.

We deduplicated the 16,000 extracted URLs into 6,003 unique addressed, then extracted and preprocessed their contents. The `newspaper` package[2] was used to extract article text and the title from the web page. Since we are interested in text articles that can serve as the source text for summarization algorithms, we needed to remove photos and video links such as those from Instagram and YouTube. To do so, we removed those links that contained fewer than a threshold of 150 words. After this preprocessing, the number of useful articles was reduced from 6003 to 3066. There were some further tweet-article pairs where the text of the tweets was identical, these were removed by further preprocessing and the number of unique tweet-article pairs came down to 2471.

The final version of the data consists of tweets along with other information about the tweet, such as links to articles, hashtags, time of publication, etc. We also retain the linked article text and preprocessed it using the CoreNLP toolkit (Manning et al., 2014). This includes the URL itself and the text extracted from the article, as well as some extracted information such as sentence boundaries, POS tags for tokens, parse trees and dependency trees. These annotations are used later during our

[2]https://pypi.python.org/pypi/newspaper

analysis in Section 4. Table 2 shows an example of an entry in the dataset.

Tweet	'#RiggsReport: #CA as the #Election-Night exception. Voters rewarded #GOP nationally, but not in the #GoldenState. http://t.co/K542wvSNVz'
Title	'The Riggs Report: California as the Election Night exception'
Text	'When the dust settled on Election Night last week...'

Table 2: Example of a tweet, title of the article and the text.

4 Analysis

We now describe the analyses we performed on the data. Our goal is to investigate what proportion of the indicative tweets that we extracted can be found in the articles that they link to, in order to determine whether indicative tweet generation can be viewed as an extractive summarization problem. Table 3 gives an example of data where the tweet that was shared about the article does not come directly from the article text, while Table 4 shows a tweet that was almost entirely extracted from the text of the article, but changed a little for the purpose of readability.

Tweet	Are #Airlines doing enough with #Ebola? http://t.co/XExWwxmjnk #travel
Title	Could shortsighted airline refund policies lead to an outbreak?
Text	The deadly Ebola virus has arrived in the United States just in time for the holiday travel season, carrying fear and uncertainty with it...

Table 3: Example of a tweet, title of the article and the text when tweet cannot be extracted from text.

We first compute the proportion of tweets that can be recovered directly from the article in its entirety (Section 4.1). Then, we calculate the degree of overlap in terms of unigrams and bigrams between the tweet and the text of the document (Sections 4.2, 4.3).

In addition, we consider locality within the article when computing the overlap. For the unigram analysis, we performed a variant of the analysis,

Tweet	Officer **Wilson will be returned to active duty if no indictment**, says #Ferguson Police **Chief** http://t.co/zrRIBxMUYJ
Title	Jackson clarifies comments on Wilson's future status
Text	...**Chief** Jackson said if the grand jury does **not indict Wilson**, he **will** immediately **return to active duty**....

Table 4: Example of a tweet, title of the article and the text when tweet can be extracted from text. The matched portions of the tweet and article are in bold.

in which we computed the overlap within three-sentence windows in the source article (Section 4.4). We also compute the least common subsequences between the tweet and the document (Section 4.5). This was done to investigate whether sentence compression techniques could be applied to local context windows to generate the tweet.

These calculations are analogous to the ROUGE-1, -2 and -L style calculations. These results give an indication of the degree to which the tweet is extracted from the document text.

For all these analyses, the stop words have been eliminated from the tweet as well as the document, so that only the informative words are taken into consideration. The comparisons were made without lemmatization or stemming, to adhere closely to existing work in extractive summarization, where the only modifications to the source text are removing discourse cue words or removing words by sentence compression techniques. The hashtags, references (@) and URLs from the tweets were all removed for analysis.

4.1 Exact Match Calculations

We first checked for a complete substring match of the tweet in the text. Out of the 2471 unique instances of tweet and article pairs, a complete match was found only 23 times. In 9 cases out of these, the tweet text matched the title of the article, which our preprocessing tool did not correctly separate from the body of the article. In the other cases, the text of the tweet appears in its entirety inside the body of the article. This suggests that the user chose the sentence that either seemed to be the most conclusive contribution of the article, or expressed the opinion of the user to be tweeted.

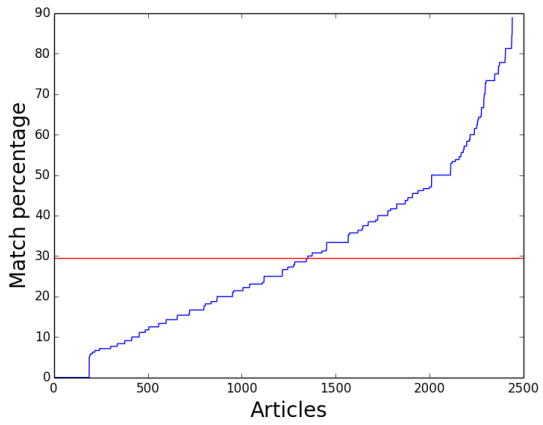

Figure 1: Distribution of unigram match percentage over unique tweets and articles. The mean is 29.53%, indicated by the red horizontal line, with a standard deviation of 20.2%

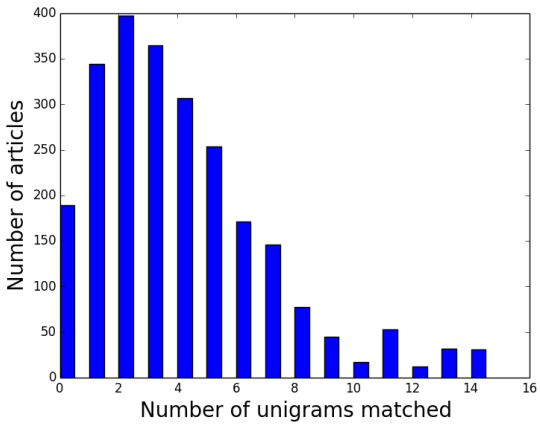

Figure 2: Histogram of number of unique tweet-article pairs vs number of unigrams matched. The mean number of unigrams matched per tweet-article pair is 3.9.

An example for this is detailed in Table 5.

Apart from the 9 times where the tweet was matched with title in the article, we also checked to see if the tweet text matched with the article titles that were separately extracted by the `newspaper` package in order to determine if tweets could be generated using the headline generation methods. We found that it did not match with the titles. However, even though there are no exact matches, there might still be matches where the tweet is a slight modification of the headline of the article, and can be measured using a partial match measure.

Tweet	@PNHP: **6. Renounce punitive and counterproductive measures such as sealing the borders,** http://t.co/LRLS2MhPRE #Ebola
Title	Physicians for a National Health Program
Text	As health professionals and trainees, we call on President Obama to take the following immediate steps to address the Ebola crisis... **6. Renounce punitive and counterproductive measures such as sealing the borders,** and take steps to address the...

Table 5: Example where tweet is extracted as is from the text, matched portion in bold.

4.2 Percentage Match for Unigrams

Next, we did a percentage match with the text of the article. This was a bag-of-words check using unigram overlap between the tweet and the document. Let $unigrams(x)$ be the set of unigrams for some text x, then u, the percentage of matching unigrams found between a given tweet, t and a given article, a, can be defined as

$$u = \frac{|unigrams(t) \cap unigrams(a)|}{|unigrams(t)|} * 100 \quad (1)$$

Figure 1 shows the percentage of matches in the tweet and the article text as compared to the number of unigrams in the tweet. The mean match percentage is 29.53% and standard deviation is 20.2%. The mean of this distribution shows that the number of matched unigrams from a tweet in the article are fairly low. Figure 2 shows the number of articles with a certain number of matching unigrams. The graph shows that the most common number of unigrams matched was 2. The number of articles with higher unigrams matched goes on decreasing. The slight rise at the end - more than 10 matched unigrams - is accounted for by the completely matched tweets described above.

4.3 Percentage Match for Bigrams

Similar to the unigram matching techniques, the bigram percentage matching was also calculated. The text of the tweet was converted into bigrams and we then looked for those bigrams in the article text. The percentage was calculated similar

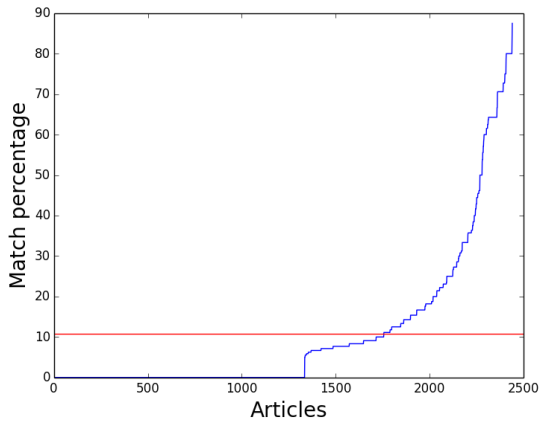

Figure 3: Distribution of bigram match percentage over the tweet-article pair. The mean here is 10.73% shown by the red horizontal line, with a standard deviation of 18.5%

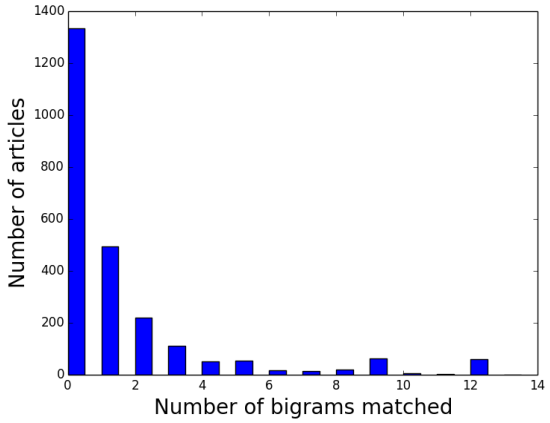

Figure 4: Histogram of number of unique tweet-article pairs vs number of bigrams matched. The mean number of bigrams matched per article is 1.9.

to the unigram matching done earlier. For the set of bigrams for a text x, $bigrams(x)$, percentage of matching bigrams b for the tweet t and article a is:

$$b = \frac{|bigrams(t) \cap bigrams(a)|}{|bigrams(t)|} * 100 \quad (2)$$

Figure 3 shows the percentages of matched bigrams found. The mean is 10.73 with a standard deviation of 18.5. As seen in the figure, most of the tweet-article pairs have no matched bigrams. The percentage then increases to reflect the complete matches found above.

Figure 4 shows frequency of the number of tweet-article pairs for the number of bigrams matched. There are no matched bigrams for most of the pairs. A smaller number of articles had one matched bigram, and the number decreased until the end, where it increases a little at more than 10 matched bigrams because of exact tweet matches.

4.4 Percentage Match Inside a Window in the Article Text

The next analysis checks for a significant word matching inside a three-sentence window inside the article text. We used a three sentence long window using the sentence boundary information obtained during preprocessing. A window of three sentences was chosen to give a smaller context for the tweet to be extracted from than the entire article. The number was chosen as a moderate context window size as not too small to reduce it to a sentence level, and not too big for the context to be diluted. This was done to investigate whether a pseudo-extractive multi-sentence compression approach could convert a small number of sentences into a tweet.

After the text of the window was extracted, we performed a similar analysis as the last one, except on a smaller set of sentences. The matching percentages from all three-sentence windows in the articles were computed and the maximum out of these was taken for the final results. Let a sentence window w_i be the set of three consecutive sentences starting from the sentence number i. For this window, the unigram match in the tweet t, and the window is the unigram match u calculated above. Then, the maximum match from all the windows, uw is

$$uw = max_{w_i \in S} u(t, w_i) \quad (3)$$

The result from this experiment is shown in Figure 5. Here, the mean of the values is 26.6% and deviation 17%. Again this shows that only a small proportion of tweets can be generated even with an approach that combines unigrams from multiple sentences in the article.

4.5 Longest Common Subsequence Match Inside a Window for the Text

The percentage match analyses were a bag-of-words approach that disregarded the order of the words inside the texts and tweets. To respect the order of the words in the sentence of the tweet, we also used the least common subsequence algorithm between the tweet text and the document

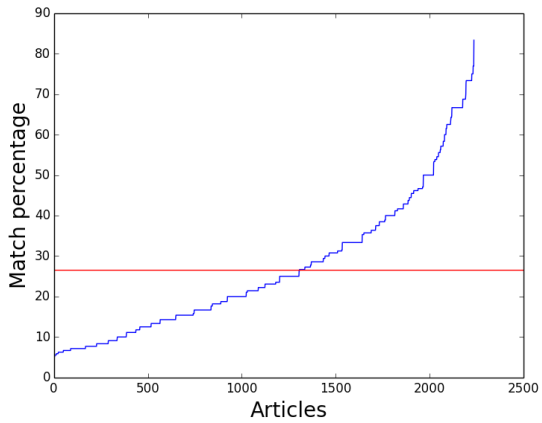

Figure 5: Percentages of common words in tweet and a three sentence window in the article. The maximum match from all percentages is chosen for an article. The red horizontal line is the mean is 26.6%, and standard deviation 17%.

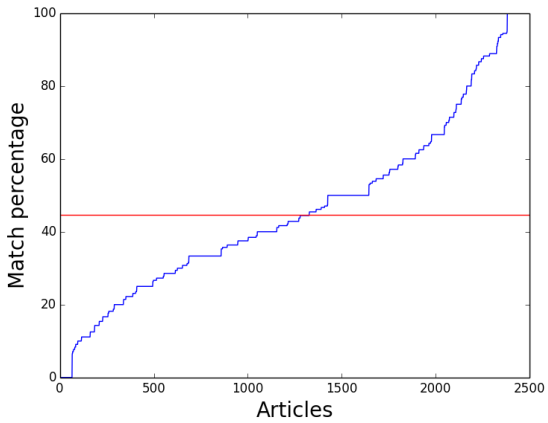

Figure 6: Percentages of words matching in tweet and document text using an LCS algorithm. Mean is 44.6%, which is shown by the red horizontal line, and standard deviation is 22.7%.

text. This subsequence matching was done inside a sentence window of 5 sentences. Again, the final result for the article was the window in which the maximum percentage was recorded among all windows. The percentage match was calculated using the number of words in the tweet as the denominator.

If *lcs(t, a)* is the longest common subsequence between the tweet t and article a, $\textit{unigrams}(x)$ is the set of unigrams for a text x, then the percentage of match for the lcs as compared to the tweet, l is

$$l = \frac{|\textit{lcs}(t,a)|}{|\textit{unigrams}(t)|} * 100 \quad (4)$$

These numbers are shown in Figure 6. The mean here is 44.6% and the standard deviation is 22.7%.

5 Interaction with Formality

As seen in the results of the analyses performed in Section 4, the tweets have little in common with the articles they are linked to. This shows that extractive summarization algorithms can only recover a small proportion of the indicative tweets.

To tie in the results of the findings above with some intuitive notions about the text and see how formality interacts with the results, we also calculated the formality of the articles. This formality score was correlated with the longest common subsequence measure that we defined above.

We assume that the formality of an article can be estimated by the formality of the words and phrases in the article. We used the formality lexicon of Brooke and Hirst (2013). They calculate formality scores for words and sentences by training a model on a large corpus based on the appearance of words in specific documents. Their model represents words as vectors and the formal and informal seeds appear in opposite halves of the graphs, suggesting that we can use these seeds to determine if an article is formal or informal. The lexicon consists of words and phrases and their degree of formality. Thus, more formal words are marked on a positive scale and informal words like those occurring in colloquial language are marked on a negative scale.

Let the set of formality expressions from the lexicon be L, and the formality score for an expression e be $\textit{score}(e)$. Let the set of all substrings from the article $\textit{substrings}(a)$ be S. Then, the formality score f for an article a is the number of formal expressions per 10 words in article is

$$f = \frac{\sum_{e \in L \& e \in S} \textit{score}(e)}{|\textit{unigrams}(a)|} * 10 \quad (5)$$

The formality lexicon gave positive weights for formal expressions and negative for informal expressions. When we computed f using both formal and informal expressions, we found that the informal words predominated and "swamped" the signal of the formal words, leading to incomprehensible results. Thus, we discarded the informal words and used only the weights from the formal words in our final calculations. To check that these

formality scores made sense intuitively, we calculated the average formality score for the articles belonging to each hashtag and ordered them, as shown in Table 7.

Lowest	Highest
#theforceawakens	#KevinVickers
#TaylorSwift	#erdogan
#winteriscoming	#apec

Table 6: Table of hashtags (broadly, topics) with highest and lowest formality according to the lexicon.

This formality score for each article was correlated with the percentage of match obtained using the longest common subsequence algorithm. The Pearson correlation value was 0.41, with a p-value of 7.08e-66, indicating that the interaction between formality and overlap was highly significant. Hence, we can say that the more formal the subject or the article, the better the tweet can be extracted from the article. Table 7 gives an example of the formality of the article, which is a low 4.2 formality words per 10 words, where the tweet is not extracted from the article, but rephrased from the article instead.

Tweet	@globetoronto: Why Buffalo got clobbered with snow and Toronto did not. #weather #snowstorm http://t.co/gcwwoDPZmX... http://t.co/BXY7EH6F3u"
Title	What caused Buffalos massive snow and why Toronto got lucky
Text	Torontonians have long been the butt of jokes about calling in the army every time a few snow flurries whip by...

Table 7: Example of a tweet, title of the article where the formality of the article is over the mean, and the tweet is extracted from the article.

We speculate that tweets associated with less formal articles may contain more abbreviations and non-standard words or spellings, which decreases the amount of overlap. We plan to experiment with tweet normalization systems to account for this factor.

6 Discussions

Having presented the above statistics showing that only a small portion of indicative tweets can be recovered from the article they link to if viewed as an extractive summarization problem, the question then becomes, how should we view the process of tweet generation?

We think that one promising direction is to model more explicitly the intent, or the purpose of the tweets. There have been several studies on classifying intents in tweets, but in many cases the intents are general, high-level intents of the tweets, more akin to classifying the topic or genre of the tweet than the intent. Wang et al. (2015) classify intents as food and drink, travel, career and so on, ones that can directly be used as intents for purchasing and can be utilized for advertisements. They also focus on finding tweets with intent and then classifying those. Banerjee et al. (2012) analyze real time data to detect presence of intents in tweets. Gómez-Adorno et al. (2014) use features from text and stylistics to determine user intentions, which are classified as news report, opinion, publicity and so on. Mohammad et al. (2013) study the classification of user intents specifically for tweets related to elections. They study one election and classify tweets as ones that agree or disagree with the candidate, ones that are meant for humour, support and so on.

These definitions of intent, while a promising start, will not be sufficient for tweet generation. For this purpose, intent would be the reason the user chose to share the article with that particular text. This would include reasons like support some cause, promote a product or an article, agree or disagree with an event, or express an opinion about it. Identifying these intents will help provide parameters for generating tweets.

7 Conclusion

We have described a study that investigates whether indicative tweet generation can be viewed as an extractive summarization problem. By analyzing a collection of indicative tweets that we collected according to measures inspired by extractive summarization evaluation measures, we find that most tweets cannot be recovered from the article that they link to, demonstrating a limit to the effectiveness of extractive methods.

We further performed an analysis to determine the role of formality differences between the source article and the Twitter genre. We find evidence that formality is an important factor, as the less formal the source article is, the less extrac-

tive the tweets seem to be. Future methods that can change the level of formality of a piece of text without changing the contents will be needed, as will those that explicitly consider the intended use of the tweet.

Acknowledgments

We would like to thank the anonymous reviewers for their comments and suggestions, and Julian Brooke for the formality lexicon used in a part of this study.

Abstract

This paper is concerned with the task of bilingual lexicon induction using image-based features. By applying features from a convolutional neural network (CNN), we obtain state-of-the-art performance on a standard dataset, obtaining a 79% relative improvement over previous work which uses bags of visual words based on SIFT features. The CNN image-based approach is also compared with state-of-the-art linguistic approaches to bilingual lexicon induction, even outperforming these for one of three language pairs on another standard dataset. Furthermore, we shed new light on the type of visual similarity metric to use for genuine similarity versus relatedness tasks, and experiment with using multiple layers from the same network in an attempt to improve performance.

1 Introduction

Bilingual lexicon induction is the task of finding words that share a common meaning across different languages. It plays an important role in a variety of tasks in information retrieval and natural language processing, including cross-lingual information retrieval (Lavrenko et al., 2002; Levow et al., 2005) and statistical machine translation (Och and Ney, 2003). Although parallel corpora have been used successfully for inducing bilingual lexicons for some languages (Och and Ney, 2003), these corpora are either too small or unavailable for many language pairs. Consequently, mono-lingual approaches that rely on comparable instead of parallel corpora have been developed (Fung and Yee, 1998; Koehn and Knight, 2002). These approaches work by mapping language pairs to a shared bilingual space and extracting lexical items from that space. Bergsma and Van Durme (2011) showed that this bilingual space need not be linguistic in nature: they used labeled images from the Web to obtain bilingual lexical translation pairs based on the visual features of corresponding images. Local features are computed using SIFT (Lowe, 2004) and color histograms (Deselaers et al., 2008) and aggregated as bags of visual words (BOVW) (Sivic and Zisserman, 2003) to get bilingual representations in a shared visual space. Their highest performance is obtained by combining these visual features with normalized edit distance, an orthographic similarity metric (Navarro, 2001).

There are several advantages to having a visual rather than a linguistic intermediate bilingual space: First, while labeled images are readily available for many languages through resources such as Google Images, language pairs that have sizeable comparable, let alone parallel, corpora are relatively scarce. Second, it has been found that meaning is often grounded in the perceptual system, and that the quality of semantic representations improves significantly when they are grounded in the visual modality (Silberer and Lapata, 2012; Bruni et al., 2014). Having an intermediate visual space means that words in different languages can be grounded in the same space. Third, it is natural to use vision as an intermediate: when we communicate with someone who does not speak our language, we often communicate by directly referring to our surroundings. Languages that are linguistically far apart will, by cognitive necessity, still refer to objects in the same visual space. While some approaches to bilingual lexicon induction rely on orthographic properties (Haghighi et al., 2008; Koehn and Knight, 2002) or properties of frequency distributions (Schafer and Yarowsky, 2002) that will work only for

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 148–158,
Lisbon, Portugal, 17-21 September 2015.

closely related languages, a visual space can work for any language, whether it's English or Chinese, Arabic or Icelandic, or all Greek to you.

It has recently been shown, however, that much better performance can be achieved on semantic similarity and relatedness tasks by using visual representations from deep convolutional neural networks (CNNs) instead of BOVW features (Kiela and Bottou, 2014). In this paper we apply such CNN-derived visual features to the task of bilingual lexicon induction. To obtain a translation of a word in a source language, we find the nearest neighbours from words in the target language, where words in both languages reside in a shared visual space made up of CNN-based features. Nearest neighbours are found by applying similarity metrics from both Kiela and Bottou (2014) and Bergsma and Van Durme (2011). In summary, the contributions of this paper are:

- We obtain a relative improvement of 79% over Bergsma and Van Durme (2011) on a standard dataset based on fifteen language pairs.
- We shed new light on the question of whether genuine similarity versus semantic relatedness tasks require different similarity metrics for optimal performance (Kiela and Bottou, 2014).
- We experiment with using different layers of the CNN and find that performance is not affected significantly in either case, obtaining a slight improvement for the relatedness task but no improvement for genuine similarity.
- Finally, we show that the visual approach outperforms the linguistic approaches on one of the three language pairs on a standard dataset. To our knowledge this is the first work to provide a comparison of visual and state-of-the-art linguistic approaches to bilingual lexicon induction.

2 Related Work

2.1 Bilingual Lexicon Learning

Bilingual lexicon learning is the task of automatically inducing word translations from raw data, and is an attractive alternative to the time-consuming and expensive process of manually building high-quality resources for a wide variety of language pairs and domains. Early approaches relied on limited and domain-restricted parallel data, and the induced lexicons were typically a by-product of word alignment models (Och and Ney, 2003). To alleviate the issue of low coverage, a large body of work has been dedicated to lexicon learning from more abundant and less restricted comparable data, e.g., (Fung and Yee, 1998; Rapp, 1999; Gaussier et al., 2004; Shezaf and Rappoport, 2010; Tamura et al., 2012). However, these models typically rely on the availability of bilingual seed lexicons to produce shared bilingual spaces, as well as large repositories of comparable data. Therefore, several approaches attempt to learn lexicons from large monolingual data sets in two languages (Koehn and Knight, 2002; Haghighi et al., 2008), but their performance again relies on language pair-dependent clues such as orthographic similarity. A further approach removed the requirement of seed lexicons, and induced lexicons using bilingual spaces spanned by multilingual probabilistic topic models (Vulić et al., 2011; Liu et al., 2013; Vulić and Moens, 2013b). However, these models require document alignments as initial bilingual signals.

In this work, following recent research in multi-modal semantics and image representation learning—in particular deep learning and convolutional neural networks—we test the ability of purely visual data to induce shared bilingual spaces and to consequently learn bilingual word correspondences in these spaces. By compiling images related to linguistic concepts given in different languages, the potentially prohibitive data requirements and language pair-dependence from prior work is removed.

2.2 Deep Convolutional Neural Networks

Deep convolutional neural networks (CNNs) have become extremely popular in the computer vision community. These networks currently provide state-of-the-art performance for a variety of key computer vision tasks such as object recognition (Razavian et al., 2014). They tend to be relatively deep, consisting of a number of rectified linear unit layers (Nair and Hinton, 2010) and a series of convolutional layers (Krizhevsky et al., 2012). Recently, such layers have been used in transfer learning techniques, where they are used as mid-level features in other computer vision tasks (Oquab et al., 2014). Although the idea of transferring CNN features is not new (Driancourt and Bottou, 1990), the simultaneous availability of

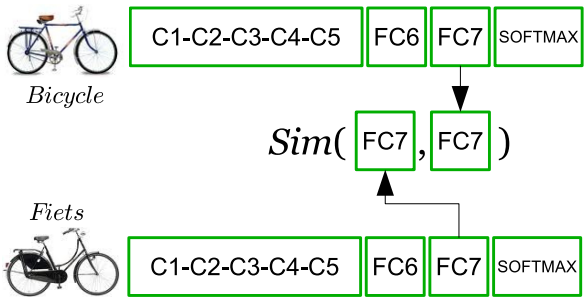

Figure 1: Illustration of calculating similarity between images from different languages.

massive amounts of data and cheap GPUs has led to considerable advances in computer vision, similar in scale to those witnessed with SIFT and HOG descriptors a decade ago (Razavian et al., 2014).

2.3 Multi-Modal Semantics

Multi-modal semantics is motivated by parallels with human concept acquisition. It has been found that semantic knowledge, from a very early age, relies heavily on perceptual information (Louwerse, 2008), and there exists substantial evidence that many concepts are grounded in the perceptual system (Barsalou, 2008). One way to accomplish such grounding is by combining linguistic representations with information from a perceptual modality, obtained from, e.g., property norming experiments (Silberer and Lapata, 2012; Silberer et al., 2013; Roller and Schulte im Walde, 2013; Hill and Korhonen, 2014) or extracting features from raw image data (Feng and Lapata, 2010; Leong and Mihalcea, 2011; Bruni et al., 2014; Kiela et al., 2014). Such multi-modal visual approaches often rely on local descriptors, such as SIFT (Lowe, 2004), SURF (Bay et al., 2008), or HOG (Dalal and Triggs, 2005), as well as pyramidal variants of these descriptors such as PHOW (Bosch et al., 2007). However, deep CNN features have recently been successfully transferred to multi-modal semantics (Kiela and Bottou, 2014; Shen et al., 2014). Deep learning techniques have also been successfully employed in cross-modal tasks (Frome et al., 2013; Socher et al., 2014; Lazaridou et al., 2014; Kiros et al., 2014). Other examples of multi-modal deep learning use restricted Boltzmann machines (Srivastava and Salakhutdinov, 2014) or auto-encoders (Wu et al., 2013; Silberer and Lapata, 2014).

3 A Purely Visual Approach to Bilingual Lexicon Learning

We assume that the best translation, or matching lexical item, of a word w_s (in the source language) is the word w_t (in the target language) that is the nearest cross-lingual neighbour to w_s in the bilingual visual space. Hence a similarity (or distance) score between lexical items from different languages is required. In this section, we describe: one, how to build image representations from sets of images associated with each lexical item, i.e. how to induce a shared bilingual visual space in which all lexical items are represented; and two, how to compute the similarity between lexical items using their visual representations in the shared bilingual space. We also describe the evaluation datasets and metrics we use.

To facilitate further research, we will make our code and data publicly available. Please see the following webpage: `http://www.cl.cam.ac.uk/~dk427/bli.html`.

3.1 Image Representations

We use Google Images to extract the top n ranked images for each lexical item in the evaluation datasets. It has been shown that images from Google yield higher quality representations than comparable sources such as Flickr (Bergsma and Goebel, 2011) and that Google-derived datasets are competitive with "hand prepared datasets" (Fergus et al., 2005). Google Images also has the advantage that it has full coverage and is multi-lingual, as opposed to other potential image sources such as ImageNet (Deng et al., 2009) or the ESP Game Dataset (von Ahn and Dabbish, 2004). For each Google search we specify the target language corresponding to the lexical item's language. Figure 2 gives some example images retrieved using the same query terms in different languages. For each image, we extract the pre-softmax layer of an AlexNet (Krizhevsky et al., 2012). The network contains a number of layers, starting with five convolutional layers, two fully connected layers and finally a softmax, and has been pre-trained on the ImageNet classification task using Caffe (Jia et al., 2014). See Figure 1 for a simple diagram illustrating the approach.

3.2 Visual Similarity

Suppose that, as part of the evaluation, the similarity between *bicycle* and *fiets* is required. Each of

the two words has n images associated with it – the top n as returned by Google image search, using *bicycle* and *fiets* as separate query terms. Hence to calculate the similarity, a measure is required which takes two sets of images as input. The standard approach in multi-modal semantics is to derive a single image representation for each word, e.g., by averaging the n images. An alternative is to take the pointwise maximum across the n image vector representations, also producing a single vector (Kiela and Bottou, 2014). Kiela and Bottou call these combined representations CNN-MEAN and CNN-MAX, respectively. Cosine is then used to calculate the similarity between the resulting pair of image vectors.

An alternative strategy, however, is to consider the similarities between individual images instead of their aggregated representations. Bergsma and Van Durme (2011) propose two similarity metrics based on this principle: taking the average of the maximum similarity scores (AVGMAX), or the maximum of the maximum similarity scores (MAXMAX) between associated images. Continuing with our example, for each of the n images for *bicycle*, the maximum similarity is found by searching over the n images for *fiets*. AVGMAX then takes the average of those n maximum similarites; MAXMAX takes the maximum. To avoid confusion, we will refer to the CNN-based models that use these metrics as CNN-AVGMAX and CNN-MAXMAX. Formally, these metrics are defined as in Table 1. We experiment with both kinds of MAX and find that they optimize for different kinds of similarity.

AVGMAX	$\frac{1}{n}\sum_{i_s \in \mathcal{I}(w_s)} \max_{i_t \in \mathcal{I}(w_t)} sim(i_s, i_t)$
MAXMAX	$\max_{i_s \in \mathcal{I}(w_s)} \max_{i_t \in \mathcal{I}(w_t)} sim(i_s, i_t)$
CNN-MEAN	$sim(\frac{1}{n}\sum_{i_s \in \mathcal{I}(w_s)} i_s, \frac{1}{n}\sum_{i_t \in \mathcal{I}(w_t)} i_t)$
CNN-MAX	$sim(\max' \mathcal{I}(w_s), \max' \mathcal{I}(w_t))$

Table 1: Visual similarity metrics between two sets of n images. $\mathcal{I}(w_s)$ represents the set of images for a given source word w_s, $\mathcal{I}(w_t)$ the set of images for a given target word w_t; $\max'$ takes a set of vectors and returns the single element-wise maximum vector.

3.3 Evaluations

Test Sets. Bergsma and Van Durme's primary evaluation dataset consists of a set of five hundred matching lexical items for fifteen language pairs, based on six languages. (The fifteen pairs results from all ways of pairing six languages). The data is publicly available online.[1] In order to get the five hundred lexical items, they first rank nouns by the conditional probability of them occurring in the pattern "{*image,photo,photograph,picture*} *of* {*a,an*} _____" in the web-scale Google N-gram corpus (Lin et al., 2010), and take the top five hundred words as their English lexicon. For each item in the English lexicon, they obtain corresponding items in the other languages—Spanish, Italian, French, German and Dutch—through Google Translate. We call this dataset BERGSMA500.

In addition to that dataset, we evaluate on a dataset constructed to measure the general performance of bilingual lexicon learning models from comparable Wikipedia data (Vulić and Moens, 2013a). The dataset comprises 1,000 nouns in three languages: Spanish (ES), Italian (IT), and Dutch (NL), along with their one-to-one gold-standard word translations in English (EN) compiled semi-automatically using Google Translate and manual annotators for each language. We call this dataset VULIC1000[2]. The test set is accompanied with comparable data for training, for the three language pairs ES/IT/NL-EN on which text-based models for bilingual lexicon induction were trained (Vulić and Moens, 2013a).

Given the way that the BERGSMA500 dataset was created, in particular the use of the pattern described above, it contains largely concrete linguistic concepts (since, eg, *image of a democracy* is unlikely to have a high corpus frequency). In contrast, VULIC1000 was designed to capture general bilingual word correspondences, and contains several highly abstract test examples, such as *entendimiento (understanding)* and *desigualdad (inequality)* in Spanish, or *scoperta (discovery)* and *cambiamento (change)* in Italian. Using the two evaluation datasets can potentially provide

Table 2: Performance on BERGSMA500 compared to Bergsma and Van Durme (B&VD).

some insight into how purely visual models for bilingual lexicon induction behave with respect to both abstract and concrete concepts.

Evaluation Metrics. We measure performance in a standard way using mean-reciprocal rank:

$$MRR = \frac{1}{M}\sum_{i=1}^{M}\frac{1}{rank(w_s, w_t)} \quad (1)$$

where $rank(w_s, w_t)$ denotes the rank of the correct translation w_t (as provided in the gold standard) in the ranked list of translation candidates for w_s, and M is the number of test cases. We also use *precision at N* (P@N) (Gaussier et al., 2004; Tamura et al., 2012; Vulić and Moens, 2013a), which measures the proportion of test instances where the correct translation is within the top N highest ranked translations.

4 Results

We evaluate the four similarity metrics on the BERGSMA500 dataset and compare the results to the systems of Bergsma and Van Durme, who report results for the AVGMAX function, having concluded that it performs better than MAXMAX on English-Spanish translations. We report their best-performing visual-only system, which combines SIFT-based descriptors with color histograms, as well as their best-performing overall system, which combines the visual approach with normalized edit distance (NED). Results are averaged over fifteen language pairs.

The results can be seen in Table 2. Each of the CNN-based methods outperforms the B&VD systems. The best performing method overall, CNN-AVGMAX, provides a 79% relative improvement over the B&VD visual-only system on the MRR measure, and a 23% relative improvement over their best-performing approach, which includes non-visual information in the form of orthographic similarity. Moreover, their methods include a tuning parameter λ that governs the contributions of SIFT-based, color histogram and normalized edit distance similarity scores, whilst our approach does not require any parameter tuning.

4.1 Similarity and Relatedness

The results in Table 2 indicate that the per-image CNN-AVGMAX metric outperforms the

Language Pair	Method	P@1	P@5	P@10	P@20	MRR
ES ⇒ EN	BOOTSTRAP	57.7	74.7	80.9	84.8	0.652

CNN-MEAN	**0.61**	0.32
CNN-MAX	0.60	0.27

Table 3: Spearman ρ_s correlation for the visual similarity metrics on a relatedness (MEN) and a genuine similarity (SimLex-999) dataset.

aggregated visual representation-based metrics of CNN-MEAN and CNN-MAX, despite the fact that Kiela and Bottou (2014) achieved optimal performance using the latter metrics on a well-known conceptual relatedness dataset. It has been noted before that there is a clear distinction between similarity and relatedness. This is one of the reasons that, for example, WordSim353 (Finkelstein et al., 2002) has been criticized: it gives high similarity scores to cases of genuine similarity as well as relatedness (Agirre et al., 2009; Hill et al., 2014). The MEN dataset (Bruni et al., 2014) that Kiela and Bottou (2014) evaluate on explicitly measures word relatedness. In contrast, the current lexicon learning task seems to require something else than relatedness: whilst a *chair* and *table* are semantically related, a translation for *chair* is not a good translation for *table*. For example, we want to make sure we translate *chair* to *stuhl* in German, and not to *tisch*. In other words, what we are interested in for this particular task is genuine similarity, rather than relatedness.

Thus, we can evaluate the quality of our similarity metrics by comparing their performance on similarity and relatedness tasks: if a metric performs well at measuring genuine similarity, this is indicative of its performance in the bilingual lexicon induction task. In order to examine this question further, we evaluate performance on the MEN dataset, which measures relatedness (Bruni et al., 2014), and the nouns-subset of the SimLex-999 dataset, which measures genuine similarity (Hill et al., 2014). For each pair in the dataset, we calculate the similarity score and report the Spearman ρ_s correlation, which measures how well the ranking of pairs given by the automatic system matches that according to the gold-standard human similarity scores. The results are reported in Table 3.

It is clear that the per-image similarity metrics perform better on genuine similarity, as measured by SimLex-999, than on relatedness, as measured by MEN. In fact, the "aggressive" CNN-MAXMAX method, which picks out a single pair of images to represent a linguistic pair, works best for SimLex-999, indicating how stringently it focuses on genuine similarity. For the aggregated visual representation-based metrics, we see the opposite effect: they perform better on the relatedness task. This sheds light on a question raised by Kiela and Bottou (2014), where they speculate

that certain errors are a result of whether their visual similarity metric measures genuine similarity on the one hand or relatedness on the other: we are better off using per-image visual metrics for genuine similarity, while aggregated visual representation-based metrics yield better performance on relatedness tasks.

4.2 Results on VULIC1000

This section compares our visual-only approach to linguistic approaches for bilingual lexicon induction. Since BERGSMA500 has not been evaluated with such methods, we evaluate on the VULIC1000 dataset (Vulić and Moens, 2013a). This dataset has been used to test the ability of bilingual lexicon induction models to learn translations from comparable data (see sect. 3.3). We do not necessarily expect visual methods to outperform linguistic ones, but it is instructive to see the comparison.

We compare our visual models against the current state-of-the-art lexicon induction model using comparable data (Vulić and Moens, 2013b). This model induces translations from comparable Wikipedia data in two steps: (1) It learns a set of highly reliable one-to-one translation pairs using a shared bilingual space obtained by applying the multilingual probabilistic topic modeling (MuPTM) framework (Mimno et al., 2009). (2) These highly reliable one-to-one translation pairs serve as dimensions of a word-based bilingual semantic space (Gaussier et al., 2004; Tamura et al., 2012). The model then bootstraps from the high-precision seed lexicon of translations and learns new dimensions of the bilingual space until convergence. This model, which we call BOOTSTRAP, obtains the current best results on the evaluation dataset. For more details about the bootstrapping model and its comparison against other approaches, we refer to Vulić and Moens (2013b).

Table 4 shows the results for the language pairs in the VULIC1000 dataset. Of the four similarity metrics, CNN-AVGMAX again performs best, as it did for BERGSMA500. The linguistic BOOTSTRAP method outperforms our visual approach for two of the three language pairs, but, for the NL-EN language pair, the visual methods in fact perform better. This can be explained by the observation that Vulić and Moens's NL-EN training data for the BOOTSTRAP model is less abundant (2-3 times fewer Wikipedia articles) and of lower quality than the data for their ES-EN and IT-EN models. We view these results as highly encouraging: while purely visual methods cannot yet reach the peak performance of linguistic approaches that are trained on sufficient amounts of high-quality text data, they outperform linguistic state-of-the-art methods when there is less or lower quality text data available —which one might reasonably expect to be the default scenario.

Method	**FC7**	**FC6+FC7**	**POOL5+ FC6+FC7**
MEN

Table 5: Spearman ρ_s correlation for the visual similarity metrics on a relatedness (MEN) and a genuine similarity (SimLex-999) dataset using more than one layer from the CNN.

4.3 Adding CNN Layers

The AlexNet (Krizhevsky et al., 2012) from which our image representations are extracted contains a number of layers. Kiela and Bottou (2014) only use the fully connected pre-softmax layer (which we call FC7) for their image representations. It has been found, however, that other layers in the network, especially the preceding fully connected (FC6) and fifth convolutional max pooling (POOL5) layers, also have good properties for usage in transfer learning (Girshick et al., 2014; Yosinski et al., 2014). Hence we performed a (very) preliminary investigation of whether performance increases with the use of additional layers.

In light of our findings concerning the difference between genuine similarity and relatedness, this also gives rise to the question of whether the additional layers might be useful for similarity or relatedness, or both. We hypothesize that the nature of the task matters here: if we are only concerned with genuine similarity, layer FC7 is likely to contain all the necessary information to judge whether two images are similar or not, since

Dataset	Language	Image dispersion
BERGSMA500	EN	0.640 (σ=0.074)
	ES	0.639 (σ=0.072)
	IT	0.646 (σ=0.071)
	FR	0.647 (σ=0.072)
	DE	0.642 (σ=0.072)
	NL	0.645 (σ=0.074)
VULIC1000	EN	0.705 (σ=0.095)
	ES	0.694 (σ=0.092)
	IT	0.725 (σ=0.078)
	NL	0.716 (σ=0.080)

Table 6: Average image dispersion for the datasets, by language.

the network has been trained for object recognition. If, however, we are interested in relatedness, related properties may just as well be encoded deeper in the network, so in the layers preceding FC7 rather than in FC7 itself.

We combined CNN layers with each other by concatenating the normalized layers. For the bilingual lexicon induction tasks, we found that performance did not signficantly increase, which is consistent with our hypothesis (since bilingual lexicon induction requires genuine similarity rather than relatedness, and so only requires FC7). We then tested on the MEN dataset (Bruni et al., 2014) for relatedness and the nouns subset of the SimLex-999 dataset (Hill et al., 2014) for genuine similarity. The results can be found in Table 5.

The results appear to indicate that adding such additional information does not have a clear effect for genuine similarity, but may lead to a small performance increase for relatedness. This could explain why we did not see increased performance on the bilingual lexicon induction task with additional layers. However, the increase in performance on the relatedness task is relatively minor, and further investigation is required into the utility of the additional layers for relatedness tasks.

5 Discussion

A possible explanation for the difference in performance between languages and datasets is that some words are more concrete than others: a visual representation for *elephant* is likely to be of higher quality than one for *happiness*. Visual representations in multi-modal models have been found to perform much better for concrete than abstract concepts (Kiela et al., 2014).

Although concreteness ratings are available for (some) English words, this is not the case for other languages, so in order to examine the concreteness of the datasets we use a substitute method that has been shown to closely mirror how abstract a concept is: image dispersion (Kiela et al., 2014). The image dispersion d of a concept word w is defined as the average pairwise cosine distance between all the image representations $\{i_1 \dots i_n\}$ in the set of images for a given word:

$$d(w) = \frac{2}{n(n-1)} \sum_{i<j\leq n} 1 - \frac{i_j \cdot i_k}{|i_j||i_k|} \quad (2)$$

The average image dispersions for the two datasets, broken down by language, are shown in Table 6. BERGSMA500 has a lower average image dispersion score in general, and thus is more concrete than VULIC1000. It also has less variance. This may explain why we score higher, in absolute terms, on that dataset than on the more abstract one.

When examining individual languages in the datasets, we note that the worst performing language on VULIC1000 is Italian, which is also the most abstract dataset, with the highest average image dispersion score and the lowest variance.

There is some evidence that abstract concepts are also perceptually grounded (Lakoff and Johnson, 1999), but in a more complex way, since abstract concepts express more varied situations (Barsalou and Wiemer-Hastings, 2005). Using an image resource like Google Images that has full coverage for almost any word, means that we can retrieve what we might call "associated" images (such as images of voters for words like *democracy*) as opposed to "extensional" images (such as images of cats for *cat*). This explains why we still obtain good performance on the more abstract VULIC1000 dataset, in some cases outperforming linguistic methods: even abstract concepts can have a clear visual representation, albeit of the associated rather than extensional kind.

However, abstract concepts are overall more likely to yield noisier image sets. Thus, one way to improve results would be to take a multi-modal approach, where we also include linguistic information, if available, especially for abstract concepts.

6 Conclusions and Future Work

We have presented a novel approach to bilingual lexicon induction that uses convolutional neural

network-derived visual features. Using only such visual features, we outperform existing visual and orthographic systems, and even a state-of-the-art linguistic approach for one language, on standard bilingual lexicon induction tasks. In doing so, we have shed new light on which visual similarity metric to use for similarity or relatedness tasks, and have experimented with using multiple layers from a CNN. The beauty of the current approach is that it is completely language agnostic and closely mirrors how humans would perform bilingual lexicon induction: by referring to the external world.

Abstract

Cross-Lingual Learning provides a mechanism to adapt NLP tools available for label rich languages to achieve similar tasks for label-scarce languages. An efficient cross-lingual tool significantly reduces the cost and effort required to manually annotate data. In this paper, we use the Recursive Autoencoder architecture to develop a Cross Lingual Sentiment Analysis (CLSA) tool using sentence aligned corpora between a pair of resource rich (English) and resource poor (Hindi) language. The system is based on the assumption that semantic similarity between different phrases also implies sentiment similarity in majority of sentences. The resulting system is then analyzed on a newly developed Movie Reviews Dataset in Hindi with labels given on a rating scale and compare performance of our system against existing systems. It is shown that our approach significantly outperforms state of the art systems for Sentiment Analysis, especially when labeled data is scarce.

1 Introduction

Sentiment Analysis is a NLP task that deals with extraction of opinion from a piece of text on a topic. This is used by a large number of advertising and media companies to get a sense of public opinion from their reviews. The ever increasing user generated content has always been motivation for sentiment analysis research, but majority of work has been done for English Language. However, in recent years, there has been emergence of increasing amount of text in Hindi on electronic sources but NLP Frameworks to process this data is sadly miniscule. A major cause for this is the lack of annotated datasets in Indian Languages.

One solution is to create cross lingual tools between a resource rich and resource poor language that exploit large amounts of unlabeled data and sentence aligned corpora that are widely available on web through bilingual newspapers, magazines, etc. Many different approaches have been identified to perform Cross Lingual Tasks but they depend on the presence of MT-System or Bilingual Dictionaries between the source and target language.

In this paper, we use Bilingually Constrained Recursive Auto-encoder (BRAE) given by (Zhang et al., 2014) to perform Cross Lingual sentiment analysis. Major Contributions of this paper are as follows: First, We develop a new Rating scale based Movie Review Dataset for Hindi. Second, a general framework to perform Cross Lingual Classification tasks is developed by modifying the architecture and training procedure for BRAE model. This model exploits the fact that phrases in two languages, that share same semantic meaning, can be used to learn language independent semantic vector representations. These embeddings can further be fine-tuned using labeled dataset in English to capture enough class information regarding Resource poor language. We train the resultant framework on English-Hindi Language pair and evaluate it against state of the art SA systems on existing and newly developed dataset.

2 Related Work

2.1 Sentiment Analysis in Hindi

In recent years, there have been emergence of works on Sentiment Analysis (both monolingual and cross-lingual) for Hindi. (Joshi et al., 2010) provided a comparative analysis of Unigram based In-language, MT based Cross Lingual and WordNet based Sentiment classifier, achieving highest accuracy of 78.14%. (Mittal et al., 2013) described a system based on Hindi SentiWordNet for assign-

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 159–168,
Lisbon, Portugal, 17-21 September 2015.

ing positive/negative polarity to movie reviews. In this approach, overall semantic orientation of the review document was determined by aggregating the polarity values of the words in the document assigned using the WordNet. They also included explicit rules for handling Negation and Discourse relations during preprocessing in their model to achieve better accuracies.

For Languages where labeled data is not present, approaches based on cross-lingual sentiment analysis are used. Usually, such methods need intermediary machine translation system (Wan et al., 2011; Brooke et al., 2009) or a bilingual dictionary (Ghorbel and Jacot, 2011; Lu et al., 2011) to bridge the language gap. Given the subtle and different ways in which sentiments can be expressed and the cultural diversity amongst different languages, an MT system has to be of a superior quality to perform well(Balamurali et al., 2012).

(Balamurali et al., 2012) present an alternative approach to Cross Lingual Sentiment Analysis (CLSA) using WordNet senses as features for supervised sentiment classification. A document in Resource Poor Language was tested for polarity through a classifier trained on sense marked and polarity labeled corpora in Resource rich language. The crux of the idea was to use the linked WordNets of two languages to bridge the language gap.

Recently, (Popat et al., 2013) describes a Cross Lingual Clustering based SA System. In this approach, features were generated using syntagmatic property based word clusters created from unlabeled monolingual corpora, thereby eliminating the need for Bilingual Dictionaries. These features were then used to train a linear SVM to predict positive or negative polarity on a tourism review dataset.

2.2 Autoencoders in NLP Tasks

Autoencoders are neural networks that learn a low dimensional vector representation of fixed-size inputs such as image segments or bag-of-word representations of documents. They can be used to efficiently learn feature encodings that are useful for classification. The Autoencoders were first applied in a recursive setting by Pollack (1990) in recursive auto-associative memories (RAAMs). However, RAAMs needed fixed recursive data structures to learn vector representations, whereas RAE given by (Socher et al., 2011) builds recursive data structure using a greedy algorithm. The RAE can be pre-trained with an unsupervised algorithm and then fine-tuned according to the label of the phrase, such as the syntactic category in parsing(Socher et al., 2013), the polarity in sentiment analysis, etc. The learned structures are not necessarily syntactically accurate but can capture more of the semantic information in the word vectors.

3 BRAE Framework

(Zhang et al., 2014) used the RAE along with a Bilingually Constrained Model to simultaneously learn phrase embeddings for two languages in semantic vector space. The core idea behind BRAE is that a phrase and its correct translation should share the same semantic meaning. Thus, they can supervise each other to learn their semantic phrase embeddings. Similarly, non-translation pairs should have different semantic meanings, and this information can also be used to guide learning semantic phrase embeddings. In this method, a standard recursive autoencoder (RAE) pre-trains the phrase embedding with an unsupervised algorithm by greedily minimizing the reconstruction error (Socher et al., 2011), while the bilingually-constrained model learns to finetune the phrase embedding by minimizing the semantic distance between translation equivalents and maximizing the semantic distance between non-translation pairs.

In this section, We will briefly present the structure and training algorithm for BRAE model. After that, we show how this model can be adapted to perform CLSA.

3.1 Recursive Auto-encoder Framework

In this model, each word w_k in the vocabulary V of given language corresponds to a vector $x_k \in \mathbb{R}^n$ and stacked into a single word embedding matrix $L \in \mathbb{R}^{n \times |V|}$. This matrix is learned using DNN (Collobert and Weston, 2008; Mikolov et al., 2013) and serves as input to further stages of RAE.

Using this matrix, a phrase $(w_1 w_2 \dots w_m)$ is first projected into a list of vectors $(x_1, x_2, \dots x_m)$. The RAE learns the vector representation of the phrase by combining two children vectors recursively in a bottom-up manner. For two children $c_1 = x_1, c_2 = x_2$, the auto-encoder computes the parent vector y_1:

$$y_1 = f(W^{(1)}[c_1; c_2] + b^{(1)}); y_1 \in \mathbb{R}^n \quad (1)$$

To assess how well the parent vector represents its children, the auto-encoder reconstructs the chil-

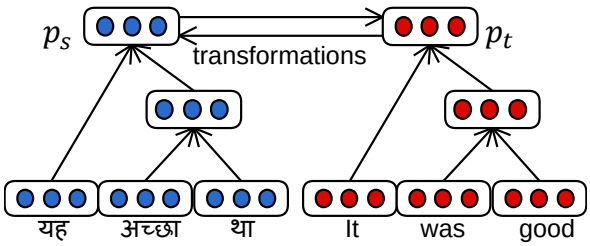

Figure 1: An illustration of BRAE structure

dren :

$$[c_1'; c_2'] = W^{(2)}p + b^{(2)} \quad (2)$$

and tries to minimize the reconstruction error (Euclidean Distance) $E_{rec}([c_1; c_2])$ between the inputs $[c_1; c_2]$ and their reconstructions $[c_1'; c_2']$.

Given y_1, Eq.1 is used again to compute y_2 by setting the children to be $[c_1; c_2] = [y_1; x_3]$. The same auto-encoder is re-used until the vector of the whole phrase is generated. For unsupervised phrase embedding, the sum of reconstruction errors at each node in binary tree y is minimized:

$$E_{rec}(x; \theta) = \arg\min_{y \in A(x)} \sum_{k \in y} E_{rec}([c_1; c_2]_k) \quad (3)$$

Where $A(x)$ denotes all the possible binary trees that can be built from inputs x. A greedy algorithm is used to generate the optimal binary tree y^*. The parameters $\theta^{rec} = (\theta^{(1)}, \theta^{(2)})$ are optimized over all the phrases in the training data. For further details, please refer (Socher et al., 2011)

3.2 Semantic Error

The BRAE model jointly learns two RAEs for source language L_S and target language L_T. Each RAE learn semantic vector representation p_s and p_t of phrases s and t respectively in translation-equivalent phrase pair (s, t) in bilingual corpora (shown in Fig.1). The transformation between the two is defined by:

$$p_t' = f(W_s^t p_s + b_s^t), p_s' = f(W_t^s p_t + b_t^s) \quad (4)$$

where $\theta_s^t = (W_s^t, b_s^t), \theta_t^s = (W_t^s, b_t^s)$ are new parameters introduced.

The semantic error between learned vector representations p_s and p_t is calculated as :

$$E_{sem}(s, t; \theta) = E_{sem}^*(t|s; \theta_t^s) + E_{sem}^*(s|t; \theta_s^t) \quad (5)$$

where $E_{sem}^*(s|t; \theta_t^s)$ is the semantic distance of p_s given p_t and vice versa. To calculate it, we first calculate Euclidean distance between original p_t and transformation p_t' as $D_{sem}(s|t, \theta_s^t) = \frac{1}{2}\|p_t - p_t'\|^2$. The max-semantic-margin distance between them is then defined as

$$E_{sem}^*(s|t, \theta_s^t) = max\{0, D_{sem}(s|t, \theta_s^t) - D_{sem}(s|t', \theta_s^t) + 1\} \quad (6)$$

where we simultaneously minimize the distance between translation pairs and maximized between non-translation pairs. Here t' in non-translation pair (s, t') is obtained by replacing the words in t with randomly chosen target language words. We calculate the $E_{sem}^*(t|s; \theta_t^s)$ in similar manner.

3.3 BRAE Objective Function

Thus, for the phrase pair (s, t), the joint error becomes:

$$\begin{aligned} E(s, t, \theta) &= E(s|t, \theta) + E(t|s, \theta) \\ E(s|t, \theta) &= \alpha E_{rec}(s; \theta_s^{rec}) + (1 - \alpha) E_{sem}^*(s|t, \theta_s^t)) \\ E(t|s, \theta) &= \alpha E_{rec}(t; \theta_t^{rec}) + (1 - \alpha) E_{sem}^*(t|s, \theta_t^s)) \end{aligned} \quad (7)$$

The hyper-parameter α weighs the reconstruction and semantic errors. The above equation indicates that the Parameter sets $\theta_t = (\theta_t^s, \theta_t^{rec})$ and $\theta_s = (\theta_s^t, \theta_s^{rec})$ on each side respectively can be optimized independently as long as the phrase representation of other side is given to compute semantic error.

The final BRAE objective over the phrase pairs training set (S, T) becomes:

$$J_{BRAE} = \frac{1}{N} \sum_{(s,t) \in (S,T)} E(s, t; \theta) + \frac{\lambda_{BRAE}}{2} \|\theta\|^2 \quad (8)$$

3.4 Unsupervised Training of BRAE

The word embedding matrices L_s and L_t are pre-trained using unlabeled monolingual data with Word2Vec toolkit (Mikolov et al., 2013). All other parameters are initialized randomly. We use SGD algorithm for parameter optimization. For full gradient calculations for each parameter set, please see (Zhang et al., 2014).

1. RAE Training Phase: Apply RAE Framework (Sec. 3.1) to pre-train the source and target phrase representations p_s and p_t respectively by optimizing θ_s^{rec} and θ_t^{rec} using unlabeled monolingual datasets.

2. Cross-Training Phase: Use target-side phrase representation p_t to update the source-side

parameters θ_s and obtain source-side phrase representation p'_s, and vice-versa for p_s. Calculate the joint error over the bilingual training corpus. On reaching a local minima or predefined no. of iterations (30 in our case), terminate this phase, otherwise set $p_s = p'_s$, $p_t = p'_t$, and repeat.

4 Adapting Model for Classifying Sentiments

At the end of previous Training procedure, we obtain high quality phrase embeddings in both source and target language and transformation function between them. We now extend that model to perform cross lingual supervised tasks, specifically CLSA.

To achieve this, we need to modify the learned semantic phrase embeddings such that they can capture information about sentiment. Since we only use monolingual labeled datasets from this point onwards, the supervised learning phases will occur independently for each RAE as we do not have any "phrase pairs" now. Thus, the new semantic vector space generated for word and phrase embeddings may no longer be in sync with their corresponding transformations.

We propose following modifications to the system to deal with this problem. Let L_S and L_T represent Resource rich and Resource poor language respectively in above model.

Modifications in architecture: We first include a softmax (σ) layer on top of each parent node in RAE for L_S to predict a K-dimensional multinomial distribution over the set of output classes defined by the task (e.g : polarity, Ratings).

$$d(p; \theta^{ce}) = \sigma(W^{ce} p) \tag{9}$$

Given this layer, we calculate cross entropy error $E_{ce}(p_k, t, W_{ce})$ generated for node p_k in binary tree, where t is target multinomial distribution or one-hot binary vector for target label. We use this layer to capture and predict actual sentiment information about the data in both L_S and L_T (described in next section). We show a node in modified architecture in Fig.2.

Penalty for Movement in Semantic Vector space: During subsequent training phases, we include the euclidean norm of the difference between the original and new phrase embeddings as penalty in reconstruction error at each node of the tree.

$$E^*_{rec}([c_1; c_2]; \theta) = E_{rec}([c_1; c_2]; \theta) + \frac{\lambda_p}{2} \|p - p^*\|^2 \tag{10}$$

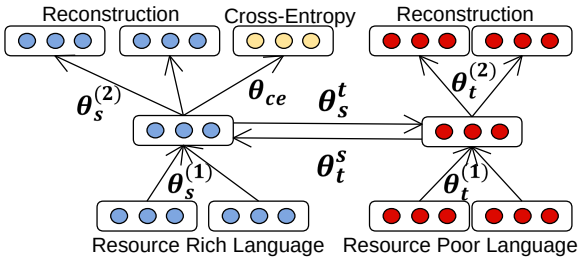

Figure 2: An illustration of BRAE segment with Cross Entropy layer

Here p is the phrase representation we get during forward propagation of current training iteration and p^* is the representation we get if we apply the parameters obtained at the end of the Cross training phase to children $[c_1; c_2]$ of that node. The reason to do this is twofold.

First, during supervised training, the error will back propagate through RAEs for both languages affecting their respective weights matrices and word embeddings. This will modify the semantic representation of phrases captured during previous phases of training procedure and adversely affect the transformations derived from them. Therefore we need to include some procedure such that the transformation information learned during Cross-training phase is not lost.

Secondly, we observe that the information about the semantic similarity of a word or phrase also implies sentiment similarity between the two. That is when dealing with bilingual data, words or phrases that appear near each other in semantic space typically represent common sentiment information and we want our model to create a decision boundary around these vectors instead of modifying them too much.

Disconnecting the RAEs: We fix the transformation weights between the two RAEs, i.e. in subsequent training steps the transformation weights(θ^t_s, θ^s_t) are not modified but rather pass the back propagated error as it is to previous layers. We observed that on optimizing the objective along with the penalty term, the transformation weights are preserved between new semantic/sentiment vector spaces, resulting in slightly degraded performance, but were still able to preserve enough information about the semantic structure of two languages.Also, it reinforced the penalty imposed on the movement of phrase embeddings in semantic vector space.On the other hand, if the weights were allowed to be updated,

the accuracies were affected severely as information learned during previous phases was lost and the weights were not been able to capture enough information about the modified phrase embeddings and generalize well on test phrases not encountered in labeled training set of Resource Scarce Language.

4.1 Supervised Training Phases

We now explain supervised training procedure using only monolingual labeled data for each language. These training phases occur at the end of BRAE training. In each training phase, we use SGD algorithm to perform parameter optimization.

4.1.1 Phase I : Resource Rich language

In this phase, we only modify the parameters of RAE_{L_S}, i.e. θ_s^{rec} and θ_{ce} by optimizing following objective over (sentence, label) pairs (x, t) in its labeled corpus.

$$J_S = \frac{1}{N} \sum_{(x,t)} E(x, t; \theta) + \frac{\lambda_S}{2} \|\theta\|^2 \qquad (11)$$

where $E(x, t; \theta)$ is the sum over the errors obtained at each node of the tree that is constructed by the greedy RAE:

$$E(x, t; \theta) = \sum_{k \in RAE_{L_S}(x)} \kappa E^*_{rec}([c_1; c_2]_k; \theta_s) + (1 - \kappa) E_{ce}(p_k, t; \theta_{ce}) \qquad (12)$$

To compute this gradient, we first greedily construct all trees and then derivatives for these trees are computed efficiently via back-propagation through structure (Goller and Kuchler, 1996). The gradient for our new reconstruction function (Eq. 10) w.r.t to p at a given node is calculated as

$$\frac{\partial E^*_{rec}}{\partial p} = \frac{\partial E_{rec}}{\partial p} + \lambda_p (p - p^*) \qquad (13)$$

The first term $\frac{\partial E_{rec}}{\partial p}$ is calculated as in standard RAE model. The partial derivative in above equation is used to compute parameter gradients in standard back-propagation algorithm.

4.1.2 Phase II : Resource Poor Language

In this phase, we modify the parameters of RAE_{L_T} and θ_{ce} by optimizing Objective J_T over (sentence, label) pairs (x, t) in labeled corpus for L_T (much smaller than that for L_S). The equation for J_T is similar to Eq.11 and Eq.12 but with θ_t and η as parameters instead of θ_s and κ respectively.

Since cross-entropy layer is only associated with L_S, we need to traverse the transformation parameters to obtain sentiment distribution for each node (green path in Fig.2). That is, we first transform p_t to source side phrase p'_s and then apply the cross entropy weights to it.

$$d(p_t, \theta_{ce}) = \sigma(W^{ce}.f(W^t_s p_t + b^t_s)) \qquad (14)$$

We use the similar back-propagation through structure approach for gradient calculation in Phase I. During back propagation, 1) we do not update the transformation weights, 2) we transfer error signals during back-propagation from Cross-entropy layer to $\theta^{(1)}_t$ as if the transformation was an additional layer in the network.

4.1.3 Predicting overall sentiment

To predict overall sentiment associated with the sentence in L_T, we use the phrase embeddings p_t of the top layer of the RAE_{L_T} and it transformation p'_s. Together, we train a softmax regression classifier on concatenation of these two vector using weight matrix $W \in \mathbb{R}^{K \times 2n}$

5 Experimental Work

We perform experiments on two kind of sentiment analysis systems : (1) that gives +ve/-ve polarity to each review and (2) assigns ratings in range 1 - 4 to each review.

5.1 External Datasets Used

For pre-training the word embeddings and RAE Training, we used HindMonoCorp 0.5(Bojar et al., 2014) with 44.49M sentences (787M Tokens) and English Gigaword Corpus.

For Cross Training, we used the bilingual sentence-aligned data from HindEnCorp[1] (Bojar et al., 2014) with 273.9k sentence pairs (3.76M English, 3.88M Hindi Tokens). This dataset contains sentence pair obtained from Bilingual New Articles, Wikipedia entries, Automated Translations, etc. Training and Validation division is 70% and 30% for all above datasets.

In Supervised Phase I, we used IMDB11 dataset available at *http://ai.stanford.edu/~amaas/data/sentiment/* and first used by (Maas et al., 2011) for +ve/-ve

[1] http://ufal.mff.cuni.cz/hindencorp

system containing 25000 +ve and 25000 -ve movie reviews.

For 4-ratings system, we use Rotten Tomatoes Review dataset (scale dataset v1.0) found at *http://www.cs.cornell.edu/People/pabo/movie-review-data*. The dataset is divided into four author-specific corpora, containing 1770, 902, 1307, and 1027 documents and each document has accompanying 4-Ratings ({0, 1, 2, 3}) label.

5.2 Rating Based Hindi Movie Review (RHMR) Dataset

We crawled the Hindi Movie Reviews Website[2] to obtain 2945 movie reviews. Each Movie Review on this site is assigned rating in range 1 to 4 by at least three reviewers. We first discard reviews that whose sum of pairwise difference of ratings is greater than two. The final rating for each review is calculated by taking the average of the ratings and rounding up to nearest integer. The fraction of Reviews obtained in ratings 1-4 are [0.20, 0.25, 0.35, 0.20] respectively. Average length of reviews is 84 words. For +ve/-ve polarity based system, we group the reviews with ratings {1, 2} as negative and {3, 4} as positive.

5.3 Experimental Settings

We used following Baselines for Sentiment Analysis in Hindi :

Majority class: Assign the most frequent class in the training set (Rating:3 / Polarity:+ve)

Bag-of-words: Softmax regression on Binary Bag-of-words

We also compare our system with state of the art Monolingual and Cross Lingual System for Sentiment Analysis in Hindi as described by (Popat et al., 2013) using the same experimental setup. The best systems in each category given by them are as below:

WordNet Based: Using Hindi-SentiWordNet[3], each word in a review was mapped to corresponding synset identifiers. These identifiers were used as features for creating sentiment classifiers based on Binary/Multiclass SVM trained on bag of words representation using libSVM library.

Cross Lingual (XL) Clustering Based: Here, joint clustering was performed on unlabeled bilingual corpora which maximizes the joint likelihood of monolingual and cross-lingual factors.. For details, please refer the work of (Popat et al., 2013). Each word in a review was then mapped to its cluster identifier and used as features in an SVM.

Our approaches

Basic RAE: We use the Semi-Supervised RAE based classification where we first trained a standard RAE using Hindi monolingual corpora, then applied supervised training procedure as described in (Socher et al., 2011). This approach doesn't use bilingual corpora, but is dependent on amount of labeled data in Hindi.

BRAE-U: We neither include penalty term, nor fix the transformations weights in our proposed system.

BRAE-P: We only include the penalty term but allow the transformation weights to be modified in proposed system.

BRAE-F: We add the penalty term and fix the transformation weights during back propagation in proposed system.

5.4 Experimental Setup

We combined the text data from all English Datasets (English Gigaword + HindEnCorp English Portion + IBMD11 + Scale Dataset) described above to train the word embeddings using Word2Vec toolkit and RAE. Similarly, we combined text data from all Hindi Datasets (HindMonoCorp + HindiEnCorp Hindi Portion + RHMR) to train word embeddings and RAE for Hindi.

We used MOSES Toolkit (Koehn et al., 2007) to obtain high quality bilingual phrase pairs from HindEnCorp to train our BRAE model. After removing the duplicates, 364.3k bilingual phrase pairs were obtained with lengths ranging from 1-6, since bigger phrases reduced the performance of the system in terms of Joint Error of BRAE model.

We randomly split our RHMR dataset into 10 segments and report the average of 10-fold cross validation accuracies for each setting for both Ratings and Polarity classifiers.

We also report 5-fold cross validation accuracy on Standard Movie Reviews Dataset (hereby referred as SMRD) given by (Joshi et al., 2010) which contains 125 +ve and 125 -ve reviews in Hindi. The dataset can be obtained at http://www.cfilt.iitb.ac.in/Resources.html.

Since this project is about reducing dependence on annotated datasets, we experiment on how accuracy varies with labeled training dataset (RHMR) size. To perform this, we train our model

[2]http://hindi.webdunia.com/bollywood-movie-review/

[3]http://www.cfilt.iitb.ac.in/

in 10% increments (150 examples) of training set size (each class sampled in proportion of original set). For each size, we sample the data 10 times with replacement and trained the model. For each sample, we calculated 10-fold cross validation accuracy as described above. Final accuracy for each size was calculated by averaging the accuracies obtained on all 10 samples. Similar kind of evaluation is done for all other Baselines explored.

In subsequent section, the word 'significant' implies that the results were statistically significant ($p < 0.05$) with paired T-test

5.5 BRAE Hyper Parameters

We empirically set the learning rate as 0.05. The word vector dimension was selected as 80 from set $[40, 60, 80, 100, 120]$ using Cross Validation. We used joint error of BRAE model to select α as 0.2 from range $[0.05, 0.5]$ in steps of 0.05. Also, λ_L was set as 0.001 for DNN trained for word embedding and λ_{BRAE} as 0.0001.

For semi-supervised phases , we used 5-fold cross validation on training set to select κ and η in range $[0.0, 1.0]$ in steps of 0.05 with optimal value obtained at $\kappa = 0.2$ and $\eta = 0.35$. Parameter λ_p was selected as 0.01 , λ_S as 0.1 and λ_T as 0.04 after selection in range $[0.0, 1.0]$ in steps of 0.01.

5.6 Results

Dataset	RHMR		SMRD
Classifier	**Ratings**	**Polarity**	**Polarity**
Majority class	35.19	51.83	52.34
Bag-of-Words	51.98	62.52	68.47
WordNet based	55.47	67.29	75.5
XL Clustering	72.34	84.46	84.71
Basic RAE	75.53	79.31	81.06
BRAE-U	76.01	82.66	84.83
BRAE-P	79.70	84.85	87.00
BRAE-F	81.22	90.50	90.21

Table 1: Accuracies obtained for various Experimental Settings. Model are trained on complete labeled training datasets

Table 1 present the results obtained for both ratings based and polarity classifier on RHMR and MRD Dataset. Our model gives significantly better performance for ratings based classification than any other baseline system currently used for SA in Hindi. The margin of accuracy obtained against next best classifier is about 8%. Also, for +ve/-ve polarity classifier, the accuracy showed an improvement of 6% over next highest baseline.

$A \downarrow / P \rightarrow$	P-1	P-2	P-3	P-4
A-1	83.19	15.28	1.53	0.00
A-2	12.23	82.20	5.57	0.00
A-3	0.00	9.03	81.26	9.71
A-4	0.00	1.87	19.69	78.44
F1-score	0.83	0.78	0.82	0.80

Table 2: Confusion Matrix for Ratings by BRAE-F, **Across**: Predicted Rating, **Downward:** Actual Rating

In Table 2, we calculate the confusion matrix for our model(BRAE-F) for the 4-Ratings case. Value in a cell (A_i, P_j) represents the percentage of examples in actual rating class i that are predicted as rating j. We also show the F1 score calculated for each individual rating class. It clearly shows that our model has low variation in F1-scores and thereby its performance among various rating classes.

In Fig. 3, we show the variation in accuracy of the classifiers with amount of sentiment labeled Training data used. We note that our approach consistently outperforms the explored baselines at all dataset sizes. Also, our model was able to attain accuracy comparable to other baselines at about 50% less labeled data showing its strength in exploiting the unlabeled resources.

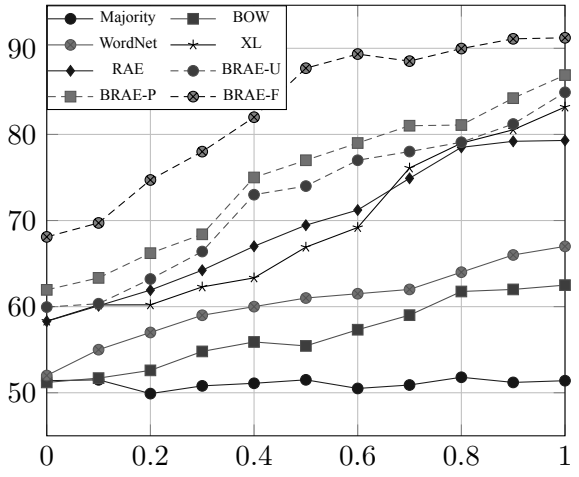

Figure 3: Variation of Accuracy (+ve/-ve Polarity) with Size of labeled Dataset(Hindi), **x-axis:** Fraction of Dataset Used, **y-axis:** %age Accuracy Obtained

We also experiment with variation of accuracies

New Word/Phrase	Similar Words/Phrases	Sentiment label
depressing निराशाजनक	gloomy उदास discouraging निराशात्मक	Rating : 1 Polarity : -ve
was painful दर्दनाक था	was difficult कठिन था was bad खराब था	Rating : 2 Polarity : -ve
should be awarded सम्मानित किया जाना चाहिए	was appreciated सराहना की गई will get accolades वाहवाही मिलना चाहिए	Rating : 4 Polarity : +ve
public won't come लोग नहीं आएगा	no one will come कोई नहीं आएगा viewers won't come दर्शक नहीं आएगा	Rating : 1 Polarity : -ve

Table 3: Semantically similar phrases obtained for new phrases and their assigned label

with amount of Unlabeled Bilingual Training Data used for Cross Lingual models explored. Again we increase size of bilingual dataset in 10% increments and calculate the accuracy as described previously. In Fig. 4, we observed that performance of the proposed approach steadily increases with amount of data added, yet even at about 50000 (20%) phrase pairs, our model produces remarkable gains in accuracy.

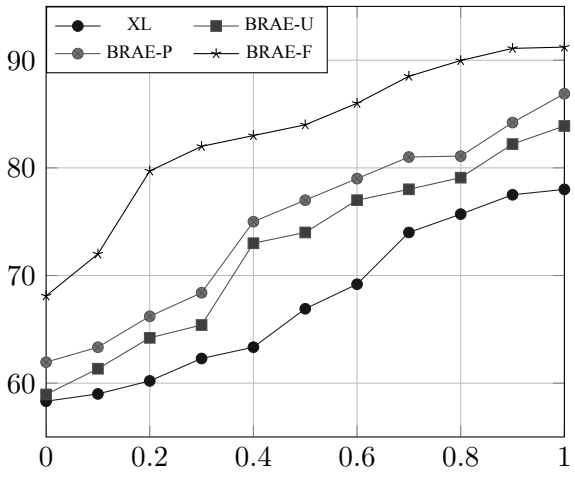

Figure 4: Variation of Accuracy (+ve/-ve polarity) with Size of Unlabeled Bilingual Corpora, **x-axis:** Fraction of Training Data Used, **y-axis:** %age Accuracy Obtained

We also observed that the model which restricts modification to transformation weights during supervised phase II does better than the one which allows the modification at all dataset sizes. This result appears to be counterintuitive to normal operation of neural network based models, but supports our hypothesis as explained in previous sections.

5.7 Performance and Error Analysis

Analysis on the test results showed that the major advantage given by our model occurs due to presence of unknown words (i.e.words not present in labeled dataset) in test data. Since we restricted the movement in semantic vector space, our model was able to infer the sentiment for a unknown word/phrase by comparing it with semantically similar words/phrases. In Table 3, we extracted the Top-2 semantically similar phrases in training set for small new phrases and sentiment labeled assigned to them by our model (the phrases are manually translated from Hindi for reader's understanding). As we can see, our model was able to extract grammatically correct phrases with similar semantic nature as given phrase and assign correct sentiment label to it.

Secondly, We found that our model was able to correctly infer word sense for polysemous words that adversely affected the quality of sentiment classifiers in our baselines. This eliminates the need for manually constructed fine grained lexical resource like WordNets and development of automated annotation resources. For example, to a phrase like *"Her acting of a schizophrenic mother made our hearts **weep"***, the baselines classifiers assigned negative polarity due to presence of words like 'weep', yet our model was correctly able to predict positive polarity and assigned it a rating of 3.

Error Analysis of test results showed that errors made by our model can be classified in two major categories :

1) A review may only give description of the object in question (in our case , the description of the film) without actually presenting any individual sentiments about it or it may express conflicting sentiments about two different aspects about the same object. This presents difficulty in assign-

ing a single polarity/rating to the review.

2) Presence of subtle contextual references affected the quality of predictions made by our classifier. For example, sentence like *"His poor acting generally destroys a movie, but this time it didn't"* got a rating of 2 due to presence of phrase with negative sense (here the phrase doesn't have ambiguous sense), yet the actual sentiment expressed is positive due to temporal dependence and generalization. Also, *"This movie made his last one looked good"* makes a reference to entities external to the review, which again forces our model to make wrong prediction of rating 3.

Analyzing these aspects and making correct predictions on such examples needs further work.

6 Conclusion and Future Work

This study focused on developing a Cross Lingual Supervised Classifier based on Bilingually Constrained Recursive Autoencoder. To achieve this, our model first learns phrase embeddings for two languages using Standard RAE, then fine tune these embeddings using Cross Training procedure. After imposing certain restrictions on these embeddings, we perform supervised training using labeled sentiment corpora in English and a much smaller one in Hindi to get the final classifier.

The experimental work showed that our model was remarkably effective for classification of Movie Reviews in Hindi on a rating scale and predicting polarity using least amount of data to achieve same accuracy as other systems explored. Moreover it reduces the need for MT System or lexical resources like Linked WordNets since the performance is not degraded too much even when we lack large quantity of labeled data.

In Future, we hope to 1) extend this system to learn phrase representations among multiple languages simultaneously, 2) apply this framework to other cross Lingual Tasks such as Paraphrase detection, Question Answering, Aspect Based Opinion Mining etc and 3) Learning different weight matrices at different nodes to capture complex relations between words and phrases.

Abstract

Opinion summarization is the task of producing the summary of a text, such that the summary also preserves the sentiment of the text. Opinion Summarization is thus a trade-off between summarization and sentiment analysis. The demand of compression may drop sentiment bearing sentences, and the demand of sentiment detection may bring in redundant sentences. We harness the power of submodularity to strike a balance between two conflicting requirements. We investigate an incipient class of submodular functions for the problem, and a partial enumeration based greedy algorithm that has performance guarantee of 63%. Our functions generate summaries such that there is good correlation between document sentiment and summary sentiment along with good ROUGE score, which outperforms the-state-of-the-art algorithms.

1 Introduction

Sentiment Analysis is often addressed as a classification task, which aims at determining the sentiment of a word, sentence, paragraph or a document as a whole into positive, negative or neutral classes (Pang et al., 2002). Summarization, on the other hand is the task of aggregating and representing information content from a single document or multiple documents in a brief and fluent manner. Due to the explosive growth of data, fine grained sentiment analysis as well as summarization on the whole chunk of data can be a very time-consuming task. Sentiment Analysis also requires filtering of text portions as either objective (factual information) or subjective (expressing some sentiment or opinion) during pre-processing and then, classifying the subjective extracts as positive or negative. Subjective extracts can also be provided to users as a summary of the sentiment-oriented content of the reviews in search engines. In this paper, we address the problem of generic extractive summarization of reviews, a task commonly known as Opinion Summarization (Liu, 2012). The goals of opinion summarization are:

1. Present a short summary that conveys the essence as well as the sentiment of the review
2. Provide a short subjective extract to NLP pipeline for faster execution (*e.g.* sentiment analysis, review clustering *etc.*).

In this paper, we use movie reviews for opinion summarization task as they often have the following parts:

1. Plot - Description of the story, which is factual in nature
2. Critique - Opinion about the movie, which is sentiment bearing

Clearly, opinion summary to be generated will have a trade-off between the two opposing parts - subjective critique and objective plot. Our goal is to strike a balance through linear combination of suitable submodular functions in our paper. Joint models of relevance and subjectivity have a great benefit in that they have a large degree of freedom as far as controlling redundancy goes. In contrast, conventional two-stage approach Pang and Lee (2004), which first generate candidate subjective sentences using min-cut and then selects top subjective sentences within budget to generate a summary, have less computational complexity than joint models. However, two-stage approaches are suboptimal for text summarization. For example, when we select subjective sentences first, the sentiment as well information content may become redundant for a particular aspect. On the

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 169–178,
Lisbon, Portugal, 17-21 September 2015.

other hand, when we extract sentences first, an important subjective sentence may fail to be selected, simply because it is long. The two stage conflict in the sense that the demand of compression may drop sentiment bearing sentences, and the demand of sentiment detection may bring in redundant sentences. We then, use partial enumeration based greedy algorithm (Khuller et al., 1999), which gives performance guarantee of $(1 - e^{-1}) \approx 0.632$ (Sviridenko, 2004). The performance guarantee reported is better than simple greedy algorithm, used by Lin and Bilmes (2010) as their proof is erroneous (Morita et al., 2013). Further, the same greedy algorithm, which was used again in Lin and Bilmes (2011) gives only performance guarantee of $\frac{1}{2}(1 - e^{1}) \approx 0.316$ (Khuller et al., 1999).

The rest of the paper is as follows - in the next section, we look at previous work and establish further motivation for our work. Following that, we build the theory and formulate suitable objectives for opinion summarization task. In the final section, we present results based on implementation and testing of the functions. Experimental results show that the functions outperform the-state-of-the-art methods.

2 Previous Work

Automatically generating opinion summaries from large review text corpora has long been studied in both information retrieval and natural language processing.

In (Pang and Lee, 2004), a mincut-based algorithm was proposed to classify each sentence as being subjective or objective. The purpose of this work was to remove objective sentences from reviews to improve document level sentiment classification. Interestingly, the cut functions are symmetrical and submodular, and the problem of finding min-cut is equivalent to minimizing a symmetric submodular function.

Lerman et al. (2009) proposed three different models - sentiment match (SM), sentiment match + aspect coverage (SMAC) and sentiment-aspect match (SAM) to perform summarization of reviews of a product. The first model is called sentiment match (SM), which extracts sentences so that the average sentiment of the summary is as close as possible to the average sentiment rating of reviews of the entity *i.e.* low MISMATCH but with high sentiment INTENSITY. The second model, called sentiment match + aspect coverage (SMAC), builds a summary that trades-off between DIVERSITY, maximally covering important aspects and MISMATCH, matching the overall sentiment of the entity along with high INTENSITY. The third model, called sentiment-aspect match (SAM), not only attempts to cover important aspects, but cover them with appropriate sentiment using KL-Divergence function. Here, INTENSITY and DIVERSITY in the first two models are linear monotone submodular functions, while KL-Divergence function *i.e.* relative entropy in last model, unlike entropy is not monotone submodular.

In (Nishikawa et al., 2010b), a more sophisticated summarization technique was proposed, which generates a traditional text summary by selecting and ordering sentences taken from multiple reviews, considering both informativeness and readability of the final summary. The readability score in this paper would have been linear monotone submodular function, if the negative polarity was not penalizing. In (Nishikawa et al., 2010a), the authors further studied this problem using an integer linear programming formulation.

On the other hand, Lin et al .(2011) treated the task of generic summarization as monotone submodular function maximization. Further, they argued that monotone non-decreasing submodular functions are an ideal class of functions to investigate for document summarization. They also show, in fact, that many well-established methods for summarization (Carbonell and Goldstein, 1998; Filatova, 2004; Riedhammer et al., 2010) correspond to submodular function optimization, a property not explicitly mentioned in these publications. Since many authors either in summarization or opinion summarization have used functions similar to submodular functions as objective, we can take this fact as testament to the value of submodular functions for opinion summarization.

3 Theoretical Background

3.1 Introduction to Submodular Functions

A submodular function is a set function ($f : 2^V \rightarrow R$) having a natural diminishing returns property. Diminishing returns property holds if the difference in the value of the function that a single element makes when added to an input set decreases as the size of the input set increases *i.e.* for every $A, B \subseteq V$ with $A \subseteq B$ and every $x \in V \backslash B$, we have that $f(A \cup \{x\}) - f(A) \geq f(B \cup \{x\}) - f(B)$.

A submodular function f is monotone if for every $A \subseteq B$, we have that $f(A) \leq f(B)$.

The extractive summarization task can be modeled as optimization problem *i.e.* finding a set $S \subseteq V$ (S is set of sentences in summary, V is set of sentences in Document) which maximizes a submodular function $f(S)$ subject to budget constraints. In the following section, we will justify the use of submodular function for opinion summarization. Another advantage of choosing monotone submodular function is that there exists a polynomial-time greedy algorithm for constrained monotone submodular objective. The greedy algorithm guarantees that the summary solution obtained is almost as good as (63%) the best possible summary solution according to the objective (Sviridenko, 2004; Wolsey, 1982).

3.2 Submodularity in Opinion Summarization

Opinion Summarization should be modeled as a monotone submodular optimization problem, since opinion summary also holds following properties:

1. Monotonicity - As more sentences are added to opinion summary, subjectivity increases along with information content as opinionated words are being added.

2. Diminishing Return - If multiple sentences of varying intensity are added to opinion summary, the effect of a lower intensity polarity bearing sentence is diluted in the presence of a higher intensity one.

To show that opinion summarization inherently follow the diminishing return property, consider the following sentences[1] with positive polarity:
A: "*Even the acting in From Hell is solid, with the dreamy Depp turning in a typically strong performance and deftly handling a British accent.*"
B: "*Worth mentioning are the supporting roles by Ians Holm and Richardsonlog.*"
(A ∪ B) : "*Even the acting in From Hell is solid, with the dreamy Depp turning in a typically strong performance and deftly handling a British accent. Worth mentioning are the supporting roles by Ians Holm and Richardsonlog.*" Compare A and its superset, A ∪ B as candidate summaries. Sentence A and B convey positive sentiment, but sentence B has less intensity compared to sentence A. After reading the text (A ∪ B), it is clear that the effect of sentence B has diminished in front of sentence A, though both are of same polarity. B can be thus, removed from the candidate summary as it does a diminishing addition in presence of sentence A to the positive sentiment over the "acting" aspect of the entity "movie". The diminishing return not only holds for same polarity but also, for opposite polarity. Consider another example[2]:
A: "*The movie is predictive with foreseeable ending.*"
B: "*Still it's very well-done that no movie in this entire year has a scene that evokes pure joy as this does.*"
(A ∪ B) : "*The movie is predictive with foreseeable ending. Still it's very well-done that no movie in this entire year has a scene that evokes pure joy as this does.*" Compare B and its superset, A ∪ B as candidate summaries. Sentence A has negative sentiment whereas sentence B conveys positive sentiment with more intensity. When we read the text (A ∪ B), it is clear that the effect of sentence A has diminished in front of sentence B in text , as usually polarity of higher intensity dominates over the polarity of lower intensity. Now, consider a general example[3],
"*Laurence plays Neo's mentor Morpheus and he does an excellent job of it. His lines flow with confidence and style that makes his acting unique and interesting. The movie has lot of special effects and action-packed scenes with part of the appeal has philosophical and religious underpinnings.*"

If the budget for summary had been only two subjective sentences, then picking up first two would have redundantly captured only single aspect (*i.e.* acting) and the redundancy of the concept (acting) also causes a diminishing return of the second sentence because of the difference in sentiment intensity. However, picking the last sentence with either one of the first two would have not just covered both the aspects (*i.e.* acting and visual effects) but since, the sentences are not overlapping in aspects, there would not have been any diminishing return of sentiment on shared aspect (acting). Thus, it can be verified that opinion polarity also holds submodular property of diminishing return, if they are on the same aspect of a distinct entity.

4 Formulation

Let V represent the set of the sentences in a document. The task of extractive opinion summarization is to select a subset $S \in V$ to represent the entirety (ground set V) . Obviously, we should have $|S| \leq |V|$ as it is a summary and should be small. Therefore, constraints on S can naturally be modeled as knapsack constraints:

$$\sum_{i \in S} c_i \leq b \tag{1}$$

where c_i is the non-negative cost of selecting unit i (*e.g.*, the number of words in the sentence) and b is our budget. If we use a set function $F : 2^V \rightarrow R$ to measure the quality of the summary set S, the summarization problem can then be formalized as the following combinatorial optimization problem:

$$S^* \in argmax_{S \subset V} F(S) \textit{ s.t. } \sum_{i \in S} c_i \leq b \tag{2}$$

where F (S) , total utility of summary is given as a linear combination of L(S), relevance and A(S), subjective coverage of aspects.

$$F(S) = \alpha L(S) + \beta A(S) \tag{3}$$

This formulation clearly brings out the trade-off between the subjective and the objective part. The intuition behind the combination of sentiment and aspect coverage in same function A(S) is that opinion polarity holds submodular property of diminishing return only if the set of sentences talk about common aspect of the same entity as discussed in previous section. L(S) , relevance is modeled same as in (Lin and Bilmes, 2011) as it captures the summary property, while our novel function, A(S) has been modeled differently through a suitable submodular function such that it captures the subjectivity property.

$$L(S) = \sum_{i \in V} min\{c_i(S), \gamma c_i(V)\} \tag{4}$$

$$c_i(S) = \sum_{j \in S} w_{i,j} \tag{5}$$

Here, $w_{i,j} > 0$ measures the similarity between i^{th} and j^{th} sentences and $c_i(S)$ measures the similarity of summary with the document.

Since, A(S), subjective coverage of aspects has to be modeled as monotone submodular function, it has been formulated as :

1. A_1 : **Modular Function**

   A_1(S) is simple linear function, which is sum of weighted subjective scores for each sentence. No budgeting constraints are added to this formulation.

   $$A_1(S) = \sum_i \sum_{j \in (P_i \cap S)} s_j * w_i \tag{6}$$

   Here $P_i; i = 1...K$ is a partition of the ground set V (*i.e.*, $\cup_i P_i = V$), which contains sentences pertaining to different distinct aspects. w_i are the weights of the partitions, based on the corresponding aspects. s_j is the subjective score of the sentence j in summary. The subjective score s_j is calculated using sentiwordnet as sum of the positive score $\in [0, 1]$ and negative score $\in [0, 1]$ (Esuli and Sebastiani, 2006).

   $$s_j = \sum_{word \in j} (pos(word) + neg(word)) \tag{7}$$

2. A_2 : **Budget-additive Function**

   $A_2(S)$ is an extension to $A_1(S)$, where maximum subjectivity score is restricted with budget based on aspect. Here, $\lambda \in [0, 1]$ is threshold coefficient for budget additive function to avoid redundancy of high sentiment on same aspect. When aspect i is saturated by S ($min(\sum_{j \in (P_i \cap S)} s_j, \lambda) = \lambda$), any new sentence j cannot further improve coverage over i and thus, other aspects, which are not yet saturated will have a better chance of being covered. This formulation ensures that produced summary is diverse enough and conveys sentiment about different aspects by budgeting.

   $$A_2(S) = \sum_i min(\sum_{j \in (P_i \cap S)} s_j, \lambda_i) * w_i \tag{8}$$

3. A_3 : **Polarity Partitioned Budget-additive Function**

   In previous formulation we have not considered the polarity of the sentences. For example, if an aspect have many positive sentences with more intensity but few negative

sentences with less intensity, A_2 more likely to reward more positive sentences because of intensity. In this formulation budgeting applied not only on aspect but polarity scores too. This ensures that both positive and negative polarity sentences are part of summary.

$$A_3(S) = \sum_i min(\sum_{j \in (P_i \cap S \cap P_{pos})} s_j, \lambda_i) * w_i + min(\sum_{j \in (P_i \cap S \cap P_{neg})} s_j, \lambda_i) * w_i \quad (9)$$

P_{pos} and P_{neg} are the partition of the sentences in the ground set V, based on their sign of polarity score. The polarity score pol_j for partitioning sentences into P_{pos} and P_{neg} is calculated as difference of the positive and negative score.

$$pol_j = \sum_{word \in j} (pos(word) - neg(word)) \quad (10)$$

Polarity based partitions bring out contrast view on a particular aspect, which is similar to contrast view opinion summarization to give the reader a direct comparative view of different strong opinions.

4. A_4 : **Facility Location Function**

   In this formulation, we model the facility location objective function (Krause and Golovin, 2014) for opinion summarization as choosing possible sentences (facilities) out of document (set of locations) to serve aspects (customers) giving service of value s_j. If each aspect (customer) chooses the sentences (facility) with the highest value, the total value provided to all aspects (customers) is modeled by this set function.

$$A_4(S) = \sum_i max_{j \in (P_i \cap S)} s_j * w_i \quad (11)$$

So A_4 rewards only a sentence which has maximum subjectivity score in each aspect.

5. A_5 : **Polarity Partitioned Facility Location Function**

   A_5 is similar to A_4, but for each aspect, A_5 rewards two sentences with positive and negative polarity but with maximum subjectivity scores in those polarity partitions.

$$A_5(S) = \sum_i max_{j \in (P_i \cap S \cap P_{pos})} s_j * w_i + \sum_i max_{j \in (P_i \cap S \cap P_{neg})} s_j * w_i \quad (12)$$

Each of the above functions are monotone submodular as the parameters s_j and w_i are positive. Since the first function is linear, it is both submodular and supermodular, thus modular. Budget additive and facility location functions (Krause and Golovin, 2014) are special types of monotone submodular functions. Since, monotone submodularity is preserved under non-negative linear combinations, polarity based partitioned function, whose sub-parts are monotone submodular is also monotone submodular.

5 Experiment

We have created Movie ontology tree manually (figure 1). Further the ontology is enriched by adding clue words to all aspects using wordnet sense propagation algorithm (Esuli and Sebastiani, 2006) for three iterations. The algorithm does a hard clustering of the sentences by assigning the sentence aspect, which has maximum number of clue words in that sentence. Clue words for 'Plot' aspect are *story, script, storyline, chief, communicative, explain, narrate, narration, narrative, narrator, report, reporter, scheme, schemer, script, scriptural, storyteller, tell, write up..,*.

For the experiments, we have used the polarity dataset from Pang et al. (2004). The dataset contains 1000 positive and 1000 negative movie reviews with size varying between 700 to 1000 words. As summary generation is time consuming task (DUC[4] only used 25 summaries to evaluate the performance of systems), we picked 100 positive and 100 negative reviews randomly from the dataset and their abstract summaries are generated manually with 200 words limit as budget for

[4]Document Understanding Conferences, http://duc.nist.gov

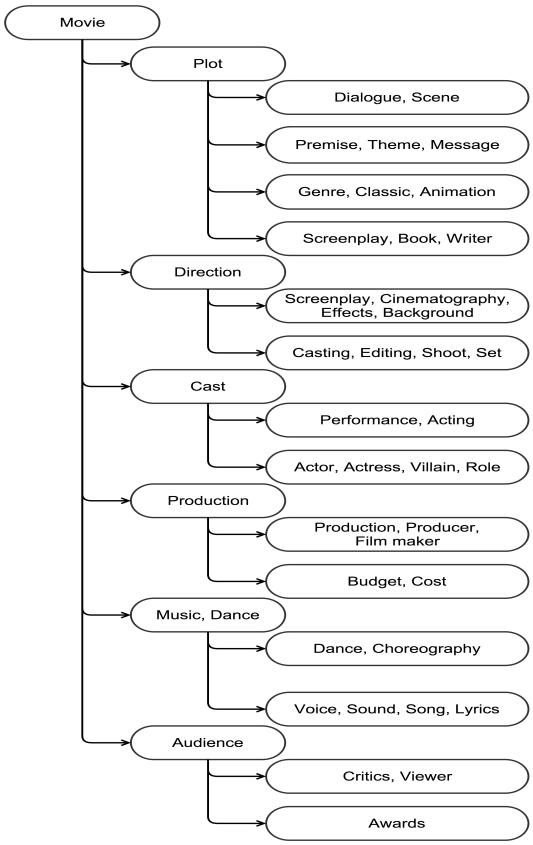

Figure 1: Movie Ontology Tree

evaluation. These 200 summaries are used as gold standard for estimating ROUGE scores of system generated summaries.

In the experiment, the partial enumeration based greedy algorithm (Khuller et al., 1999) is used for summary generation of 200 test documents within budget of 200 words. The algorithm has two parts. In the first part, the algorithm compares function values of all feasible solutions (sets) of cardinality one or two. Let $Summ_1$ be a feasible set of cardinality one or two that has the largest value of the objective function $F(S)$. In the second part, the algorithm enumerates all feasible sets of cardinality three. The algorithm, then completes each such set greedily and keeps the current solution feasible with respect to the knapsack constraint. Let $Summ_2$ be the solution obtained in the second part that has the largest value of objective function over all choices of the starting set for the greedy algorithm. Finally, the algorithm outputs $Summ_1$ if $F(Summ_1) > F(Summ_2)$ else $Summ_2$ otherwise. The algorithm does O(n^2) function calculations in first part, while O(n^5) in second part. This algorithm gives a performance guarantee of $(1-e^{-1})$ for solving monotone submodular objective with knapsack constraint (Khuller et al., 1999; Sviridenko, 2004). As far as we know, the algorithm has not been implemented for such problems because of complexity constraints (Lin and Bilmes, 2011).

In the algorithm, the sentences are clustered in different partitions, corresponding to different aspects in the ontology tree using the clue words. In the experiment, hard clustering of the sentences in aspect-based partitions is considered but soft-clustering of the sentences will also work with this approach, which has been left out to avoid further parameter tuning for soft clustering assigments. The weights of the partitions as well as the threshold parameters for the A(S) are currently kept proportional to the inverse of the depth of that aspect in the ontology-tree as sentiment expressed on the concepts at higher level in the ontology tree should have more weightage.

$\forall$ Aspects i,

$$w_i = \lambda_i = \frac{1}{Level(i)}$$

The linear combination parameter β is set as $1-\alpha$ to bring out the trade-off between relevance and subjective coverage of aspects and α is varied from 0 to 1 with step size 0.05 to find optimal α. γ in L(S) is set to 0.5. The parameter learning, esp. α and its impact have been already studied in (Lin and Bilmes, 2011) and thus, is not addressed in the paper. We have used the same approach of grid search to find the optimal value of α.

6 Results

We use ROUGE (Lin, 2004) for evaluating the content of summaries. We have used the 200 test documents that are manually summarized as gold standard data for ROUGE evaluation. For figuring out the sentiment correlation between manual and system generated summaries, we trained Naive Bayes sentiment classifier (Pang et al., 2002) on training data using bag of words approach with features as unigrams and bigrams and then, using minimum Pearson's chi-square score of 3 for feature extraction (Pecina and Schlesinger, 2006) before calculating the sentiment. The measure of sentiment preservation is calculated as Pearson correlation between the sentiment score of the document and the corresponding summary sentiment, both calculated by the Naive Bayes sentiment classifier while the measure of coverage of information content is given by ROUGE-1 and ROUGE-2 f-scores. Mathematically,

$$Correlation(X,Y) = \frac{Covariance(X,Y)}{std.dev(X) * std.dev(Y)} \quad (13)$$

Here, random variable X is the sentiment score of the document sample and random variable Y is the sentiment score of the corresponding summary sample. For 200 documents, it will be $[(X_1,Y_1),(X_2,Y_2),...,(X_{200},Y_{200})]$ sample points for the above correlation function.

Following five baselines are used for comparison:

1. **Baseline-1/TOP** : Sentences selected consecutively from the start of the review within the budget.

2. **Baseline-2/TOP-SUBJ** : Sentences ranked based on their subjectivity and then, selected with in the budget.

3. **Baseline-3/LER-SM** : (Lerman et al., 2009) Sentences which have sentiment close to document sentiment are chosen as Summary. We have used same NaiveBayes classifier (Pang et al., 2002) trained on imdb corpus to predict the sentiment of a sentence and document.

$$min_{S \subset V} \sum_{j \in S} (|senti(V) - senti(j)|) \quad (14)$$

4. **Baseline-4/TEXTRANK** : TextRank summarizer is based on Graph based unsupervised algorithm. Graph is constructed by creating a vertex for each sentence in the document and edges between vertices based on the number of words two sentences (of vertices) have in common and then, ranking them by applying PageRank to the resulting graph. Summary is generated with sentences having more vertex score (Mihalcea and Tarau, 2004).

5. **Baseline-5/MINCUT** : Mincut algorithm (Pang and Lee, 2004) classifies the sentences as subjective and objective sentences, by finding minimum s-t cuts in graph of sentences using maximum flow algorithm. In the graph, each sentence is a vertex and the edge between the vertex to the source or sink is taken as probability of the sentence being subjective or objective (individual scores). To ensure the graph connectivity, edges are drawn between every pair of sentence vertices, with edge weights taken proportional to the degree of proximity (association scores). After maximum flow algorithm, the cut in which source vertex lies is classified as subjective and vice-versa. We pick top subjective sentences within the budget as summary.

Among the five baselines, TOP and TOP-SUBJ are simplistic. Though both TEXTRANK and MINCUT were not originally proposed for opinion summarization but a number of papers in opinion summarization have built over these two methods and also, used them as baselines and thus, comparing with the "well-known" baselines will give the readers from the sentiment analysis field an intuitive idea of the performance of our system. MINCUT, however was reproposed specifically for subjective summarization by Pang and Lee (2004) and we use that formulation for comparison.

Table 1 compares the five functions with the above baselines based on optimal values of tradeoff α. From the table, it can be inferred that all the

Table 2: ROUGE F-score and sentiment correlation for optimal values of α with baseline 6

proposed functions not only outperform the baselines in terms of ROUGE scores for optimal parameters but also, give better correlation with the document sentiment. This can be quantitively verified by test of significance, unpaired one-tailed t-test without assuming equal variance between the baselines and the systems. The p-values are 0.0203 and 0.0066 respectively for ROUGE-1 F Score and Sentiment Correlation, justifying that the performance improvement by our system over the baselines is statistically significant at $p < 0.05$. The main reason being that the functions with optimal values of trade-off parameter α strike out a balance between relevance and subjectivity. Clearly, the facility location based monotone submodular functions are the best choice as objective for opinion summarization task as they select sentences with maximum subjectivity (facilities giving best service).

Our system is able to access the information of aspect and polarity of each sentence, while some baselines do not. So, the improvement over the baselines may be attributed to those additional information rather than the optimality of the partial enumeration greedy algorithm over submodular functions. So, we therefore, introduced the following baseline to question this misdoubt on the experiment:

6. **Baseline-6/LIN** :

In this baseline, the greedy algorithm (Lin and Bilmes, 2010) is used for summary generation, using the same functions and information in the formulation. This algorithm fills the empty summary set greedily by adding a single sentence in each

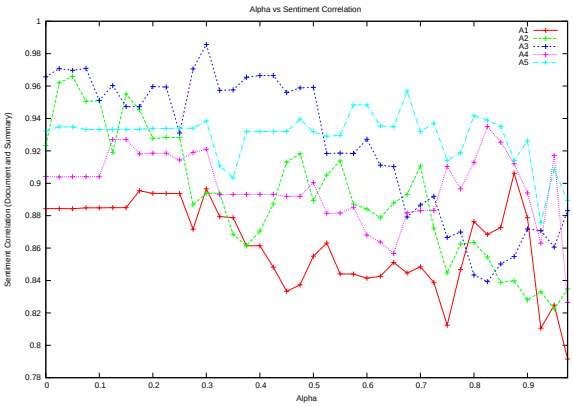

Figure 2: Sentiment Correlation *vs* α

iteration, which gives maximum return over cost ratio ($\frac{F(S^*)-F(S)}{len(s)}$), ensuring that current solution is feasible with respect to the knapsack constraint (cost($S \cup \{newSentence\}$) $\leq$ B). This algorithm has a complexity of O(n^2) but gives only performance guarantee of $\frac{1}{2}(1 - e^1) \approx 0.316$ (Khuller et al., 1999).

Table 2 compares the same five functions in our system with (Lin and Bilmes, 2010) system based on optimal values of tradeoff α. From the table, it can be inferred that our system also outperforms this baseline both in terms of ROUGE scores and sentiment correlation, which can be quantitively verified by test of significance, unpaired one-tailed t-test without assuming equal variance between the baselines and the systems. The p-values are 0.02517 and 0.003965 respectively for ROUGE-1 F Score and Sentiment Correlation, justifying that the performance improvement by our system over LIN system is statistically significant at $p < 0.05$.

The figures 2 and 3 plot the value of senti-

Table 3: Maximum ROUGE F-score and their corresponding sentiment correlation

ment correlation and ROUGE-1 F score for the formulated submodular functions with respect to the trade-off parameter, α respectively. Looking at the graph 2, we can observe that more weightage to relevance over subjective coverage of aspects decreases the sentiment correlation, which was expected because the summary generated misses out on subjective sentiment due to trade-off. Similarly, by looking at the graph 3, we also observe that more weightage to relevance over subjective coverage of aspects increases the ROUGE score as expected. The erratic behaviour in figure 3 can be explained by arguing that subjective words are also important for summary and thus, giving less weightage to them over relevance, ROUGE score will increase but not properly.

The table 3 presents the value of sentiment correlation corresponding to maximum ROUGE score (for $\alpha \approx 1$). Clearly, A_4 and A_2 have maximum ROUGE scores as they neglect polarities and instead, reward on aspect based partitions, thus increasing coverage. The table 4 presents the value of ROUGE score corresponding to maximum sentiment correlation (for $\alpha \approx 0$). Clearly, A_4 also has maximum sentiment correlation as it rewards maximum subjectivity, irrespective of polarities and

Table 4: Maximum sentiment correlation and corresponding ROUGE F-Score

the corresponding ROUGE-2 F-score is also highest among all functions. Tables 1 and 2 contain the ROUGE F-score and sentiment correlation for optimal values of α, found after grid search while tables 3 and 4 contain the peak values in the figures 2 and 3. For example, table 3 contains the peak value of ROUGE-1 F score from figure 3 and the corresponding value of Sentiment Correlation from figure 2, at the same α.

7 Conclusion

In this paper, we show that conflict between subjectivity and relevance naturally arises in opinion summarization. To address this problem, we introduce new monotone submodular functions that are well suited to document summarization (Lin and Bilmes, 2010; Lin and Bilmes, 2011; Morita et al., 2013) by modeling two important properties of opinion summary - relevance and subjective coverage of aspects. We then, design different possible combinations of objective functions to model the task. To solve the algorithm effectively, we use the partial enumeration based algorithm, which is though computationally expensive (O(n^5) function calls), gives a performance guarantee of 63% for an NP-hard problem like summarization (McDonald, 2007). We have justified the submodular property of opinion summary through examples and significant performance of the system over the baselines. Further, this optimal trade-off between relevance and subjectivity can be used to design an evaluation framework for opinion summarization task as both part of the objective functions are proportional to the ROUGE and Sentiment Correlation respectively, which are widely used evaluation measures (Kim et al., 2011). As opinion summarization task lies in the intersection of opinion mining and summarization problems, both IR and NLP communities will benefit from our work.

Abstract

In this work, we build an entity/event-level sentiment analysis system, which is able to recognize and infer both explicit and implicit sentiments toward entities and events in the text. We design Probabilistic Soft Logic models that integrate explicit sentiments, inference rules, and +/-effect event information (events that positively or negatively affect entities). The experiments show that the method is able to greatly improve over baseline accuracies in recognizing entity/event-level sentiments.

1 Introduction

There are increasing numbers of opinions expressed in various genres, including reviews, newswire, editorials, and forums. While much early work was at the document or sentence level, to fully understand and utilize opinions, researchers are increasingly carrying out more fine-grained sentiment analysis to extract components of **opinion frames**: the source (whose sentiment is it), the polarity, and the target (what is the sentiment toward). Much fine-grained analysis is span or aspect based (Yang and Cardie, 2014; Pontiki et al., 2014). In contrast, this work contributes to **entity/event**-level sentiment analysis. A system that could recognize sentiments toward entities and events would be valuable in an application such as Automatic Question Answering, to support answering questions such as "Who is negative/positive toward X?" (Stoyanov et al., 2005), where X could be any entity or event.

Let us consider an example from the MPQA opinion annotated corpus (Wiebe et al., 2005a; Wilson, 2007; Deng and Wiebe, 2015).

Ex(1) When the Imam (may God be satisfied with him $_1$) issued the fatwa against $_2$ Salman Rushdie for insulting $_3$ the Prophet (peace be upon him $_4$), the countries that are so-called $_5$ supporters of human rights protested against $_6$ the fatwa.

There are several sentiment expressions annotated in MPQA. In the first clause, the writer is positive toward Imam and Prophet as expressed by *may God be satisfied with him* (1) and *peace be upon him* (4), respectively. Imam is negative toward Salman Rushdie and the insulting event, as revealed by the expression *issued the fatwa against* (2). And Salman Rushdie is negative toward *Prophet*, as revealed by the expression *insulting* (3). In the second clause, the writer is negative toward the countries, as expressed by *so-called* (5). And the countries are negative toward fatwa, as revealed by the expression *protested against* (6). Using the source and the target, we summarize the positive opinions above in a set P, and the negative opinions above in another set N. Thus, P contains {(writer, Imam), (writer, Prophet)}, and N contains {(Imam, Rushdie), (Imam, insulting), (Rushdie, Prophet), (writer, countries), (countries, fatwa)}.[1]

An (ideal) explicit sentiment analysis system is expected to extract the above sentiments expressed by (1)-(6). However, there are many more sentiments communicated by the writer but not expressed via explicit expressions. First, Imam is positive toward the Prophet, because Rushdie insults the Prophet and Imam is angry that he does

[1] Sources in MPQA are nested, having the form ⟨writer⟩ or ⟨writer, $S_1, \ldots, S_n$⟩. This work only deals with the rightmost source, writer or S_n. Also, actions like *issuing a fatwa* are treated the same as private states. Please see (Wiebe et al., 2005a).

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 179–189,
Lisbon, Portugal, 17-21 September 2015.

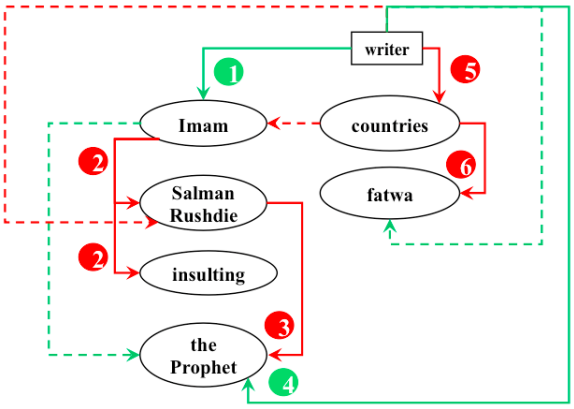

Figure 1: Explicit and implicit sentiments in Ex(1).

so. Second, the writer is negative toward Rushdie, because the writer is positive toward the Prophet but Rushdie insults him! Also, the writer is probably positive toward the fatwa since it is against Rushdie. Third, the countries are probably negative toward Imam, because the countries are negative toward fatwa and it is Imam who issued the fatwa. Thus, the set P should also contain {(Imam, Prophet), (writer, fatwa)}, and the set N should also contain {(writer, Rushdie), (countries, Imam)}. These opinions are not directly expressed, but are **inferred** by a human reader.[2] The explicit and implicit sentiments are summarized in Figure 1, where each green line represents a positive sentiment and each red line represents a negative sentiment. The solid lines are explicit sentiments and the dashed lines are implicit sentiments.

In this work, we detect sentiments such as those in P and N, where the sources are entities (or the writer) and the targets are entities and events.

Previous work in sentiment analysis mainly focuses on detecting explicit opinions. Recently there is emerging focus on sentiment inference, which recognizes implicit sentiments by inferring them from explicit sentiments via inference rules. Current works in sentiment inference differ on how the sentiment inference rules are defined and how they are expressed. For example, Zhang and Liu (2011) define linguistic templates to recognize phrases that express implicit sentiments, while previously we (Deng et al., 2014) represent a few simple rules as (in)equality constraints in Integer Linear Programming. In contrast to previous work, we propose a more general set of inference rules and encode them in a probabilistic soft logic (PSL) framework (Bach et al., 2015). We chose PSL because it is designed to have efficient inference and, as similar methods in Statistical Relational Learning do, it allows probabilistic models to be specified in first-order logic, an expressive and natural way to represent if-then rules, and it supports joint prediction. Joint prediction is critical for our task because it involves multiple, mutually constraining ambiguities (the source, polarity, and target).

Thus, this work aims at detecting both implicit and explicit sentiments expressed by an entity toward another entity/event (i.e., an **eTarget**) within the sentence. The contributions of this work are: (1) defining a method for entity/event-level sentiment analysis to provide a deeper understanding of the text; (2) exploiting first-order logic rules to infer such sentiments, where the source is not limited to the writer, and the target may be any entity, event, or even another sentiment; and (3) developing a PSL model to jointly resolve explicit and implicit sentiment ambiguities by integrating inference rules.

2 Related Work

Fined-grained sentiment analysis. Most fine-grained sentiment analysis is span or aspect based. Previous work differs from the entity/event-level sentiment analysis task we address in terms of targets and sources. In terms of targets, in a span-based sentiment analysis system, the target is a span instead of the exact head of the phrase referring to the target. The target in a span-based system is evaluated by measuring the overlapping proportion of an extracted span against the gold standard phrase (Yang and Cardie, 2013), while the eTarget in an entity/event-level system is evaluated against the exact word (i.e., head of NP/VP) in the gold standard. It is a stricter evaluation. While the targets in aspect-based sentiment analysis are often entity targets, they are mainly product aspects, which are a predefined set.[3] In contrast, the target in the entity/event-level task may be any noun or verb. In terms of sources, previous work in sentiment analysis trained on review data assumes that the source is the writer of the review (Hu and Liu, 2004; Titov and McDonald, 2008).

[2] Note that the inferences are conversational implicatures; they are defeasible and may not go through in context (Deng et al., 2014; Wiebe and Deng, 2014).

[3] As stated in SemEval-2014: "we annotate only aspect terms naming particular aspects".

Our work is rare in that it allows sources other than the writer *and* finds sentiments toward eTargets which may be any entity or event.

Sentiment Inference. There is some recent work investigating features that directly indicate implicit sentiments (Zhang and Liu, 2011; Feng et al., 2013). That work assumes the source is only the writer. Further, as it uses features to directly extract implicit sentiments, it does not perform general sentiment inference.

Previously, we (Deng et al., 2013; Deng and Wiebe, 2014; Deng et al., 2014) develop rules and models to infer sentiments related to *+/-effect events*, events that positively or negatively affect entities. That work assumes that the source is only the writer, and the targets are limited to entities that participate in +/-effect events. Further, our previous models all require certain manual (oracle) annotations to be input. In this work we use an expanded set of more general rules. We allow sources other than the writer, and targets that may be any entity or event. In fact, under our new rules, the targets of sentiments may be other sentiments; we model such novel "sentiment toward sentiment" structures in Section 4.3. Finally, our method requiring no manual annotations as input when the inference is conducted.

Previously, we also propose a set of sentiment inference rules and develop a rule-based system to infer sentiments (Wiebe and Deng, 2014). However, the rule-based system requires *all* information regarding explicit sentiments and +/-effect events to be provided as oracle information by manual annotations.

Probabilistic Soft Logic. Probabilistic Soft Logic (PSL) is a variation of Markov Logic Networks, which is a framework for probabilistic logic that employs weighted formulas in first-order logic to compactly encode complex undirected probabilistic graphical models (i.e., Markov networks) (Bach et al., 2015; Beltagy et al., 2014). PSL is a new statistical relational learning method that has been applied to many NLP and other machine learning tasks in recent years (Beltagy et al., 2014; London et al., 2013; Pujara et al., 2013; Bach et al., 2013; Huang et al., 2013; Memory et al., 2012). Previously, PSL has not been applied to entity/event-level sentiment analysis.

3 Task Definition

In this section, we introduce the definition of the entity/event-level sentiment analysis task, followed by a description of the gold standard corpus.

For each sentence s, we define a set E consisting of entities, events, and the writer of s, and sets P and N consisting of positive and negative sentiments, respectively. Each element in P is a tuple, representing a **positive pair** of two entities, (e_1, e_2) where e_1, $e_2 \in E$, and e_1 is positive toward e_2. A positive pair (e_1,e_2) aggregates all the positive sentiments from e_1 to e_2 in the sentence. N is the corresponding set for **negative pairs**.

The goal of this work is to automatically recognize a set of positive pairs (P_{auto}) and a set of negative pairs (N_{auto}). We compare the system output ($P_{\text{auto}} \cup N_{\text{auto}}$) against the gold standard ($P_{\text{gold}} \cup N_{\text{gold}}$) for each sentence.

3.1 Gold Standard Corpus: MPQA 3.0

MPQA 3.0 is a recently developed corpus with entity/event-level sentiment annotations (Deng and Wiebe, 2015).[4] It is built on the basis of MPQA 2.0 (Wiebe et al., 2005b; Wilson, 2007), which includes editorials, reviews, news reports, and scripts of interviews from different news agencies, and covers a wide range of topics.

In both MPQA 2.0 and 3.0, the top-level annotations include **direct subjective**s (**DS**). Each DS has a **nested-source** annotation. Each DS has one or more attitude links, meaning that all of the attitudes share the same nested source. The attitudes differ from one another in their attitude types, polarities, and/or targets. Moreover, both corpora contain **expressive subjective element** (**ESE**) annotations, which pinpoint specific expressions used to express subjectivity. We ignore neutral ESEs and only consider ESEs whose polarity is positive or negative.

MPQA 2.0 and 3.0 differ in their target annotations. In 2.0, each target is a span. A target annotation of an opinion captures the most important target this opinion is expressed toward. Since the exact boundaries of the spans are hard to define even for human annotators (Wiebe et al., 2005a; Yang and Cardie, 2013), the target span in MPQA 2.0 could be a single word, an NP or VP, or a text span covering more than one constituent. In contrast, in MPQA 3.0, each target is anchored to the head of an NP or VP, which is a single word. It is called an

[4] Available at http://mpqa.cs.pitt.edu/corpora/

eTarget since it is an entity or an event. In MPQA 2.0, only attitudes have target-span annotations. In MPQA 3.0, both attitudes and ESEs have eTarget annotations. Importantly, the eTargets include the targets of both explicit and implicit sentiments.

Recall Ex(1) in Section 1. $P_{\text{gold}} = \{$(writer, Imam), (writer, Prophet), (Imam, Prophet), (writer, fatwa)$\}$, and $N_{\text{gold}} = \{$(Imam, Rushdie), (Imam, insulting), (Rushdie, Prophet), (writer, countries), (countries, fatwa), (writer, Rushdie), (countries, Imam)$\}$.

4 PSL for Sentiment Analysis

We need to resolve three components for an opinion frame: the source, the polarity, and the eTarget. Each of these ambiguities has several candidates. For example in Ex(1), the eTarget of the opinion expression *insulting* is an ambiguity. The candidates include *Prophet*, *countries*, and so on.

In this work, we use Probabilistic Soft Logic (PSL). A PSL model is defined using a set of atoms to be grounded, and a set of weighted if-then rules expressed in first-order logic. For example, we define the atom ETARGET(y,t) to represent an opinion y having eTarget t. If y and t are constants, then ETARGET(y,t) is a ground atom (e.g., ETARGET(insulting, Prophet)). Each ground atom is assigned a score by a local system. PSL takes as input all the local scores as well as the constraints defined by the rules among atoms, so that it is able to jointly resolve all the ambiguities. In the final output, for example, the score ETARGET(insulting, Prophet) > 0 means that PSL considers Prophet to be an eTarget of *insulting*, while ETARGET(insulting, countries) $= 0$ means that PSL does not consider *countries* to be an eTarget of *insulting*.

In this section, we first introduce PSL in Section 4.1. We then present three PSL models in turn. PSL1 (Section 4.2) aggregates span-based opinions into P_{auto} and N_{auto}. PSL2 (Section 4.3) adds sentiment inference rules to PSL1. For PSL3 (Section 4.4), rules involving +/-effect events are added to PSL2, resulting in the richest overall model.

4.1 Probabilistic Soft Logic

PSL (Bach et al., 2015) uses logical representations to compactly define large graphical models with continuous variables, and includes methods for performing efficient probabilistic inference for the resulting models (Beltagy et al., 2014). As mentioned above, a PSL model is defined using a set of atoms to be grounded, and a set of weighted if-then rules in first-order logic. For example,

friend(x,y) $\wedge$ votesFor(y,z) $\Rightarrow$ votesFor(x,z)

means that a person may vote for the same person as his/her friend. Each predicate in the rule is an atom (e.g., friend(x,y)). A ground atom is produced by replacing variables with constants (e.g., friend(Tom, Mary)). Each rule is associated with a weight, indicating the importance of this rule in the whole rule set.

A key distinguishing feature of PSL is that each ground atom a has a soft, continuous truth value in the interval [0, 1], denoted as $I(a)$, rather than a binary truth value as in Markov Logic Networks and most other probabilistic logic frameworks (Beltagy et al., 2014). To compute soft truth values for logical formulas, Lukasiewicz relaxations are used:

$l_1 \wedge l_2 = \max\{0, I(l_1) + I(l_2) - 1\}$
$l_1 \vee l_2 = \min\{I(l_1) + I(l_2), 1\}$
$\neg l_1 = 1 - I(l_1)$

A rule $r \equiv r_{body} \rightarrow r_{head}$, is satisfied (i.e. $I(r) = 1$) iff $I(r_{body}) \leq I(r_{head})$. Otherwise, a distance to satisfaction $d(r)$ is calculated, which defines how far a rule r is from being satisfied: $d(r) = \max\{0, I(r_{body}) - I(r_{head})\}$. Using $d(r)$, PSL defines a probability distribution over all possible interpretations I of all ground atoms:

$$p(I) = \frac{1}{Z} \exp\{-1 * \sum_{r \in R} \lambda_r (d(r))^p\}$$

where Z is the normalization constant, λ_r is the weight of rule r, R is the set of all rules, and p defines loss functions. PSL seeks the interpretation with the minimum distance $d(r)$ and which satisfies all rules to the extent possible.

4.2 PSL for Sentiment Aggregation (PSL1)

The first PSL model, PSL1, aggregates span-based opinions into P_{auto} and N_{auto}. We call this *sentiment aggregation* because, instead of building an entity/event-level sentiment system from scratch, we choose to fully utilize previous work on span-based sentiment analysis. PSL1 aggregates span-based opinions into entity/event-level opinions.

Consistent with the task definition in Section 3, we define two atoms in PSL:
(1) POSPAIR(s,t): a positive pair from s toward t
(2) NEGPAIR(s,t): a negative pair from s toward t

Both s and t are chosen from the set E. The values of ground atoms (1) and (2) are not observed and are inferred by PSL.

Then, we define atoms to model an entity/event-level opinion:

(3) POS(y): y is a positive sentiment
(4) NEG(y): y is a negative sentiment
(5) SOURCE(y,s): the source of y is s
(6) ETARGET(y,t): the eTarget of y is t

Two rules are defined to aggregate various opinions extracted by span-based systems into positive pairs and negative pairs, shown in Part 1 of Table 1 as Rules 1.1 and 1.2. Thus, under our representation, the PSL model not only finds a set of eTargets of an opinion (ETARGET(y,t)), but also represents the aggregated sentiments among entities and events (POSPAIR(s,t) and NEGPAIR(s,t)) in the sentence.

Next, we turn to assigning local scores to ground atoms (3)-(6).

POS(y) and NEG(y): We build upon three span-based sentiment analysis systems. The first, S1 (Yang and Cardie, 2013), and the second, S2 (Yang and Cardie, 2014), are both trained on MPQA 2.0, which does not contain any eTarget annotations. S1 extracts triples of ⟨source span, opinion span, target span⟩, but does not extract opinion polarities. S2 extracts opinion spans and opinion polarities, but it does not extract sources or targets. The third system, S3 (Socher et al., 2013), is trained on movie review data. It extracts opinion spans and polarities. The source is always assumed to be the writer.

We take the union set of opinions extracted by S1, S2 and S3. For each opinion y, a ground atom is created, depending on the polarity (POS(y) if y is positive and NEG(y) is y is negative). The polarity is determined as follows. If S2 assigns a polarity to y, then that polarity is used. If S3 but not S2 assigns a polarity to y, then S3's polarity is used. In both cases, the score assigned to the ground atom is 1.0. If neither S2 nor S3 assigns a polarity to y, we use the MPQA subjectivity lexicon to determine its polarity. The score assigned to the ground atom is the proportion of the words in the opinion span that are included in the subjectivity lexicon.

SOURCE(y,s): S1 extracts the source of each opinion, S2 does not extract the source, and S3 assumes the source is always the writer. Thus, for an opinion y, if the source s is assigned by S1, a ground atom SOURCE(y,s) is created with score 1.0. Otherwise, if S3 extracts opinion y, a ground atom SOURCE(y,writer) is created with score 1.0 (since S3 assumes the source is always the writer). Otherwise, we run the Stanford named entity recognizer (Manning et al., 2014; Finkel et al., 2005) to extract named entities in the sentence. The nearest named entity to the opinion span on the dependency parse graph will be treated as the source. The score is the reciprocal of the length of the path between the opinion span and the source span in the dependency parse.

ETARGET(y,t): Though each eTarget is an entity or event, it is difficult to determine which nouns and verbs should be considered. Taking into consideration the trade-off between precision and recall, we experimented with three methods to select eTarget candidates. For each opinion y, a ground atom ETARGET(y,t) is created for each eTarget candidate t.

ET1 considers all the nouns and verbs in the sentence, to provide a full recall of eTargets.

ET2 considers all the nouns and verbs in the target spans and opinion spans that are automatically extracted by systems S1, S2 and S3. We hypothesized that ET2 would be useful because most of the eTargets in MPQA 3.0 appear within the opinion or the target spans of MPQA 2.0.

ET3 considers the heads of the target and opinion spans that are automatically extracted by systems S1, S2 and S3.[5] ET3 also considers the heads of siblings of target spans and opinion spans. Among the three methods, ET3 has the lowest recall but the highest precision.

In addition, for the eTarget candidate set extracted by ET2, or ET3, we run the Stanford co-reference system (Manning et al., 2014; Recasens et al., 2013; Lee et al., 2013) to expand the set in two ways. First, for each eTarget candidate t, the co-reference system extracts the entities that co-refer with t. We add the referring entities into the candidate set. Second, the co-reference system extracts words which the Stanford system judges to be entities, regardless of whether they have any referent or not. We add this set of entities to the candidate set as well.

We train an SVM classifier (Cortes and Vapnik, 1995) to assign a score to the ground atom ETARGET(y,t). Syntactic features describing the

[5]The head of a phrase is extracted by the Collins head finder in the Stanford parser (Manning et al., 2014).

Part 1.	Aggregation Rules.	
1.1	SOURCE(y,s) $\wedge$ ETARGET(y,t) $\wedge$ POS(y)	$\Rightarrow$ POSPAIR(s,t)
1.2	SOURCE(y,s) $\wedge$ ETARGET(y,t) $\wedge$ NEG(y)	$\Rightarrow$ NEGPAIR(s,t)
Part 2.	Inference Rules.	
2.1	POSPAIR(s_1,y_2) $\wedge$ SOURCE(y_2,s_2)	$\Rightarrow$ POSPAIR(s_1,s_2)
2.2	POSPAIR(s_1,y_2) $\wedge$ ETARGET(y_2,t_2) $\wedge$ POS(y_2)	$\Rightarrow$ POSPAIR(s_1,t_2)
2.3	POSPAIR(s_1,y_2) $\wedge$ ETARGET(y_2,t_2) $\wedge$ NEG(y_2)	$\Rightarrow$ NEGPAIR(s_1,t_2)
2.4	NEGPAIR(s_1,y_2) $\wedge$ SOURCE(y_2,s_2)	$\Rightarrow$ NEGPAIR(s_1,s_2)
2.5	NEGPAIR(s_1,y_2) $\wedge$ ETARGET(y_2,t_2) $\wedge$ POS(y_2)	$\Rightarrow$ NEGPAIR(s_1,t_2)
2.6	NEGPAIR(s_1,y_2) $\wedge$ ETARGET(y_2,t_2) $\wedge$ NEG(y_2)	$\Rightarrow$ POSPAIR(s_1,t_2)
Part 3.	Inference Rules w.r.t +/-Effect Event Information.	
3.1	POSPAIR(s,x) $\wedge$ AGENT(x,a)	$\Rightarrow$ POSPAIR(s,a)
3.2	POSPAIR(s,x) $\wedge$ THEME(x,h) $\wedge$ +EFFECT(x)	$\Rightarrow$ POSPAIR(s,h)
3.3	POSPAIR(s,x) $\wedge$ THEME(x,h) $\wedge$ -EFFECT(x)	$\Rightarrow$ NEGPAIR(s,h)
3.4	NEGPAIR(s,x) $\wedge$ AGENT(x,a)	$\Rightarrow$ NEGPAIR(s,a)
3.5	NEGPAIR(s,x) $\wedge$ THEME(x,h) $\wedge$ +EFFECT(x)	$\Rightarrow$ NEGPAIR(s,h)
3.6	NEGPAIR(s,x) $\wedge$ THEME(x,h) $\wedge$ -EFFECT(x)	$\Rightarrow$ POSPAIR(s,h)
3.7	POSPAIR(s,a) $\wedge$ AGENT(x,a)	$\Rightarrow$ POSPAIR(s,x)
3.8	POSPAIR(s,h) $\wedge$ THEME(x,h) $\wedge$ +EFFECT(x)	$\Rightarrow$ POSPAIR(s,x)
3.9	POSPAIR(s,h) $\wedge$ THEME(x,h) $\wedge$ -EFFECT(x)	$\Rightarrow$ NEGPAIR(s,x)
3.10	NEGPAIR(s,a) $\wedge$ AGENT(x,a)	$\Rightarrow$ NEGPAIR(s,x)
3.11	NEGPAIR(s,h) $\wedge$ THEME(x,h) $\wedge$ +EFFECT(x)	$\Rightarrow$ NEGPAIR(s,x)
3.12	NEGPAIR(s,h) $\wedge$ THEME(x,h) $\wedge$ -EFFECT(x)	$\Rightarrow$ POSPAIR(s,x)

Table 1: Rules in First-Order Logic.

relations between an eTarget and the extracted opinion span and target span are considered, including: (1) whether the eTarget is in the opinion/target span; (2) the unigrams and bigrams on the path from the eTarget to the opinion/target span in the constituency parse tree; and (3) the unigrams and bigrams on the path from the eTarget to the opinion/target word in the dependency parse graph. We normalize the SVM scores into the range of a ground atom score, [0,1].

4.3 PSL for Sentiment Inference (PSL2)

The two rules defined in Section 4.2 aggregate various opinions into positive pairs and negative pairs, but inferences have not yet been introduced. PSL2 is defined using the atoms and rules in PSL1. But it also includes some rules defined in (Wiebe and Deng, 2014), represented here in first-order logic in Part 2 of Table 1. Let us go through an example inference for Ex(1), in particular, the inference that Imam is positive toward the Prophet. Rule 2.6 supports this inference. Recall the two explicit sentiments: Imam is negative toward the insulting sentiment (revealed by *issued the fatwa against*), and Rushdie is negative toward the Prophet (revealed by *insulting*). Thus, we can instantiate Rule 2.6, where s_1 is Imam, y_2 is the negative sentiment (*insulting*), and t_2 is the Prophet. The inference is: since Imam is negative that there is any negative opinion expressed toward the Prophet, we infer that Imam is positive toward the Prophet.

NEGPAIR(Imam, insulting)
$\wedge$ ETARGET(insulting, Prophet)
$\wedge$ NEG(insulting)
$\Rightarrow$ POSPAIR(Imam, Prophet).

The inference rules in Part 2 of Table 1 are novel in that eTargets may be sentiments (e.g., NEGPAIR(Imam,insulting) means that Imam is negative toward the negative sentiment revealed by *insulting*). The inference rules link sentiments to sentiments and, transitively, link entities to entities (e.g., from Imam to Rushdie to the Prophet).

To support such rules, more groundings of ETARGET(y,t) are created in PSL2 than in PSL1. For two opinions y_1 and y_2, if the target span of y_1 overlaps with the opinion span of y_2, we create ETARGET(y_1,y_2) as a ground atom representing that y_2 is an eTarget of y_1.

4.4 PSL Augmented with +/-Effect Events (PSL3)

Finally, for PSL3, +/-effect event atoms and rules are added to PSL2 for the inference of additional sentiments.

According to (Deng et al., 2013), a +effect event has positive effect on the theme (examples are *help*, *increase*, and *save*), and a -effect event has negative effect on the theme (examples are *obstruct*, *decrease*, and *kill*).[6] We define the following atoms to represent such events:

(7) +EFFECT(x): x is a +effect event
(8) -EFFECT(x): x is a -effect event
(9) AGENT(x,a): the agent of x is a
(10) THEME(x,h): the theme of x is h

Next we assign scores to these ground atoms.

+EFFECT(x) and -EFFECT(x): We use the +/-effect sense-level lexicon (Choi and Wiebe, 2014)[7] to extract the +/-effect events in each sentence. The score of +EFFECT(x) is the fraction of that word's senses that are +effect senses according to the lexicon, and the score of -EFFECT(x) is the fraction of that word's senses that are -effect senses according to the lexicon. If a word does not appear in the lexicon, we do not treat it as a +/-effect event, and thus assign 0 to both +EFFECT(x) and -EFFECT(x).

AGENT(x,a) and THEME(x,h): We consider all nouns in the same or in sibling constituents of a +/-effect event as potential agents or themes. An SVM classifier is run to assign scores to AGENT(x,a), and another SVM classifier is run to assign scores to THEME(x,h). Both SVM classifiers are trained on a separate corpus, the +/-effect corpus (Deng et al., 2013) used in (Deng et al., 2014), which is annotated with +/-effect event, agent, and theme spans. The features we use to train the agent and theme classifier include unigram, bigram and syntax information.

Generalizations of the inference rules used in (Deng et al., 2014) are expressed in first-order logic, shown in Part 3 of Table 1. Let us go through an example inference for Ex(1), in particular, the inference that the countries are negative toward Imam. Recall that we infer this because the countries are negative toward the fatwa and it is Imam who issued the fatwa. The rules supporting this inference are Rules 3.11 and 3.4 in Table 1, where s is the countries, h is the fatwa, x is the issue event, and a is Imam.

The application of Rule 3.11 can be explained as follows. The countries are negative toward the fatwa, and the issue event is a +effect event with theme fatwa (the issue event is +effect for the fatwa because it creates the fatwa; creation is one type of +effect event identified in (Deng et al., 2013)); thus, the countries are negative toward the issue event.

NEGPAIR(countries, fatwa)
$\wedge$ THEME(issue, fatwa)
$\wedge$ +EFFECT(issue)
$\Rightarrow$ NEGPAIR(countries, issue) .

The application of Rule 3.4 can be explained as follows. The countries are negative toward the issue event, and it is Imam who conducted the event; thus, the countries are negative toward Imam.

NEGPAIR(countries, issue)
$\wedge$ AGENT(issue, Imam)
$\Rightarrow$ NEGPAIR(countries, Imam) .

Finally, to support the new inferences, more groundings of ETARGET(y,t) are defined in PSL3. For a +/-effect event x whose agent is a, if one of x and a is an eTarget candidate of y, the other will be added to the eTarget candidate set for y (sentiments toward both +effect and -effect events and their agents have the same polarity according to the rules (Deng et al., 2014)). For +effect event x whose theme is h, if one of x and h is an eTarget candidate of y, the other is added to the eTarget candidate set for y (sentiments toward +effect events and their themes have the same polarity).

5 Experiments

We carry out experiments on the MPQA 3.0 corpus. Currently, there are 70 documents, 1,634 sentences, and 1,921 DS and ESEs in total. The total number of POSPAIR(s,t) and NEGPAIR(s,t) are 867 and 1,975, respectively. Though the PSL inference does not need supervision and the SVM classifier for agents and themes in Section 4.4 is trained on a separate corpus, we still have to train the eTarget SVM classifier to assign local scores as described in Section 4.2. Thus, the experiments are carried out using 5-fold cross validation. For each fold test set, the eTarget classifier is trained on the other folds. The trained classifier is then run on the test set, and PSL inference is carried out on the test set.

[6] In (Deng et al., 2013), such events are called *goodFor/badFor* events; they are later renamed as *+/-effect* events.

[7] Available at: http://mpqa.cs.pitt.edu/lexicons/effect_lexicon/

In total, we have three methods for eTarget candidate selection (ET1, ET2, ET3) and three models for sentiment analysis (PSL1, PSL2, PSL3).

Baselines. Since each noun and verb may be an eTarget, the first baseline (All NP/VP) regards all the nouns and verbs as eTargets. The first baseline estimates the difficulty of this task.

The second baseline (SVM) uses the SVM local classification results from Section 4.2. The score of ETARGET(y,t) is assigned by the SVM classifier. Then it is normalized as input into PSL. Before normalization, if the score assigned by the SVM classifier is above 0, the SVM baseline considers it as a correct eTarget.

5.1 Evaluations

First, we examine the performance of the PSL models on correctly recognizing eTargets of a particular opinion. This evaluation is carried out on a subset of the corpus: we only examine the opinions which are automatically extracted by the span-based systems (S1, S2 and S3). If an opinion expression in the gold standard is not extracted by any span-based system, it is not input into PSL, so PSL cannot possibly find its eTargets.

The second and third evaluations assess performance of the PSL models on correctly extracting positive and negative pairs. Note that our sentiment analysis system has the capability, through inference, to recognize positive and negative pairs even if corresponding opinion expressions are not extracted. Thus, the second and third evaluations are carried out on the entire corpus. The second evaluation uses ET3, and compares PSL1, PSL2 and PSL3. The third evaluation uses PSL3 and compares performance using ET1, ET2 and ET3. The results for the other combinations follow the same trends.

ETargets of An Opinion. According to the gold standard in Section 3.1, each opinion has a set of eTargets. But not all eTargets are equally important. Thus, our first evaluation assesses the performance of extracting the most important eTarget. As introduced in Section 3.1, a span-based target annotation of an opinion in MPQA 2.0 captures the most important target this opinion is expressed toward. Thus, the head of the target span can be considered to be the most important eTarget of an opinion. We model this as a ranking problem to compare models. For an opinion y automatically extracted by a span-based system, both the SVM baseline and PSL assign scores to ETARGET(y,t). We rank the eTargets according to the scores. Because the ALL NP/VP baseline does not assign scores to the nouns and verbs, we do not compare with that baseline in this ranking experiment. We use the Precision@N evaluation metric. If the top N eTargets of an opinion contain the head of target span, we consider it as a correct hit. The results are in Table 2.

	Prec@1	Prec@3	Prec@5
SVM	0.0370	0.0556	0.0820
PSL1	0.5105	0.6905	0.7831
PSL2	0.5317	0.7486	0.7883
PSL3	0.5503	0.7434	0.8148

Table 2: Precision@N of Most Important ETarget.

Table 2 shows that SVM is poor at ranking the most important eTarget. The PSL models are much better, even PSL1, which does not include any inference rules. This shows that SVM, which only uses local features, cannot distinguish the most important eTarget from the others. But the PSL models consider all the opinions, and can recognize a true negative even if it ranks high in the local results. The ability of PSL to rule out true negative candidates will be repeatedly shown in the later evaluations.

We not only evaluate the ability to recognize the most important eTarget of a particular opinion, we also evaluate the ability to extract all the eTargets of that opinion. The F-measure of SVM is 0.2043, while the F-measures of PSL1, PSL2 and PSL3 are 0.3135, 0.3239, and 0.3275, respectively. Correctly recognizing all the eTargets is difficult, but all the PSL models are better than the baseline.

Positive Pairs and Negative Pairs. Now we evaluate the performance in a stricter way. We compare automatically extracted sets of sentiment pairs: $P_{\text{auto}} = \{\text{POSPAIR}(s,t) > 0\}$ and $N_{\text{auto}} = \{\text{NEGPAIR}(s,t) > 0\}$, against the gold standard sets P_{gold} and N_{gold}. Table 3 shows the accuracies using ET3. Note that higher accuracies can be achieved, as shown later. Here we use ET3 just to show the trend of results.

As shown in Table 3, the low accuracy of baseline All NP/VP shows that entity/event-level sentiment analysis is a difficult task. Even the SVM baseline does not have good accuracy. Note that the SVM baseline in Table 3 uses ET3. The baseline classifies the heads of target spans and opin-

	PosPair	NegPair
All NP/VP	0.1280	0.1654
SVM	0.0765	0.0670
PSL1	0.3356	0.3754
PSL2	0.3705	0.3705
PSL3	0.4315	0.3892

Table 3: Accuracy comparing PSL models (ET3 used for all)

ion spans, which are extracted by state-of-the-art span-based sentiment analysis systems. This shows the results from span-based sentiment analysis systems do not provide enough accurate information for the more fine-grained entity/event-level sentiment analysis task. In contrast, PSL1 achieves much higher accuracy than the baselines. PSL2 and PSL3, which add sentiment toward sentiment and +/-effect event inferences, give further improvements. A reason is that SVM uses a hard constraint to cut off many eTarget candidates, while the PSL models take the scores as soft constraints.

A more critical reason is due to the definition of accuracy: (TruePositive+TrueNegative)/All. A significant benefit of using PSL is correctly recognizing true negative eTarget candidates and eliminating them from the set. Interestingly, even though both PSL2 and PSL3 introduce more eTarget candidates, both are able to recognize more true negatives and improve the accuracy.

Note that F-measure does not count true negatives. Precision is $\frac{TP}{TP+FP}$, and recall is $\frac{TP}{TP+FN}$; neither considers true negatives (TN). As shown in Table 4, the increment of PSL model over baselines on F-measure is not as large as the increase in accuracy. Comparing PSL2 and PSL3 to PSL1, the inference rules largely increase recall but lower precision. However, the accuracy in Table 3 keeps growing. Thus, the biggest advantage of PSL models is to correctly rule out true negative eTargets. For the baselines, though the SVM baseline has higher precision, it eliminates so many eTarget candidates that the F-measure is not high.

ETarget Selection. To assess the methods for eTarget selection, we run PSL3 (the fullest PSL model) using each method in turn. The F-measures and accuracies are listed in Table 5. The F-measure of ET1 is slightly lower than the F-measures of ET2 and ET3, while the accuracy of

	Precision	Recall	F-measure
	PosPair		
All NP/VP	0.1481	0.4857	0.2270
SVM	0.3791	0.0870	0.1415
PSL1	0.2234	0.2687	0.2440
PSL2	0.1666	0.2738	0.2072
PSL3	0.1659	0.3523	0.2256
	NegPair		
All NP/VP	0.1824	0.6408	0.2840
SVM	0.3568	0.0761	0.1254
PSL1	0.2857	0.3872	0.3288
PSL2	0.2772	0.3883	0.3235
PSL3	0.2586	0.4529	0.3292

Table 4: F-measure comparing PSL models (ET3 used for all)

ET1 is much better than the accuracies of ET2 and ET3. Again, this is because PSL recognizes true negatives in the eTarget candidates. Since ET1 considers more eTarget candidates, ET1 gives PSL a greater opportunity to remove true negatives, leading to an overall increase in accuracy.

6 Conclusion

This work builds upon state-of-the-art span-based sentiment analysis systems to perform entity/event-level sentiment analysis covering both explicit and implicit sentiments expressed among entities and events in text. Probabilistic Soft Logic models incorporating explicit sentiments, inference rules and +/-effect event information are able to jointly disambiguate the ambiguities in the opinion frames and improve over baseline accuracies in recognizing entity/event-level sentiments.

Abstract

A *simile* is a comparison between two essentially unlike things, such as *"Jane swims like a dolphin"*. Similes often express a positive or negative sentiment toward something, but recognizing the polarity of a simile can depend heavily on world knowledge. For example, *"memory like an elephant"* is positive, but *"memory like a sieve"* is negative. Our research explores methods to recognize the polarity of similes on Twitter. We train classifiers using lexical, semantic, and sentiment features, and experiment with both manually and automatically generated training data. Our approach yields good performance at identifying positive and negative similes, and substantially outperforms existing sentiment resources.

1 Introduction

A *simile* is a form of figurative language that compares two essentially unlike things (Paul, 1970), such as *"Jane swims like a dolphin"*. Similes often express a positive or negative view toward an entity, object, or experience (Li et al., 2012; Fishelov, 2007). Sometimes, the sentiment of a simile is expressed explicitly, such as *"Jane swims **beautifully** like a dolphin!"*. But in many cases the sentiment is implicit, evoked entirely from the comparison itself. *"Jane swims like a dolphin"* is easily understood to be a compliment toward Jane's swimming ability because dolphins are known to be excellent swimmers.

A simile consists of four key components: the **topic** or **tenor** (subject of the comparison), the **vehicle** (object of the comparison), the **event** (act or state), and a **comparator** (usually "as", "like", or "than") (Niculae and Danescu-Niculescu-Mizil, 2014). A **property** (shared attribute) can be optionally included as well (e.g., *"He is as **red** as a tomato"*). Our research aims to identify the affective polarity of a simile as *positive*, *negative*, or *neutral*, based on its component phrases.

Table 1 shows examples of similes and their polarity. A simile can have *neutral* polarity if it offers an objective observation. Example (a) is a neutral simile because, although bananas have a distinctive smell, it is not generally considered to be a particularly good or bad scent. Example (b) illustrates that using the subjective verb "stink" instead of "smell" indicates a negative polarity toward the scent of bananas. Example (c) shows that including a subjective adjective such as "rotten" suggests a negative sentiment. Example (d) has negative polarity because the vehicle term, "garbage", carries a strong negative connotation.

	Simile	Polarity
(a)	smells like bananas	*neutral*
(b)	stinks like bananas	*negative*
(c)	smells like rotten bananas	*negative*
(d)	smells like garbage	*negative*
(e)	memory like an elephant	*positive*
(f)	memory like a sieve	*negative*
(g)	looks like a celebrity	*positive*
(h)	acts like a celebrity	*negative*

Table 1: Simile Examples with Affective Polarity.

However, the affective polarity of a simile often emerges from multiple component terms. For instance, all of the words in Examples (e) and (f) have neutral polarity. But Example (e) is positive because elephants are widely known to have excellent memories, while Example (f) is negative because a sieve has holes, which is metaphorical with memory lapses. Examples (g) and (h) illustrate that a prior connotation can even be overridden depending upon the property being compared. In general, the word "celebrity" tends to have a positive connotation and looking like a celebrity is generally a compliment. But acting like a celebrity is a negative simile because it alludes to negative attributes such as narcissism or entitlement.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 190–200,
Lisbon, Portugal, 17-21 September 2015.

Our research explores the challenge of identifying the affective polarity of similes. First, we introduce a new data set of similes extracted from Twitter. We describe a manual annotation study to label them with affective polarity. We also present several approaches for identifying some instances of positive and negative similes using existing sentiment resources, to automatically create labeled data to train a classifier. Second, we describe a machine learning classifier to recognize the affective polarity of similes by considering lexical, semantic, and sentiment properties of their components. Third, we present experimental results for the simile polarity classifier, using both manually annotated training data and automatically labeled training data. Our evaluation shows that the classifier trained with manually labeled data achieves good performance at identifying positive and negative similes. Training with automatically labeled data produces classifiers that are not quite as good as those trained with manually labeled data, but they still substantially outperform existing sentiment resources and offer a way to easily train simile classifiers for different domains.

2 Related Work

Although similes are a popular form of comparison, there has been relatively little prior research on understanding affective polarity in similes. Veale and Hao (2007) created a large simile case-base using the pattern "as ADJ as a/an NOUN". They collected similes by querying the web after instantiating part of the pattern with adjectives, and then had a human annotate 30,991 of the extracted similes for validity. Their focus was on extracting salient properties associated with simile **vehicles**, and the affective perception on vehicles that the salient properties bring about.

Veale (2012) took a step further and automatically recognized the affect toward vehicles when properties reinforce each other (e.g., hot and humid). They built a support graph of properties and determined how they connect to unambiguous positive and negative words. Li et al. (2012) used similar patterns to retrieve similes and determine basic sentiment toward simile vehicles across different languages using the compared properties. One major difference with their work and ours is that they determine sentiment or affective perception toward entities or concepts extracted from simile **vehicles**. In contrast, our work is focused on determining affective polarity of a simile as a whole, where the affective polarity typically relates to an act or state of the **tenor**. In many cases, a simile vehicle does not have positive or negative polarity by itself. For example, "sauna" is not a positive or negative concept, but "room feels like a sauna" is a negative simile because it suggests that the room is humid and unpleasant.

Niculae and Danescu-Niculescu-Mizil (2014) created a simile data set from Amazon product reviews, and determined when comparisons are figurative. They did not identify affective polarity, but showed that sentiment and figurative comparisons are correlated. Fishelov (2007) conducted a study of 16 similes where the connection between tenor and vehicle is obvious or not obvious, and when a conventional or unconventional explicit property is present or absent. Fishelov analyzed responses from participants to understand the positive and negative impression a simile conveys toward its tenor. Hanks (2005) presented an analysis of semantic categories of simile vehicles (animal, roles in society, artifact, etc.) that people most commonly use in similes.

Previous research has also explored sentiment expressed through metaphor. Rumbell et al. (2008) presented an analysis of animals that are metaphorically used to describe a person. Rentoumi et al. (2009) determined use of figurative language by disambiguating word senses, and then determined sentiment polarity at the sense level using ngram graph similarity. Wallington et al. (2011) identified affect in metaphor and similes when a comparison is made with an animal (e.g., dog, fox) or mythical creature (e.g., dragon, angel) by analyzing WordNet sense glosses of the compared terms. More recently, the SemEval-2015 Shared Task 11 (Ghosh et al., 2015) has addressed the sentiment analysis of figurative language such as irony, metaphor and sarcasm in Twitter.

Our work is also related to sentiment analysis in general. The most common approach applies supervised classification with features such as ngrams, parts-of-speech, punctuation, lexicon features, etc. (e.g., (Kouloumpis et al., 2011; Davidov et al., 2010; Mohammad et al., 2013)). To overcome the challenge of acquiring manually labeled data, some work automatically collects noisy training data using emoticons and hashtags (e.g., (Go et al., 2009; Purver and Battersby, 2012)). In addition to determining overall sen-

timent, research has also focused on understanding people's sentiment during specific events such as stock market fluctuations, presidential elections, Oscars, tsunamis, or toward entities such as movies, companies, or aspects of a product (Bollen et al., 2011; Thelwall et al., 2011; Jiang et al., 2011; Hu and Liu, 2004; Jo and Oh, 2011).

To our knowledge, we are the first to explore recognition of affective polarity in similes as a whole, where the polarity relates to an act or state of the tenor. Unlike previous work, we do not rely on the presence of explicit properties. We also present a data set annotated with affective polarity in similes, and experiment with both manually annotated and automatically acquired training data.

3 Simile Data Set Creation

One of the major challenges of supervised classification is acquiring sufficient labeled data for training, since manual annotation is time consuming. However, similes sometimes contain words with explicit polarity (e.g., "bed feels like *heaven*" or "he *cries* like a baby"). Many of these cases can be identified with existing sentiment resources and then used to provide a classifier with training instances. But because sentiment resources have limitations (e.g., sentiment classifiers are not perfect, sentiment lexicons do not possess knowledge of context), these instances will have some noise. Therefore, we experiment with both manually labeled data sets that are smaller in size but high quality, and automatically labeled data sets that are comparatively larger but noisier.

Twitter is a popular microblogging platform and is widely used for sentiment analysis. Thus it is an excellent source for collecting similes that people use in everyday conversation. For this research, we extracted similes from 140 million tweets we harvested using the Twitter streaming API from March 2013 to April 2014. We started by selecting tweets containing three common **comparator** keywords: *"like"*, *"as"*, and *"than"*. We removed tweets with exact duplicate content, and tweets containing a retweet token. An additional challenge of tweets is that many are "near duplicates" (e.g., shared tweets with an added symbol or comment). So we performed an additional de-duplication step using Jaccard similarity of trigrams to measure overlap in the text content between pairs of tweets. When Jaccard similarity between two tweets was > 0.5, we kept only the longer tweet, and repeated the process.

We used the UIUC Chunker (Punyakanok and Roth, 2001) to identify phrase sequences with the syntax of similes (e.g., NP_1 + VP + PP-like + NP_2, or NP_1 + VP + ADJP + PP-like + NP_2, where NP_1 is the tenor, NP_2 is the vehicle, VP is the event, and ADJP is any explicitly mentioned property). We generalized over the extracted similes by removing the comparator, and the optional explicit property component. Our simile representation is thus a triple of the tenor, event and vehicle. We also lemmatized all words using Stanford CoreNLP (Manning et al., 2014). For a tenor phrase, we kept only the head noun, which is usually sufficient to understand the affective polarity target. We kept the entire noun phrase for the vehicle, since vehicles like "ice box" and "gift box" may represent two different concepts with different polarities in similes. We replaced personal pronouns (e.g., he, she) with a general PERSON token and other pronouns (e.g., it, this, that) with a general IT token. Table 2 presents examples of positive and negative similes in the annotated data set.

Positive	**Negative**
PERSON, smile, sun	PERSON, look, zombie
PERSON, feel, kid	PERSON, treat, stranger
PERSON, be, older brother	PERSON, feel, poo
IT, sound, heaven	PERSON, look, clown
PERSON, look, superman	word, cut, knife
IT, be, old time	PERSON, act, child
IT, feel, home	PERSON, look, voldemort
IT, fit, glove	PERSON, look, wet dog
IT, would be, dream	PERSON, treat, baby
IT, smell, spring	PERSON, look, drug addict

Table 2: Sample Similes from Annotated Data.

Sometimes, vehicle phrases contain adjective modifiers indicating explicit sentiment (e.g., "she looks like a *beautiful* model"). Since a simile is trivial to classify with such a modifier, we removed the instances that already had positive or negative adjective modifiers. To identify these cases, we used the AFINN sentiment lexicon (Nielsen, 2011). Similes that contain profanity (e.g., "You look like *crap*") are nearly always negative, and trivial to classify, so we filtered out these cases using a freely available profanity list[1]. We also removed any simile where the vehicle is a pronoun (e.g., "it looks like that"), and discard similes appearing fewer than 5 times. Our final data set contains 7,594 similes.

[1] http://www.bannedwordlist.com/lists/swearWords.txt

3.1 Manually Annotated Simile Data Set

To obtain manual annotation, we randomly selected 1500 similes occurring at least 10 times, from the 7,594 similes. Our expectation was that more frequent similes will be easier for the annotators to understand. We used Amazon's Mechanical Turk to obtain gold standard annotations for affective polarity. We asked the annotators to determine if a simile expresses affective polarity toward the subject (i.e., the **tenor** component), and to assign one of four labels: *positive*, *negative*, *neutral*, or *invalid*. The first two labels are for similes that clearly express positive polarity (e.g., *"Jane swims like a dolphin"*) or negative polarity (e.g., *"Fred's hair looks like a bird's nest"*). The *neutral* label is for similes that do not have positive or negative polarity (e.g., *"the cloud looks like a turtle"* isn't a positive or negative comment about the cloud) or similes that are ambiguous without the benefit of context (e.g., *"he is like my dog"* could be good or bad depending on the context).

The data also contained many misidentified similes, typically due to parsing errors. For example, sometimes there is an entire clause in place of the vehicle (e.g., "I feel like im gonna puke"). Other times, the informal text of Twitter makes the tweet hard to parse (e.g., "he is like whatttt") or a verb occurs after "like" (e.g., "he is like hyperventilating"). The *invalid* label covers these types of erroneously extracted similes.

The annotation task was first conducted on a small sample of 50 similes, to select workers that had high annotation agreement with each other and gold standard labels we prepared. The best three workers then all annotated the official set of 1500 similes. The average Cohen's Kappa (κ) (Carletta, 1996) between each pair of annotators was 0.69. We then assigned the final label through majority vote. However, none of the annotators agreed on the same label for 78 of the 1500 similes, and 303 instances were labeled as *invalid* similes by the annotators. So we removed these 381 instances from the annotated data set. Finally, we randomly divided the remaining similes into an evaluation (Eval) set of 741 similes, and a development (Dev) set of 378 similes. Table 3 shows the label distribution of these sets.

Label	# of Similes (Dev Data)	# of Similes (Eval Data)
Positive	164	312
Negative	181	343
Neutral	33	86
Total	378	741

Table 3: Manually Annotated Data.

3.2 Automatically Labeled Similes

For any new domain (e.g., Amazon product reviews), manual annotations for supervised training may not be readily available, and being able to automatically obtain training instances can be valuable. We therefore create and experiment with six types of automatically labeled training data.

Using AFINN Sentiment Lexicon Words: Our first training data set is created using the AFINN sentiment lexicon (Nielsen, 2011) containing 2,477 manually labeled words with integer values ranging from -5 (negativity) to 5 (positivity). For each simile, we sum the sentiment scores for all lexicon words in the simile components, assigning positive/negative polarity depending on whether the sum is positive/negative. This method yields 460 positive and 423 negative similes.

Using MPQA Sentiment Lexicon Words: Our second training data set is created using the 2,718 positive words and 4,910 negative words from the MPQA lexicon (Wilson et al., 2005). We applied the CMU part-of-speech tagger for tweets (Owoputi et al., 2013) to match the MPQA parts-of-speech for each word. We assign positive/negative polarity to similes with more positive/negative lexicon words. This method yields 629 positive and 522 negative similes.

Using Sentiment Classifiers: We create our third training data set using a state-of-the-art sentiment classifier designed for tweets. For this, we reimplemented the NRC Canada sentiment classifier (Zhu et al., 2014) using the same set of features described by the authors. We use a Java implementation[2] of SVM from LIBLINEAR (Fan et al., 2008), with the original parameter values used by the NRC Canada system. We trained the sentiment classifier with all of the tweet training data from SemEval 2013 subtask B (Nakov et al., 2013). We label a simile as positive or negative if the sentiment classifier labels it as positive or negative, respectively. This method yields 1185 positive and 402 negative similes.

Using Sentiment in Surrounding Words: The previous approaches for labeling training instances will primarily identify similes that contain one or more strongly affective words. This

[2]http://liblinear.bwaldvogel.de/

can potentially bias the training data and limit the classifier's ability to learn to recognize affective similes that do not contain words with a positive or negative connotation. Therefore, we explore an additional approach where instead of judging the sentiment of the words in the simile, we analyze the words in the tweet surrounding the simile. We hypothesize that there are often redundant sentiment indicators in the tweet. For example, "I *hate* it when my room is as cold as Antarctica". For each simile, we identify all tweets that contain the simile and collect all of the words surrounding the simile in these tweets as a collective "context" for the tweet. We then count the number of distinct positive and negative sentiment words and compute the probability of positive or negative polarity given all the sentiment words surrounding a simile, and retain positive or negative similes with probability higher than a threshold (here, 0.7 to ensure high quality). As our sentiment lexicon, we combined the MPQA and the AFINN lexicon.

One issue is that when people feel amused (e.g., "he looks like a complete zombie, haha") or sarcastic (e.g., "my room feels like an igloo. great! LOL."), seemingly positive words in the context can be misleading because the sentiment is actually negative. As a simple measure to mitigate this issue, we manually removed a small set of laughter indicators from the lexicons (e.g., lol, haha).

This method yielded 492 positive and 181 negative similes.

Combination of Training Instances: As our last two training sets, we combined sets of instances labeled using the different methods above. As the fifth set, we combined training instances collected using the MPQA and AFINN lexicons and the NRC Canada sentiment classifier, which yielded a total of 2274 positive similes and 1347 negative similes. As our sixth set, we added the instances recognized from the surrounding words of a simile, producing the largest data set of 2766 positive and 1528 negative similes.

We also select neutral instances that are not identified as positive or negative by the above approaches and that also do not contain a sentiment lexicon (AFINN + MPQA) word in their collective context. For each approach, we then randomly select our final training instances for positive, negative and neutral classes maintaining the distribution of the development data. The final training data sizes are reported in Table 5.

4 Classifying Simile Polarity

Our goal is to create a classifier that can determine whether a simile expresses positive or negative affective polarity toward its subject. We present a classifier designed to label similes as Positive, Negative, or Neutral polarity. In this section, we describe the feature set and the classification framework of the supervised classifiers.

4.1 Feature Set

We extract three types of features from a simile, representing the lexical, semantic, and sentiment properties of the simile components.

4.1.1 Lexical Features

Unigrams: A binary feature indicates the presence of a unigram in a simile. This feature is not component specific, so the unigram can be from any simile component (tenor, event or vehicle).

Simile Components: We define a binary feature for each tenor, event and vehicle phrase in the data set. This feature is component specific, (e.g., "dog" as a tenor is a different feature from "dog" as a vehicle).

Paired Components: We use a binary feature for each pair of simile components. Our intuition is that a pair of components may indicate affective polarity when used together. For example, "event:feel, vehicle:ice box" is negative for many different tenors (e.g., house, room, hotel). Similarly, "tenor:person, vehicle:snail" is negative for many different events (e.g., move, run, drive).

Explicit Properties Associated with Vehicle: Sometimes a simile explicitly mentions a property that is common to the tenor and the vehicle (e.g., "my pillow is *soft* like a cloud"). Although the properties are not part of our triples because they are optional components, we can still use them as valuable features, whenever present in the original corpus. For each simile vehicle, we therefore extract all explicit properties mentioned with that vehicle in our corpus, and create a binary feature for each (e.g., "Jane swims like a dolphin" and "Jim runs like a cheetah" can both share the feature *fast*, if *fast* appears with both "dolphin" and "cheetah" in the corpus as an explicit property).

Vehicle Pre-modifiers: We use a binary feature for each noun or adjective pre-modifier that appears with the vehicle (the vehicle head noun itself is excluded). Our intuition is that the same pre-modifiers appearing with different vehicles indi-

cate the same affective polarity (e.g., "smells like *wet* dog" and "smells like *wet* clothes").

4.1.2 Semantic Features

Hypernym Class: We obtain up to two levels of hypernym classes for each simile component head, using WordNet (Miller, 1995). For words with multiple senses, we only use the first synset of a word from WordNet, for simplicity. Once the hypernym classes are obtained for a word, we no longer keep the level information, and use a binary feature to represent each hypernym class. Our intuition is that groups of similar words can be used in different similes with the same affective polarity (e.g., room, bedroom).

Perception Verb: We create a binary feature to indicate if the event component is a perception verb. Perception verbs are fairly common in similes (e.g., "*looks* like a model", "*smells* like garbage"). We use a set of the 5 most common perception verbs in similes (look, feel, sound, smell, taste).

4.1.3 Sentiment Features

We add sentiment features that can be recognized in the simile using existing sentiment resources. For this purpose, we combined the MPQA (Wilson et al., 2005), and the AFINN lexicon (Nielsen, 2011) to use as our sentiment lexicon.

Component Sentiment: We use 3 binary features (one for each component) to indicate the presence of a positive sentiment word, and 3 binary features to indicate the presence of a negative sentiment word in each simile component.

Explicit Property Sentiment: We use 2 numeric features that count the number of positive and negative properties that appear with the vehicle in our corpus. We look for the property words in the combined AFINN and MPQA sentiment lexicons.

Sentiment Classifier Label: We use 2 binary features (one for positive and one for negative) to represent the label that the NRC-Canada Sentiment Classifier assigns to a simile.

Simile Connotation Polarity: We use 2 binary features (one for positive and one for negative) to indicate the overall connotation of a simile. We count whether the number of positive (or negative) connotation words is greater in a simile using a Connotation Lexicon (Feng et al., 2013), which contains 30,881 words with positive connotation and 33,724 words with negative connotation.

4.2 Classification Framework

As our supervised classification algorithm, we use a linear SVM classifier from LIBLINEAR (Fan et al., 2008), with its default parameter settings. Our goal is to assign one of three labels to a simile: *Positive*, *Negative*, or *Neutral*. We train two binary classifiers, one for positive and one for negative polarity. For positive polarity, we use similes labeled *positive* as positive training instances, and similes labeled *negative* or *neutral* as the negative training instances. For the negative polarity classifier, we use similes labeled *negative* as the positive training instances, and similes labeled *positive* or *neutral* as the negative instances.

To classify a simile, we apply both classifiers. If the simile is labeled as *positive* or *negative*, then it is assigned that label. If the simile is labeled as both *positive* and *negative*, or not labeled as either, then it is assigned a *neutral* label. We did not create a classifier to solely identify neutral similes because neutral similes are much less common than positive/negative similes, making up only 8.7% of the extracted similes in our development set (Table 3). Consequently, obtaining a large set of neutral similes via manual annotation would have required substantially more manual annotation effort. Secondly, we did not have a good way to reliably identify neutral similes automatically.

5 Evaluation

5.1 Classification Performance with Manually Annotated Data

Table 4 presents the results for supervised classification with our manually annotated data set using 10-fold cross-validation. As baselines, we used existing sentiment resources as described in Section 3.2, but now applied to evaluation data. We also used the connotation lexicon (Feng et al., 2013) the same way as the MPQA sentiment lexicon (Wilson et al., 2005) to compare as an additional baseline. The top section of Table 4 shows how effective these four existing sentiment resources are at assigning polarity to similes. Although precision was sometimes very high, recall was low across the board.

The lower section of Table 4 shows results for our classifiers. We first trained a classifier using only the sentiment features in order to shed light on the effectiveness of traditional sentiment indicators. Row (a) in Table 4 shows that this classifier produces reasonable precision (65-72%) but recall

	Positive			Negative			Neutral		
	P	R	F	P	R	F	P	R	F
Sentiment Resource Baselines									
AFINN Lexicon	**88**	17	28	**95**	18	31	13	**95**	23

(e) SVM with labeled data using sentiment in surrounding words	164	181	34	60	57	59	62	**57**	**60**	13	20	16
(f) SVM with labeled data from (a), (b), (c), + (e)	1221	1342	242	64	**61**	**62**	75	48	59	11	30	16

Table 5: Results with Automatically Labeled Training Data (P = Precision, R = Recall, F = F1-score).

levels only around 50% for both positive and negative polarity. The Neutral class has extremely low precision, which indicates that many unrecognized positive and negative similes are being classified as Neutral.

Row (b) shows the results for a baseline classifier trained only with unigram features. Unigrams perform substantially better than the sentiment features for negative polarity, but only slightly better for positive polarity. Row (c) shows that the additional lexical features described in Section 4.1.1 further improve performance.

Row (d) shows that adding the semantic features did not improve performance. One reason could be that some WordNet hypernym classes are very specific and may not generalize well. Also, similes can have different polarities with vehicle words from the same general semantic class (e.g., "he runs like a *cheetah*" vs "he runs like a *turtle*").

Finally, Row (e) shows that adding the sentiment features along with all the other features yields a precision gain for positive polarity and a recall gain for negative polarity. Overall, the full feature set improves the F score from 61% to 67% for positive polarity, and from 72% to 78% for negative polarity, over the unigram baseline.

5.2 Classification Performance with Automatically Acquired Training Data

Table 5 shows the performance of the classifiers (using our full feature set) when they are trained with automatically acquired training instances. The upper section of Table 5 shows results using training instances labeled by three different sentiment resources. Row (d) shows that combining the training instances labeled by all three resources produces the best results.

Row (e) of Table 5 shows the performance of the classifiers when they are trained with instances selected by analyzing sentiment in the surrounding words of the similes. We observe a substantial recall gain, which validates our hypothesis that similes obtained by recognizing sentiment in their surrounding words provide the classifier with a more diverse set of training examples. Finally, Row (f) shows that using both types of training instances further improves performance for positive polarity, and increases precision for negative polarity but with some loss of recall.

Comparing these results with Table 4, we see that there is still a gap between the performance of classifiers trained with manually annotated data versus automatically acquired data. However, the classifiers trained with automatically acquired data produce substantially higher F scores than all of

the baseline systems in Table 4. Using automatically acquired training data is a practical approach for creating simile classifiers for specific domains, such as Amazon product reviews (e.g., "headphone sounds like garbage", or "each song is like a snow-flake") which were studied in previous work on figurative comparisons in similes (Niculae and Danescu-Niculescu-Mizil, 2014).

5.3 Impact of Training Data Size

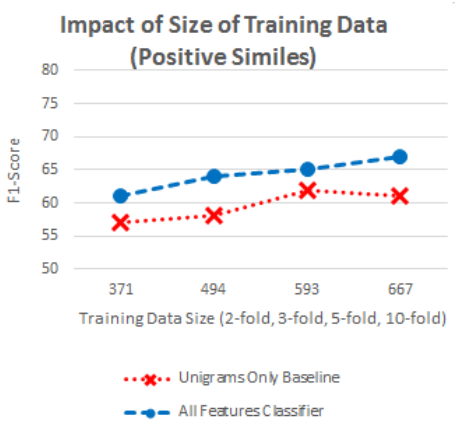

Figure 1: Learning Curve for Positive Similes.

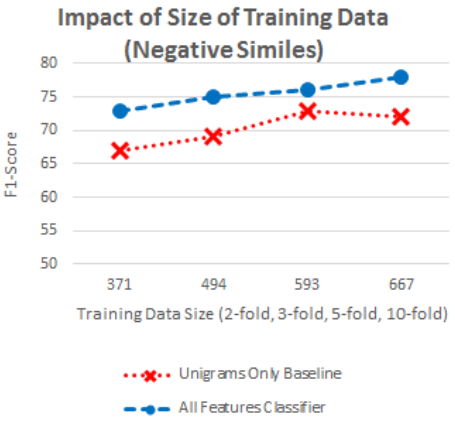

Figure 2: Learning Curve for Negative Similes.

We also generated learning curves to determine how much the size of the training set matters. Figures 1 and 2 show the performance of classifiers trained using varying amounts of manually annotated data. We show results for the classifiers trained only with unigram features and classifiers trained with our full feature set, for positive similes in Figure 1 and negative similes in Figure 2. The results were produced from 2-fold, 3-fold, 5-fold and 10-fold cross-validation experiments, with the size of the corresponding training sets shown on the X-axis. These figures show that the classifiers with unigram features hit a plateau at about 600 training instances. However the classifiers with the full feature set continually benefited from more training data. Table 6 presents a sample of similes where the vehicle appears only once in our data set. The unigram-based classifier could not classify these instances, but the classifier with the full feature set could.

Positive	Negative
PERSON, feel, superhero	PERSON, feel, old woman
PERSON, be, friend	PERSON, be, hurricane
beast, look, beauty	IT, feel, eternity
PERSON, feel, hero	PERSON, feel, peasant
PERSON, feel, champion	PERSON, eat, savage
PERSON, seem, sweetheart	PERSON, be, witch
IT, be, sleepover	PERSON, feel, prisoner
IT, be, reunion	IT, be, north pole
PERSON, feel, president	IT, feel, winter
ronaldo, be, messi	PERSON, be, wolf

Table 6: Similes with unique vehicles that were correctly classified using the full feature set.

6 Analysis and Discussion

We also conducted a qualitative analysis of our new corpus of similes and the behavior of the classifiers. We hypothesized that there are at least two reasons why similes might be difficult to classify. First, the interpretation of a simile can be highly context-dependent and subjective, depending on the speaker or the perceiver. To illustrate, Table 7 presents examples of similes that can have different polarity depending on the speaker or perceiver's personal experience or location, and other subjective aspects of the context. For example, *it looks like snow* may be a good thing to someone who lives in Utah where people look forward to skiing, but a bad thing to someone living in Boston during the winter of 2015. Similarly *she smells like a baby* is typically positive to new mothers, but was viewed as negative by the Mechanical Turk annotators.

Polarity	Simile	Context
positive	PERSON, smell, baby	young mother
negative	PERSON, smell, baby	MTurkers
negative	IT, look, snow	lives in Boston
positive	IT, look, snow	lives in Utah
negative	IT, look, rain	lives in England
positive	IT, look, rain	lives in California

Table 7: Similes with Context-dependent Polarity.

Second, we hypothesized that the polarity of a simile might interact with the distinction made in previous work between figurative and literal

uses of similes (Bredin, 1998; Addison, 1993), for example Niculae and Danescu-Niculescu-Mizil (2014) showed that sentiment and figurative comparisons are strongly correlated. Thus our expectation was that most literal comparisons would be neutral while most figurative comparisons would carry polarity. To explore this issue, we conducted an informal analysis of the 378 similes in our development data set to examine the literal vs. figurative distinction. For this analysis, we looked at the simile component triples as well as the context of ten tweets in which the simile appeared.

Our analysis suggests that the picture is more complex than we initially hypothesized. We found that, 1) the distinction between positive and negative similes in our data is orthogonal to the figurative vs. literal distinction, 2) some similes are used both figuratively and literally, and cannot be differentiated without context, 3) even in cases when all sample uses were literal, it is easy to invent contexts where the simile might be used figuratively, and vice versa, and 4) for a particular instance (simile + context), it is usually possible to tell whether a figurative or literal use is intended by examining the simile context, but some cases remain ambiguous. Table 8 shows examples of some similes that we identified as being figurative, literal, or both depending on context.

Use	Polarity	Simile
fig	positive	house, smell, heaven
fig	positive	PERSON, look, queen
fig	negative	PERSON, look, tomato
lit	negative	hair, smell, smoke
lit	neutral	PERSON, look, each other
both	neutral	house, smell, pizza
both	negative	IT, smell, skunk
both	negative	PERSON, look, frankenstein

Table 8: Similes with figurative (fig) or literal (lit) interpretation, or ambiguous depending on the context.

These observations reinforce the difficulty with making the figurative/literal distinction noted by Niculae and Danescu-Niculescu-Mizil (2014), whose annotation task required Turkers to label comparisons on a scale of 1 to 4 ranging from very literal to very figurative. Even with Master Turkers, a qualification task, filtering annotators by gold standard items, and collapsing scalar 1,2 values to literal and 3,4 values to figurative, the inter-annotator agreement with Fleiss' κ was 0.54. They note that out of 2400 automatically extracted comparison candidates, only 12% end up being selected confidently as figurative comparisons.

Selected cases that the classifiers fail on are further illustrated in Table 9. Examples S1 to S9 could be related to the difficulties noted above with subjectivity of interpretation. Many people for example like the smell of coffee and pizza, but perhaps not when a person smells that way. Similarly, *a baby* is often positive as a vehicle, but smelling and sounding like a baby may not be positive depending on the circumstances, while the positive or negative interpretation of *sounding like a pirate* and *looking like a pirate* might also be context dependent.

ID	Simile	Gold	Man	Auto
S1	PERSON, smell, coffee	neg	pos	pos
S2	PERSON, smell, pizza	pos	neg	neut
S3	IT, smell, pizza	neut	pos	neut
S4	PERSON, sleep, baby	pos	pos	neut
S5	PERSON, smell, baby	neg	neg	neut
S6	PERSON, feel, baby	pos	neg	pos
S7	PERSON, sound, baby	neg	pos	neut
S8	PERSON, sound, pirate	pos	neg	neg
S9	PERSON, look, pirate	neg	neg	neut

Table 9: Error Analysis of Classifier Output (Man = Classifier trained with manually annotated instances, Auto = Classifier trained with automatically annotated instances).

7 Conclusions

Similes are one example of a tractable case of sentiment-bearing expressions that are not recognized well by current sentiment analysis tools or lexicons. Making progress on sentiment analysis may require tackling many different types of linguistic phenomena such as this one. To this end, we have presented a simile data set labeled with affective polarity and have presented a supervised classification framework for recognizing affective polarity in similes. We have also presented our experiments with both manually labeled and automatically acquired training instances. We have shown that with manually labeled data, our feature set can substantially improve performance over a unigram only baseline. We have also shown that good performance can be achieved with automatically acquired training instances, when manually labeled data may not be available.

Abstract

In this paper we focus on a new problem of event coreference resolution across television news videos. Based on the observation that the contents from multiple data modalities are complementary, we develop a novel approach to jointly encode effective features from both closed captions and video key frames. Experiment results demonstrate that visual features provided 7.2% absolute F-score gain on state-of-the-art text based event extraction and coreference resolution.

1 Introduction

TV news is the medium that broadcasts events, stories and other information via television. The broadcast is conducted in programs with the name of "**Newscast**". Typically, newscasts require one or several anchors who are introducing stories and coordinating transition among topics, reporters or journalists who are presenting events in the fields and scenes that are captured by cameramen. Similar to newspapers, the same stories are often reported by multiple newscast agents. Moreover, in order to increase the impact on audience, the same stories and events are reported for mutliple times. TV audience passively receives redundant information, and often has difficulty in obtaining clear and useful digest of ongoing events. These properties lead to needs for automatic methods to cluster information and remove redundancy. We propose a new research problem of event coreference resolution across multiple news videos.

To tackle this problem, a good starting point is processing the **C**losed **C**aptions (**CC**) which is accompanying videos in newcasts. The **CC** is either generated by automatic speech recognition (ASR) systems or transcribed by a human stenotype operator who inputs phonetics which are instantly and automatically translated into texts, where events can be extracted. There exist some previous event coreference resolution work such as (Chen and Ji, 2009b; Chen et al., 2009; Lee et al., 2012; Bejan and Harabagiu, 2010). However, they only focused on formally written newswire articles and utilized textual features. Such approaches do not perform well on CC due to (1). the propagated errors from upper stream components (e.g., automatic speech/stenotype recognition and event extraction); (2). the incompleteness of information. Different from written news, newscasts are often limited in time due to fixed TV program schedules, thus, anchors and journalists are trained and expected to organize reports

Figure 1: Similar visual contents improve detection of a coreferential event pair which has a low text-based confidence score.
Closed Captions: "*It 's not clear when it was **killed**.*"; "*Jordan just executed two ISIS prisoners, direct retaliation for the capture of the **killing** Jordanian pilot.*"

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 201–206,
Lisbon, Portugal, 17-21 September 2015.

which are comprehensively informative with complementary visual and CC descriptions within a short time. These two sides have minimal overlapped information while they are inter-dependent. For example, anchors and reporters introduce the background story which are not presented in the videos, and thus the events extracted from CC often lack information about participants.

For example, as shown in Figure 1, these two **Conflict.Attack** event mentions are coreferential. However, in the first event mention, a mistake in Closed Caption ("*he was killed*" → "*it was killed*") makes event extraction and text based coreference systems unable to detect and link "*it*" to the entity of "*Jordanian pilot*". Fortunately, videos often illustrate brief descriptions by vivid visual contents. Moreover, diverse anchors, reporters and TV channels tend to use similar or identical video contents to describe the same story, even though they usually use different words and phrases. Therefore, the challenges in coreference resolution methods based on text information can be addressed by incorporating visual similarity. In this example, the visual similarity between the corresponding video frames is high because both of them show the scene of the Jordanian pilot.

Similar work such as (Kong et al., 2014), (Ramanathan et al., 2014), (Motwani and Mooney, 2012) and (Ramanathan et al., 2013) have explored methods of linking visual materials with texts. However, these methods mainly focus on connecting image concepts with entities in text mentions; and some of them do not clearly distinguish *entity* and *event* in the documents since the definition of visual concepts often require both of them. Moreover, the aforementioned work mainly focuses on improving visual contents recognition by introducing text features while our work will take the opposite route, which takes advantage of visual information to improve event coreference resolution.

In this paper, we propose to jointly incorporate features from both speech (textual) and video (visual) channels for the first time. We also build a newscast crawling system that can automatically accumulate video records and transcribe closed captions. With the crawler, we created a benchmark dataset which is fully annotated with cross-document coreferential events [1].

[1]Dataset can be found at http://www.ee.columbia.edu/dvmm/newDownloads.htm

2 Approach

2.1 Event Extraction

Given unstructured transcribed CC, we extract entities and events and present them in structured forms. We follow the terminologies used in **ACE** (Automatic Content Extraction) (NIST, 2005):

- Entity: an object or set of objects in the world, such as person, organization and facility.
- Entity mention: words or phrases in the texts that mention an entity.
- Event: a specific occurrence involving participants.
- Event trigger: the word that most clearly expresses an event's occurrence.
- Event argument: an entity, or a temporal expression or a value that has a certain role (e.g., Time-Within, Place) in an event.
- Event mention: a sentence (or a text span extent) that mentions an event, including a distinct trigger and arguments involved.

2.2 Text based Event Coreference Resolution

Coreferential events are defined as the same specific occurrence mentioned in different sentences, documents and transcript texts. Coreferential events should happen in the same place and within the same time period, and the entities involved and their roles should be identical. From the perspective of extracted events, each specific attribute and argument from those events should match. However, mentions for the same event may appear in forms of diverse words and phrases; and they do not always cover all arguments or attributes.

To tackle these challenges, we adopt a Maximum Entropy (MaxEnt) model as in (Chen and Ji, 2009b). We consider every pair of event mentions which share the same event type as a candidate and exploit features proposed in (Chen and Ji, 2009b; Chen et al., 2009). Note that the goal in (Chen and Ji, 2009b; Chen et al., 2009) was to resolve event coreference within the same document, whereas our scenario yields to a cross-document/video transcript setting, so we remove some improper and invalid features. We also investigated the approaches by (Lee et al., 2012) and (Bejan and Harabagiu, 2010), but the confidence estimation results from these alternative methods are not reliable. Moreover, the input of event coreference are automatic results from event extraction instead of gold standard, so the noise and errors significantly impact the corefer-

ence performance, especially for unsupervised approaches (Bejan and Harabagiu, 2010). Nevertheless, we still incorporate features from the aforementioned methods. Table 1 shows the features that constitute the input of the MaxEnt model.

2.3 Visual Similarity

Visual content provides useful cues complementary with those used in text-based approach in event coreference resolution. For example, two coreferential events typically show similar or even duplicate scenes, objects, and activities in the visual channel. Coherence of such visual content has been used in grouping multiple video shots into the same video story (Hsu et al., 2003), but it has not been used for event coreference resolution. Recent work in computer vision has demonstrated tremendous progress in large-scale visual content recognition. In this work, we adopt the state-of-the-art techniques (Krizhevsky et al., 2012) and (Simonyan and Zisserman, 2014) that train robust convolutional neural networks (CNN) over millions of web images to detect 20,000 semantic categories defined in ImageNet (Deng et al., 2009) from each image. The 2nd to the last layer features from such deep network can be considered as high-level visual representation that can be used to discriminate various semantic classes (scenes, objects, activity). It has been found effective in computing visual similarity between images, by directly computing the L2 distance of such features or through further metric learning. To compute the similarity between videos associated with two candidate event mentions, we sample multiple frames from each video and aggregate the similarity scores of the few most similar image pairs between the videos. Let $\{f_1^i, f_2^i, ..., , f_l^i\}$ be the key frames sampled from video V_i and $\{f_1^j, f_2^j, ..., , f_l^j\}$ be key frames sampled from video V_j. All the frames are resized to a fixed resolution of 256 x 256 and fed into our pretrained CNN model. We get the high-level visual representation $F_m = FC7(f_m)$ for each frame f_m from the output of the 2nd to the last fully connected layer (FC7) of CNN model. F_m is a 4096 dimension vector. The visual distance of frames f_m and f_n is defined by L_2 distance, which is

$$D_{mn} = ||FC7(f_m^i) - FC7(f_n^j)||_2. \quad (1)$$

The distance of video pair (V_i, V_j) is computed as

$$\bar{D}_{ij} = \frac{1}{k} * \sum_{(f_m, f_n)} D_{mn} \quad (2)$$

, where (f_m, f_n) is the top k of most similar frame pairs. In our experiment, we use $k = 3$. Such aggregation method among the top matches is intended to capture similarity between videos that share only partially overlapped content.

Each news video story typically starts with an introduction by an anchor person followed by news footages showing the visual scenes or activities of the event. Therefore, when computing visual similarity, it's important to exclude the anchor shot and focus on the story-related clips. Anchor frame detection (Hsu et al., 2003) is a well studied problem. In order to detect anchor frames automatically, a face detector is applied to all I-frames of a video. We can obtain the location and size of each detected face. After checking the temporal consistency of the detected faces within each shot, we get a set of candidate anchor faces. The detected face regions are further extended to regions of interest that may include hair and upper body. All the candidate faces detected from the same video are clustered based on their HSV color histogram. It is reasonable to assume that the most frequent face cluster is the one corresponding to the anchor faces. Once the anchor frames are detected, they are excluded and only the non-anchor frames are used to compute the visual similarity between videos associated with event mentions.

2.4 Joint Re-ranking

Using the visual distance calculated from Section 2.3, we can rerank the confidence values from Section 2.2 using the text-based MaxEnt model. We use the following empirical equation to adjust the confidence:

$$W'_{ij} = W_{ij} * e^{-\frac{\bar{D}_{ij}}{\alpha}+1}, \quad (3)$$

where W_{ij} denotes the original coreference confidence between event mentions i and j, D_{ij} denotes the visual distance between the corresponding video frames where the event mentions were spoken and α is a parameter which is used to adjust the impact of visual distance. In the current implementation, we empirically set it as the average of pair-wised visual distances between videos of all event coreference candidates. With this α

Category	Features	Remarks (EM_i: the first event mention, EM_j: the second event mention)
Baseline	type_subtype	pair of event type and subtype in EM_i
	trigger_pair	trigger pair of EM_i and EM_j
	pos_pair	part-of-speech pair of triggers of EM_i and EM_j
	nominal	1 if the trigger of EM_i is nominal
	nom_number	"plural" or "singular" if the trigger of EM_i is nominal
	pronominal	1 if the trigger of EM_i is pronominal
	exact_match	1 if the trigger spelling in EM_i matches that in EM_j
	stem_match	1 if the trigger stem in EM_i matches that in EM_j
	trigger_sim	the semantic similarity scores between triggers of EM_i and EM_j using WordNet(Miller, 1995)
Arguments	argument_match	1 if arguments holding the same roles in both EM_i and EM_j matches
Attributes	mod,pol,gen,ten	four event attributes in EM_i: modality, polarity, genericity and tense
	mod_conflict, pol_conflict, gen_conflict, ten_conflict	1 if the attributes of EM_i and EM_j conflict

Table 1: Features for Event Coreference Resolution

we generally enhance the confidence of event pairs with small visual distances and penalize those with large ones. An alternative way for setting the alpha parameter is through cross validation over separate data partitions.

3 Experiments

3.1 Data and Setting

We establish a system that actively monitors over 100 U.S. major broadcast TV channels such as ABC, CNN and FOX, and crawls newscasts from these channels for more than two years (Li et al., 2013a). With this crawler, we retrieve 100 videos and their correspondent transcribed CC with the topic of "ISIS"[2]. This system also temporally aligns the CC text with the transcribed text from automatic speech recognition following the methods in (Huang et al., 2003). This provides accurate time alignment between the CC text and the video frames. As CC consists of capitalized letters, we apply the true-casing tool from Standford CoreNLP (Manning et al., 2014) on CC. Then we apply a state-of-the-art event extraction system (Li et al., 2013b; Li et al., 2014) to extract event mentions from CC. We asked two human annotators to investigate all event pairs and annotate coreferential pairs as the ground truth. Kappa coefficient for measuring inter-annotator agreement is 74.11%. In order to evaluate our system performance, we rank the confidence scores of all event mention pairs and present the results in Precision vs. Detection Depth curve. Finally we find the video frames corresponding to the event mentions, remove the anchor frames and calculate the visual similarity between the videos. Our final dataset consists of 85 videos, 207 events and 848 event pairs, where 47 pairs are considered coreferential.

We adopt the MaxEnt-based coreference resolution system from (Chen and Ji, 2009b; Chen et al., 2009) as our baseline, and use ACE 2005 English Corpus as the training set for the model. A 5-fold cross-validation is conducted on the training set and the average f-score is 56%. It is lower than results from (Chen and Ji, 2009a) since we remove some features which are not available for the cross-document scenario.

3.2 Results

The peak F-score for the baseline system is 44.23% while our cross-media method boosts it to 51.43%. Figure 2 shows the improvement after incorporating the visual information. We adopt Wilcoxon signed-rank test to determine the significance between the pairs of precision scores at the same depth. The z-ratio is 3.22, which shows the improvement is significant.

For example, the event pair "*So why hasn't U.S. air strikes targeted Kobani within the city*

[2]abbreviation for *Islamic State of Iraq and Syria*

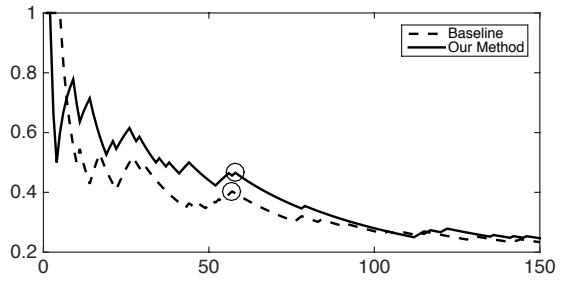

Figure 2: Performance comparison between baseline and our cross-media method on top 150 pairs. Circles indicate the peak F-scores.

limits" and "*Our strikes continue alongside our partners.*" was mistakenly considered coreferential by text features. In fact, the former "strikes" mentions the airstrike and the latter refers to the war or battle, therefore, they are not coreferential. The corresponding video shots demonstrate two different scenes: the former one shows bombing while the latter shows that the president is giving a speech about the strike. Thus the visual distance successfully corrected this error.

3.3 Error Analysis

However, from Figure 2 we can also notice that there are still some errors caused by the visual features. One major error type resides in the negative pairs with both "relatively" high textual coreference confidence scores and "relatively" high visual similarity. From the text side, the event pair contains similar events, for example: "*The Penn(tagon) says coalition air strikes in and around the Syrian city of Kobani have kill hundreds of ISIS fighters but more are streaming in even as the air campaign intensifies.*" and "*Throughout the day, explosions from coalition air strikes sent plums of smoke towering into the sky.*". They talk about two airstrikes during different time periods and are not coreferential, but the baseline system produces a high rank. Our current approach limits the image frames to those overlapped with the speech of an event mention, and in this error, both videos show "battle" scene, yielding a small visual distance. The aforementioned assumption that anchors and journalists tend to use similar videos when describing the same events , which may introduce risk of error caused by similar text event mentions with similar video shots. For such errors, one potential solution is to expand the video frame windows to capture more events and concepts from videos. Expanding the detection range to include visual events in the temporal neighborhood can also differentiate the events.

3.4 Discussion

A systematic way of choosing α in Equation 3 will be useful. One idea is to adapt the α value for different types of events, e.g., we expect some event types are more visually oriented than others and thus use a smaller α value.

We also notice the impact of the errors from the upstream event extraction system. According to (Li et al., 2014) the F-score of event trigger labeling is 65.3%, and event argument labeling is 45%. Missing arguments in events is a main problem, thus the performance on automatically extracted event mentions is significantly worse. About 20 more coreferential pairs could be detected if events and arguments are perfectly extracted.

4 Conclusions and Future Work

In this paper, we improved event coreference resolution on newscast speech by incorporating visual similarity. We also build a crawler that provides a benchmark dataset of videos with aligned closed captions. This system can also help create more datasets to conduct research on video description generation. In the future, we will focus on improving event extraction from texts by introducing more fine-grained cross-media information such as object, concept and event detection results from videos. Moreover, joint detection of events from both sides is our ultimate goal, however, we need to explore the mapping among events from both text and visual sides, and automatic detection of a wide range of objects and events from news video itself is still challenging.

Abstract

Integrating vision and language has long been a dream in work on artificial intelligence (AI). In the past two years, we have witnessed an explosion of work that brings together vision and language from images to videos and beyond. The available corpora have played a crucial role in advancing this area of research. In this paper, we propose a set of quality metrics for evaluating and analyzing the vision & language datasets and categorize them accordingly. Our analyses show that the most recent datasets have been using more complex language and more abstract concepts, however, there are different strengths and weaknesses in each.

1 Introduction

Bringing together language and vision in one intelligent system has long been an ambition in AI research, beginning with SHRDLU as one of the first vision-language integration systems (Winograd, 1972) and continuing with more recent attempts on conversational robots grounded in the visual world (Kollar et al., 2013; Cantrell et al., 2010; Matuszek et al., 2012; Kruijff et al., 2007; Roy et al., 2003). In the past few years, an influx of new, large vision & language corpora, alongside dramatic advances in vision research, has sparked renewed interest in connecting vision and language. Vision & language corpora now provide alignments between visual content that can be recognized with Computer Vision (CV) algorithms and language that can be understood and generated using Natural Language Processing techniques.

Fueled in part by the newly emerging data, research that blends techniques in vision and in language has increased at an incredible rate. In just the past year, recent work has proposed methods for image and video captioning (Fang et al., 2014; Donahue et al., 2014; Venugopalan et al., 2015), summarization (Kim et al., 2015), reference (Kazemzadeh et al., 2014), and question answering (Antol et al., 2015; Gao et al., 2015), to name just a few. The newly crafted large-scale vision & language datasets have played a crucial role in defining this research, serving as a foundation for training/testing and helping to set benchmarks for measuring system performance.

Crowdsourcing and large image collections such as those provided by Flickr[1] have made it possible for researchers to propose methods for vision and language tasks alongside an accompanying dataset. However, as more and more datasets have emerged in this space, it has become unclear how different methods generalize beyond the datasets they are evaluated on, and what data may be useful for moving the field beyond a single task, towards solving larger AI problems.

In this paper, we take a step back to document this moment in time, making a record of the major available corpora that are driving the field. We provide a quantitative analysis of each of these corpora in order to understand the characteristics of each, and how they compare to one another. The quality of a dataset must be measured and compared to related datasets, as low quality data may distort an entire subfield. We propose a set of criteria for analyzing, evaluating and comparing the quality of vision & language datasets against each other. Knowing the details of a dataset compared to similar datasets allows researchers to define more precisely what task(s) they are trying to solve, and select the dataset(s) best suited to their goals, while being aware of the implications and biases the datasets could impose on a task.

We categorize the available datasets into three major classes and evaluate them against these cri-

*F.F. and N.M. contributed equally to this work.

Lisbon, Portugal, 17-21 September 2015.

teria. The datasets we present here were chosen because they are all available to the community and cover the data that has been created to support the recent focus on image captioning work. More importantly, we provide an evolving website[2] containing pointers and references to many more vision-to-language datasets, which we believe will be valuable in unifying the quickly expanding research tasks in language and vision.

2 Quality Criteria for Language & Vision Datasets

The quality of a dataset is highly dependent on the sampling and scraping techniques used early in the data collection process. However, the content of datasets can play a major role in narrowing the focus of the field. Datasets are affected by both *reporting bias* (Gordon and Durme, 2013), where the frequency with which people write about actions, events, or states does not directly reflect real-world frequencies of those phenomena; they are also affected by *photographer's bias* (Torralba and Efros, 2011), where photographs are somewhat predictable within a given domain. This suggests that new datasets may be useful towards the larger AI goal if provided alongside a set of quantitative metrics that show how they compare against similar corpora, as well as more general "background" corpora. Such metrics can be used as indicators of dataset bias and language richness. At a higher level, we argue that clearly defined metrics are necessary to provide quantitative measurements of how a new dataset compares to previous work. This helps clarify and benchmark how research is progressing towards a broader AI goal as more and more data comes into play.

In this section, we propose a set of such metrics that characterize vision & language datasets. We focus on methods to measure *language quality* that can be used across several corpora. We also briefly examine metrics for *vision quality*. We evaluate several recent datasets based on all proposed metrics in Section 4, with results reported in Tables 1, 2, and Figure 1.

2.1 Language Quality

We define the following criteria for evaluating the captions or instructions of the datasets:

• **Vocabulary Size** (*#vocab*), the number of unique vocabulary words.

• **Syntactic Complexity** (*Frazier*, *Yngve*) measures the amount of embedding/branching in a sentence's syntax. We report mean Yngve (Yngve, 1960) and Frazier measurements (Frazier, 1985); each provides a different counting on the number of nodes in the phrase markers of syntactic trees.

• **Part of Speech Distribution** measures the distribution of nouns, verbs, adjectives, and other parts of speech.

• **Abstract:Concrete Ratio** (*#Conc*, *#Abs*, *%Abs*) indicates the range of visual and non-visual concepts the dataset covers. Abstract terms are ideas or concepts, such as 'love' or 'think' and concrete terms are all the objects or events that are mainly available to the senses. For this purpose, we use a list of most common abstract terms in English (Vanderwende et al., 2015), and define concrete terms as all other words except for a small set of function words.

• **Average Sentence Length** (*Sent Len.*) shows how rich and descriptive the sentences are.

• **Perplexity** provides a measure of data skew by measuring how expected sentences are from one corpus according to a model trained on another corpus. We analyze perplexity (*Ppl*) for each dataset against a 5-gram language model learned on a generic 30B words English dataset. We further analyze pair-wise perplexity of datasets against each other in Section 4.

2.2 Vision Quality

Our focus in this survey is mainly on language, however, the characteristics of images or videos and their corresponding annotations is as important in vision & language research. The quality of vision in a dataset can be characterized in part by the variety of visual subjects and scenes provided, as well as the richness of the annotations (e.g., segmentation using bounding boxes (*BB*) or visual dependencies between boxes). Moreover, a vision corpus can use abstract or real images (*Abs/Real*).

3 The Available Datasets

We group a representative set of available datasets based on their content. For a complete list of datasets and their descriptions, please refer to the supplementary website.[2]

3.1 Captioned Images

Several recent vision & language datasets provide one or multiple captions per image. The captions

[2] http://visionandlanguage.net

of these datasets are either the original photo title and descriptions provided by online users (Ordonez et al., 2011; Thomee et al., 2015), or the captions generated by crowd workers for existing images. The former datasets tend to be larger in size and contain more contextual descriptions.

3.1.1 User-generated Captions

• **SBU Captioned Photo Dataset** (Ordonez et al., 2011) contains 1 million images with original user generated captions, collected in the wild by systematic querying of Flickr. This dataset is collected by querying Flickr for specific terms such as objects and actions and then filtered images with descriptions longer than certain mean length.

• **Déjà Images Dataset** (Chen et al., 2015) consists of 180K unique user-generated captions associated with 4M Flickr images, where one caption is aligned with multiple images. This dataset was collected by querying Flickr for 693 high frequency nouns, then further filtered to have at least one verb and be judged as "good" captions by workers on Amazon's Mechanical Turk (Turkers).

3.1.2 Crowd-sourced Captions

• **UIUC Pascal Dataset** (Farhadi et al., 2010) is probably one of the first datasets aligning images with captions. Pascal dataset contains 1,000 images with 5 sentences per image.

• **Flickr 30K Images** (Young et al., 2014) extends previous Flickr datasets (Rashtchian et al., 2010), and includes 158,915 crowd-sourced captions that describe 31,783 images of people involved in everyday activities and events.

• **Microsoft COCO Dataset (MS COCO)** (Lin et al., 2014) includes complex everyday scenes with common objects in naturally occurring contexts. Objects in the scene are labeled using per-instance segmentations. In total, this dataset contains photos of 91 basic object types with 2.5 million labeled instances in 328k images, each paired with 5 captions. This dataset gave rise to the CVPR 2015 image captioning challenge and is continuing to be a benchmark for comparing various aspects of vision and language research.

• **Abstract Scenes Dataset (Clipart)** (Zitnick et al., 2013) was created with the goal of representing real-world scenes with clipart to study scene semantics isolated from object recognition and segmentation issues in image processing. This removes the burden of low-level vision tasks. This dataset contains 10,020 images of children playing outdoors associated with total 60,396 descriptions.

3.1.3 Captions of Densely Labeled Images

Existing caption datasets provide images paired with captions, but such brief image descriptions capture only a subset of the content in each image. Measuring the magnitude of the reporting bias inherent in such descriptions helps us to understand the discrepancy between what we can learn for the specific task of image captioning versus what we can learn more generally from the photographs people take. One dataset useful to this end provides image annotation for content selection:

• **Microsoft Research Dense Visual Annotation Corpus** (Yatskar et al., 2014) provides a set of 500 images from the Flickr 8K dataset (Rashtchian et al., 2010) that are densely labeled with 100,000 textual labels, with bounding boxes and facets annotated for each object. This approximates "gold standard" visual recognition.

To get a rough estimate of the reporting bias in image captioning, we determined the percentage of top-level objects[3] that are mentioned in the captions for this dataset out of all the objects that are annotated. Of the average 8.04 available top-level objects in the image, each of the captions only reports an average of 2.7 of these objects.[4] A more detailed analysis of reporting bias is beyond the scope of this paper, but we found that many of the biases (e.g., people selection) found with abstract scenes (Zitnick et al., 2013) are also present with photos.

3.2 Video Description and Instruction

Video datasets aligned with descriptions (Chen et al., 2010; Rohrbach et al., 2012; Regneri et al., 2013; Naim et al., 2015; Malmaud et al., 2015) generally represent limited domains and small lexicons, which is due to the fact that video processing and understanding is a very compute-intensive task. Available datasets include:

• **Short Videos Described with Sentences** (Yu and Siskind, 2013) includes 61 video clips (each 35 seconds in length, filmed in three different

[3]This visual annotation consists of a two-level hierarchy, where multiple Turkers enumerated and located objects and stuff in each image, and these objects were then further labeled with finer-grained object information (*Has* attributes).

[4]We did not use an external synonym or paraphrasing resource to perform the matching between labels and captions, as the dataset itself provides paraphrases for each object: each object is labeled by multiple Turkers, who labeled *Isa* relations (e.g., "eagle" is a "bird").

		Size(k)		Language								Vision

Table 1: Summary of statistics and quality metrics of a sample set of major datasets. For Brown, we report Frazier and Yngve scores on automatically acquired parses, but we also compute them for the 24K sentences with gold parses: in this setting, the mean Frazier score is 15.26 while the mean Yngve score is 58.48.

outdoor environments), showing multiple simultaneous events between a subset of four objects: a person, a backpack, a chair, and a trash-can. Each video was manually annotated (with very restricted grammar and lexicon) with several sentences describing what occurs in the video.

• **Microsoft Research Video Description Corpus (MS VDC)** (Chen and Dolan, 2011) contains parallel descriptions (85,550 English ones) of 2,089 short video snippets (10-25 seconds long). The descriptions are one sentence summaries about the actions or events in the video as described by Amazon Turkers. In this dataset, both paraphrase and bilingual alternatives are captured, hence, the dataset can be useful translation, paraphrasing, and video description purposes.

3.3 Beyond Visual Description

Recent work has demonstrated that n-gram language modeling paired with scene-level understanding of an image trained on large enough datasets can result in reasonable automatically generated captions (Fang et al., 2014; Donahue et al., 2014). Some works have proposed to step beyond description generation, towards deeper AI tasks such as question answering (Ren et al., 2015; Malinowski and Fritz, 2014). We present two of these attempts below:

• **Visual Madlibs Dataset (VML)** (Yu et al., 2015) is a subset of 10,783 images from the MS COCO dataset which aims to go beyond describing which objects are in the image. For a given image, three Amazon Turkers were prompted to complete one of 12 fill-in-the-blank template questions, such as 'when I look at this picture, I feel –', selected automatically based on the image content. This dataset contains a total of 360,001 MadLib question and answers.

• **Visual Question Answering (VQA) Dataset** (Antol et al., 2015) is created for the task of open-ended VQA, where a system can be presented with an image and a free-form natural-language question (e.g., 'how many people are in the photo?'), and should be able to answer the question. This dataset contains both real images and abstract scenes, paired with questions and answers. Real images include 123,285 images from MS COCO dataset, and 10,000 clip-art abstract scenes, made up from 20 'paperdoll' human models with adjustable limbs and over 100 objects and 31 animals. Amazon Turkers were prompted to create 'interesting' questions, resulting in 215,150 questions and 430,920 answers.

• **Toronto COCO-QA Dataset (CQA)** (Ren et al., 2015) is also a visual question answering dataset, where the questions are automatically generated from image captions of MS COCO dataset. This dataset has a total of 123,287 images with 117,684 questions with one-word answer about objects, numbers, colors, or locations.

4 Analysis

We analyze the datasets introduced in Section 3 according to the metrics defined in Section 2, using the Stanford CoreNLP suite to acquire parses and part-of-speech tags (Manning et al., 2014). We also include the Brown corpus (Francis and Kucera, 1979; Marcus et al., 1999) as a reference point. We find evidence that the VQA dataset captures more abstract concepts than other datasets, with almost 20% of the words found in our abstract concept resource. The Deja corpus has the least number of abstract concepts, followed by COCO and VDC. This reflects differences in col-

	Brown	Clipart	Coco	Flickr30K	CQA	VDC	VQA	Pascal	SBU

#vocab	*14.0k*	*1.1k*	*13k*	*9.4k*	*5.3k*	*4.9k*	*1.4k*	*1.0k*	*65.1k*

Table 2: Perplexities across corpora, where rows represent test sets (20k sentences) and columns training sets (remaining sentences). To make perplexities comparable, we used the same vocabulary frequency cutoff of 3. All models are 5-grams.

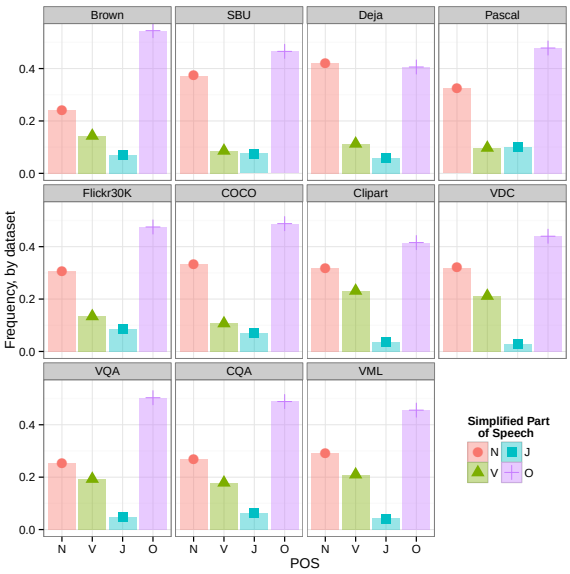

Figure 1: Simplified part-of-speech distributions for the eight datasets. We include the POS tags from the balanced Brown corpus (Marcus et al., 1999) to contextualize any very shallow syntactic biases. We mapped all nouns to "N," all verbs to "V," all adjectives to "J" and all other POS tags to "O."

lecting the various corpora: For example, the Deja corpus was collected to find *specifically* visual phrases that can be used to describe multiple images. This corpus also has the most syntactically simple phrases, as measured by both Frazier and Yngve; this is likely caused by the phrases needing to be general enough to capture multiple images.

The most syntactically complex sentences are found in the Flickr30K, COCO and CQA datasets. However, the CQA dataset suffers from a high perplexity against a background corpus relative to the other datasets, at odds with relatively short sentence lengths. This suggests that the automatic caption-to-question conversion may be creating unexpectedly complex sentences that are less reflective of general language usage. In contrast, the COCO and Flickr30K dataset's relatively high syntactic complexity is in line with their relatively high sentence length.

Table 2 illustrates further similarities between datasets, and a more fine-grained use of perplexity to measure the usefulness of a given training set for predicting words of a given test set. Some datasets such as COCO, Flickr30K, and Clipart are generally more useful as out-domain data compared to the QA datasets. Test sets for VQA and CQA are quite idiosyncratic and yield poor perplexity unless trained on in-domain data. As shown in Figure 1, the COCO dataset is balanced across POS tags most similarly to the balanced Brown corpus (Marcus et al., 1999). The Clipart dataset provides the highest proportion of verbs, which often correspond to actions/poses in vision research, while the Flickr30K corpus provides the most nouns, which often correspond to object/stuff categories in vision research.

We emphasize here that the distinction between a qualitatively good or bad dataset is task dependent. Therefore, all these metrics and the obtained results provide the researchers with an objective set of criteria so that they can make the decision whether a dataset is suitable to a particular task.

5 Conclusion

We detail the recent growth of vision & language corpora and compare and contrast several recently released large datasets. We argue that newly introduced corpora may measure how they compare to similar datasets by measuring *perplexity*, *syntactic complexity*, *abstract:concrete* word ratios, among other metrics. By leveraging such metrics and comparing across corpora, research can be sensitive to how datasets are biased in different directions, and define new corpora accordingly.

Combining Geometric, Textual and Visual Features for Predicting Prepositions in Image Descriptions

Abstract

We investigate the role that geometric, textual and visual features play in the task of predicting a preposition that links two visual entities depicted in an image. The task is an important part of the subsequent process of generating image descriptions. We explore the prediction of prepositions for a pair of entities, both in the case when the labels of such entities are known and unknown. In all situations we found clear evidence that all three features contribute to the prediction task.

1 Introduction

In recent years, there has been an increased interest in the task of automatic generation of natural language image descriptions at sentence level, compared to earlier work that annotates images with a laundry list of terms (Duygulu et al., 2002). The task is important in that such detailed annotations are more informative and discriminative compared to isolated textual labels, and are essential for improved text and image retrieval.

The most standard approach to generating such descriptions involves first detecting instances of pre-defined concepts in the image, and then reasoning about these concepts to generate image descriptions e.g. (Kulkarni et al., 2011; Yang et al., 2011). Our work is also based on this paradigm. However, we assume that object instances have already been pre-detected by visual recognisers, and concentrate on a specific subtask of description generation. More specifically, given two visual entity instances where one could potentially act as a modifier to the other, we address the problem of identifying the appropriate preposition to connect these two entities (Figure 1). The inferred prepositional relations will subsequently act as an important intermediate representation towards the eventual goal of generating image descriptions.

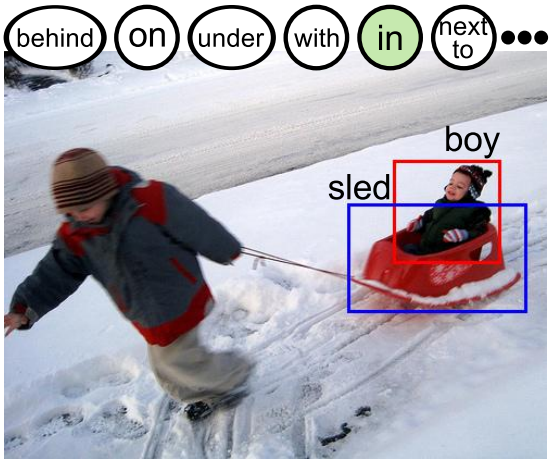

Figure 1: Given a subject *boy* and an object *sled* and their location in the image, what would the best preposition be to connect the two entities?

The main contribution of this paper is therefore to learn to predict the most suitable preposition given its context, and to learn this jointly from images and their descriptions. In particular, we concentrate on learning from (i) geometric relations between two visual entities from image annotations; (ii) textual features from textual descriptions; (iii) visual features from images. Previous work exists (Yang et al., 2011) that uses text corpora to 'guess' the prepositions given the context without considering the appropriate spatial relations between the entities in the image, signifying a gap between visual content and its corresponding description. For example, although *person on horse* might commonly occur in text corpora, a particular image might actually depict a person standing beside a horse. On the other hand, work that does consider the image content for generating prepositions (Kulkarni et al., 2011; Elliott and Keller, 2013) map geometric relations to a limited set of prepositions using manually defined rules,

*A. Ramisa and J. Wang contributed equally to this work.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 214–220,
Lisbon, Portugal, 17-21 September 2015.

not as humans would naturally use them with a richer vocabulary. We would like to have the best of both worlds, by considering image content as well as textual information to select the preposition best used to express the relation between two entities. Our hypothesis is that the combination of geometric, textual and visual features can help with the task of predicting the most appropriate preposition, since incorporating geometric and visual information should help generate a relation that is consistent with the image content, whilst incorporating textual information should help generate a description that is consistent with natural language.

2 Related Work

The Natural Language Processing Community has significant interest in different aspects of prepositions. The Prepositions Project (Litkowski and Hargraves, 2005) analysed and produced a lexicon of English prepositions and their senses, and subsequently used them in the Word Sense Disambiguation of Prepositions task in SemEval-2007 (Litkowski and Hargraves, 2007). In SemEval-2012, Kordjamshidi et al. (2012) introduce the more fine-grained task of spatial role labelling to detect and classify spatial relations expressed by triples *(trajector, landmark, spatial_indicator)*. In the latest edition of SemEval-2015, the SpaceEval task (Pustejovsky et al., 2015) introduce further tasks of identifying spatial and motion signals, as well as spatial configurations/orientation and motion relation.

In work that links prepositions more strongly to image content, Gupta and Davis (2008) model prepositions implicitly to disambiguate image regions, rather than for predicting prepositions. Their work also require manual annotation of prepositional relations. In image description generation work, Kulkarni et al. (2011) manually map spatial relations to pre-defined prepositions, whilst Yang et al. (2011) predict prepositions from large-scale text corpora solely based on the complement term, with the prepositions constrained to describing scenes (*on the street*). Elliott and Keller (2013) define a list of eight spatial relations and their corresponding prepositional term for sentence generation. Although they also present alternative models that use text corpora for descriptions that are more human-like, they are limited to verbs and do not cover prepositions. Le et al. (2014) examine prepositions modifying human actions (verbs), and conclude that these relate to positional information to a certain extent. Other related work include training classifiers for prepositions with spatial relation features to improve image segmentation and detection (Fidler et al., 2013); this work is however limited to four prepositions.

3 Task Definition

We formally define the task of predicting prepositions as follows: Let P be the set of possible prepositions. Let L be the set of possible *landmark* entities acting as the complement of a preposition, and let T be the set of possible *trajector* entities modified by the prepositional phrase comprising a preposition and its landmark[1]. For example, for the phrase *person on bicycle*, *on* would be the preposition, *bicycle* the landmark, and *person* the trajector. For this paper, we constrain *trajector* and *landmark* to be entities that are visually identifiable in an image since we are interested in discovering the role of visual features and geometric configurations between two entities in the preposition prediction task.

Let $D = \{d_1, d_2, ..., d_N\}$ be the set of N observations, where each d_i for $i = 1, 2..., N$ is represented by $d_i = (x_i, y_i, r_i)$, where x_i and y_i are the feature representations for the trajector and the landmark entities respectively, and r_i the relative geometric feature between the two visual entities.

Given d_i, the objective of the preposition prediction task is to produce a ranked list of prepositions $(p_1, p_2, ...p_{|P|})$ according to how likely they are to express the appropriate spatial relation between the given trajector and landmark entities that are either known (Section 6.1) or only represented by visual features (Section 6.2).

4 Dataset

We base the preposition prediction task on two large-scale image datasets with human authored descriptions, namely MSCOCO (Lin et al., 2014) and Flickr30k (Young et al., 2014; Plummer et al., 2015). To extract instances of triples *(trajector, preposition, landmark)* from image descriptions, we used the Neural Network, transition-based dependency parser of Chen and Manning (2014) as implemented in Stanford CoreNLP (Manning et al., 2014). Dependencies signifying prepositional

[1]The terminologies *trajector* and *landmark* are adopted from spatial role labelling (Kordjamshidi et al., 2011)

Bounding Box feature (number of dimensions)
• Vector (x, y) from centroid of trajector to centroid of landmark, normalised by the size of the bounding box enclosing both objects (2)
• Area of trajector bounding box relative to landmark (1)
• Aspect ratio of each bounding box (2)
• Area of each bounding box w.r.t. enclosing box (2)
• Intersection over union of the bounding boxes (1)
• Euclidean distance between the trajector and landmark bounding boxes, normalised by the image size (1)
• Area of each bounding box w.r.t. the whole image (2)

Table 1: Geometric features derived from bounding boxes.

relations are retained where both the governor and its dependent overlap with the entity mentions in the descriptions, and where both mentions have corresponding bounding boxes. The MSCOCO validation set is further annotated to remove errors arising from dependency parsing (notably PP attachment errors), and is used as our clean test set. Our final dataset comprises 8,029 training and 3,431 test instances for MSCOCO, and 46,847 training and 20,010 test instances for Flickr30k. Details on how the triples were extracted from captions and matched to instances in images are available in the supplementary material.

We consider two variants of trajector and landmark terms in our experiments: (i) using the provided high level categories as terms (80 for MSCOCO and 8 for Flickr30k); (ii) using the terms occurring in the sentence directly, which constitute a bigger and more realistic challenge. For Flickr30k, the descriptive phrases may cause data sparseness (*the furry, black and white dog*). Thus, we extracted the lemmatised head word of each phrase, using a 'semantic head' variant of the head finding rules of Collins (2003) in Stanford CoreNLP. Entities from the same coreference chain are denoted with a common head noun chosen by majority vote among the group, with ties broken by the most frequent head noun in the corpus, and further ties broken at random.

5 Features

Geometric Features: Geometric features between a trajector and a landmark entity are derived from bounding box annotations. We defined an 11-dimensional vector of bounding box features, covering geometric relations such as distance, orientation, relative bounding box sizes and overlaps between bounding boxes (Table 1). We chose to use continuous features as we felt these may be more powerful and expressive compared to discrete, binned features. Despite some of these features being correlated, we left it to the classifier to determine the most useful features for discrimination without having to withhold any unnecessarily.

Textual features: We consider two textual features to encode the trajector and landmark terms w_i^t and w_i^l. The first feature is a one-hot indicator vector x_i^I and y_i^I for the trajector and landmark respectively, where $x_{i,t}^I = 1$ if index t corresponds to the trajector term w_i^t and 0 elsewhere (and similarly for landmark). As data sparseness may be an issue, we also explore an alternative textual feature which encodes the terms as word2vec embeddings (Mikolov et al., 2013). This encodes each term as a vector such that semantically related terms are close in the vector space. This allows information to be transferred across semantically related terms during training (e.g. information from *person on boat* can help predict the preposition that mediates *man* and *boat*).

Image Features: While it is ideal to have vision systems produce a firm decision about the visual entity instance detected in an image, in reality it may be beneficial to defer the decision by allowing several possible interpretations of the instance being detected. In such cases, we will not have a single concept label for the entity, but instead a high-level visual representation. For this scenario, we extracted visual representations from the final layer of a Convolutional Neural Network trained on ImageNet (Krizhevsky et al., 2012), and used them as representations for entity instances in place of textual features.

6 Preposition Prediction

Here we highlight interesting findings from experiments performed for the task of predicting prepositions for two different scenarios (Sections 6.1 and 6.2). Detailed results can be found in the supplementary material.

Evaluation metrics. As there may be more than one 'correct' preposition for a given context (*person on horse* and *person atop horse*), we propose the mean rank of the correct preposition as the main evaluation metric, as it accommodates

		IND	W2V	GF	IND+GF	W2V+GF	Baseline
Mean rank	MSCOCO (max rank 17)	1.45	1.43	1.72	1.44	**1.42**	2.14
	MSCOCO (balanced)	3.20	3.10	4.60	3.00	**2.90**	5.40
	Flickr30k (max rank 52)	1.91	1.87	2.35	1.88	**1.85**	2.54
	Flickr30k (balanced)	11.10	9.04	15.55	10.23	**8.90**	15.13
Accuracy	MSCOCO	79.7%	80.3%	68.4%	79.8%	**80.4%**	40.2%
	MSCOCO (balanced)	52.5%	**54.2%**	31.5%	52.7%	53.9%	11.9%
	Flickr30k	75.4%	75.2%	58.5%	**75.8%**	75.4%	53.7%
	Flickr30k (balanced)	24.6%	25.9%	9.0%	25.2%	**26.9%**	4.0%

Table 2: Top: Mean rank of the correct preposition (lower is better). Bottom: Accuracy with different feature configurations. All results are with the original trajector/landmark terms from descriptions. IND stands for Indicator Vectors, W2V for Word2Vec, and GF for Geometric Features. As baseline we rank the prepositions by their relative frequencies in the training dataset.

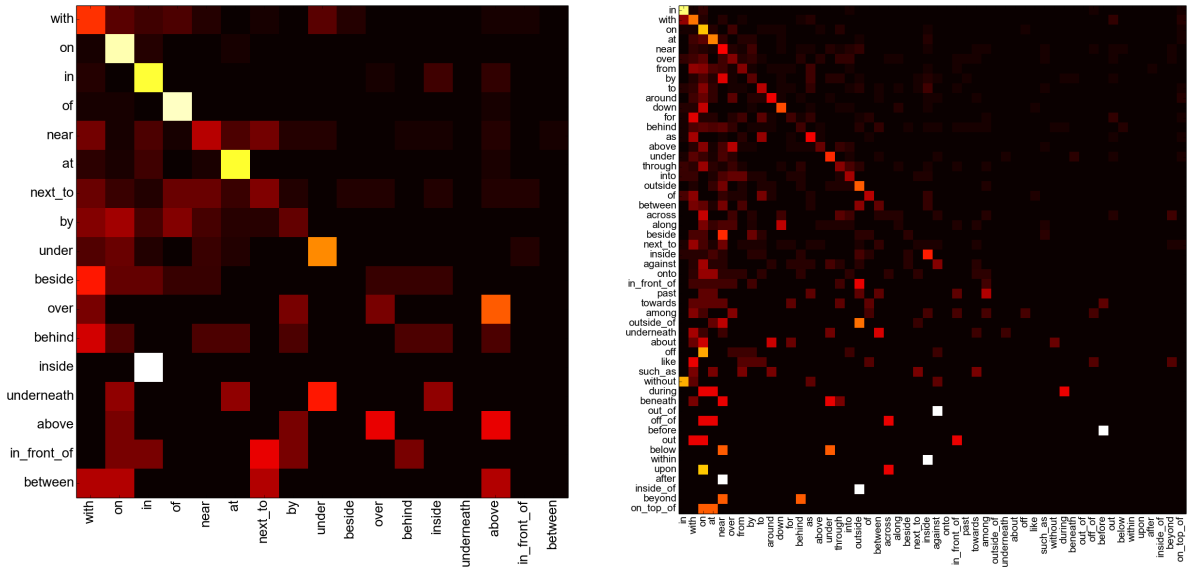

Figure 2: Normalised confusion matrices on the balanced test subsets for the two datasets (left: MSCOCO, right: Flickr30k), using geometric features and word2vec with the original terms.

multiple possible prepositions that may be equally valid. For completeness we also report classification accuracy results.

Baseline. As baseline, we rank the prepositions by their relative frequencies in the training dataset. We found this to be a sufficiently strong baseline, as ubiquitous prepositions such as *with* and *in* tend to occur frequently in the dataset.

6.1 Ranking with known entity labels

In this section, we focus on predicting the best preposition given the geometric and textual features of the trajector and landmark entities. This simulates the scenario of a vision detector providing a firm decision on the concept label for the detected entities. We use a multi-class logistic regression classifier (Fan et al., 2008), and concatenate multiple features into a single vector. We compare high-level categories and terms from descriptions as trajector/landmark labels. Prepositions are ranked in descending order of the classifier output scores.

We found a few prepositions (e.g. *with*) dominating the datasets. Thus, we also evaluated our models on a balanced subset where each preposition is limited to a maximum of 50 random test samples. The training samples are weighted according to their class frequency in order to train non-biased classifiers to predict this balanced test set. The results on both the original and balanced

Dataset	Prep (known labels)		Preposition		Trajector		Landmark	
	acc	rank	acc	rank	acc	rank	acc	rank
MSCOCO	79.8%	1.46 (17)	62.9%	1.92 (17)	65.6%	4.64 (74)	44.5%	7.30 (77)
Flickr30k	67.1%	2.16 (52)	61.7%	2.28 (52)	77.3%	1.43 (8)	66.4%	1.64 (8)

Table 3: Accuracy (**acc**) and mean rank (**rank**, with max rank in parenthesis) for each variable of the CRF model, trained using the high-level concept labels. Columns under **Prep (known labels)** refer to the results of predicting prepositions with the trajector and landmark labels fixed to the correct values.

test sets are compared.

As shown in Table 2, the system performed significantly better than the baseline in most cases. In general, geometric features perform better than the baseline, and when combined with text features further improve the results. In a per-preposition analysis, the geometric features show up to 14% improvement in the mean rank for Flickr30k.

In feature ablation tests on MSCOCO (balanced), we found the y component of the trajector to landmark vector to be important to most prepositions, especially for *under*, *above* and *on*. Other important geometric features include the final two features in Table 1 (Euclidean distance and area).

The benefit of the word2vec text feature is clear when moving from high-level categories to original terms from descriptions, where it consistently improves the mean rank (up to 25%). In contrast, the indicator vectors resulted in a less significant improvement, if not worse performance, when using the sparse original terms.

We also evaluated the relative importance of the trajector and the landmark, by withholding either from the textual feature vector. We found that the landmark plays a larger role in preposition prediction as omitting the trajector produces 10%-30% better results than omitting the landmark.

Figure 2 shows the confusion matrices of the best-performing systems. Note that many mistakes arise from prepositions that are often equally valid (e.g. predicting *near* instead of *next_to*).

6.2 Ranking with unknown entity labels

Here, we investigate the task of jointly predicting prepositions with the entity labels given geometric and visual features (*without* the trajector and landmark labels). This simulates the scenario of a vision detector output. For this structured prediction task, we use a 3-node chain CRF model[2], with the centre node representing the preposition and the two end nodes representing the trajector and landmark. We use *image features* for the entity nodes, and *geometric features* for the preposition node (Section 5). Due to computational constraints only high-level category labels are used, but as seen in Section 6.1, this may actually be *hurting* the performance.

Table 3 shows the results of the structured model used to predict the most likely *(trajector, preposition, landmark)* combination. To facilitate comparison with Section 6.1, column **Prep (known labels)** shows the results with the trajector and landmark labels as known conditions and fixed to the correct values, thus only needing to predict the preposition. The model achieved excellent performance considering the added difficulty of the task.

7 Conclusions and Future Work

We explored the role of geometric, textual and visual features in learning to predict a preposition given two bounding box instances in an image, and found clear evidence that all three features play a part in the task. Our system performs well even with uncertainties surrounding the entity labels. Future work could include non-prepositional terms like verbs, having prepositions modify verbs, adding word2vec embeddings to the structured prediction model, and providing stronger features – whether textual, visual or geometric.

Abstract

IBM Model 1 is a classical alignment model. Of the first generation word-based SMT models, it was the only such model with a concave objective function. For concave optimization problems like IBM Model 1, we have guarantees on the convergence of optimization algorithms such as Expectation Maximization (EM). However, as was pointed out recently, the objective of IBM Model 1 is not strictly concave and there is quite a bit of alignment quality variance within the optimal solution set. In this work we detail a strictly concave version of IBM Model 1 whose EM algorithm is a simple modification of the original EM algorithm of Model 1 and does not require the tuning of a learning rate or the insertion of an l_2 penalty. Moreover, by addressing Model 1's shortcomings, we achieve AER and F-Measure improvements over the classical Model 1 by over 30%.

1 Introduction

The IBM translation models were introduced in (Brown et al., 1993) and were the first-generation Statistical Machine Translation (SMT) systems. In the current pipeline, these word-based models are the seeds for more sophisticated models which need alignment tableaus to start their optimization procedure. Among the original IBM Models, only IBM Model 1 can be formulated as a concave optimization problem. Recently, there has been some research on IBM Model 2 which addresses either the model's non-concavity (Simion et al., 2015) or over parametrization (Dyer et al., 2013). We make the following contributions in this paper:

- We utilize and expand the mechanism introduced in (Simion et al., 2015) to construct *strictly* concave versions of IBM Model 1[1]. As was shown in (Toutanova and Galley, 2011), IBM Model 1 is not a strictly concave optimization problem. What this means in practice is that although we can initialize the model with random parameters and get to the same objective cost via the EM algorithm, there is quite a bit of alignment quality variance within the model's optimal solution set and ambiguity persists on which optimal solution truly is the best. Typically, the easiest way to make a concave model strictly concave is to append an l_2 regularizer. However, this method does not allow for seamless EM training: we have to either use a learning-rate dependent gradient based algorithm directly or use a gradient method within the M step of EM training. In this paper we show how to get via a simple technique an infinite supply of models that still allows a straightforward application of the EM algorithm.

- As a concrete application of the above, we detail a very simple strictly concave version of IBM Model 1 and study the performance of different members within this class. Our strictly concave models combine some of the elements of word association and positional dependance as in IBM Model 2 to yield a significant model improvement. Furthermore,

Lisbon, Portugal, 17-21 September 2015.

we now have guarantees that the solution we find is unique.

- We detail an EM algorithm for a subclass of strictly concave IBM Model 1 variants. The EM algorithm is a small change to the original EM algorithm introduced in (Brown et al., 1993).

Notation. Throughout this paper, for any positive integer N, we use $[N]$ to denote $\{1 \dots N\}$ and $[N]_0$ to denote $\{0 \dots N\}$. We denote by $\mathbb{R}^n_+$ the set of nonnegative n dimensional vectors. We denote by $[0,1]^n$ the $n-$dimensional unit cube.

2 IBM Model 1

We begin by reviewing IBM Model 1 and introducing the necessary notation. To this end, throughout this section and the remainder of the paper we assume that our set of training examples is $(e^{(k)}, f^{(k)})$ for $k = 1 \dots n$, where $e^{(k)}$ is the k'th English sentence and $f^{(k)}$ is the k'th French sentence. Following standard convention, we assume the task is to translate from *French* (the "source" language) into *English* (the "target" language). We use E to denote the English vocabulary (set of possible English words), and F to denote the French vocabulary. The k'th English sentence is a sequence of words $e^{(k)}_1 \dots e^{(k)}_{l_k}$ where l_k is the length of the k'th English sentence, and each $e^{(k)}_i \in E$; similarly the k'th French sentence is a sequence $f^{(k)}_1 \dots f^{(k)}_{m_k}$ where each $f^{(k)}_j \in F$. We define $e^{(k)}_0$ for $k = 1 \dots n$ to be a special NULL word (note that E contains the NULL word).

For each English word $e \in E$, we will assume that $D(e)$ is a *dictionary* specifying the set of possible French words that can be translations of e. The set $D(e)$ is a subset of F. In practice, $D(e)$ can be derived in various ways; in our experiments we simply define $D(e)$ to include all French words f such that e and f are seen in a translation pair.

Given these definitions, the IBM Model 1 optimization problem is given in Fig. 1 and, for example, (Koehn, 2008). The parameters in this problem are $t(f|e)$. The $t(f|e)$ parameters are *translation* parameters specifying the probability of English word e being translated as French word f. The objective function is then the log-likelihood of the training data (see Eq. 3):

$$\frac{1}{n}\sum_{k=1}^{n}\sum_{j=1}^{m_k}\log p(f^{(k)}_j|e^{(k)}) \ ,$$

where $\log p(f^{(k)}_j|e^{(k)})$ is

$$\log\sum_{i=0}^{l_k}\frac{t(f^{(k)}_j|e^{(k)}_i)}{1+l_k} = C + \log\sum_{i=0}^{l_k} t(f^{(k)}_j|e^{(k)}_i) \ ,$$

and C is a constant that can be ignored.

Input: Define E, F, L, M, $(e^{(k)}, f^{(k)}, l_k, m_k)$ for $k = 1 \dots n$, $D(e)$ for $e \in E$ as in Section 2.

Parameters:

• A parameter $t(f|e)$ for each $e \in E, f \in D(e)$.

Constraints:

$$\forall e \in E, f \in D(e), \quad t(f|e) \geq 0 \tag{1}$$

$$\forall e \in E, \quad \sum_{f \in D(e)} t(f|e) = 1 \tag{2}$$

Objective: Maximize

$$\frac{1}{n}\sum_{k=1}^{n}\sum_{j=1}^{m_k}\log\sum_{i=0}^{l_k} t(f^{(k)}_j|e^{(k)}_i) \tag{3}$$

with respect to the $t(f|e)$ parameters.

Figure 1: The IBM Model 1 Optimization Problem.

While IBM Model 1 is concave optimization problem, it is not strictly concave (Toutanova and Galley, 2011). Therefore, optimization methods for IBM Model 1 (specifically, the EM algorithm) are typically only guaranteed to reach a global maximum of the objective function (see the Appendix for a simple example contrasting convex and strictly convex functions). In particular, although the objective cost is the same for any optimal solution, the translation quality of the solutions is not fixed and will still depend on the initialization of the model (Toutanova and Galley, 2011).

3 A Strictly Concave IBM Model 1

We now detail a very simple method to make IBM Model 1 strictly concave with a unique optimal solution without the need for appending an l_2 loss.

Theorem 1. *Consider IBM Model 1 and modify its objective to be*

$$\frac{1}{n}\sum_{k=1}^{n}\sum_{j=1}^{m_k}\log\sum_{i=0}^{l_k} h_{i,j,k}(t(f^{(k)}_j|e^{(k)}_i)) \tag{4}$$

where $h_{i,j,k} : \mathbb{R}_+ \rightarrow \mathbb{R}_+$ is strictly concave. With the new objective and the same constraints as IBM Model 1, this new optimization problem is strictly concave.

Proof. To prove concavity, we now show that the new likelihood function

$$L(\mathbf{t}) = \frac{1}{n}\sum_{k=1}^{n}\sum_{j=1}^{m_k}\log\sum_{i=0}^{l_k} h_{i,j,k}(t(f_j^{(k)}|e_i^{(k)}))\ ,$$

is strictly concave (concavity follows in the same way trivially). Suppose by way of contradiction that there is $(\mathrm{t}) \neq (\mathrm{t}')$ and $\theta \in (0,1)$ such that equality hold for Jensen's inequality. Since $h_{i,j,k}$ is strictly concave and $(\mathrm{t}) \neq (\mathrm{t}')$ we must have that there must be some (k,j,i) such that $t(f_j^{(k)}|e_i^{(k)}) \neq t'(f_j^{(k)}|e_i^{(k)})$ so that Jensen's inequality is strict for $h_{i,j,k}$ and we have

$$\begin{aligned}&h_{i,j,k}(\theta t(f_j^{(k)}|e_i^{(k)}) + (1-\theta)t'(f_j^{(k)}|e_i^{(k)}))\\ &\quad > \theta h_{i,j,k}(t(f_j^{(k)}|e_i^{(k)})) + (1-\theta)h_{i,j,k}(t'(f_j^{(k)}|e_i^{(k)}))\end{aligned}$$

Using Jensen's inequality, the monotonicity of the log, and the above strict inequality we have

$$\begin{aligned}&L(\theta\mathbf{t} + (1-\theta)\mathbf{t}')\\ &= \sum_{k=1}^{n}\sum_{j=1}^{m_k}\log\sum_{i=0}^{l_k} h_{i,j,k}(\theta t(f_j^{(k)}|e_i^{(k)}) + (1-\theta)t'(f_j^{(k)}|e_i^{(k)}))\\ &> \sum_{k=1}^{n}\sum_{j=1}^{m_k}\log\sum_{i=0}^{l_k} \theta h_{i,j,k}(t(f_j^{(k)}|e_i^{(k)})) + (1-\theta)h_{i,j,k}(t'(f_j^{(k)}|e_i^{(k)}))\\ &\geq \theta\sum_{k=1}^{n}\sum_{j=1}^{m_k}\log\sum_{i=0}^{l_k} h_{i,j,k}(t(f_j^{(k)}|e_i^{(k)}))\\ &+ (1-\theta)\sum_{k=1}^{n}\sum_{j=1}^{m_k}\log\sum_{i=0}^{l_k} h_{i,j,k}(t'(f_j^{(k)}|e_i^{(k)}))\\ &= \theta L(\mathbf{t}) + (1-\theta)L(\mathbf{t}')\end{aligned}$$

□

The IBM Model 1 strictly concave optimization problem is presented in Fig. 2. In (7) it is crucial that each $h_{i,j,k}$ be strictly concave within $\sum_{i=0}^{l_k} h_{i,j,k}(t(f_j^{(k)}|e_i^{(k)}))$. For example, we have that $\sqrt{x_1} + x_2$ is concave but not strictly concave and the proof of Theorem 1 would break down. To see this, we can consider $(x_1, x_2) \neq (x_1, x_3)$ and note that equality holds in Jensen's inequality. We should be clear: the main reason why Theorem 1 works is that we have $h_{i,j,k}$ are strictly concave (on $\mathbb{R}_+$) and all the lexical probabilities that are arguments to L are present within the log-likelihood.

Input: Define E, F, L, M, $(e^{(k)}, f^{(k)}, l_k, m_k)$ for $k = 1 \ldots n$, $D(e)$ for $e \in E$ as in Section 2. A set of strictly concave functions $h_{i,j,k} : \mathbb{R}_+ \rightarrow \mathbb{R}_+$.

Parameters:

• A parameter $t(f|e)$ for each $e \in E$, $f \in D(e)$.

Constraints:

$$\forall e \in E, f \in D(e), \quad t(f|e) \geq 0 \tag{5}$$

$$\forall e \in E, \quad \sum_{f \in D(e)} t(f|e) = 1 \tag{6}$$

Objective: Maximize

$$\frac{1}{n}\sum_{k=1}^{n}\sum_{j=1}^{m_k}\log\sum_{i=0}^{l_k} h_{i,j,k}(t(f_j^{(k)}|e_i^{(k)})) \tag{7}$$

with respect to the $t(f|e)$ parameters.

Figure 2: The IBM Model 1 strictly concave optimization problem.

4 Parameter Estimation via EM

For the IBM Model 1 strictly concave optimization problem, we can derive a clean EM Algorithm if we base our relaxation of

$$h_{i,j,k}(t(f_j^{(k)}|e_i^{(k)})) = \alpha(e_i^{(k)}, f_j^{(k)})(t(f_j^{(k)}|e_i^{(k)}))^{\beta(e_i^{(k)}, f_j^{(k)})}$$

with $\beta(e_i^{(k)}, f_j^{(k)}) < 1$. To justify this, we first need the following:

Lemma 1. *Consider $h : \mathbb{R}_+ \rightarrow \mathbb{R}_+$ given by $h(x) = x^\beta$ where $\beta \in (0,1)$. Then h is strictly concave.*

Proof. The proof of this lemma is elementary and follows since the second derivative given by $h''(x) = \beta(\beta-1)x^{\beta-2}$ is strictly negative. □

For our concrete experiments, we picked a model based on Lemma 1 and used $h(x) = \alpha x^\beta$ with $\alpha, \beta \in (0,1)$ so that

$$h_{i,j,k}(t(f_j^{(k)}|e_i^{(k)})) = \alpha(f_j^{(k)}, e_i^{(k)})(t(f_j^{(k)}|e_i^{(k)}))^{\beta(f_j^{(k)}, e_i^{(k)})}\ .$$

Using this setup, parameter estimation for the new model can be accomplished via a slight modification of the EM algorithm for IBM Model 1. In particular, we have that the posterior probabilities of this model factor just as those of the standard Model 1 and we have an M step that requires optimizing

$$\sum_{a^{(k)}} q(a^{(k)}|e^{(k)}, f^{(k)}) \log p(f^{(k)}, a^{(k)}|e^{(k)})$$

Input: Define E, F, L, M, $(e^{(k)}, f^{(k)}, l_k, m_k)$ for $k = 1 \ldots n$, $D(e)$ for $e \in E$ as in Section 2. An integer T specifying the number of passes over the data. A set of weighting parameter $\alpha(e, f)$, $\beta(e, f) \in (0, 1)$ for each $e \in E$, $f \in D(e)$. A tuning parameter $\lambda > 0$.
Parameters:
• A parameter $t(f|e)$ for each $e \in E$, $f \in D(e)$.
Initialization:
• $\forall e \in E,\ f \in D(e)$, set $t(f|e) = 1/|D(e)|$.
EM Algorithm:
for all $t = 1 \ldots T$ **do**
  $\forall e \in E,\ f \in D(e),\ count(f, e) = 0$
  $\forall e \in E,\ count(e) = 0$
  EM Algorithm: Expectation
  for all $k = 1 \ldots n$ **do**
    for all $j = 1 \ldots m_k$ **do**
      $\delta_1[i] = 0\ \forall i \in [l_k]_0$
      $\Delta_1 = 0$
      for all $i = 0 \ldots l_k$ **do**
        $\delta_1[i] = \alpha(f_j^{(k)}, e_i^{(k)})(t(f_j^{(k)}|e_i^{(k)}))^{\beta(f_j^{(k)}, e_i^{(k)})}$
        $\Delta_1 \mathrel{+}= \delta_1[i]$
      for all $i = 0 \ldots l_k$ **do**

where

$$q(a^{(k)}|e^{(k)}, f^{(k)}) \propto \prod_{j=1}^{m_k} h_{a_j^{(k)}, j, k}(t(f_j^{(k)}|e_{a_j^{(k)}}^{(k)}))$$

are constants gotten in the E step. This optimization step is very similar to the regular Model 1 M step since the β drops down using $\log t^\beta = \beta \log t$; the exact same count-based method can be applied. The details of this algorithm are in Fig. 3.

5 Choosing α and β

The performance of our new model will rely heavily on the choice of $\alpha(e_i^{(k)}, f_j^{(k)})$, $\beta(e_i^{(k)}, f_j^{(k)}) \in (0, 1)$ we use. In particular, we could make β depend on the association between the words, or the words' positions, or both. One classical measure of word association is the dice coefficient (Och and Ney, 2003) given by

$$dice(e, f) = \frac{2c(e, f)}{c(e) + c(f)}\ .$$

In the above, the count terms c are the number of training sentences that have either a particular word or a pair of of words (e, f). As with the other choices we explore, the dice coefficient is a fraction between 0 and 1, with 0 and 1 implying less and more association, respectively. Additionally, we make use of positional constants like those of the IBM Model 2 distortions given by

$$d(i|j, l, m) = \begin{cases} \frac{1}{(l+1)Z(j,l,m)} & : i = 0 \\ \frac{le^{-\lambda|\frac{i}{l} - \frac{j}{m}|}}{(l+1)Z(j,l,m)} & : i \neq 0 \end{cases}$$

In the above, $Z(j, l, m)$ is the partition function discussed in (Dyer et al., 2013). The previous measures all lead to potential candidates for $\beta(e, f)$, we have $t(f|e) \in (0, 1)$, and we want to enlarge competing values when decoding (we use αt^β instead of t when getting the Viterbi alignment). The above then implies that we will have the word association measures inversely proportional to β, and so we set $\beta(e, f) = 1 - dice(e, f)$ or $\beta(e, f) = 1 - d(i|j, l, m)$. In our experiments we picked $\alpha(f_j^{(k)}, e_i^{(k)}) = d(i|j, l_k, m_k)$ or 1; we hold λ to a constant of either 16 or 0 and do not estimate this variable ($\lambda = 16$ can be chosen by cross validation on a small trial data set).

6 Experiments

6.1 Data Sets

For our alignment experiments, we used a subset of the Canadian Hansards bilingual corpus with 247,878 English-French sentence pairs as training data, 37 sentences of development data, and 447 sentences of test data (Michalcea and Pederson, 2003). As a second validation corpus, we considered a training set of 48,706 Romanian-English sentence-pairs, a development set of 17 sentence pairs, and a test set of 248 sentence pairs (Michalcea and Pederson, 2003).

6.2 Methodology

Below we report results in both AER (lower is better) and F-Measure (higher is better) (Och and Ney, 2003) for the English → French translation direction. To declare a better model we have to settle on an alignment measure. Although the relationship between AER/F-Measure and translation quality varies (Dyer et al., 2013), there are some positive experiments (Fraser and Marcu, 2004) showing that F-Measure may be more useful, so perhaps a comparison based on F-Measure is ideal.

Table 1 contains our results for the Hansards data. For the smaller Romanian data, we obtained similar behavior, but we leave out these results due

Table 1: Results on the English-French data for various (α, β) settings as discussed in Section 5. For the d parameters, we use $\lambda = 16$ throughout. The standard IBM Model 1 is column 1 and corresponds to a setting of (1,1). The not necessarily strictly concave model with (d,1) setting gives the best AER, while the strictly concave model given by the $(1, 1-d)$ setting has the highest F-Measure.

to space limitations. Our experiments show that using

$$h_{i,j,k}(t(f_j^{(k)}|e_i^{(k)})) = (t(f_j^{(k)}|e_i^{(k)}))^{1-d(i|j,l_k,m_k)}$$

yields the best F-Measure performance and is not far off in AER from the "fake"[2] IBM Model 2 (gotten by setting $(\alpha, \beta) = (d, 1)$) whose results are in column 2 (the reason why we use this model at all is since it should be better than IBM 1: we want to know how far off we are from this obvious improvement). Moreover, we note that dice does not lead to quality β exponents and that, unfortunately, combining methods as in column 5 $((\alpha, \beta) = (d, 1-d))$ does not necessarily lead to additive gains in AER and F-Measure performance.

[2]Generally speaking, when using

$$h_{i,j,k}(t(f_j^{(k)}|e_i^{(k)})) = d(i|j,l_k,m_k)t(f_j^{(k)}|e_i^{(k)})$$

with d constant we cannot use Theorem 3 since h is linear. Most likely, the strict concavity of the model will hold because of the asymmetry introduced by the d term; however, there will be a necessary dependency on the data set.

7 Comparison with Previous Work

In this section we take a moment to also compare our work with the classical IBM 1 work of (Moore, 2004). Summarizing (Moore, 2004), we note that this work improves substancially upon the classical IBM Model 1 by introducing a set of heuristics, among which are to (1) modify the lexical parameter dictionaries (2) introduce an initialization heuristic (3) modify the standard IBM 1 EM algorithm by introducing smoothing (4) tune additional parameters. However, we stress that the main concern of this work is not just heuristic-based empirical improvement, but also structured learning. In particular, although using an regularizer l_2 and the methods of (Moore, 2004) would yield a strictly concave version of IBM 1 as well (with improvements), it is not at all obvious how to choose the learning rate or set the penalty on the lexical parameters. The goal of our work was to offer a new, alternate form of regularization. Moreover, since we are changing the original log-likelihood, our method can be thought of as way of *bringing the l_2 regularizer inside the log likelihood*. Like (Moore, 2004), we also achieve appreciable gains but have just one tuning parameter (when $\beta = 1 - d$ we just have the centering λ parameter) and do not break the probabilistic interpretation any more than appending a regularizer would (our method modifies the log-likelihood but the simplex constrains remain).

8 Conclusion

In this paper we showed how IBM Model 1 can be made into a strictly convex optimization problem via functional composition. We looked at a specific member within the studied optimization family that allows for an easy EM algorithm. Finally, we conducted experiments showing how the model performs on some standard data sets and empirically showed 30% important over the standard IBM Model 1 algorithm. For further research, we note that picking the optimal $h_{i,j,k}$ is an open question, so provably finding and justifying the choice is one topic of interest.

Abstract

This paper discusses the use of factorization techniques in distributional semantic models. We focus on a method for redistributing the weight of latent variables, which has previously been shown to improve the performance of distributional semantic models. However, this result has not been replicated and remains poorly understood. We refine the method, and provide additional theoretical justification, as well as empirical results that demonstrate the viability of the proposed approach.

1 Introduction

Distributional Semantic Models (DSMs) have become standard paraphernalia in the natural language processing toolbox, and even though there is a wide variety of models available, the basic parameters of DSMs (context type and size, frequency weighting, and dimension reduction) are now well understood. This is demonstrated by the recent convergence of state-of-the-art results (Baroni et al., 2014; Levy and Goldberg, 2014).

However, there are a few notable exceptions. One is the performance improvements demonstrated in two different papers using a method for redistributing the weight of principal components (PCs) in factorized DSMs (Caron, 2001; Bullinaria and Levy, 2012). In the latter of these papers, the factorization of latent variables in DSMs is used to reach a perfect score of 100% correct answers on the TOEFL synonym test. This result is somewhat surprising, since the factorization method is *the inverse of what is normally used*.

Neither the result nor the method has been replicated, and therefore remains poorly understood. The goal of this paper is to replicate and explain the result. In the following sections, we first provide a brief review of DSMs and factorization, and review the method for redistributing the weight of latent variables. We then replicate the 100% score on the TOEFL test and provide additional state-of-the-art scores for the BLESS test. We also provide a more principled reformulation of the factorization method that is better suited for practical applications.

2 Distributional Semantics

Consider a set of words $W = \{w_1, \ldots, w_n\}$ and a set of context words $C = \{c_1, \ldots, c_m\}$. The DSM representation is created by registering an occurrence of a word w_i with a set of context words $c_j, \ldots, c_k$ with a corresponding increment of the projection of w_i on the $c_j, \ldots, c_k$ bases. In other words, each cell f_{ij} in the matrix representation F represents a co-occurrence count between a word w_i and a context c_j. In the following, we use $W = C$, making the co-occurrence matrix symmetric $F_{n \times n}$. We also adhere to standard practice of weighting the co-occurrence counts with Positive Pointwise Mutual Information (PPMI) (Niwa and Nitta, 1994), which is a variation of the standard PMI weighting,[1] which simply discards non-positive PMI values.

3 Singular Value Decomposition

The high dimensionality of the co-occurrence matrix makes it necessary in most practical applications to apply some form of dimensionality reduction to F, with the goal of finding a basis $\{\hat{x_j}, ..., \hat{x_k}\}$ that restates the original basis $\{x_k, ...\}$ in a lower-dimensional space $\hat{F}$, where $\hat{F}$ denotes the rank-k approximation of F:

$$\min_{\hat{F} \in R^n \times R^k} |F - \hat{F}| \quad (1)$$

[1] $\text{PMI}(f_{ij}) = \log \frac{f_{ij}(\sum_{ij} f_{ij})^2}{\sum_i f_{ij} \sum_j f_{ij} \sum_{ij} f_{ij}}$.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 227–231,
Lisbon, Portugal, 17-21 September 2015.

Assuming Gaussian-like distributions,[2] a canonical way of achieving this is to maximize the variance of the data in the new basis. This enables ordering of the new basis according to how much of the variance in the original data each component describes.

A standard co-occurrence matrix is positive and symmetric and thus has, by the spectral theorem, a spectral decomposition of an ordered set of positive eigenvalues and an orthogonal set of eigenvalues:

$$F = U\Sigma V^T \tag{2}$$

where U holds the eigenvectors of F, Σ holds the eigenvalues, and $V \in U(w)$ is a unitary matrix mapping the original basis of F into its eigenbasis. Hence, by simply choosing the first k eigenvalues and their respective eigenvectors we have the central result:

$$\min_k |F - \hat{F}| \rightarrow \hat{F} \approx U_k \Sigma_k V_k^T \tag{3}$$

where $\hat{F}$ is the best rank-k approximation in the Frobenius-norm. This is commonly referred to as *truncated* Singular Value Decomposition (SVD).

Finally, using cosine similarity,[3] V is redundant due to invariance under unitary transformations, which means we can represent the principal components of $\hat{F}$ in its most compact form $\hat{F} \equiv U\Sigma$ without any further comment.

This projection onto the eigenbasis does not only provide an efficient compression of the sparse co-occurrence data, but has also been shown to improve the performance and noise tolerance of DSMs (Schütze, 1992; Landauer and Dumais, 1997; Bullinaria and Levy, 2012).

4 The Caron p-transform

Caron (2001) introduce a method for renormalization of the latent variables through an exponent factor $p \in R$:

$$U\Sigma \rightarrow U\Sigma^p \tag{4}$$

which is shown to improve the results of factorized models using both information retrieval and question answering test collections. We refer to this renormalization as the *Caron p-transform*. Bullinaria and Levy (2012) further corroborate Caron's result, and show that the optimum exponent parameter p for DSMs is with strong statistical significance $p < 1$. Moreover, due to the redistribution of weight to the lower variance PCs, Bullinaria and Levy (2012) show that similar performance improvements can be achieved by simply *removing* the first PCs. We refer to this as *PC-removal*. A highlight of their results is a perfect score of 100% on the TOEFL synonym test.

Apart form the perfect score on the TOEFL test, it is noteworthy that the PC-removal scheme is the inverse of how SVD is normally used in DSMs; instead of retaining only the first PCs – which is the standard way of using the SVD in DSMs – the PC-removal scheme *deletes* them, and instead retains all the rest.

5 Experiments

We replicate the experiment setup of Bullinaria and Levy (2012) by removing punctuation and decapitalizing the ukWaC corpus (Baroni et al., 2009). The DSM includes the 50,000 most frequent words along with the remaining 23 TOEFL words and is populated using a ± 2-sized context window. Co-occurrence counts are weighted with PPMI, and SVD is applied to the resulting matrix, reducing the dimensionality to 5,000. The results of removing the first PCs versus applying the Caron p-transform are shown in Figure 1, which replicates the results from Bullinaria and Levy (2012).

In order to better understand what influence the transform has on the representations, we also provide results on the BLESS test (Baroni and Lenci, 2011), which lists a number of related terms to 200 target terms. The related terms represent 8 different kinds of semantic relations (co-hyponymy, hypernymy, meronymy, attribute, event, and three random classes corresponding to randomly selected nouns, adjectives and verbs), and it is thus possible to use the BLESS test to determine what type of semantic relation a model favors. Since our primary interest here is in *paradigmatic* relations, we focus on the hypernymy and co-hyponymy relations, and require that the model scores one of the related terms from these classes higher than the related terms from the other classes. The corpus was split into different sizes to test the statistical significance of the weight redistribution effect. Furthermore, it shows that the optimal weight distribution depends on the size of the data.

[2] It is well known that the Gaussian assumption does not hold in reality, and consequently there are also other approaches to dimensionality reduction based on multinomial distributions, which we will not consider in this paper.

[3] $\cos(w_i, w_j) = \frac{w_i \cdot w_j}{|w_i||w_j|}$

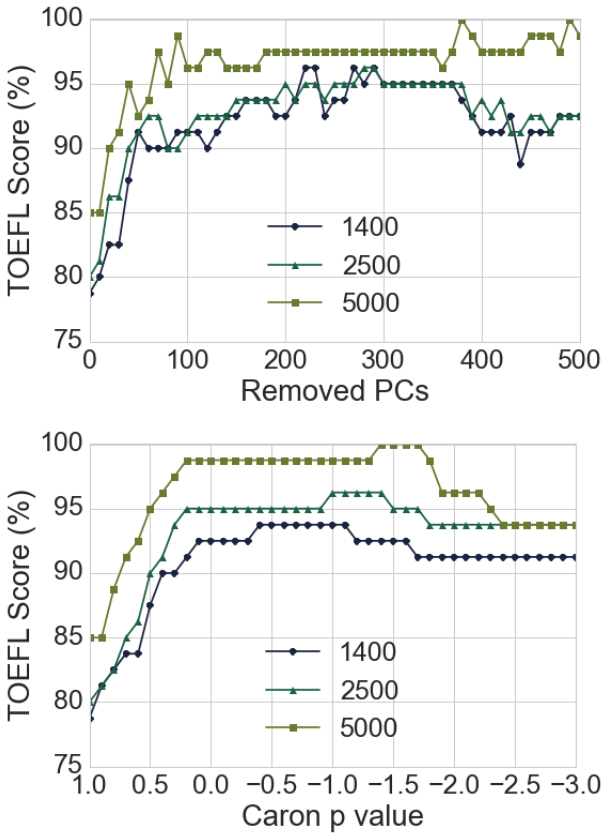

Figure 1: TOEFL score for the PC-removal scheme and the Caron p-transform for the span of PCs.

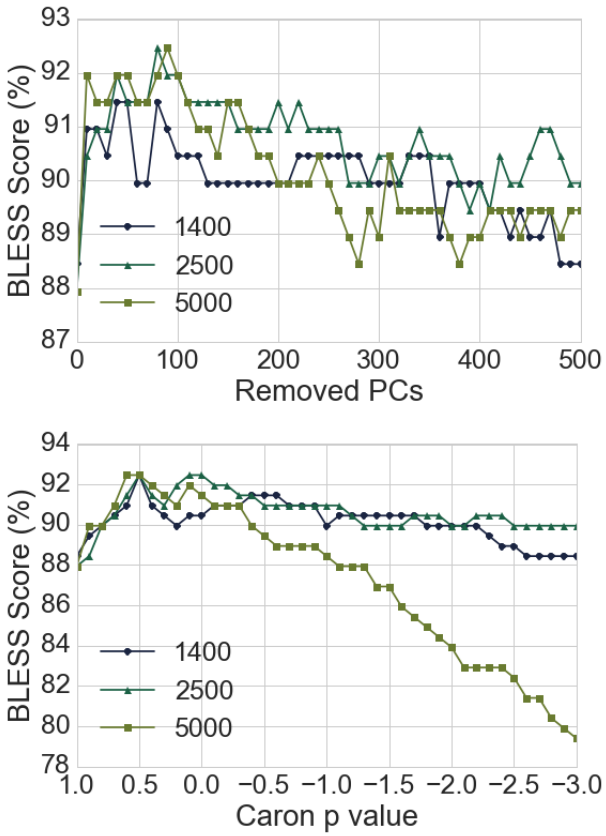

Figure 2: BLESS score for the PC-removal scheme and the Caron p-transform for the span of PCs.

Figure 2 shows the BLESS results for both the PC removal scheme and the Caron p-transform for different sizes of the corpus. The best score is 92.96% for the PC removal, and 92.46% for the Caron p-transform, both using the full data set. Similarly to the TOEFL results, we see better results for a larger number of removed PCs. Interestingly, there is clearly a larger improvement in performance of the Caron p-transform than for the PC removal scheme.

Figure 3 shows how the redistribution affects the different relations in the BLESS test. The violin plots are based on the maximum values of each relation, and the width of the violin represents the normalized probability density of cosine measures. The cosine distributions, Θ_i, are based on the best matches for each category i, and normalized by the total mean and variance amongst all categories $\hat{\Theta}_i = \frac{\Theta_i - \mu}{\sigma}$. Thus, the figure illustrates how well each category is separated from each other, the larger separation the better.

The results in Figure 3 indicate that the top 120 PCs contain a higher level of co-hyponymy relations than the lower; removing the top 120 PCs gives a violin shape that resembles the inverse of the plot for the top 120 PCs. Although neither part of the PC span is significantly better in separating the categories, it is clear that removing the first 120 PCs increases the variance within the categories

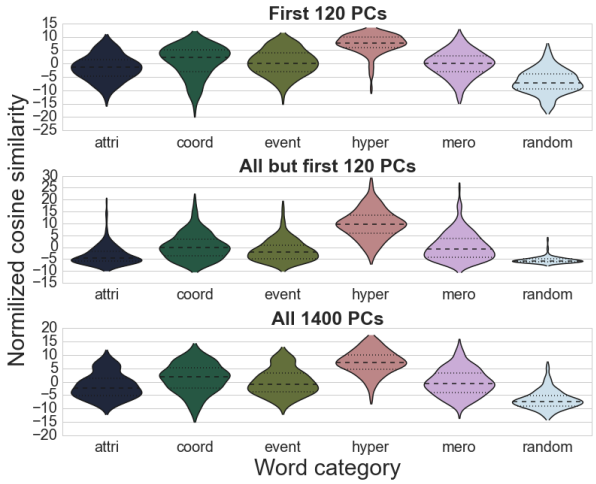

Figure 3: BLESS targets versus categories from 1,400 PCs representation of the entire corpus.

and especially amongst the coord-category. This is an interesting result, since it seems to contradict the hypothesis that removing the first PCs improves the semantic quality of the representations – there is obviously valuable semantic information in the first PCs.

Table 1 summarizes our top results on the TOEFL, BLESS, and also the SimLex-999 similarity test (Hill et al., 2014), and compares them to a baseline score from the Skipgram model (Mikolov et al., 2013a), trained on the same data using a window size of 2, negative samples, and 400-dimensional vectors.

	TOEFL	BLESS	SimLex-999
PC removal	100	92.96	46.52
Caron p	100	92.46	46.66
Skipgram	83.75	83.00	39.91

Table 1: Top results for the PC removal and Caron p on each test compared to the Skipgram model.

Unfortunately, the optimal redistribution of weight on the PCs for the respective top scores differ between the experiments. For the PC removal the optimal number of removed PCs is 379 for TOEFL, 15 for BLESS and 128 for SimLex-999, while the optimal number for the Caron p-transform is -1.4 for TOEFL, 0.5 for BLESS and -0.40 for SimLex-999. Hence, there is likely no easy way to find a general expression of the optimal redistribution of weight on the PCs for a given application.

6 The Pareto Principle

It is common practice to reduce the dimensionality of an n-dimensional space to as many PCs as it takes to cover 80% of the total eigenvalue mass. This convention is known as the *Pareto principle* (or 80/20-rule), and generally gives a good trade-off between compression and precision. The results presented in the previous section suggest a type of inversion of this principle in the case of DSMs.

Given a computational and practical limit of the number of PCs m with weights $\Sigma = \{\sigma_1, ..., \sigma_m\}$, the optimal redistribution of weight on these components is such that the first $l - m$ components $\sigma_1, ..., \sigma_{m-l}$ is transformed such that they constitute 20% of the new total mass. Where $l - m$ is the number of components representing the last 20 % of the original mass. In other words, the function $f : \Sigma \rightarrow \hat{\Sigma}$ performing this redistribution is such that:

$$\frac{\sum_{i=1}^{m-l} \hat{\sigma}_i}{\sum_{i=1}^{m} \hat{\sigma}_i} \approx 20\% \quad (5)$$

In this formulation, we can consider the Caron p-transform and the PC-removal scheme as special cases, where the Caron p-transform is given by:

$$f(\sigma_i) = \sigma_i^p \quad \forall i,\ p \in R \quad (6)$$

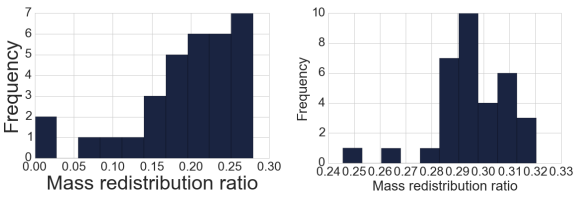
and the PC-removal scheme by:

$$f(\sigma_i) = (1 - \delta(F))\sigma_i \quad \forall i,\ F = \{1....l\} \quad (7)$$

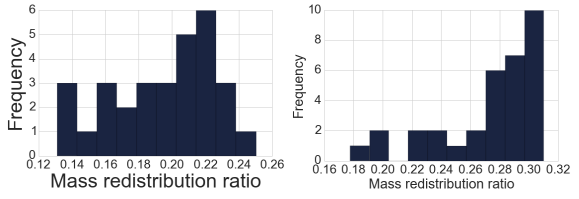
where $\delta(F)$ denotes the generalized Kronecker delta function.

To test this claim, we form this quotient for the distributions of weights at the optimal parameters for the Caron p-transform and the PC-removal scheme for both the BLESS and TOEFL tests for each of the 40 sub-corpora.

Even though the results are not as optimal for the BLESS test as for the TOEFL, the results in Figure 4 point in favor of this measure. The optimal mass distributions for the Caron p-transform and the PC removal are all around 20 %.



(a) TOEFL - PC removal (b) BLESS - PC removal



(c) TOEFL - Caron p (d) BLESS - Caron p

Figure 4: The mass redistribution ratio for the best results on the 1,400 PC models.

This result does not only apply for 1,400 PCs, but has also been verified on a smaller set of matrices with sizes of 2,500 PCs, 4,000 PCs and 5,000 PCs. The results for 1,400 PCs and 5,000 PCs are shown in Table 2. As can be seen in this table, the rule of thumb yields reasonable good guesses for both Caron p and PC removal, over the different tests and for various number of PCs.

5,000 PC representation

	PC removal	Caron p
Parameter	493	-0.80

BLESS	89.95	90.95
SimLex	45.45	46.47

Table 2: Results for the PC removal and Caron p using the 80/20 rule

7 Conclusions and future work

This paper has discussed the method of redistributing the weight of the first PCs in factorized DSMs. We have replicated previously published results, and provided additional empirical justification for the method. The method significantly outperforms the baseline Skipgram model on all tests used in the experiments. Our results also suggest a slight refinement of the method, for which we have provided both theoretical and empirical justification. The resulting rule of thumb method leads to stable results that may be useful in practice.

Although the experiments in this paper has provided further evidence for the usefulness of redistributing the weight in factorized models, it also raises additional interesting research questions. For example, does the method also improve models that have been trained on smaller data sets? Does it also hold for non-Gaussian factorization like Non-negative Matrix Factorization? How does the method affect the (local) structural properties of the representations; do factorized models display the same type of structural regularities as has been observed in word embeddings (Mikolov et al., 2013b), and would it be possible to use methods such as relative neighborhood graphs (Gyllensten and Sahlgren, 2015) to explore the local effects of the transformation?

Abstract

In this paper we explore a POS tagging application of neural architectures that can infer word representations from the raw character stream. It relies on two modelling stages that are jointly learnt: a convolutional network that infers a word representation directly from the character stream, followed by a prediction stage. Models are evaluated on a POS and morphological tagging task for German. Experimental results show that the convolutional network can infer meaningful word representations, while for the prediction stage, a well designed and structured strategy allows the model to outperform state-of-the-art results, without any feature engineering.

1 Introduction

Most modern statistical models for natural language processing (NLP) applications are strongly or fully lexicalized, for instance part-of-speech (POS) and named entity taggers, as well as language models, and parsers. In these models, the observed word form is considered as the elementary unit, while its morphological properties remain neglected. As a result, the vocabulary observed on training data heavily restricts the generalization power of lexicalized models.

Designing subword-level systems is appealing for several reasons. First, words sharing morphological properties often share grammatical function and meaning, and leveraging that information can yield improved word representations. Second, a subword-level analysis can address the out-of-vocabulary issue *i.e* the fact that word-level models fail to meaningfully process unseen word forms. This allows a better processing of morphologically rich languages in which there is a combinatorial explosion of word forms, most of which are not observed during training. Finally, using subword units could allow processing of noisy text such as user-generated content on the Web, where abbreviations, slang usage and spelling mistakes cause the number of word types to explode.

This work investigates models that do not rely on a fixed vocabulary to make a linguistic prediction. Our main focus in this paper is POS tagging, yet the proposed approach could be applied to a wide variety of language processing tasks. Our main contribution is to show that neural networks can successfully learn unlexicalized models that infer a useful word representation from the character stream. This approach achieves state of-the-art performance on a German POS tagging task. This task is difficult because German is a morphologically rich language[1], as reflected by the large number of morphological tags (255) in our study, yielding a grand total of more than 600 POS+MORPH tags. An aggravating factor is that these morphological categories are overtly marked by a handful of highly ambiguous inflection marks (suffixes). We therefore believe that this case study is well suited to assess both the representation and prediction power of our models.

The architecture we explore in section 2 differs from previous work that only consider the character level. Following (Santos and Zadrozny, 2014), it consists in two stages that are jointly learnt. The lower stage is a convolutional network that infers a word embedding from a character string of arbitrary size, while the higher network infers the POS tags based on this word embedding sequence. For the latter, we investigate different architectures of increasing complexities: from a feedforward and context-free inference to a bi-recurrent network that predicts the global sequence. Experimental results (section 4) show that the proposed approach can achieve state of the art performance

[1]Besides inflected forms, German is characterized by a possibly infinite and evolving set of compound nouns.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 232–237,
Lisbon, Portugal, 17-21 September 2015.

and that the choice of architecture for the prediction part of the model has a significant impact.

2 Network Architectures

The different architectures we propose act in two stages to infer, for a sentence $s = \{w_1, \ldots, w_{|s|}\}$, a sequence of tags $\{t_1, \ldots, t_{|s|}\}$. Each tag belongs to the tagset $\mathcal{T}$. The first stage is designed to represent each word *locally*, and focuses on capturing the meaningful morphological information. In the second stage, we investigate different ways to predict the tag sequence that differ in how the *global* information is used.

2.1 From character to word level

To obtain word embeddings, the usual approach introduced by (Bengio et al., 2003) relies on a fixed vocabulary $\mathcal{W}$ and each word $w \in \mathcal{W}$ is mapped to a vector of n_f real valued features by a look-up matrix $W \in \mathbb{R}^{|\mathcal{W}|*n_f}$. To avoid the use of a fixed vocabulary, we propose to derive a word representation from a sequence of character embedding: if $\mathcal{C}$ denotes the finite set of characters, each character is mapped on a vector of n_c features gathered in the look-up matrix C.

To infer a word embedding , we use a *convolution layer* (Waibel et al., 1990; Collobert et al., 2011), build as in (Santos and Zadrozny, 2014). As illustrated in figure 1, a word w is a character sequence $\{c_1, .., c_{|w|}\}$ represented by their embeddings $\{C_{c_1}, .., C_{c_{|w|}}\}$, where C_{c_i} denotes the row in C associated to the character c_i. A convolution filter $W^{conv} \in \mathbb{R}^{n_f} \times \mathbb{R}^{d_c * n_c}$ is applied over a sliding window of d_c characters, producing local features :

$$x_n = W^{conv}(C_{c_{n-d_c+1}} : .. : C_{c_n})^T + b^{conv},$$

where x_n is a vector of size n_f obtained for each position n in the word[2]. The i-th element of the embedding of w is the maximum over the i-th elements of the feature vectors :

$$[f]_i = \tanh(\max_{1 \leq n \leq |s|} [x_n]_i)$$

Using a maximum after a sliding convolution window ensures that the embedding combines local features from the whole word, and selects the more useful ones. The parameters of the layer are the matrices C and W^{conv} and the bias b^{conv}.

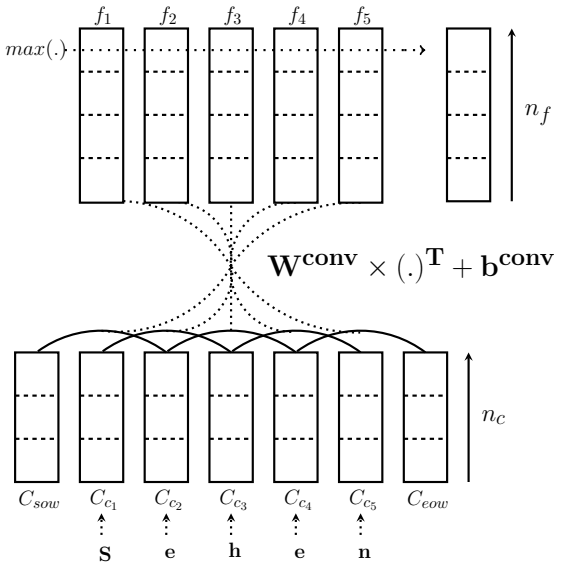

Figure 1: Architecture of the layer for character-level encoding of words.

2.2 From words to prediction

To predict the tag sequence associated to a sentence s, we first use **a feedforward architecture**, with a single hidden layer. To compute the probability of tagging the n-th word in the sentence with tag t_i, we use a window of d_w word embeddings[3] centered around the word w_n:

$$x_n = f_{n-\frac{d_w-1}{2}} : ... : f_{n+\frac{d_w-1}{2}},$$

followed by a hidden and output layers:

$$s_n = W^o \tanh(W^h x_n + b^h) + b^o. \qquad (1)$$

The parameters of the hidden an output layers are respectively W^h, b^h and W^o, b^o.

We also experiment with a **a bidirectional recurrent layer**, as described in (Graves et al., 2013). The forward and backward passes allow each prediction to be conditioned on the complete past and future contexts, instead of merely a neighboring window. As illustrated in figure 2, the forward hidden state, at position n, will be computed using the previous forward hidden state and the word embedding in position n:

$$\overrightarrow{h^n} = \tanh(\overrightarrow{W^{fh}} f_n + \overrightarrow{W^{hh}} \overrightarrow{h^{n-1}} + b^h)$$

[2]Two padding character tokens are used to deal with border effects. The first is added at the beginning and the second at the end of the word, as many times as it is necessary to obtain the same number of windows than the length of the word. Their embeddings are added to C.

[3]Similarly, we use special word tokens for padding.

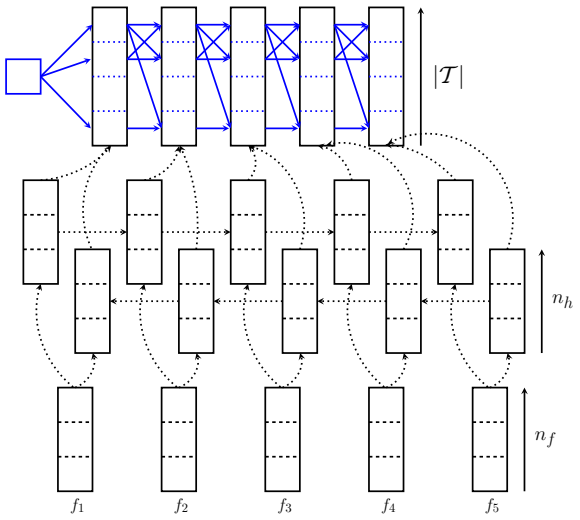

Figure 2: Bidirectional recurrent architecture for tag prediction. The upper part is used in the case of structured inference.

$\overrightarrow{W^{fh}}$ and $\overrightarrow{W^{hh}}$ are the transition matrices of the forward part of the layer, and b_h is the bias. The backward hidden states are computed similarly, and the hidden states of each direction are concatenated to pass through an output layer:

$$s_n = W^o(\overrightarrow{h^n} : \overleftarrow{h^n}) + b^o. \quad (2)$$

2.3 Inference and Training

To infer the tag sequence from the sequence of output layers defined by equations 1 or 2, we explore two strategies. The first simply applies a softmax function to the output layer of the network described in the previous section. In this case, each tag prediction is made independently of the surrounding predictions.

For sequence labeling, a more appropriate solution relies on the approach of (Collobert, 2011), also used in (Santos and Zadrozny, 2014). Let consider each possible tag sequence $\{t_1, \ldots, t_{|s|}\}$ as a possible path over a sequence of hidden states. We can add a transition matrix W^{trans} and then compute the score of a sequence as follows:

$$s(\{t\}_1^{|s|}, \{w\}_1^{|s|}) = \sum_{1 \leq n \leq |s|} \left(W^{trans}_{t_{n-1}, t_n} + [s_n]_{t_n} \right)$$

The Viterbi algorithm (Viterbi, 1967) offers an exact solution to infer the path that gives the maximum score. It is worth noticing that both these strategies can be applied to the feedforward and bidirectional recurrent networks. For both strategies, the whole network can estimate conditional log-likelihood of a tag sequence given a sentence s and the set of parameters θ. This criterion can then be optimized using a stochastic gradient ascent with the back-propagation algorithm.

3 Related Work

The choice to consider words from the character level has recently been more and more explored. While its raw application to language modeling did not achieve clear improvement over the word-based models (Mikolov et al., 2012), this approach shown impressive results for text generation (Sutskever et al., 2011; Graves, 2013). However, for this line of work, the main issue is to learn long range dependencies at the character level since the word level is not considered by the model.

More recently, the character level was considered as more interpretable and convenient way to explore and understand recurrent networks (Karpathy et al., 2015). In (Zhang and LeCun, 2015), the authors build a text understanding model that does not require any knowledge and uses hierarchical feature extraction. Here the character level allows the model to ignore the definition *a priori* of a vocabulary and let the model build its own representation of a sentence or a document, directly from the character level. To some extent, our work can be considered as an extension of their work, tailored for POS tagging.

(Santos and Zadrozny, 2014) applies a very similar model to the POS tagging of Portuguese and English. (Luong et al., 2013) also descends lower than the word level, using a dictionary of morphemes and recursive neural networks to model the structure of the words. Similarly, this allows a better representation of rare and complex words, evaluated on a word similarity task.

4 Experiments and Results

Experiments are carried out on the Part-of-Speech and Morphological tagging tasks using the German corpus TIGER Treebank (Brants et al., 2002). To the best of our knowledge, the best results on this task were published in (Mueller et al., 2013), who applied a high-order CRF that includes an intensive feature engineering to five different languages. German was highlighted as having 'the most ambiguous morphology'. The corpus, de-

scribed in details in (Fraser et al., 2013), contains a training set of 40472 sentences, a development and a test set of both 5000 sentences. We consider the two tagging tasks, with first a coarse tagset (54 tags), and then a morpho-syntactical rich tagset (619 items observed on the the training set).

4.1 Experimental settings

All the models are implemented[4] with the Theano library (Bergstra et al., 2010). For optimization, we use Adagrad (Duchi et al., 2011), with a learning rate of 0.1. The other hyperparameters are: the window sizes, d_c and d_w, respectively set to 5 and 9, the dimension of character embeddings, word embeddings and of the hidden layer, n_c, n_f and n_h, that are respectively of 100, 200 and 200[5]. The models were trained on 7 epochs. Parameter initialization and corpus ordering are random, and the results presented are the average and standard deviation of the POS Tagging error rate over 5 runs.

[4]Implementation is available at `https://github.com/MatthieuLabeau/NonlexNN`

[5]For both the learning rate and the embedding sizes, results does not differ in a significant way in a large range of hyperparameters, and their impact resides more in convergence speed and computation time

4.2 Results

The first experiment aims to evaluate the efficiency of a convolutional encoding with the basic feedforward architecture for prediction. We compare a completely non-lexicalized model which relies only on a character-level encoding with a lexicalized model where we use conventional word embeddings stored with a fixed vocabulary[6]. Results are reported in Table 1 along with with the state-of-the-art results published in (Mueller et al., 2013). Results show that a character-level encoding yields better results than the conventional word-level encoding. Moreover, the structured inference allows the model to achieve accuracy reasonably close to the performance of a high-order CRF that uses handcrafted features. Finally, the model that uses the concatenation of both the character and word-level embeddings outperforms the state-of-the-art system on the more difficult task, without any feature engineering.

To give an idea of how a simple model would perform on such task, the reader can refer to (Schmid and Laws, 2008) and (Mueller et al., 2013). For instance in the former, by choosing the most probable tag position-by-position, the error rate on the development set of the TIGER dataset

[6]Every word that appears in the training set.

is 32.7 for the simple POS Tagging task.

We further analyze the results by looking at the error rates respectively on known and unknown words[7]. From table 2, we observe that the number of unknown words wrongly labeled is divided by 3 for POS and almost divided by 2 for POS+Morph tagging, showing the ability of character-level encoding to generalize to new words. Moreover, a strictly non-lexical encoding makes slightly more mistakes on words already seen, whereas the model that concatenates both embeddings will make less mistakes for both unknown and known words.

This shows that information from the context and from the morphology are complementary, which is conjectured in (Mueller et al., 2013) by using a morphological analyzer in complement of higher-order CRF.

		Lex.	Non-lex.	Both
POS	Unknown	2970	1054	1010
	Known	1974	2981	1620
POS+Morph	Unknown	5827	3472	3384
	Known	8652	10205	7232

Table 2: Error counts for known/unknown words in the test set, with a structured feedforward prediction model for the tagging task.

In the second set of experiments, we evaluate the convolutional encoding with a bidirectional recurrent network for prediction. Results are presented in the second half of Table 1. Surprisingly, this architecture performs poorly with simple inference, but clearly improves when predicting a structured output using the Viterbi algorithm, both for training and testing. Moreover, a non-lexical model trained to infer a tag sequence with the Viterbi algorithm achieves results that are close to the state-of-the-art, thus validating our approach. We consider that this improvement comes from the synergy between using a global training objective with a global hidden representation, complexifying the model but allowing a more efficient solution. Finally, the model that uses the combination of both the character and word-level embeddings yields the best results. It is interesting to notice that the predictive architecture has no influence on the results of the simple task when the prediction is structured, but improves them on the difficult task. This also shows that the contribution of word embeddings to our model corresponds to a difference of 1.5 to 2 points in performance.

[7]Unknown words refer to words present in the development or test sets, but not in the training set.

5 Conclusion

In this paper, we explored new models that can infer meaningful word representations from the raw character stream, allowing the model to exploit the morphological properties of words without using any handcrafted features or external tools. These models can therefore efficiently process words that were unseen in the training data. The evaluation was carried out on a POS and morphological tagging task for German. We described different architectures that act in two stages: the first stage is a convolutional network that infers a word representation directly from the character stream, while the second stage performs the prediction. For the prediction stage, we investigated different solutions showing that a bidirectional recurrent network can outperform state-of-the-art results when using a structured inference algorithm.

Our results showed that character-level encoding can address the unknown words problem for morphologically complex languages. In the future, we plan to extend these models to other tasks such as syntactic parsing and machine translation. Moreover, we will also investigate other architectures to infer word embeddings from the character level. For instance, preliminary experiments show that bidirectional recurrent network can achieve very competitive and promising results.

Online Representation Learning in Recurrent Neural Language Models

Abstract

We investigate an extension of continuous online learning in recurrent neural network language models. The model keeps a separate vector representation of the current unit of text being processed and adaptively adjusts it after each prediction. The initial experiments give promising results, indicating that the method is able to increase language modelling accuracy, while also decreasing the parameters needed to store the model along with the computation required at each step.

1 Introduction

In recent years, neural network models have shown impressive performance on many natural language processing tasks, such as speech recognition (Chorowski et al., 2014; Graves et al., 2013), machine translation (Kalchbrenner and Blunsom, 2013; Cho et al., 2014), text classification (Le and Mikolov, 2014; Kalchbrenner et al., 2014) and image description generation (Kiros et al., 2014). One of the main advantages of these methods is the ability to learn smooth vector representations for words, thereby reducing the sparsity problem inherent in any natural language dataset.

Language modelling is another task where neural networks have delivered excellent results (Bengio et al., 2003; Mikolov et al., 2011). Chelba et al. (2014) have recently benchmarked several well-known language models by training on very large datasets. They found that a recurrent neural network language model (RNNLM) combined with a 9-gram MaxEnt model was able to give the best results and lowest perplexity.

In this work we investigate a possible extension of RNNLM, by allowing it to continue learning and adapting during testing. The model keeps a vector representation of the current sentence that is being processed, and continuously modifies it based on an error signal. We refer to this as a version of online learning, as gradient descent is used to optimise the vector even during testing.

The technique is inspired by work on representation learning (Collobert and Weston, 2008; Mnih and Hinton, 2008; Mikolov et al., 2013), especially Le and Mikolov (2014) who use a related model to learn representations for text classification. We extend the idea to recurrent models and apply it to the task of language modelling. Our results indicate that by exchanging some existing model parameters for a component using online learning, the system is able to achieve lower perplexity while also reducing the necessary computation.

2 RNNLM

We base our implementation of the RNNLM on Mikolov et al. (2011), shown in Figure 1. The input layer to the network consists of a 1-hot vector representing the previous word in the sequence, and the hidden vector from the previous time step. These are multiplied by corresponding weight matrices and the resulting vectors are passed through an activation function to calculate the hidden vec-

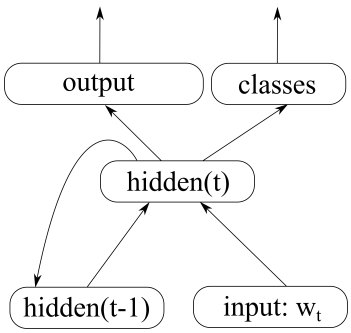

Figure 1: Recurrent neural network language model (RNNLM)

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 238–243,
Lisbon, Portugal, 17-21 September 2015.

tor at the current time step.[1]

Class-based output architecture is used to avoid calculating the softmax over all words in the vocabulary. The probability distributions over words and classes are calculated by multiplying the hidden vector with the corresponding weight matrix and applying the softmax function:

$$hidden_t = \sigma(E \cdot input_t + W_h \cdot hidden_{t-1})$$

$$classes = softmax(W_c \cdot hidden_t)$$

$$output = softmax(W_o^{(c)} \cdot hidden_t)$$

where σ is the logistic function and $W_o^{(c)}$ is the weight matrix between the hidden layer and the output words in class c.

Finally, we multiply the probability of the next word belonging to class c with the output probability of the next word given the class to get the overall probability of the next word given the previous words:

$$P(w_{t+1}|w_1^t) \approx classes_c \cdot output_{w_{t+1}}$$

Negative log-probability is used as the loss function, which optimises the network to assign a high probability to the correct words. The network is trained using gradient descent and backpropagation through time. In the basic model, this means unrolling the recurrent network for a fixed number of time steps, essentially turning it into a deep feedforward network which outputs probability distributions on different layers. Instead of using a fixed number of steps, our implementation unrolls each sentence from the last word to the first word, making it more suitable for processing individual sentences as opposed to longer texts.

In addition, we introduce a special vector to use as the hidden vector at the start of each sentence. The values in this vector are treated as parameters and optimised during training. This allows the network to learn a suitable starting point when no other information is available, giving slight performance improvements in our experiments.

3 RNNLM with online learning

We extend the RNNLM by introducing an additional document/context vector, shown as *doc* in Figure 2. This vector will represent the current

[1]Explicit multiplication for the word vectors can be avoided by using data structures that retrieve the correct vector in constant time.

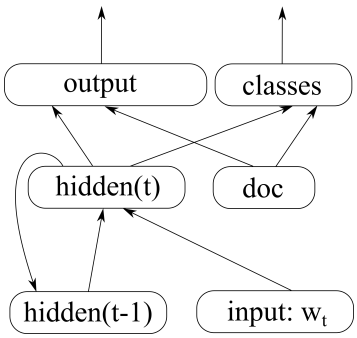

Figure 2: RNNLM with an additional document vector for active learning

document being processed, whether that is a sentence, paragraph or a larger text. When calculating output probabilities over classes and words, we also condition them on this new document vector:

$$classes = softmax(W_c \cdot hidden_t + W_{dc} \cdot doc)$$

$$output = softmax(W_o^{(c)} \cdot hidden_t + W_{do}^{(c)} \cdot doc)$$

where W_{dc} is the weight matrix between the document vector and class layer, and $W_{do}^{(c)}$ is the weight matrix between the document vector and output words in class c.

We construct the document vector by treating the values as parameters and optimising them during both training and testing using backpropagation. At each time step, the system first performs a forward pass through the network and outputs probability distributions over classes and words. We then use the next word in the sequence to calculate the error derivatives in the output and backpropagate them back into the document vector. The update is not able to to affect the output at the current time step, but it will modify the document vector which will be used in the next time step. The same word that is used for modifying the document vector for the next time step is also available in the input layer of the next time step, therefore the system receives no additional knowledge as input.

We are interested in modelling individual sentences, therefore at the beginning of each sentence the document vector is reset to a specific starting state, which is optimised during training and shared between all sentences. During testing, the values in the document vector are continuously modified depending on the error derivatives being backpropagated from the output layer, while all other parameters in the model stay constant.

When dealing with larger texts and domain-specific corpora, similar ideas of iterative learning can be applied to any language model. After processing a certain amount of data during testing, a new model could be trained using the previously seen testing examples as additional training data. Since this process adds more training data which is likely to be similar to upcoming testing examples, the system is likely to achieve a better performance.

However, when dealing with independent sentences, online learning becomes more difficult to apply. Each sentence contains very little additional data, and even if the language model is adjusted after every individual word, it only obtains evidence of previous words in the sentence, whereas these words are relatively unlikely to occur again in the same sentence. Therefore, instead of adjusting individual word representations, our approach learns a distributed document vector to represent the specific unit of text that is currently being processed. This vector is then used as additional evidence when calculating output probabilities.

Le and Mikolov (2014) use a similar method for learning vector representations of documents and paragraphs. They construct a feedforward language model and include a paragraph vector as an additional vector in the input layer. The model parameters are trained on the training set, and when given unseen test data, the system optimises the paragraph vector according to the error signal. They use these vectors as input to a logistic regression classifier and achieve state-of-the-art performance on sentiment classification of movie reviews. However, they did not consider the effect of this model modification directly on the task of language modelling.

While the system of Le and Mikolov (2014) uses a basic feedforward language model, we extend the idea to recurrent neural network language models, as they are currently used in state-of-the-art language modelling systems (Chelba et al., 2014). Attaching the document vector to the input layer is not preferable for RNNLM, as the error is only backpropagated into the input layer after several time steps. When this time step is reached and the network is unrolled to perform backpropagation through time, several words have already passed without receiving any additional information. Since our implementation performs the unrolling only at the end of each sentence, the updates would not have any effect. Therefore, we attach the document vector directly to the output layer, in parallel with the recurrent hidden component. Parameters in the document vector can then be updated at each time step, while the unrolling and backpropagation through time still happens at the end of the sentence.

4 Experiments

We constructed a dataset from English Wikipedia to evaluate language modelling performance over individual sentences. The text was tokenised, sentence split and lowercased. The sentences were shuffled, in order to minimise any transfer effects between consecutive sentences, and then split into training, development and test sets. The final sentences were sampled randomly, in order to obtain reasonable training times for the experiments. The dataset sizes are shown in Table 2.

	Train	Dev	Test
Words	9,990,782	237,037	4,208,847
Sentences	419,278	10,000	176,564

Table 2: Dataset sizes

Model performance is measured using perplexity, therefore lower values indicate a model which is able to better predict the data. Special tokens are used to mark the beginning and end of a sentence. The sentence end token is also included in the evaluation, whereas the sentence start token is only used as context in the input layer. Any words that occur less than 30 times in the training data were replaced by a special token for unknown words, leaving a vocabulary of 16,514 unique words. General learning rate was set to 0.1 and decreased during training, whereas the learning rate of the document vector was fixed at 0.1 for both training and testing.

As the baseline, we use the regular RNNLM with 100-dimensional hidden layers and word vectors ($M = 100$). In the experiments we increase the capacity of the model and measure how that affects the perplexity on the datasets. First, we increase the value of M, allowing more information to be stored into word representations, while also increasing the number of hidden-hidden and hidden-output connections. As can be seen in Table 1, this improves the overall performance of the

	Train PPL	Dev PPL	Test PPL	+Parameters	+Operations
Baseline M=100	92.65	103.56	102.51	–	–
M=120	88.60	98.78	97.79	666,960	7,400
M=100, D=20	**87.28**	**95.36**	**94.39**	**332,300**	**6,000**
M=135	85.17	96.33	95.71	1,167,705	13,475
M=100, D=35	**80.11**	**91.05**	**90.29**	**581,525**	**10,500**

Table 1: Perplexity and additional parameters/operations for different language model configurations

model – setting M to 120 and 135 leads to progressively lower perplexity.

Next, instead of increasing M, we add a D-dimensional document vector to the model and use this for online learning. When the same number of elements is added to M or D, our results show consistently better performance when using the document vector. Increasing M by 35 gives perplexity 95.71, whereas using a 35-dimensional document vector gives perplexity 90.29. We also performed the same experiment using only half of the training data, and the difference was even larger – 105.50 and 98.23 correspondingly.

One reason why online learning during model deployment is not commonly used is because it is computationally expensive. Continuously retraining the model and adjusting parameters can be very time-consuming compared to a simple feed-forward process through the network. However, extra computation is also needed when using a hidden vector of size M, as opposed to using a smaller value. When increasing the value of M to $M + X$, the RNNLM will contain

$$X \cdot C + 2 \cdot X \cdot V + 2 \cdot X \cdot M + X^2$$

additional parameters and needs to perform

$$2 \cdot X \cdot M + X^2 + X \cdot C + X \cdot E[O]$$

additional operations at each time step.[2] C is the number of classes, V is vocabulary size, and $E[O]$ is the expected number of words that need to be processed in the output layer during one step.

The corresponding number of additional parameters in a RNNLM model using a D-dimensional document vector for online learning is

$$D + D \cdot V + D \cdot C$$

and additional operations

$$2 \cdot D \cdot E[O] + 2 \cdot D \cdot C$$

which includes the error backpropagation at each time step. For our experiments $V = 16,514$, $C = 100$ and $E[O] \approx 50$. Table 1 contains the additional values for the experiments, showing that replacing some hidden vector parameters with the actively learned document vector leads to fewer total parameters and fewer operations, along with lower perplexity.

Figure 3 presents the relationship between perplexity and the number of additional parameters, when increasing either M or D. The results are averaged over 10 runs with different random initialisations. As can be seen, using a small document vector lowers the perplexity with fewer parameters, compared to simply increasing the main components of the network. The graph of perplexity with respect to additional operations in the model also has a very similar shape.

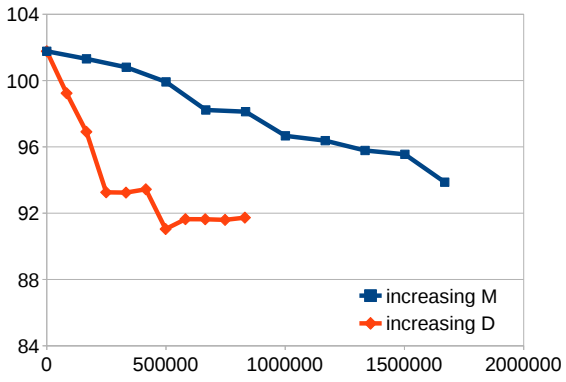

Figure 3: Perplexity as a function of additional parameters when increasing either M or D. The x-axis shows the number of additional parameters in the model, with respect to the baseline of $M = 100$, $D = 0$. The y-axis shows the perplexity on the test set.

[2]We only count the matrix multiplication operations, as they take the majority of the time in a neural network language model.

Both Hufnagel and Marston also joined the long-standing technical death metal band Gorguts. 1. The band eventually went on to become the post-hardcore band Adair. 2. The band members originally came from different death metal bands, bonding over a common interest in d-beat. 3. The proceeds went towards a home studio, which enabled him to concentrate on his solo output and songs that were to become his debut mini-album "Feeding The Wolves".
The Chiefs reclaimed the title on September 29, 2014 in a Monday Night Football game against the New England Patriots, hitting 142.2 decibels. 1. He played in twenty-four regular season games for the Colts, all off the bench. 2. In May 2009 the Warriors announced they had re-signed him until the end of the 2011 season. 3. The team played inconsistently throughout the campaign from the outset, losing the opening two matches before winning four consecutive games during September 1927.
He was educated at Llandovery College and Jesus College, Oxford, where he obtained an M.A. degree. 1. He studied at the Orthodox High School, then at the Faculty of Mathematics. 2. Kaigama studied for the priesthood at St. Augustine's Seminary in Jos with further study in theology in Rome. 3. Under his stewardship, Zahira College became one of the leading schools in the country.

Table 3: Examples of using the document vectors to find similar sentences in the development data.

In order to further explore the relationship between D and M, we trained a number of smaller models with different values, under the constraint $D + M = 100$. To reduce computation time, only half of the training data was used in these experiments. The lowest perplexity was achieved in the region of $D = 23$ and $M = 77$, and making the document vectors much smaller or larger led to a decrease in performance. This indicates that including the document vector does help increase model accuracy, but as it contains no information about the training data, this vector should be small compared to the main model.

Intuitively, this approach works by having the document vector capture the unique aspects of each sentence. While the general RNNLM is a smooth static representation of the entire training data, the document vector is optimised to represent how each sentence differs from the main language model. Therefore we performed a qualitative evaluation and found that the learned sentence vectors were also very good predictors of semantic similarity. The RNN language model was trained on the training set, and then used to process the development set. The last state of the document vector of each sentence was used to calculate cosine similarity. Table 3 contains randomly sampled sentences from the development set, together with corresponding development sentences that have the highest similarity (excluding the original sentence). Even though there is almost no word overlap, the retrieved sentences are semantically very similar.

5 Conclusion

We have described a possible extension of RNNLM which uses continuous online learning. The model includes a separate vector to represent the unit of text, such as a sentence, being currently processed. The vector starts in a default state and is continuously updated using backpropagation, leading to a more informative representation. The modified language model achieves lower perplexity with a more optimal use of parameters.

The idea of continuous training and adaptation is natural and also established in biological learning processes, yet it is not widely used due to computational complexity. Our experiments indicate that by including this active learning component in the neural network model, the system is able to achieve higher accuracy, while also decreasing the parameters needed to store the model and decreasing the computation required.

Abstract

When building spoken dialogue systems for a new domain, a major bottleneck is developing a spoken language understanding (SLU) module that handles the new domain's terminology and semantic concepts. We propose a statistical SLU model that generalises to both previously unseen input words and previously unseen output classes by leveraging unlabelled data. After mapping the utterance into a vector space, the model exploits the structure of the output labels by mapping each label to a hyperplane that separates utterances with and without that label. Both these mappings are initialised with unsupervised word embeddings, so they can be computed even for words or concepts which were not in the SLU training data.

1 Introduction

Spoken Language Understanding (SLU) in dialogue systems is the task of taking the utterance output by a speech recognizer and assigning it a semantic label that represents the dialogue actions of that utterance accompanied with their associated attributes and values. For example, the utterance "I would like Chinese food" is labelled with *inform(food=Chinese)*, in which *inform* is the dialogue action that provides the value of the attribute *food* that is *Chinese*.

Dialogue systems often use hand-crafted grammars for SLU, such as Phoenix (Ward, 1994), which are expensive to develop, and expensive to extend or adapt to new attributes and values. Statistical SLU models are usually trained on the data obtained from a specific domain and location, using a structured output classifier that can be discriminative (Pradhan et al., 2004; Kate and Mooney, 2006; Henderson et al., 2012) or generative (Schwartz et al., 1996; He and Young, 2005). Gathering and annotating SLU data is costly and time consuming and therefore SLU datasets are small compare to the number of possible labels.

Because training sets for a new domain are small, or non-existent, learning is often an instance of Zero-shot or One-shot learning problems (Palatucci et al., 2009; L. Fei-Fei; Fergus, 2006), in which zero or few examples of some output classes are available during the training. For example, in the restaurant reservation domain, not all possible combinations of foods and dialogue actions may be included in the training set. The general idea to solve this type of problems is to map the input and class labels to a semantic space of usually lower dimension in which similar classes are represented by closer points in the space (Palatucci et al., 2009; Weston et al., 2011; Weston et al., 2010). Usually unsupervised knowledge sources are used to form semantic codes of the labels that helps us to generalize to unseen labels.

On the other hand, there are also different ways to express the same meaning, and similarly, most of them can not be included in the training set. For instance, the system may have seen "Please give me the telephone number" in training, but the user might ask "Please give me the phone" at test time. This problem, feature sparsity, is a common issue in many NLP tasks. Decomposition of input feature parameters using vector-matrix multiplication (Bengio et al., 2003; Collobert et al., 2011; Collobert and Weston, 2008) has addressed this sparsity issue successfully in previous work. In this way, by sharing the word representations and composition matrices, we can overcome feature sparsity by producing similar representations for similar utterances.

In order to represent words and concepts we use word embeddings, which are a form of vector space model. Word embeddings have proven to be effective models of semantic representation

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 244–249,
Lisbon, Portugal, 17-21 September 2015.

of words in various NLP tasks (Baroni et al., 2014; Yazdani and Popescu-Belis, 2013; Collobert et al., 2011; Collobert and Weston, 2008; Huang et al., 2012; Mikolov et al., 2013b). In addition to parameter sharing, these representations enable us to leverage large scale unlabelled data. Because word embeddings trained on unlabeled data reflect the similarity between words, they help the model generalize from the words in the original training corpora to the words in the new extended domain, and help generalize from small amounts of data in the extended domain.

The contribution of this paper is to build a representation learning classifier for the SLU task that can generalize to unseen words and labels. For every utterance we learn how to compose the word vectors to form the semantics of that utterance for this task of language understanding. Furthermore, we learn how to compose the semantics of each label from the semantics of the words used to name that label. This enables us to generalize to unseen labels.

In this work we use the word2vec software of Mikolov et al. (2013a)[1] to induce unsupervised word embeddings that are used to initialize word embedding parameters. For this, we use an English Wikipedia dump as our unlabelled training corpus, which is a diverse broad-coverage corpus. It has been shown (Baroni et al., 2014; Mikolov et al., 2013b) that these embeddings capture lexical similarities even when they are trained on a diverse corpus like Wikipedia. We test our models on a restaurant booking domain. We investigate domain adaptation by adding new attribute types (e.g. *goodformeal*) and new attribute values (e.g. *Hayes Valley* as a restaurant location). Our experiments indicate that our model has better performance compared to a hand-crafted system as well as a SVM baseline.

2 SLU Datasets

The dialogue utterances used to build the SLU dataset were collected during a trial of online dialogue policy adaptation for a restaurant reservation system based in San Francisco. The trial began with (*area*, *pricerange* and *food*), and adapted the Interaction Manager online to handle the additional attribute types *near*, *allowedforkids*, and *goodformeal* (Gašic et al., 2014). User utterances from these trials were transcribed and annotated with dialogue acts by an expert, and afterwards edited by another expert[2]. Each user utterance was annotated with a set of labels, where each label consists of an act type (e.g. inform, request), an attribute type (e.g. foodtype, pricerange), and an attribute value (e.g. Chinese, Cheap).

The dataset is separated into four subsets, `SFCore`, `SF1Ext`, `SF2Ext` and `SF3Ext`, each with an increasing set of attribute types, as specified in Table 1. This table also gives the total number of utterances in each data set. For our first experiment, we split each dataset into about 15% for the testing set and 85% for the training set. For our second experiment we use each extended subset for testing and its preceding subsets for training.

Ontology	Attribute types (# of values)	# of utterances
SFCore	*food*(59), *area*(155), *pricerange*(3)	1103
SF1Ext	SFCore + *near*(39)	1810
SF2Ext	SF1Ext + *allowedforkids*(2)	1571
SF3Ext	SF2Ext +*goodformeal*(4)	1518

Table 1: Domains for San Francisco (SF) restaurants expanding in complexity

3 A Dialogue Act Representation Learning Classifier

The SLU model is run on each hypothesis output by the ASR component, and tries to predict the correct set of dialogue act labels for each hypothesis. This problem is in general an instance of multi-label classification, because a single utterance can have multiple dialogue act labels. Also, these labels are structured, since each label consist of an act type, an attribute type, and an attribute value. Each label component also has canonical text associated with it, which is the text used to name the label component (e.g. "Chinese" as a value).

The number of possible dialogue acts grows rapidly as the domain is extended with new attribute types and values, making this task one of multi-label classification with a very large number of labels. One natural approach to this task is to train one binary classifier for each possible label, to decide whether or not to include it in the output. In our case, this requires training a large number of classifiers, and it is impossible to generalize to

[1] `https://code.google.com/p/word2vec/`

[2] This data is publically available from `https://sites.google.com/site/parlanceprojectofficial/home/datarepository`

dialogue acts that include attributes or values that were not in the training set since there won't be any parameter sharing among label classifiers.

In our alternative approach, we build the representation of the utterance and the representation of the label from their constituent words, then we check if these representations match or not. In the following we explain in details this representation learning model.

3.1 Utterance Representation Learning

In this section we explain how to build the utterance representation from its constituent words. In addition to words, we use bigrams, since they have been shown previously to be effective features for this task (Henderson et al., 2012). Following the success in transfer learning from parsing to understanding tasks (Henderson et al., 2013; Socher et al., 2013), we use dependency parse bigrams in our features as well. We learn to build a local representation at each word position in the utterance by using the word representation, adjacent word representations, and the head word representation. Let $\phi(w)$ be a d dimensional vector representing the word w, and $\phi(U_i)$ be a h dimensional vector which is the local representation at word position i. We compute the local representation as follows:

$$\phi(U_i) = \sigma(\phi(w_i)W_{word} + \phi(w_h)W_{parse_{R_k}} + \phi(w_j)W_{previous} + \phi(w_k)W_{next}) \quad (1)$$

in which w_h is the head word with the dependency relation R_k to w_i, and w_j and w_k are the previous and next words. W_{word} is a $d \times h$ matrix that transforms the word embedding to hidden representation inputs. $W_{parse_{R_k}}$ is a $d \times h$ matrix for the relation R_k that similarly transforms the head word embedding (so W_{parse} is a tensor), and $W_{previous}$ and W_{next} similarly transform the previous and next words' embeddings. Figure 1 depicts this representation building at each word.

3.2 Label Representation Learning

One standard way to address the problem of multi-label classification is building binary classifiers for each possible label. Large margin classifiers have been shown to be an effective tool for this task (Pradhan et al., 2004; Kate and Mooney, 2006). We use the same idea of binary classifiers to learn one hyperplane per label, which separates the utterances with this label from all other utterances, with a large margin. In the standard way of

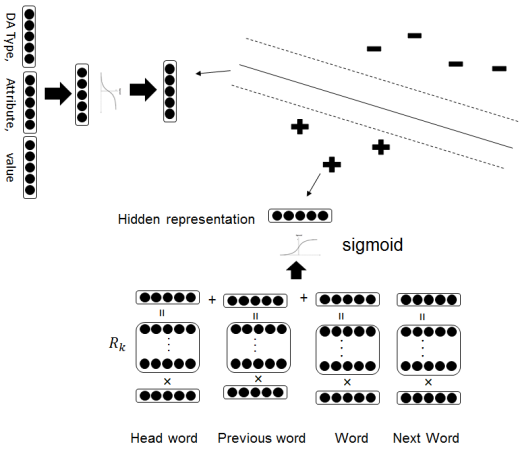

Figure 1: The multi-label classifier

building the classifier, each label's hyperplane is independent of other labels. To extend this model to a zero-shot learning classifier, we use parameter sharing among label hyperplanes so that similar labels have similar hyperplanes.

We exploit the structure of labels by assuming that each hyperplane representation is a composition of representations of the label's constituent components, namely dialogue action, attribute and attribute value. We learn the composition function and the constituent representations while training the classifiers, using the labelled SLU data. The constituent representations are initialised as the word embeddings for the label constituent's name string, such as "inform", "food" and "Chinese", where these embeddings are trained on the unlabelled data. Figure 1 depicts the classifier model.

We define the hyperplane of the label $a_j(att_k = val_l)$ with its normal vector W_{a_j,att_k,val_l} as:

$$W_{a_j,att_k,val_l} = \sigma([\phi(a_j), \phi(att_k), \phi(val_l)]W_{ih})W_{ho}$$

where $\phi(\cdot)$ is the same mapping to d dimensional word vectors that is used above in the utterance representation, W_{ih} is a $3d \times h$ matrix and W_{ho} is a $h \times h$ matrix. The score of each local representation vector $\phi(U_i)$ is its distance from this label hyperplane, which is computed as the dot product of the local vector $\phi(U_i)$ with the normal vector W_{a_j,att_k,val_l}.

We sum these local scores for each position i to build the whole utterance score: $\sum_i \phi(U_i)W^T_{a_j,att_k,val_l}$. Alternatively we can think of this computation as summing the local vectors to get a whole-utterance representation $\phi(U) = \sum_i \phi(U_i)$ and then doing the dot product. The

pooling method (sum) used in the model is (intentionally) over-simplistic. We did not want to distract from the main contribution of the paper, and our dataset did not justify any more complex solution since utterances are short. It can be replaced by more powerful approaches if it is needed.

To train a large margin classifier, we train all the parameters such that the score of an utterance is bigger than a margin for its labels and less than the negative margin for all other labels. Thus, the loss function is as follows:

$$\min_{\theta} \frac{\lambda}{2}\theta^2 + \sum_{U} \max(0, 1 - y \sum_{i} \phi(U_i) W^T_{a_j, att_k, val_l}) \quad (2)$$

where θ is all the parameters of the model, namely $\phi(w_i)$ (word embeddings), W_{word}, W_{Parse}, $W_{previous}$, W_{next}, W_{ih}, and W_{ho}. y is either 1 or -1 depending whether the input U has that label or not.

To optimize this large margin classifier we perform stochastic gradient descent by using the adagrad algorithm on this primal loss function, similarly to Pegasos SVM (Shalev-Shwartz et al., 2007), but here we backpropagate the errors to the representations to train the word embeddings and composition functions. In each iteration of the stochastic training algorithm, we randomly select an utterance and its labels as positive examples and choose randomly another utterance with a different label as a negative example. When choosing the negative sample randomly, we sample utterances with the same dialogue act but different attribute or value with 4 times higher probability than utterances with a different dialogue act. This biased negative sampling speeds up the training process since it provides more difficult training examples to the learner.

The model is able to address the adaptivity issues because the utterance and the dialogue act representations are in the same space using the same shared parameters $\phi(w)$, which are initialised with unsupervised word embeddings. It has been shown that such word embeddings capture word similarities and hence the classifier is no longer ignorant about any new attribute type or attribute value. Also, there is parameter sharing between dialogue acts because these word/label embeddings are shared, and the matrices for the composition of these representations are the same across all dialogue acts. This can help overcome sparsity in the SLU training set by transferring learning between similar situations and similar dialogue act triples. For example, if the training set does not contain any examples of the act "request(postcode)", but many examples of "request(phone)", sharing the parameters can help with the recognition of "request(postcode)" in utterances similar to "request(phone)". Moreover, the SLU model is to some extent robust against paraphrasing in the input utterance because it maps the utterance to a semantic space, and uses parse bigrams. More sophisticated vector-space semantic representations of the utterance are an area for future work, but should be largely orthogonal to the contribution of this paper.

To find the set of compatible dialogue acts for a given utterance, we should check all possible dialogue acts. This can severely slow down SLU. To avoid testing all possible dialogue combinations, we build three different classifiers: The first one recognises the act types in the utterance, the second one recognises the attribute types for each of the chosen act types, and the third classifier recognises the full dialogue acts as we described above, but only for the chosen pairs of act types and attribute types.

4 SLU Experiments

In the first experiment, we measure SLU performance trained on all available data, by building a dataset that is the union of all the above datasets. This measures the performance of SLU when there is a small amount of data for an extended domain. This dataset, similarly to `SF3Ext`, has 6 main attribute types. Table 2 shows the performance of this model. We report as baselines the performance of the Phoenix system (hand crafted for this domain) and a binary linear SVM trained on the same data. The hidden layers have size h=d=50. For this experiment, we split each dataset into about 15% for the testing set and 85% for the training set.

System	Outputs	Precision	Recall	F-core
Phoenix	516	84.10	41.65	55.71
SVM	690	65.03	52.45	58.06
Our	932	90.24	81.15	85.45

Table 2: Performance on union of data (SF-Core+SF1Ext+SF2Ext+SF3Ext)

Our SLU model can adapt well to the extended domain with more attribute types. We observe

model, train set	Test set SF1Ext P—R—F	SF2Ext P—R—F	SF3Ext P—R—F
Our SFcore	73.36—66.11—69.54	74.61—59.73—66.34	72.54—53.86—61.81
SVM SFcore	50.66— 38.7— 43.87	49.64—34.70— 40.84	48.99—30.91—37.90
Our SF1Ext		83.18—66.08—73.65	78.32—59.98—67.93
SVM SF1Ext		58.72—41.71—48.77	53.25—34.88—42.15
Our SF2Ext			84.12—67.78—75.07
SVM SF2Ext			59.27—42.80—49.70

Table 3: SLU performance: trained on a smaller domain and tested on more inclusive domains.

particularly that the recall is almost twice as high as the hand-crafted baseline. This shows that our SLU can recognise most of the dialogue acts in an utterance, where the rule-based Phoenix system and a classifier without composed output cannot. Overall there are 1042 dialogue acts in the test set. SLU recall is very important in the overall dialogue system performance, as the effect of a missed dialogue act is hard to handle for the Interaction Manager. Both hand-crafted and our system show relatively high precision.

In the next experiment, we measure how well the new SLU model performs in an extended domain without any training examples from that extended domain. We train a SLU model on each subset, and test it on each of the more inclusive subsets. Table 3 shows the results.

Not surprisingly, the performance is better if SLU is trained on a similar domain to the test domain, and adding more attribute types and values decreases the performance more. But our SLU can generalise very well to the extended domain, achieving much better generalisation that the SVM model.

4.1 Conclusion

In this paper, we describe a new SLU model that is designed for improved domain adaptation. The multi-label classification problem of dialogue act recognition is addressed with a classifier that learns to build an utterance representation and a dialogue act representation, and decides whether or not they are compatible. The dialogue act representation is a vector composition of its constituent labels' embeddings, and is trained as the hyperplane of a large margin binary classifier for that dialogue act. The utterance representation is trained as a composition of word embeddings. Since the utterance and the dialogue act representations are both built using unsupervised word embeddings and share these embedding parameters, the model can address the issues of domain adaptation. Word embeddings capture word similarities, and hence the classifier is able to generalise from known attribute types or values to similar novel attribute types or values. We tested this SLU model on datasets where the number of attribute types and values is increased, and show much better results than the baselines, especially in recall. The model succeeds in both adapting to an extended domain using relatively few training examples and in recognising novel attribute types and values.

Abstract

Research on modeling time series text corpora has typically focused on predicting what text will come next, but less well studied is predicting when the next text event will occur. In this paper we address the latter case, framed as modeling continuous inter-arrival times under a log-Gaussian Cox process, a form of inhomogeneous Poisson process which captures the varying rate at which the tweets arrive over time. In an application to rumour modeling of tweets surrounding the 2014 Ferguson riots, we show how inter-arrival times between tweets can be accurately predicted, and that incorporating textual features further improves predictions.

1 Introduction

Twitter is a popular micro-blogging service which provides real-time information on events happening across the world. Evolution of events over time can be monitored there with applications to disaster management, journalism etc. For example, Twitter has been used to detect the occurrence of earthquakes in Japan through user posts (Sakaki et al., 2010). Modeling the temporal dynamics of tweets provides useful information about the evolution of events. Inter-arrival time prediction is a type of such modeling and has application in many settings featuring continuous time streaming text corpora, including journalism for event monitoring, real-time disaster monitoring and advertising on social media. For example, journalists track several rumours related to an event. Predicted arrival times of tweets can be applied for ranking rumours according to their activity and narrow the interest to investigate a rumour with a short inter-arrival time over that of a longer one.

Modeling the inter-arrival time of tweets is a challenging task due to complex temporal patterns exhibited. Tweets associated with an event stream arrive at different rates at different points in time. For example, Figure 1a shows the arrival times (denoted by black crosses) of tweets associated with an example rumour around Ferguson riots in 2014. Notice the existence of regions of both high and low density of arrival times over a one hour interval. We propose to address inter-arrival time prediction problem with log-Gaussian Cox process (LGCP), an inhomogeneous Poisson process (IPP) which models tweets to be generated by an underlying intensity function which varies across time. Moreover, it assumes a non-parametric form for the intensity function allowing the model complexity to depend on the data set. We also provide an approach to consider textual content of tweets to model inter-arrival times. We evaluate the models using Twitter rumours from the 2014 Ferguson unrest, and demonstrate that they provide good predictions for inter-arrival times, beating the baselines e.g. homogeneous Poisson Process, Gaussian Process regression and univariate Hawkes Process. Even though the central application is rumours, one could apply the proposed approaches to model the arrival times of tweets corresponding to other types of memes, e.g. discussions about politics.

This paper makes the following contributions: 1. Introduces log-Gaussian Cox process to predict tweet arrival times. 2. Demonstrates how incorporating text improves results of inter-arrival time prediction.

2 Related Work

Previous approaches to modeling inter-arrival times of tweets (Perera et al., 2010; Sakaki et al., 2010; Esteban et al., 2012; Doerr et al., 2013) were not complex enough to consider their time varying characteristics. Perera et al. (2010) modeled

inter-arrival times as independent and exponentially distributed with a constant rate parameter. A similar model is used by Sakaki et al. (2010) to monitor the tweets related to earthquakes. The renewal process model used by Esteban et al. (2012) assumes the inter-arrival times to be independent and identically distributed. Gonzalez et al. (2014) attempts to model arrival times of tweets using a Gaussian process but assumes the tweet arrivals to be independent every hour. These approaches do not take into account the varying characteristics of arrival times of tweets.

Point processes such as Poisson and Hawkess process have been used for spatio-temporal modeling of meme spread in social networks (Yang and Zha, 2013; Simma and Jordan, 2010). Hawkes processes (Yang and Zha, 2013) were also found to be useful for modeling the underlying network structure. These models capture relevant network information in the underlying intensity function. We use a log-Gaussian cox process which provides a Bayesian method to capture relevant information through the prior. It has been found to be useful e.g. for conflict mapping (Zammit-Mangion et al., 2012) and for frequency prediction in Twitter (Lukasik et al., 2015).

3 Data & Problem

In this section we describe the data and we formalize the problem of modeling tweet arrival times.

Data We consider the Ferguson rumour data set (Zubiaga et al., 2015), consisting of tweets on rumours around 2014 Ferguson unrest. It consists of conversational threads that have been manually labeled by annotators to correspond to rumours[1]. Since some rumours have few posts, we consider only those with at least 15 posts in the first hour as they express interesting behaviour (Lukasik et al., 2015). This results in 114 rumours consisting of a total of 4098 tweets.

Problem Definition Let us consider a time interval $[0, 2]$ measured in hours, a set of rumours $R = \{E_i\}_{i=1}^{n}$, where rumour E_i consists of a set of m_i posts $E_i = \{p_j^i\}_{j=1}^{m_i}$. Posts are tuples $p_j^i = (\mathbf{x}_j^i, t_j^i)$, where $\mathbf{x}_j^i$ is text (in our case a vector of Brown clusters counts, see section 5) and t_j^i is time of occurrence of post p_j^i, measured in time since the first post on rumour E_i.

We introduce the problem of predicting the exact time of posts in the future unobserved time interval, which is studied as *inter-arrival time prediction*. In our setting, we observe posts over a target rumour i for one hour and over reference rumours (other than i) for two hours. Thus, the training data set is $R^O = \{E_i^O\}_{i=1}^{n}$, where $E_i^O = \{p_j^i\}_1^{m_i^O}$ (m_i^O represents number of posts observed for i^{th} rumour). We query the model for a complete set of times $\{t_j^i\}_{m_i^O+1}^{m_i}$ of posts about rumour i in the future one hour time interval.

[1]For a fully automated approach, a system for early detection of rumours (Zhao et al., 2015) could be run first and our models then applied to the resulting rumours.

4 Model

The problem of modeling the inter-arrival times of tweets can be solved using Poisson processes (Perera et al., 2010; Sakaki et al., 2010). A homogeneous Poisson process (HPP) assumes the intensity to be constant (with respect to time and the rumour statistics). It is not adequate to model the inter-arrival times of tweets because it assumes constant rate of point arrival across time. Inhomogeneous Poisson process (IPP) (Lee et al., 1991) can model tweets occurring at a variable rate by considering the intensity to be a function of time, *i.e.* $\lambda(t)$. For example, in Figure 1a we show intensity functions learnt for two different IPP models. Notice how the generated arrival times vary according to the intensity function values.

Log-Gaussian Cox process We consider a log-Gaussian Cox process (LGCP) (Møller and Syversveen, 1998), a special case of IPP, where the intensity function is assumed to be stochastic. The intensity function $\lambda(t)$ is modeled using a latent function $f(t)$ sampled from a Gaussian process (Rasmussen and Williams, 2005). To ensure positivity of the intensity function, we consider $\lambda(t) = \exp(f(t))$. This provides a non-parametric Bayesian approach to model the intensity function, where the complexity of the model is learnt from the training data. Moreover, we can define the functional form of the intensity function through appropriate GP priors.

Modeling inter-arrival time Inhomogeneous Poisson process (unlike HPP) uses a time varying intensity function and hence, the distribution of inter-arrival times is not independent and identically distributed (Ross, 2010). In IPP, the number of tweets y occurring in an interval $[s, e]$ is Poisson distributed with rate $\int_s^e \lambda(t)dt$.

$$p(y|\lambda(t),[s,e]) = \text{Poisson}(y|\int_s^e \lambda(t)dt) = \frac{(\int_s^e \lambda(t)dt)^y \exp(-\int_s^e \lambda(t)dt)}{y!} \quad (1)$$

Assume that n^{th} tweet occurred at time $E_n = s$ and we are interested in the inter-arrival time T_n of the next tweet. The arrival time of next tweet E_{n+1} can be obtained as $E_{n+1} = E_n + T_n$. The cumulative distribution for T_n, which provides the probability that a tweet occurs by time $s + u$ can be obtained as[2]

$$\begin{aligned} p(T_n \le u) &= 1 - p(T_n > u|\lambda(t), E_n = s) \\ &= 1 - p(0 \text{ events in } [s, s+u]|\lambda(t)) \\ &= 1 - \exp(-\int_s^{s+u} \lambda(t)dt) \\ &= 1 - \exp(-\int_0^u \lambda(s+t)dt) \end{aligned} \quad (2)$$

The derivation is obtained by considering a Poisson probability for 0 counts with rate parameter given by $\int_s^{s+u} \lambda(t)dt$ and applying integration by substitution to obtain (2). The probability density function of the random variable T_n is obtained by taking the derivative of (2) with respect to u:

$$p(T_n = u) = \lambda(s+u)\exp(-\int_0^u \lambda(s+t)dt). \quad (3)$$

The computational difficulties arising from integration are dealt by assuming the intensity function to be constant in an interval and approximating the inter-arrival time density as (Møller and Syversveen, 1998; Vanhatalo et al., 2013)

$$p(T_n = u) = \lambda(s+u)\exp(-u\lambda(s+\frac{u}{2})). \quad (4)$$

We associate a distinct intensity function $\lambda_i(t) = \exp(f_i(t))$ with each rumour E_i as they have varying temporal profiles. The latent function f_i is modelled to come from a zero mean Gaussian process (GP) (Rasmussen and Williams, 2005) prior with covariance defined by a squared exponential (SE) kernel over time, $k_{time}(t,t') = a\exp(-(t-t')^2/l)$. We consider the likelihood of posts E_i^{O} over the entire training period to be product of Poisson distribution (1) over equal length sub-intervals with the rate in a sub-interval $[s, e]$ approximated as $(e-s)\exp(f_i(\frac{1}{2}(s+e)))$. The likelihood of posts in the rumour data is obtained by taking the product of the likelihoods over individual rumours.

The distribution of the posterior $p(f_i|E_i^{\text{O}})$ is intractable and a Laplace approximation (Rasmussen and Williams, 2005) is used to obtain the posterior. The predictive distribution $f_i(t_*^i)$ at time t_*^i is obtained using the approximated posterior. The intensity function value at the point t_*^i is then obtained as

$$\lambda_i(t_*^i|E_i^{\text{O}}) = \int \exp\left(f_i(t_*^i)\right) p\left(f_i(t_*^i)|E_i^{\text{O}}\right) df_i(t_*^i).$$

[2] We suppress the conditioning variables for brevity.

Algorithm 1 Importance sampling for predicting the next arrival time

1: **Input:** Intensity function $\lambda(t)$, previous arrival time s, proposal distribution $q(t) = \exp(t; 2)$, number of samples N
2: **for** $i = 1$ **to** N **do**
3: Sample $u_i \sim q(t)$.
4: Obtain weights $w_i = \frac{p(u_i)}{q(u_i)}$, where $p(t)$ is given by (4).
5: **end for**
6: Predict expected inter-arrival time as $\bar{u} = \sum_{i=1}^{N} u_i \frac{w_i}{\sum_{j=1}^{N} w_j}$
7: Predict the next arrival time as $\bar{t} = s + \bar{u}$.
8: **Return:** $\bar{t}$

Importance sampling We are interested in predicting the next arrival time of a tweet given the time at which the previous tweet was posted. This is achieved by sampling the inter-arrival time of occurrence of the next tweet using equation (4). We use the importance sampling scheme (Gelman et al., 2003) where an exponential distribution is used as the proposal density. We set the rate parameter of this exponential distribution to 2 which generates points with a mean value around 0.5. Assuming the previous tweet occurred at time s, we obtain the arrival time of next tweet as outlined in Algorithm 1. We run this algorithm sequentially, i.e. the time $\bar{t}$ returned from Algorithm 1 becomes starting time s in the next iteration. We stop at the end of the interval of interest, for which a user wants to find times of post occurrences.

Incorporating text We consider adding the kernel over text from posts to the previously introduced kernel over time. We join text from the observed posts together, so a different component is added to kernel values across different rumours. The full kernel then takes form $k_{\text{TXT}}((t,i),(t',i')) = k_{time}(t,t') + k_{text}\big(\sum_{p_j^i \in E_i^O} \mathbf{x}_j^i, \sum_{p_j^{i'} \in E_{i'}^O} \mathbf{x}_j^{i'}\big)$. We compare text via linear kernel with additive underlying base similarity, expressed by $k_{text}(\mathbf{x}, \mathbf{x}') = b + c\mathbf{x}^T\mathbf{x}'$.

Optimization All model parameters (a, l, b, c) are obtained by maximizing the marginal likelihood $p(E_i^O) = \int p(E_i^O|f_i)p(f_i)df_i$ over all rumour data sets.

5 Experiments

Data preprocessing In our experiments, we consider the first two hours of each rumour lifespan. The posts from the first hour of a target rumour is considered as observed (training data) and we predict the arrival times of tweets in the second hour. We consider observations over equal sized time intervals of length six minutes in the rumour lifespan for learning the intensity function. The text in the tweets is represented by using Brown cluster ids associated with the words. This is obtained using 1000 clusters acquired on a large scale Twitter corpus (Owoputi et al., 2013).

Evaluation metrics Let the arrival times predicted by a model be $(\hat{t}_1, \ldots, \hat{t}_M)$ and let the actual arrival times be $(t_1, \ldots, t_N)$. We introduce two metrics based on root mean squared error (RMSE) for evaluating predicted inter-arrival times. First is aligned root mean squared error (ARMSE), where we align the initial $K = \min(M, N)$ arrival times and calculate the RMSE between such two subsequences. The second is called penalized root mean squared error (PRMSE). In this metric we penalize approaches which predict a different number of inter-arrival times than the actual number. The PRMSE metric is defined as the square root of the following expression.

$$\frac{1}{K}\sum_{i=1}^{K}(\hat{t}_i - t_i)^2 + \mathbb{I}[M > N] \sum_{i=N+1}^{M} (T - \hat{t}_i)^2 + \mathbb{I}[M < N] \sum_{i=M+1}^{N} (T - t_i)^2 \quad (5)$$

The second and third term in (5) respectively penalize for the excessive or insufficient number of points predicted by the model.

Baselines We consider a homogeneous Poisson process (HPP) (Perera et al., 2010) as a baseline which results in exponentially distributed inter-arrival times with rate λ. The rate parameter is set to the maximum likelihood estimate, the reciprocal of the mean of the inter-arrival times in the training data. The second baseline is a GP with a linear kernel (GPLIN), where the inter-arrival time is modeled as a function of time of occurrence of last tweet. This model tends to predict small inter-arrival times yielding a huge number of points. We limit the number of predicted points

method	ARMSE	PRMSE
GPLIN	20.60±22.01⋆	1279.78±903.90⋆
HPP	21.85±22.82⋆	431.4±96.5⋆
HP	15.94±18.20	363.70±59.01⋆
LGCP	13.31±14.28	261.26±92.97⋆
LGCP Pooled	19.18±20.36⋆	183.25±102.20⋆
LGCPTXT	15.52±18.79	154.05±115.70

Table 1: ARMSE and PRMSE between the true event times and the predicted event times expressed in minutes (lower is better) over the 114 Ferguson rumours, showing mean ± std. dev. Key ⋆ denotes significantly worse than LGCPTXT method according to one-sided Wilcoxon signed rank test ($p < 0.05$). In case of ARMSE, LGCP is not significantly better than LGCP TXT according to Wilcoxon test.

to 1000 (above the maximum count yielded by any rumour from our dataset), thus reducing the error from this method.

We also compare against Hawkes Process (HP) (Yang and Zha, 2013), a self exciting point process where an occurrence of a tweet increases the probability of tweets arriving soon afterwards. We consider a univariate Hawkes process where the intensity function is modeled as $\lambda_i(t) = \mu + \sum_{t^i_j < t} k_{time}(t^i_j, t)$. The kernel parameters and μ are learnt by maximizing the likelihood. We apply the importance sampling algorithm discussed in Algorithm 1 for generating arrival times for Hawkess process. We consider this baseline only in the single-task setting, where reference rumours are not considered.

LGCP settings In the case of LGCP, the model parameters of the intensity function associated with a rumour are learnt from the observed inter-arrival times from that rumour alone. LGCP Pooled and LGCPTXT consider a different setting where this is learnt additionally using the inter-arrival times of all other rumours observed over the entire two hour life-span.

Results Table 1 reports the results of predicting arrival times of tweets in the second hour of the rumour lifecycle. In terms of ARMSE, LGCP is the best method, performing better than LGCP-TXT (though not statistically significantly) and outperforming other approaches. However, this metric does not penalize for the wrong number of predicted arrival times. Figure 1b depicts an example rumour, where LGCP greatly overestimates the number of points in the interval of interest. Here, the three points from the ground truth (denoted by black crosses) and the initial three points predicted by the LGCP model (denoted by red pluses), happen to lie very close, yielding a low ARMSE error. However, LGCP predicts a large number of arrivals in this interval making it a bad model compared to LGCPTXT which predicts only four points (denoted by blue dots). ARMSE fails to capture this and hence we use PRMSE. Note that Hawkes Process is performing worse than the LGCP approach.

According to PRMSE, LGCPTXT is the most successful method, significantly outperforming all other according to Wilcoxon signed rank test. Figure 1a depicts the behavior of LGCP and LGCP-TXT on rumour 39 with a larger number of points from the ground truth. Here, LGCPTXT predicts relatively less number of arrivals than LGCP. The performance of Hawkes Process is again worse than the LGCP approach. The self excitory nature of Hawkes process may not be appropriate for this dataset and setting, where in the second hour the number of points tends to decrease as time passes.

We also note, that GPLIN performs very poorly according to PRMSE. This is because the inter-arrival times predicted by GPLIN for several rumours become smaller as time grows resulting in a large number of arrival times.

6 Conclusions

This paper introduced the log-Gaussian Cox processes for the problem of predicting the inter-arrival times of tweets. We showed how text from posts helps to achieve significant improvements. Evaluation on a set of rumours from Ferguson riots showed efficacy of our methods comparing to baselines. The proposed approaches are generalizable to problems other than rumours, e.g. disaster management and advertisement campaigns.

Abstract

In the last several years, neural network models have significantly improved accuracy in a number of NLP tasks. However, one serious drawback that has impeded their adoption in production systems is the slow runtime speed of neural network models compared to alternate models, such as maximum entropy classifiers. In Devlin et al. (2014), the authors presented a simple technique for speeding up feed-forward embedding-based neural network models, where the dot product between each word embedding and part of the first hidden layer are *pre-computed* offline. However, this technique cannot be used for hidden layers beyond the first. In this paper, we explore a neural network architecture where the embedding layer feeds into multiple hidden layers that are placed "next to" one another so that each can be pre-computed independently. On a large scale language modeling task, this architecture achieves a 10x speedup at runtime and a significant reduction in perplexity when compared to a standard multi-layer network.

1 Introduction

Neural network models have become extremely popular in the last several years for a wide variety of NLP tasks, including language modeling (Schwenk, 2007), sentiment analysis (Socher et al., 2013), translation modeling (Devlin et al., 2014), and many others (Collobert et al., 2011). However, a serious drawback of neural network models is their slow speeds in training and test time (runtime) relative to alternative models such as maximum entropy (Berger et al., 1996) or back-off models (Kneser and Ney, 1995).

One popular application of neural network models in NLP is using neural network language models (NNLMs) as an additional feature in an existing machine translation (MT) or automatic speech recognition (ASR) engines. NNLMs are particularly costly in this scenario, since decoding a single sentence typically requires tens of thousands or more n-gram lookups. Although we will focus on this particular scenario in this paper, it is important to note that the techniques presented generalize to any feed-forward embedding-based neural network model.

One popular technique for improving the runtime speed of NNLMs involves training the network to be "approximately normalized," so that the softmax normalizer does not have to be computed after training. Two algorithms have been proposed to achieve this: (1) noise-contrastive estimation (NCE) (Mnih and Teh, 2012; Vaswani et al., 2013) and (2) explicit self-normalization (Devlin et al., 2014), which is used in this paper.

However, even with self-normalized networks, computing the output of an intermediate hidden layer still requires a costly matrix-vector multiplication. To mitigate this, Devlin et al. (2014) made the observation that for 1-layer NNLMs, the dot product between each embedding+position pair and the first hidden layer can be *pre-computed* after training is complete, which allows the matrix-vector multiplication to be replaced by a handful of vector additions. Using these two techniques in combination improves the runtime speed of NNLMs by several orders of magnitude with no degradation to accuracy.

To understand pre-computation, first assume that we are training a NNLM that uses 250-dimensional word embeddings, a four word context window, and a 500-dimensional hidden layer. The weight matrix for the first hidden layer is thus 1000×500. For each word in the vocabulary and each of the four positions in the context vector, we

Lisbon, Portugal, 17-21 September 2015.

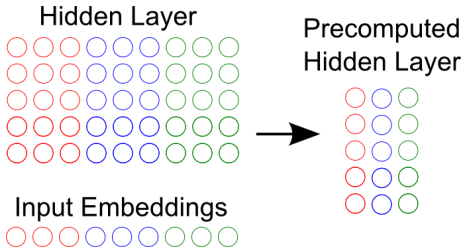

Figure 1: The "pre-computation trick." The dot product between each word embedding and each section of the hidden layer can be computed offline.

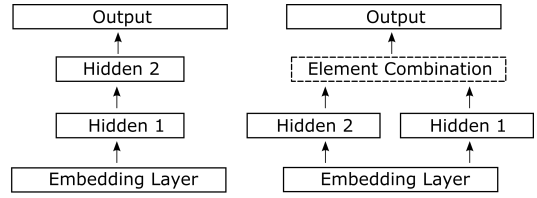

Figure 2: Network architectures.

can pre-compute the dot product between the 250-dimensional word embedding and the 250×500 section of the hidden layer. This results in four 500-dimensional vectors for each word that can be stored in a lookup table. At test time, we can simply sum four vectors to obtain the output of the first hidden layer. This is shown visually in Figure 1. Note that this is *not* an approximation, and the resulting output vector is identical to the original matrix-vector product. However, the major limitation of the "pre-computation trick" is that it only works with 1-hidden layer architectures, even though more accurate models can nearly always be obtained by training multi-layer networks.

In this paper, we explore a network architecture where multiple hidden layers are placed "next to" one another instead of "on top of" one another, as is usually done. The output of these *lateral* layers are combined using an inexpensive element-wise function and fed into the output layer. Crucially, then, we can apply the pre-computation trick to *each* hidden layer independently, allowing for very powerful models that are orders of magnitude faster at runtime than a standard multi-layer network.

Mathematically, this can be thought of as a generalization of maxout networks (Goodfellow et al., 2013), where different element-wise combination functions are explored rather than just the max function.

2 Lateral Network

In a standard feed-forward embedding-based neural network, the input tokens are mapped into a continuous vector using an embedding table[1], and this embedding vector is fed into the first hidden layer. The output of each hidden layer is then fed into the next hidden layer. We refer to this as the *stacked* architecture. For a two layer network, we can represent the output of the final hidden layer as:

$$H = \phi(W_2\phi(W_1E(x)))$$

where x is the input vector, $E(x)$ is the output of the embedding layer, W_i is the weight matrix for layer i, and ϕ is the transfer function such as $tanh$. Generally, H is then multiplied by an output matrix and a softmax is performed to obtain the output probabilities.

In the lateral network architecture, the embedding layer is fed into two or more "side-by-side" hidden layers, and the outputs of these hidden layers are combined using an element-wise function such as maximum or multiplication. This is represented as:

$$H = C(\phi(W_1E(x)), \phi(W_2E(x)))$$

Where C is a combination function that takes two or more k-dimensional vectors as inputs and produces as k-dimensional vector as output. If $C(h_1, h_2) = max(h_1, h_2)$ then this is equivalent to a maxout network (Goodfellow et al., 2013). To generalize this, we explore three different combination functions: [2]

$$C_{max}(h_1, h_2) = max(h_1, h_2)$$
$$C_{mul}(h_1, h_2) = h_1 * (h_2 + 1)$$
$$C_{add}(h_1, h_2) = h_1 + h_2$$

The three-or-more hidden layer versions are constructed as expected.[3]

A visualization is given in Figure 2. Crucially, for the lateral architecture, each hidden layer can be pre-computed independently, allowing for very fast n-gram probability lookups at runtime.

[1]The embeddings may or may not be trained jointly with the rest of the model.

[2]Note that C is an element-wise function, so these represent the operation on a single dimension of the input vectors.

[3]The + 1 in C_{mul} is used for all hidden layers after the first. This is used to prevent the value from being very close to 0.

3 Language Modeling Results

In this section we report results on a large scale language modeling task.

3.1 Data

Our LM training corpus consists of 120M words from the New York Times portion of the English GigaWord data set. This was chosen instead of the commonly used 1M word Penn Tree Bank corpus in order to better represent real world LM training scenarios. We use all data from 2008 and 2009 as training, the first 100k words from June 2010 as validation, and the first 100k words from December 2010 as test. The data is segmented and tokenized using the Stanford Word Segmenter with default settings.

3.2 Neural Network Training

Training was performed with an in-house toolkit using stochastic gradient descent. The vocabulary is limited to 16k words so that the output layer can be trained using a basic softmax with self-normalization. All experiments use 250-dimensional word embeddings and a $tanh$ activation function. The weights were initialized in the range [-0.05, 0.05], the batch size was 256, and the initial learning rate was 0.25.

3.3 5-gram LM Perplexity

5-gram results are shown in Table 1. The 1-layer NNLM achieves a 13.2 perplexity improvement over the Kneser-Ney smoothed baseline (Kneser and Ney, 1995). Consistent with Schwenk et al. (2014), using additional hidden layers to the stacked (standard) network results in 2.0-3.0 perplexity improvements on top of the 1-layer model.

The lateral architecture significantly outperforms any of the stacked networks, achieving a 6.5 perplexity reduction over the 1-layer model. The multiplicative combination function performs better than the additive and max functions by a small margin, which suggests that it better allows for modeling complex relationships between input words.

Perhaps most surprisingly, the additive function performs as well as the max function, despite the fact that it provides no additional modeling power compared to a 1-layer network. However, it does allow the model to *generalize* better than a 1-layer network by explicitly tying together two or three hidden nodes from each node in the output layer.

Condition	PPL
5-gram KNLM	91.1
1-Layer (k=500)	77.9
1-Layer (k=1000)	77.7
2-Stacked (k=500)	76.3
2-Stacked (k=1000)	76.2
3-Stacked (k=1000)	74.8
2-Lateral Max (k=500)	73.8
2-Lateral Mul ...	72.7
2-Lateral Add	73.7
3-Lateral Max	73.1
3-Lateral Mul	71.1
3-Lateral Add	72.3

Table 1: Perplexity of 5-gram models on the New York Times test set. k is the size of the hidden layer(s).

3.4 Runtime Speed

The runtime speed of the various models is shown in Table 2. These are computed on a single core of a E5-2650 2.6 GHz CPU. Consistent with Devlin et al. (2014), we see that the baseline model achieves only 230 n-gram lookups per second (LPS) at test time, while the pre-computed, self-normalized 1-layer network achieves 600,000 LPS. Adding a second stacked layer slows this down to 24,000 LPS due to the 500×500 matrix-vector multiplication that must be performed. However, the lateral configuration achieves 305,000 LPS while obtaining a better perplexity than the stacked network. In comparison, the fastest backoff LM implementation, KenLM (Heafield, 2011), achieves 1-2 million lookups per second.

In terms of memory usage, it is difficult to fairly compare backoff LMs and NNLMs because neural networks scale linearly with the vocabulary size, while backoff LMs scale linearly with the number of unique n-grams. In this case, the non-precomputed neural network model is 25 MB, and the pre-computed 2-lateral network is 136 MB.[4] The KenLM models are 1.1 GB for the Probing model and 317 MB for the Trie model. With a vocabulary of 50k, the 2-lateral network would be 425MB. In general, a pre-computed NNLM is comparable to or smaller than an equivalent backoff LM in terms of model size.

[4]The floats can be quantized to 2 bytes after training without loss of accuracy.

Condition	Lookups Per Sec.
KenLM Probing	1,923,000
KenLM Trie	950,000
1-Layer (No PC, No SN)	230
1-Layer (No PC)	13,000
1-Layer	600,000
2-Stacked	24,000
2-Stacked (Batch=128)	58,000
2-Lateral Mul	305,000

Table 2: Runtime speed of the 5-gram LM on a single CPU core. "PC" = pre-computation, "SN" = self-normalization, which are used in all but the first two experiments. The batch size is 1 except when specified. 500-dimensional hidden layers are used in all cases. "Float Ops." is the approximate number of floating point operations per lookup.

3.5 High-Order LM Perplexity

We also report results on a 10-gram LM trained on the same data, to explore whether the lateral network can achieve an even higher relative gain when a large input context window is available. Results are shown in Table 3. Although there is a large absolute improvement over the 5-gram LM, the relative improvement between the 1-layer, 3-stacked, and 3-lateral systems are similar to the 5-gram scenario.

Condition	PPL
1-Layer (k=500)	69.8
3-Stacked (k=1000)	65.8
3-Lateral Mul (k=500)	63.4
Gated Recurrent (k=1000)	55.4

Table 3: Perplexity of 10-gram models on the New York Times test set. The Gated Recurrent model uses the full word history.

As another point of comparison we report results with an gated recurrent network (Cho et al., 2014). As is consistent with the literature, the recurrent network significantly outperforms any of the feed-forward models (Sundermeyer et al., 2013).

However, recurrent models have two major downsides. First, they cannot easily be integrated into existing MT/ASR engines without significantly altering the search algorithm and search space, since they require a fully expanded target context. Second, the matrix-vector product between the previous hidden state and the hidden weight matrix cannot be pre-computed, which makes the models significantly slower than pre-computable feed-forward networks.

Condition	Test BLEU	Test PPL
Baseline	37.95	-
+NNLM 1-Layer	38.89	138.3
+NNLM 2-Stacked	39.13	136.2
+NNLM 2-Lateral	39.15	132.3
+NNJM 1-Layer	40.71	6.33
+NNJM 2-Stacked	40.82	6.25
+NNJM 2-Lateral	40.89	6.13

Table 4: Results on English-German machine translation test set.

4 Machine Translation Results

Although the lateral networks achieve a significant reduction in LM perplexity over the 1-layer network, it is not clear how much this will improved performance in a downstream task. To evaluate this, we trained two neural network models for use as additional features in a machine translation (MT) system.

The first feature is a 5-gram NNLM, which used 1000 dimensions for the stacked network and 500 for the lateral network. The second feature is a neural network joint model (NNJM), which predicts each target word using 5-gram target context *and* 7-gram source context. For evaluation, we present both the model perplexity and the BLEU score when using the model as an additional MT feature.

Results are presented on a large scale English-German speech translation task. The parallel training data consists of 600M words from a variety of sources, including OPUS (Tiedemann, 2012) and a large in-house web crawl. The baseline 4-gram Kneser-Ney smoothed LM is trained on 7B words of German data. The NNLM and NNTMs are trained only on the parallel data. Our MT decoder is a proprietary engine similar to Moses (Koehn et al., 2007). The tuning set consists of 4000 utterances from conversational and newswire data, and the test set consists of 1500 sentences of collected conversational data.

Results are show in Table 4. We can see that perplexity improvements are similar to what is

seen in the English NYT data, and that improvements in BLEU over a 1-layer model are small but consistent. There is not a significant difference in BLEU between the 2-Stacked and 2-Lateral configuration.

5 Conclusion

In this paper, we explored an alternate architecture for embedding-based neural network models which allows for a fully pre-computable network with multiple hidden layers. The resulting models achieve better perplexity than a standard multilayer network *and* is at least an order of magnitude faster at runtime.

In future work, we can assess the impact of this model on a wider array of feed-forward embedding-based neural network models, such as the DSSM (Huang et al., 2013).

Abstract

A wide range of applications, from social media to scientific literature analysis, involve graphs in which documents are connected by links. We introduce a topic model for link prediction based on the intuition that linked documents will tend to have similar topic distributions, integrating a max-margin learning criterion and lexical term weights in the loss function. We validate our approach on the tweets from 2,000 Sina Weibo users and evaluate our model's reconstruction of the social network.

1 Introduction

Many application areas for text analysis involve documents connected by links of one or more types—for example, analysis of scientific papers (citations, co-authorship), Web pages (hyperlinks), legislation (co-sponsorship, citations), and social media (followers, mentions, etc.). In this paper we work within the widely used framework of topic modeling (Blei et al., 2003, LDA) to develop a model that is simple and intuitive, but which identifies high quality topics while also accurately predicting link structure.

Our work here is inspired by the phenomenon of *homophily*, the tendency of people to associate with others who are like themselves (McPherson et al., 2001). As manifested in social networks, the intuition is that people who are associated with one another are likely to discuss similar topics, and vice versa. The new topic model we propose therefore takes association links into account so that a document's topic distribution is influenced by the topic distributions of its neighbors. Specifically, we propose a joint model that uses link structure to define clusters (cliques) of documents and, following the intuition that documents in the same cluster are likely to have similar topic distributions, assigns each cluster its own separate Dirichlet prior over the cluster's topic distribution. This use of priors is consistent with previous work that has shown document-topic priors to be useful in encoding various types of prior knowledge and improving topic modeling performance (Mimno and McCallum, 2008). We then use distributed representations to "seed" the topic representations before getting down to modeling the documents. Our joint objective function uses a discriminative, max-margin approach (Zhu et al., 2012; Zhu et al., 2014) to both model the contents of documents and produce good predictions of links; in addition, it improves prediction by including lexical terms in the decision function (Nguyen et al., 2013).

Our baseline for comparison is the Relational Topic Model (Chang and Blei, 2010, henceforth RTM), which jointly captures topics and binary link indicators in a style similar to supervised LDA (McAuliffe and Blei, 2008, sLDA), instead of modeling links alone, e.g., as in the Latent Multi-group Membership Graph model (Kim and Leskovec, 2012, LMMG). We also compare our approach with Daumé III (2009), who uses document links to create a Markov random topic field (MRTF). Daumé does not, however, look at link prediction, as his upstream model (Mimno and McCallum, 2008) only generates documents *conditioned on* links. In contrast, our downstream model allows the prediction of links, like RTM.

Our model's primary contribution is in its novel combination of a straightforward joint modeling approach, max-margin learning, and exploitation of lexical information in both topic seeding and regression, yielding a simple but effective model for topic-informed discriminative link prediction. Like other topic models which treat binary values "probabilistically", our model can convert binary link indicators into non-zero weights, with potential application to improving models like Volkova

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 261–266,
Lisbon, Portugal, 17-21 September 2015.

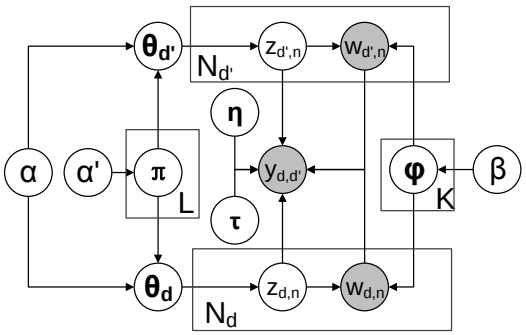

Figure 1: A graphical model of our model for two documents. The contribution of our model is the use of document clusters (π), the use of words (w) in the prediction of document links (y), and a max-margin objective.

et al. (2014), who use neighbor relationships to improve prediction of user-level attributes.

Our corpus is collected from Sina Weibo with three types of links between documents. We first conduct a reality check of our model against LDA and MRTF and then perform link prediction tasks. We demonstrate improvements in link prediction as measured by predictive link rank and provide both qualitative and quantitative perspectives on the improvements achieved by the model.

2 Discriminative Links from Topics

Figure 1 is a two-document segment of our model, which has the following generative process:

1. For each related-document cluster $l \in \{1, \ldots, L\}$
   Draw $\boldsymbol{\pi_l} \sim \mathrm{Dir}(\alpha')$
2. For each topic $k \in \{1, \ldots, K\}$
   (a) Draw word distribution $\boldsymbol{\phi_k} \sim \mathrm{Dir}(\beta)$
   (b) Draw topic regression parameter $\eta_k \sim \mathcal{N}(0, \nu^2)$
3. For each word $v \in \{1, \ldots, V\}$
   Draw lexical regression parameter $\tau_v \sim \mathcal{N}(0, \nu^2)$
4. For each document $d \in \{1, \ldots, D\}$
   (a) Draw topic proportions $\boldsymbol{\theta_d} \sim \mathrm{Dir}(\alpha \boldsymbol{\pi_{l_d}})$
   (b) For each word $t_{d,n}$ in document d
      i. Draw a topic assignment $z_{d,n} \sim \mathrm{Mult}(\boldsymbol{\theta_d})$
      ii. Draw a word $t_{d,n} \sim \mathrm{Mult}(\boldsymbol{\phi_{z_{d,n}}})$
5. For each linked pair of documents d and d'
   Draw binary link indicator
   $y_{d,d'} | \boldsymbol{z}_d, \boldsymbol{z}_{d'}, \boldsymbol{w}_d, \boldsymbol{w}_{d'} \sim \Psi(\cdot | \boldsymbol{z}_d, \boldsymbol{z}_{d'}, \boldsymbol{w}_d, \boldsymbol{w}_{d'}, \boldsymbol{\eta}, \boldsymbol{\tau})$

Step 1: Identifying birds of a feather. Prior to the generative process, given a training set of documents and document-to-document links, we begin by identifying small clusters or cliques using strongly connected components, which automatically determines the number of clusters from the link graph. Intuitively, documents in the same clique are likely to have similar topic distributions. Therefore, each of the L cliques l (the "birds of a feather" of our title) is assigned a separate Dirichlet prior $\boldsymbol{\pi_l}$ over K topics.

Step 2a: Using seed words to improve topic quality. To improve topic quality, we identify *seed words* for the K topics using distributed lexical representations: the key idea is to complement the more global information captured in LDA-style topics with representations based on local contextual information. We cluster the most frequent words' word2vec representations (Mikolov et al., 2013) into K word-clusters using the k-means algorithm, based on the training corpus.[1] We then enforce a one-to-one association between these discovered word clusters and the K topics. For any word token $w_{d,n}$ whose word type is in cluster k, the associated topic assignment $z_{d,n}$ can only be k. To choose topic k's seed words, within its word-cluster we compute each word $w_{k,i}$'s skip-gram transition probability sum $S_{k,i}$ to the other words as

$$S_{k,i} = \sum_{j=1, j \neq i}^{N_k} p(w_{k,j} \,|\, w_{k,i}), \qquad (1)$$

where N_k denotes the number of words in topic k.

We then select the three words with the highest sum of transition probabilities as the seed words for topic k. In the sampling process (Section 3), seed words are only assigned to their corresponding topics, similar to the use of hard constraints by Andrzejewski and Zhu (2009).

Steps 2b-3: Link regression parameters. Given two documents d and d', we want to predict whether they are linked by taking advantage of their topic patterns: the more similar two documents are, the more likely it is that they should be linked together. Like RTM, we will compute a regression in Step 5 using the topic distributions of d and d'; however, we follow Nguyen et al. (2013) by also including a document's word-level distribution as a regression input.[2] The regression value of document d and d' is

$$R_{d,d'} = \boldsymbol{\eta}^{\mathrm{T}}(\overline{\boldsymbol{z}}_d \circ \overline{\boldsymbol{z}}_{d'}) + \boldsymbol{\tau}^{\mathrm{T}}(\overline{\boldsymbol{w}}_d \circ \overline{\boldsymbol{w}}_{d'}), \qquad (2)$$

where $\overline{\boldsymbol{z}}_d = \frac{1}{N_d} \sum_n z_{d,n}$, and $\overline{\boldsymbol{w}}_d = \frac{1}{N_d} \sum_n w_{d,n}$; $\circ$ denotes the Hadamard product; $\boldsymbol{\eta}$ and $\boldsymbol{\tau}$ are the

[1] In the experiment, seed words must appear at least 1,000 times.

[2] Both approaches contrast with the links-only approach of Kim and Leskovec (2012).

weight vectors for topic-based and lexically-based predictions, respectively.

Step 4: Generating documents. Documents are generated as in LDA, where each document's topic distribution $\boldsymbol{\theta}$ is drawn from the cluster's topic prior (a parametric analog to the HDP of Teh et al. (2006)) and each word's topic assignment is drawn from the document's topic distribution (except for seed words, as described above).

Step 5: Generating links. Our model is a "downstream" supervised topic model, i.e., the prediction of the observable variable (here, document links) is informed by the documents' topic distributions, as in sLDA (Blei and McAuliffe, 2007). In contrast to Chang and Blei (2010), who use a sigmoid as their link prediction function Ψ, we instead use hinge loss: the probability Ψ that two documents d and d' are linked is

$$p(y_{d,d'} = 1 \mid \overline{\boldsymbol{z}}_d, \overline{\boldsymbol{z}}_{d'}, \overline{\boldsymbol{w}}_d, \overline{\boldsymbol{w}}_{d'}) = \exp(-2c\max(0, \zeta_{d,d'})),$$

where c is the regularization parameter. In the hinge loss function, $\zeta_{d,d'}$ is

$$\zeta_{d,d'} = 1 - y_{d,d'} R_{d,d'}. \quad (3)$$

3 Posterior Inference

Sampling Topics. Following Polson and Scott (2011), by introducing an auxiliary variable $\lambda_{d,d'}$, we derive the conditional probability of a topic assignment

$$p(z_{d,n} = k \mid \boldsymbol{z}_{-d,n}, \boldsymbol{w}_{-d,n}, w_{d,n} = v) \propto \frac{N_{k,v}^{-d,n} + \beta}{N_{k,\cdot}^{-d,n} + V\beta} \times (N_{d,k}^{-d,n} + \alpha\pi_{l_d,k}^{-d,n}) \times \prod_{d'} \exp\left(-\frac{(c\zeta_{d,d'} + \lambda_{d,d'})^2}{2\lambda_{d,d'}}\right), \quad (4)$$

where $N_{k,v}$ denotes the count of word v assigned to topic k; $N_{d,k}$ is the number of tokens in document d that are assigned to topic k.[3] Marginal counts are denoted by $\cdot$; $^{-d,n}$ denotes that the count excludes token n in document d; d' denotes the indexes of documents which are linked to document d; $\pi_{l_d,k}^{-d,n}$ is estimated based on the maximal path assumption (Wallach, 2008)

$$\pi_{l_d,k}^{-d,n} = \frac{\sum_{d' \in S(l_d)} N_{d',k}^{-d,n} + \alpha'}{\sum_{d' \in S(l_d)} N_{d',\cdot}^{-d,n} + K\alpha'}, \quad (5)$$

where $S(l_d)$ denotes the cluster which contains document d (Step 1 in the generative process).

[3]More details here and throughout this section appear in the supplementary materials.

Optimizing topic and lexical regression parameters. While topic regression parameters $\boldsymbol{\eta}$ and lexical regression parameters $\boldsymbol{\tau}$ can be sampled (Zhu et al., 2014), the associated covariance matrix is huge (approximately $12K \times 12K$ in our experiments). Instead, we optimize these parameters using L-BFGS.

Sampling auxiliary variables. The likelihood of auxiliary variables $\boldsymbol{\lambda}$ follows a generalized inverse Gaussian distribution $\mathrm{GIG}(\lambda_{d,d'}; \frac{1}{2}, 1, c^2\zeta_{d,d'}^2)$. Thus we sample $\lambda_{d,d'}^{-1}$ from a an inverse Gaussian distribution

$$p(\lambda_{d,d'}^{-1} \mid \boldsymbol{z}, \boldsymbol{w}, \boldsymbol{\eta}, \boldsymbol{\tau}) = \mathrm{IG}\left(\lambda_{d,d'}^{-1}; \frac{1}{c|\zeta_{d,d'}|}, 1\right). \quad (6)$$

4 Experimental Results

4.1 Dataset

We crawl data from Sina Weibo, the largest Chinese micro-blog platform. The dataset contains 2,000 randomly-selected verified users, each represented by a single document aggregating all the user's posts. We also crawl links between pairs of users when both are in our dataset. Links correspond to three types of interactions on Weibo: mentioning, retweeting and following.[4]

4.2 Perplexity Results

As an initial reality check, we first apply a simplified version of our model which only uses user interactions for topic modeling and does not predict links. This permits a direct comparison of our model's performance against LDA and Markov random topic fields (Daumé III, 2009, MRTF) by evaluating perplexity.

We set $\alpha = \alpha' = 15$ and run the models on 20 topics for all models in this and following sections. The results are the average values of five independent runs. Following Daumé, in each run, for each document, 80% of its tokens are randomly selected for training and the remaining 20% are for test. As the training corpus is generated randomly, seeding is not applied in this section. The results are given in Table 1, where I- denotes that the model incorporates user interactions.

The results confirm that our model outperforms both LDA and MRTF and that its use of user interactions holds promise.

[4]We use ICTCLAS (Zhang et al., 2003) for segmentation. After stopword and low-frequency word removal, the vocabulary includes 12,257 words, with ∼755 tokens per document and 5,404 links.

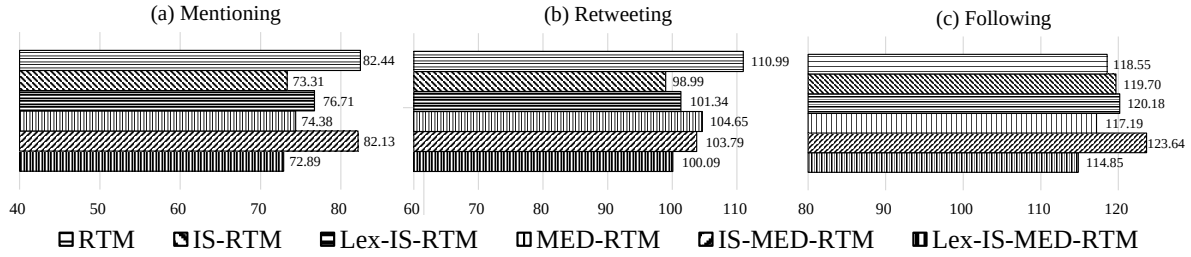

Figure 2: Lex-IS-MED-RTM, combining all three extensions, performs the best on predicting mentioning and following links, although IS-RTM achieves a close value on mentioning links and even a slightly better value on retweeting links. User interactions (denoted by "I") sometimes bring down the performance, as cluster priors are not applied in this intrinsic evaluation.

Link	Model	Perplexity
–	LDA	2605.06
Mentioning	MRTF	2582.08
	I-LDA	2522.58
Retweeting	MRTF	2588.30
	I-LDA	2519.27
Following	MRTF	2587.26
	I-LDA	2530.67

Table 1: Our simplified model I-LDA achieves lower perplexities than both LDA and MRTF, by incorporating different cliques extracted from three types of user interactions.

4.3 Link Prediction Results

In this section, we apply our model on link prediction tasks and evaluate by predictive link rank (PLR). A document's PLR is the average rank, among all documents, of the documents to which it actually links. This means that lower values of PLR are better.

Figure 2 breaks out the 5-fold cross validation results and the distinct extensions of RTM.[5] The results support the value in combining all three extensions using Lex-IS-MED-RTM, although for mentioning and retweeting, Lex-IS-MED-RTM and IS-RTM are quite close.

Applying user interactions does not always produce improvements. This is because in our intrinsic evaluation, we assume that the links on the test set are not observable and cluster priors are not applied. However, according to the training performance (extrinsic evaluations which we are still in progress), user interactions do benefit link prediction performance when links are partially available, e.g., suggesting more links based on observed links. In contrast, hinge loss and lexical term weights do not depend on metadata availability and generally produce improvements in link prediction performance.

4.4 Illustrative Example

We illustrate model behavior qualitatively by looking at two test set users, designated A and B. User A is a reporter who runs "We Media" on his account, sending news items to followers, and B is a consultant with a wide range of interests. Their tweets reveal that both are interested in social news—a topic emphasizing words like *society*, *country*, *government*, *laws*, *leaders*, *political party*, *news*, etc. Both often retweet news related to unfairness in society and local government scandals (*government*, *police*, *leaders*, *party*, *policy*, *chief secretary*). For example, User A retweeted a report that a person about to be executed was unable to take a photo with his family before his execution, writing *I feel heartbroken*. User B retweeted news that a mayor was fired and investigated because of a bribe; in his retweet, he expresses his dissatisfaction with what the mayor did when he was in power. In addition, User A follows new technology (*smart phone*, *Apple*, *Samsung*, *software*, *hardware*, etc.) and B is interested in food (*snacks*, *noodles*, *wine*, *fish*, etc.).

As ground truth, there is a *mentioning* link from A to B; Table 2 shows this link's PLR in the *mentioning* models, which generally improves with model sophistication. The mentioning tweet is a news item that is consistent with the model's

[5]IS- denotes that the model incorporates user interactions and seed words, Lex- means that lexical terms were included in the link probability function (Equation 3), and MED- denotes max-margin learning (Zhu et al., 2014; Zhu et al., 2012). Each type of link is applied separately; e.g., in Figure 2(a) results are based *only* on mentioning links, ignoring retweeting and following links.

Model		RTM	IS-RTM	Lex-IS-RTM	MED-RTM	IS-MED-RTM	Lex-IS-MED-RTM
PLR of the Link		24	10	9	74	18	26
Social News	**User A**	0.018	0.021	0.034	0.016	0.027	0.030
Topic Proportion	**User B**	0.309	0.413	0.408	0.318	0.355	0.392

Table 2: Data for Illustrative Example

Model		RTM	IS-RTM	Lex-IS-RTM	MED-RTM	IS-MED-RTM	Lex-IS-MED-RTM
Topic PMI		1.186	1.224	1.216	1.214	1.294	1.229
Average Regression Values	**Linked Pairs**	0.2403	0.3692	0.4031	0.7220	0.6321	0.7668
	All Pairs	0.06636	0.07729	0.08020	0.2482	0.2041	0.2428
	Ratio	3.621	4.777	5.026	2.909	3.097	3.158
	SD/Avg	0.9415	1.2081	1.2671	0.6364	0.7254	0.7353

Table 3: Values for Quantitative Analysis

characterization of the users' interests (particularly social news and technology): a Samsung Galaxy S4 exploded and caused a fire while charging. Consistent with intuition, the prevalence of the social news topic also generally increases as the models grow more sophisticated.[6]

4.5 Quantitative Analysis

Topic Quality. Automatic coherence detection (Lau et al., 2014) is an alternative to manual evaluations of topic quality (Chang et al., 2009). In each topic, the top n words' average pointwise mutual information (PMI)—based on a reference corpus—serves as a measure of topic coherence.[7]

Topic quality improves with user interactions and max-margin learning (Table 3). PMI drops when lexical terms are added to the link probability function, however. This is consistent with the role of lexical terms in the model; their purpose is to improve link prediction performance, not improve topic quality.

Average Regression Value. One way to assess the quality of link prediction is to compare the scores of (ground-truth) linked documents to documents in general. In Table 3, the Average Regression Values show this comparison as a ratio. The higher the ratio, the more linked document pairs differ from unlinked pairs, which means that linked documents are easier to distinguish. This ratio improves as RTM extensions are added, indicating better link modeling quality.

In the SD/Avg row of Table 3, we also compute a ratio of standard deviations to mean values. Ratios given by the models with hinge loss are lower than those not using hinge loss. This means that the regression values given by the models with hinge loss are more concentrated around the average value, suggesting that these models can better identify linked pairs, even though the ratio of linked pairs' average regression value to all pairs' average value is lower.

5 Conclusions and Future Work

We introduce a new topic model that takes advantage of document links, incorporating link information straightforwardly by deriving clusters from the link graph and assigning each cluster a separate Dirichlet prior. We also take advantage of locally-derived distributed representations to "seed" the model's latent topics in an informed way, and we integrate max-margin prediction and lexical regression to improve link prediction quality. Our quantitative results show improvements in predictive link rank, and our qualitative and quantitative analysis illustrate that the model's behavior is intuitively plausible.

In future work, we plan to engage in further model analysis and comparison, to explore alterations to model structure, e.g. introducing hierarchical topic models, to use other clustering methods to obtain priors, and to explore the value of predicted links for downstream tasks such as friend recommendation (Pennacchiotti and Gurumurthy, 2011) and inference of user attributes (Volkova et al., 2014).

[6] Numerically its proportion is consistently lower for User A, whose interests are more diverse.

[7] We set $n = 20$ and use a reference corpus of 1,143,525 news items from Sogou Lab, comprising items from June to July 2012, `http://www.sogou.com/labs/dl/ca.html`. Each averages ∼347 tokens, using the same segmentation scheme as the experimental corpus.

Abstract

We study the problem of jointly embedding a knowledge base and a text corpus. The key issue is the alignment model making sure the vectors of entities, relations and words are in the same space. Wang et al. (2014a) rely on Wikipedia anchors, making the applicable scope quite limited. In this paper we propose a new alignment model based on text descriptions of entities, without dependency on anchors. We require the embedding vector of an entity not only to fit the structured constraints in KBs but also to be equal to the embedding vector computed from the text description. Extensive experiments show that, the proposed approach consistently performs comparably or even better than the method of Wang et al. (2014a), which is encouraging as we do not use any anchor information.

1 Introduction

Knowledge base embedding has attracted surging interest recently. The aim is to learn continuous vector representations (embeddings) for entities and relations of a structured knowledge base (KB) such as Freebase. Typically it optimizes a global objective function over all the facts in the KB and hence the embedding vector of an entity / relation is expected to encode global information in the KB. It is capable of reasoning missing facts in a KB and helping facts extraction (Bordes et al., 2011; Bordes et al., 2012; Bordes et al., 2013; Socher et al., 2013; Chang et al., 2013; Wang et al., 2014b; Lin et al., 2015).

Although seeming encouraging, the approaches in the aforementioned literature suffer from two common issues: (1) Embeddings are exclusive to entities/relations within KBs. Computation between KBs and text cannot be handled, which are prevalent in practice. For example, in fact extraction, a candidate value may be just a phrase in text. (2) KB sparsity. The above approaches are only based on structured facts of KBs, and thus cannot work well on entities with few facts.

An important milestone, the approach of Wang et al. (2014a) solves issue (1) by jointly embedding entities, relations, and words into the same vector space and hence is able to deal with words/phrases beyond entities in KBs. The key component is the so-called *alignment model*, which makes sure the embeddings of entities, relations, and words are in the same space. Two alignment models are introduced there: one uses entity names and another uses Wikipedia anchors. However, both of them have drawbacks. As reported in the paper, using entity names severely pollutes the embeddings of words. Thus it is not recommended in practice. Using Wikipedia anchors completely relies on the special data source and hence the approach cannot be applied to other customer data.

To fully address the two issues, this paper proposes a new alignment method, aligning by entity descriptions. We only assume some entities in KBs have text descriptions, which almost always holds in practice. We require the embedding of an entity not only fits the structured constraints in KBs but also equals the vector computed from the text description. Meanwhile, if an entity has few facts, the description will provide information for embedding, thus the issue of KB sparsity is also well handled. We conduct extensive experiments on the tasks of triplet classification, link prediction, relational fact extraction, and analogical reasoning to compare with the previous approach (Wang et al., 2014a). Results show that our approach consistently achieves better or comparable performance.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 267–272,
Lisbon, Portugal, 17-21 September 2015.

2 Related Work

TransE This is a representative knowledge embedding model proposed by Bordes et al. (2013). For a fact (h, r, t) in KBs, where h is the head entity, r is the relation, and t is the tail entity, TransE models the relation r as a translation vector $\mathbf{r}$ connecting the embeddings $\mathbf{h}$ and $\mathbf{t}$ of the two entities, i.e., $\mathbf{h} + \mathbf{r}$ is close to $\mathbf{t}$. The model is simple, effective and efficient. Most knowledge embedding models thereafter including this paper are variants of this model (Wang et al., 2014b; Wang et al., 2014a; Lin et al., 2015).

Skip-gram This is an efficient word embedding method proposed by Mikolov et al. (2013a), which learns word embeddings from word concurrencies in text windows. Without any supervision, it amazingly recovers the semantic relations between words in a vector space such as 'King' − 'Queen' ≈ 'Man' − 'Women'. However, as it is unsupervised, it cannot tell the exact relation between two words.

Knowledge and Text Jointly Embedding Wang et al. (2014a) combines knowledge embedding and word embedding in a joint framework so that the entities/relations and words are in the same vector space and hence operators like inner product (similarity) between them are meaningful. This brings convenience to tasks requiring computation between knowledge bases and text. Meanwhile, jointly embedding utilizes information from both structured KBs and unstructured text and hence the knowledge embedding and word embedding can be enhanced by each other. Their model is composed of three components: a *knowledge model* to embed entities and relations, a *text model* to embed words, and an *alignment model* to make sure entities/relations and words are in the same vector space. The knowledge model and text model are variants of TransE and Skip-gram respectively. The key component is the alignment model. They introduced two: alignment by entity names and alignment by Wikipedia anchors. (1) **Alignment by Entity Names** makes a replicate of KB facts but replaces each entity ID with its name string, i.e., the vector of a name phrase is encouraged to equal to the vector of the entity (identified by ID). It has problems with ambiguous entity names and observed polluting word embeddings thus it is not recommended by the authors. (2) **Alignment by Wikipedia Anchors** replaces the surface phrase v of a Wikipedia anchor with its corresponding Freebase entity e_v and defines the likelihood

$$\mathcal{L}_{AA} = \sum_{(w,v)\in\mathcal{C}, v\in\mathcal{A}} \log \Pr(w|e_v) \quad (1)$$

where $\mathcal{C}$ is the collection of observed word and context pairs and $\mathcal{A}$ refers to the set of all anchors in Wikipedia. $\Pr(w|e_v)$ is the probability of the anchor predicting its context word, which takes a form similar to Skip-gram for word embedding. Alignment by anchors works well in both improving knowledge embedding and word embeddings. However, it completely relies on the special data source of Wikipedia anchors and cannot be applied to other general data settings.

3 Alignment by Entity Descriptions

We first describe the settings and notations. Given a knowledge base, i.e., a set of facts (h, r, t), where $h, t \in \mathcal{E}$ (the set of entities) and $r \in \mathcal{R}$ (the set of relations). Some entities have text descriptions. The description of entity e is denoted as D_e. $w_{i,n}$ is the n^{th} word in the description of e_i. N_i is the length (in words) of the description of e_i. We try to learn embeddings $\mathbf{e}_i$, $\mathbf{r}_j$ and $\mathbf{w}_l$ for each entity e_i, relation r_j and word w_l respectively. The vocabulary of words is $\mathcal{V}$. The union vocabulary of entities and words together is $\mathcal{I} = \mathcal{E} \cup \mathcal{V}$. In this paper "word(s)" refers to "word(s)/phrase(s)".

We follow the jointly embedding framework of (Wang et al., 2014a), i.e., learning optimal embeddings by minimizing the following loss

$$\mathcal{L}\left(\{\mathbf{e}_i\}, \{\mathbf{r}_j\}, \{\mathbf{w}_l\}\right) = \mathcal{L}_K + \mathcal{L}_T + \mathcal{L}_A, \quad (2)$$

where $\mathcal{L}_K$, $\mathcal{L}_T$ and $\mathcal{L}_A$ are the component loss functions of the knowledge model, text model and alignment model respectively. Our focus is on a new alignment model $\mathcal{L}_A$ while the knowledge model $\mathcal{L}_K$ and text model $\mathcal{L}_T$ are the same as the counterparts in (Wang et al., 2014a). However, to make the content self-contained, we still need to briefly explain $\mathcal{L}_K$ and $\mathcal{L}_T$.

Knowledge Model Describes the plausibility of a triplet (h, r, t) by defining

$$\Pr(h|r,t) = \frac{\exp\{z(h,r,t)\}}{\sum_{\tilde{h}\in\mathcal{I}} \exp\{z(\tilde{h},r,t)\}}, \quad (3)$$

where $z(h, r, t) = b - 0.5 \cdot \|\mathbf{h} + \mathbf{r} - \mathbf{t}\|_2^2$, $b = 7$ as suggested by Wang et al. (2014a). $\Pr(r|h, t)$ and

$\Pr(t|h,r)$ are defined in the same way. The loss function of knowledge model is then defined as

$$\mathcal{L}_K = -\sum_{(h,r,t)} \big[\log \Pr(h|r,t) + \log \Pr(t|h,r) + \log \Pr(r|h,t)\big] \quad (4)$$

Text Model Defines the probability of a pair of words w and v co-occurring in a text window:

$$\Pr(w|v) = \frac{\exp\{z(w,v)\}}{\sum_{\tilde{w}\in\mathcal{V}} \exp\{z(\tilde{w},v)\}} \quad (5)$$

where $z(w,v) = b - 0.5 \cdot \|\mathbf{w} - \mathbf{v}\|_2^2$. Then the loss function of text model is

$$\mathcal{L}_T = -\sum_{(w,v)} \log \Pr(w|v) \quad (6)$$

Alignment Model This part is different from Wang et al. (2014a). For each word w in the description of entity e, we define $\Pr(w|e)$, the conditional probability of predicting w given e:

$$\Pr(w|e) = \frac{\exp\{z(e,w)\}}{\sum_{\tilde{w}\in\mathcal{V}} \exp\{z(e,\tilde{w})\}}, \quad (7)$$

where $z(e,w) = b - 0.5 \cdot \|\mathbf{e} - \mathbf{w}\|_2^2$. Notice that $\mathbf{e}$ is the same vector of entity e appearing in the knowledge model of Eq. (3).

We also define $\Pr(e|w)$ in the same way by revising the normalization term

$$\Pr(e|w) = \frac{\exp\{z(e,w)\}}{\sum_{\tilde{e}\in\mathcal{E}} \exp\{z(\tilde{e},w)\}} \quad (8)$$

Then the loss function of alignment model is

$$\mathcal{L}_A = -\sum_{e\in\mathcal{E}} \sum_{w\in D_e} [\log \Pr(w|e) + \log \Pr(e|w)] \quad (9)$$

Training We use stochastic gradient descent (SGD) to minimize the overall loss of Eq. (2), which sequentially updates the embeddings. Negative sampling is used to calculate the normalization items over large vocabularies. We implement a multi-threading version to deal with large data sets, where memory is shared and lock-free.

4 Experiments

We conduct experiments on the following tasks: link prediction (Bordes et al., 2013), triplet classification (Socher et al., 2013), relational fact extraction (Weston et al., 2013), and analogical reasoning (Mikolov et al., 2013b). The last one evaluates quality of word embeddings. We try to study whether the proposed alignment model, without using any anchor information, is able to achieve comparable or better performance than alignment by anchors. As to the methods, "Separately" denotes the method of separately embedding knowledge bases and text. "Jointly(anchor)" and "Jointly(name)" denote the jointly embedding methods based on Alignment by Wikipedia Anchors and Alignment by Entity Names in (Wang et al., 2014a) respectively. "Jointly(desp)" is the joint embedding method based on alignment by entity descriptions.

Table 1: Link prediction results.

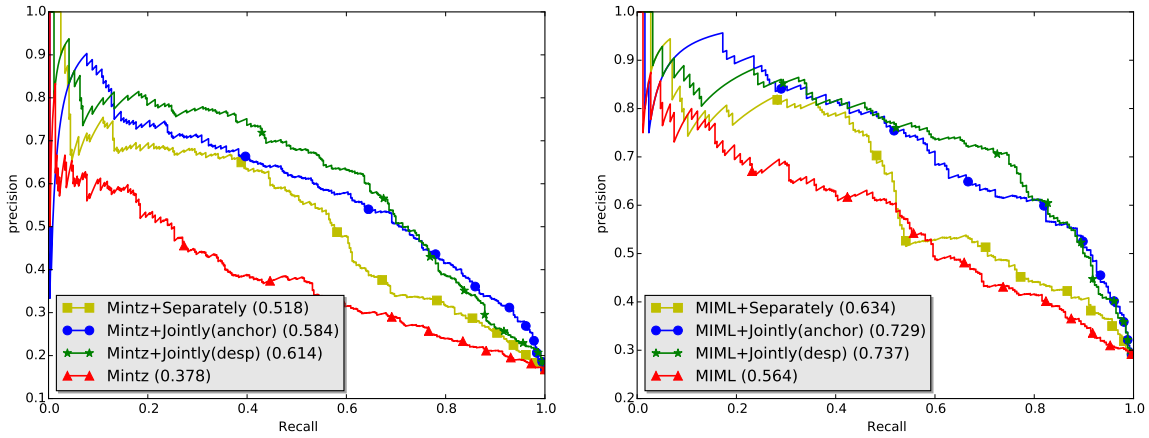
Metric	MEAN		HITS@10	
	Raw	Filtered	Raw	Filtered
TransE	243	125	34.9	47.1
Jointly(anchor)	**166**	47	49.9	72.0
Jointly(desp)	167	**39**	**51.7**	**77.3**

Table 2: Triplet classification results.

Type	e - e	w - e	e - w	w - w	all
Separately	94.0	51.7	51.0	69.0	73.6
Jointly(anchor)	95.2	65.3	65.1	76.2	79.9
Jointly(desp)	**96.1**	**66.7**	**66.1**	**76.4**	**80.9**

Data For link prediction, FB15K from (Bordes et al., 2013) is used as the knowledge base. For triplet classification, a large dataset provided by (Wang et al., 2014a) is used as the knowledge base. Both sets are subsets of Freebase. For all tasks, Wikipedia articles are used as the text corpus. As many Wikipedia articles can be mapped to Freebase entities, we regard a Wikipedia article as the description for the corresponding entity in Freebase. Following the settings in (Wang et al., 2014a), we apply the same preprocessing steps, including sentence segmentation, tokenization, and named entity recognition. We combine the consecutive tokens covered by an anchor or identically tagged as "Location/Person/Organization" and regard them as phrases.

Link Prediction This task aims to complete a fact (h,r,t) in absence of h or t, simply based on $\|\mathbf{h}+\mathbf{r}-\mathbf{t}\|$. We follow the same protocol in (Bordes et al., 2013). We directly copy the results of the baseline (TransE) from (Bordes et al., 2013) and implement "Jointly(anchor)". The results are in Table 1. "MEAN" is the average rank of the true absent entity. "HITS@10" is accuracy of the top



(a) (b)

Figure 1: Precision-recall curves for relation extraction. (a) Mintz (Mintz et al., 2009) as base extractor (b) MIML (Surdeanu et al., 2012) as base extractor.

10 predictions containing the true entity. Lower "MEAN" and higher "HITS@10" is better. "Raw" and "Filtered" are two settings on processing candidates (Bordes et al., 2013).

We train "Jointly(anchor)" and "Jointly(desp)" with the embedding dimension k among $\{50, 100, 150\}$, the learning rate α in $\{0.01, 0.025\}$, the number of negative examples per positive example c in $\{5, 10\}$, the max skip-range s in $\{5, 10\}$ and traverse the text corpus with only 1 epoch. The best configurations of "Jointly(anchor)" and "Jointly(desp)" are exactly the same: $k = 100, \alpha = 0.025, c = 10, s = 5$.

From the results, we observe that: (1) Both jointly embedding methods are much better than the baseline TransE, which demonstrates that external textual resources make entity embeddings become more discriminative. Intuitively, "Jointly(anchor)" indicates "*how to use an entity in text*", while "Jointly(desp)" shows "*what is the definition/meaning of an entity*". Both are helpful to distinguish an entity from others. (2) Under the setting of "Raw", "Jointly(desp)" and "Jointly(anchor)" are comparable. In other settings "Jointly(desp)" wins.

Triplet Classification This is a binary classification task, predicting whether a candidate triplet (h, r, t) is a correct fact or not. It is used in (Socher et al., 2013; Wang et al., 2014b; Wang et al., 2014a). We follow the same protocol in (Wang et al., 2014a).

We train their models via our own implementation on our dataset. The results are in Table 2. "e-e" means both sides of a triplet (h, r, t) are entities in KB, "e-w" means the tail side is a word out of KB entity vocabulary, similarly for "w-e" and "w-w". The best configurations of the models are: $k = 150, \alpha = 0.025, c = 10, s = 5$ and traversing the text corpus with 6 epochs.

The results reveal that: (1) Jointly embedding is indeed effective. Both jointly embedding methods can well handle the cases of "e-w", "w-e" and "w-w", which means the vector computation between entities/relations and words are really meaningful. Meanwhile, even the case of "e-e" is also improved. (2) Our method, "Jointly(desp)", outperforms "Jointly(anchor)" on all types of triplets. We believe that the good performance of "Jointly(desp)" is due to the appropriate design of the alignment mechanism. Using entity's description information is a more straightforward and effective way to align entity embeddings and word embeddings.

Relational Fact Extraction This task is to extract facts (h, r, t) from plain text. Weston et al. (2013) show that combing scores from TransE and some text side base extractor achieved much better precision-recall curve compared to the base extractor. Wang et al. (2014a) confirm this observation and show that jointly embedding brings further encouraging improvement over TransE. In this experiment, we follow the same settings as (Wang et al., 2014a) to investigate the performance of our new alignment model. We use the

Table 3: Analogical reasoning results

Metric	Words		Phrases	
	Acc.	Hits@10	Acc.	Hits@10
Skip-gram	67.4	86.7	22.0	63.6
Jointly(anchor)	**69.4**	87.7	26.2	68.1
Jointly(name)	44.5	69.7	11.5	46.0
Jointly(desp)	69.3	**88.3**	**49.0**	**86.5**

same public dataset NYT+FB, released by Riedel et al. (2010) and used in (Weston et al., 2013) and (Wang et al., 2014a). We use Mintz (Mintz et al., 2009) and MIML (Surdeanu et al., 2012) as our base extractors.

In order to combine the score of a base extractor and the score from embeddings, we only reserve the testing triplets whose entitites and relations can be mapped to the embeddings learned from the triplet classification experiment. Since both Mintz and MIML are probabilistic models, we use the same method in (Wang et al., 2014a) to linearly combine the scores.

The precision-recall curves are plot in Fig. (1). On both base extractors, the jointly embedding methods outperform separate embedding. Moreover, "Jointly(desp)" is slightly better than "Jointly(anchor)", which is in accordance with the results from the link prediction experiment and the triplet classification experiment.

Analogical Reasoning This task evaluates the quality of word embeddings (Mikolov et al., 2013b). We use the original dataset released by (Mikolov et al., 2013b) and follow the same evaluation protocol of (Wang et al., 2014a). For a true analogical pair like ("France", "Paris") and ("China", "Beijing"), we hide "Beijing" and predict it by selecting the word from the vocabulary whose vector has highest similarity with the vector of "China" + "Paris" - "France". We use the word embeddings learned for the triplet classification experiment and conduct the analogical reasoning experiment for "Skip-gram", "Jointly(anchor)", "Jointly(name)" and "Jointly(desp)".

Results are presented in Table 3. "Acc" is the accuracy of the predicted word. "HITS@10" is the accuracy of the top 10 candidates containing the ground truth. The evaluation analogical pairs are organized into two groups, "Words" and "Phrases", by whether an analogical pair contains phrases (i.e., multiple words). From the table we observe that: (1) Both "Jointly(anchor)" and "Jointly(desp)" outperform "Skip-gram". (2) "Jointly(desp)" achieves the best results, especially for the case of "Phrases". Both "Jointly(anchor)" and "Skip-gram" only consider the context of words, while "Jointly(desp)" not only consider the context but also use the whole document to disambiguate words. Intuitively, the whole document is also a valuable resource to disambiguate words. (3) We further verify that "Jointly(name)", i.e., using entity names for alignment, indeed pollutes word embeddings, which is consistent with the reports in (Wang et al., 2014a).

The above four experiments are consistent in results: without using any anchor information, alignment by entity description is able to achieve better or comparable performance, compared to alignment by Wikipedia anchors proposed by Wang et al. (2014a).

5 Conclusion

We propose a new alignment model based on entity descriptions for jointly embedding a knowledge base and a text corpus. Compared to the method of alignment using Wikipedia anchors Wang et al. (2014a), our method has no dependency on special data sources of anchors and hence can be applied to any knowledge bases with text descriptions for entities. Extensive experiments on four prevalent tasks to evaluate the quality of knowledge and word embeddings produce very consistent results: our alignment model achieves better or comparable performance.

University of California, Berkeley
Berkeley, CA 94720, USA
{jkk,tberg,klein}@cs.berkeley.edu

Abstract

Despite the convexity of structured max-margin objectives (Taskar et al., 2004; Tsochantaridis et al., 2004), the many ways to optimize them are not equally effective in practice. We compare a range of online optimization methods over a variety of structured NLP tasks (coreference, summarization, parsing, etc) and find several broad trends. First, margin methods do tend to outperform both likelihood and the perceptron. Second, for max-margin objectives, primal optimization methods are often more robust and progress faster than dual methods. This advantage is most pronounced for tasks with dense or continuous-valued features. Overall, we argue for a particularly simple online primal subgradient descent method that, despite being rarely mentioned in the literature, is surprisingly effective in relation to its alternatives.

1 Introduction

Structured discriminative models have proven effective across a range of tasks in NLP including tagging (Lafferty et al., 2001; Collins, 2002), reranking parses (Charniak and Johnson, 2005), and many more (Taskar, 2004; Smith, 2011). Common approaches to training such models include margin methods, likelihood methods, and mistake-driven procedures like the averaged perceptron algorithm. In this paper, we primarily consider the relative empirical behavior of several online optimization methods for margin-based objectives, with secondary attention to other approaches for calibration.

It is increasingly common to train structured models using a max-margin objective that incorporates a loss function that decomposes in the same way as the dynamic program used for inference (Taskar, 2004). Fortunately, most structured margin objectives are convex, so a range of optimization methods with similar theoretical properties are available – in short, any of these methods will work in the end. However, in practice, how fast each method converges varies across tasks. Moreover, some of the most popular methods more loosely associated with the margin objective, such as the MIRA algorithm (Crammer and Singer, 2003) or even the averaged perceptron (Freund and Schapire, 1999) are not global optimizations and can have different properties.

We analyze a range of methods empirically, to understand on which tasks and with which feature types, they are most effective. We modified six existing, high-performance, systems to enable loss-augmented decoding, and trained these models with six different methods. We have released our learning code as a Java library.[1] Our results provide support for the conventional wisdom that margin-based optimization is broadly effective, frequently outperforming likelihood optimization and the perceptron algorithm. We also found that directly optimizing the primal structured margin objective based on subgradients calculated from single training instances is surprisingly effective, performing consistently well across all tasks.

2 Learning Algorithms

We implemented a range of optimization methods that are widely used in NLP; below we categorize them into margin, likelihood, and perceptron-like methods. In each case, we used a structured loss function, modified to suit each task. In general, we focus on online methods because of their substantial speed advantages, rather than algorithms such as LBFGS (Liu and Nocedal, 1989) or batch Exponentiated Gradient (Collins et al., 2008).

Lisbon, Portugal, 17-21 September 2015.

Algorithm 1 The Online Primal Subgradient Algorithm with ℓ_1 or ℓ_2 regularization, and sparse updates

Parameters:

iters	Number of iterations
C	Regularization constant (10^{-1} to 10^{-8})
η	Learning rate (10^{0} to 10^{-4})
δ	Initializer for q (10^{-6})

$\mathbf{w} = \mathbf{0}$ Weight vector
$\mathbf{q} = \boldsymbol{\delta}$ Cumulative squared gradient
$\mathbf{u} = \mathbf{0}$ Time of last update for each weight
$n = 0$ Number of updates so far
for iter $\in [1, \text{iters}]$ **do**
  for batch $\in$ data **do**
    Sum gradients from loss-aug. decodes
    $\mathbf{g} = \mathbf{0}$
    for $(x_i, y_i) \in$ batch **do**
      $y = \underset{y' \in Y(x_i)}{\text{argmax}}[\text{SCORE}(y') + \mathbf{L}(y', y_i)]$
      $\mathbf{g}$ += $(\mathbf{f}(y) - \mathbf{f}(y_i))$
    Update the active features
    $\mathbf{q}$ += $\mathbf{g}^2$ Element-wise square
    n += 1
    for $f \in$ nonzero features in $\mathbf{g}$ **do**
      $w_f = \text{UPDATE-ACTIVE}(w_f, g_f, q_f)$
      $u_f = n$

The AdaGrad update
function UPDATE-ACTIVE(w, g, q)
  return $\frac{w\sqrt{q} - \eta g}{\eta \mathrm{C} + \sqrt{q}}$ $[\ell_2]$
  $\mathrm{d} = |w - \frac{\eta}{\sqrt{q}} g| - \frac{\eta}{\sqrt{q}} \mathrm{C}$ $[\ell_1]$
  return $\text{sign}(w - \frac{\eta}{\sqrt{q}} g) \cdot \max(0, \mathrm{d})$ $[\ell_1]$

Functions only needed for sparse updates

A single update equivalent to a series of AdaGrad updates where the weight's subgradient was zero
function UPDATE-CATCHUP(w, q, t)
  return $w \left(\frac{\sqrt{q}}{\eta \mathrm{C} + \sqrt{q}}\right)^t$ $[\ell_2]$
  return $\text{sign}(w) \cdot \max(0, |w| - \frac{\eta \mathrm{C}}{\sqrt{q}} t)$ $[\ell_1]$

Compute $\mathbf{w}^\top \mathbf{f}(y')$, but for each weight, apply an update to catch up on the steps in which the gradient for that weight was zero
function SCORE(y')
  $s = 0$
  for $f \in \mathbf{f}(y')$ **do**
    $w_f = \text{UPDATE-CATCHUP}(w_f, q_f, n - u_f)$
    $u_f = n$
    s += w_f
  return s

Note: To implement without the sparse update, use SCORE $= \mathbf{w}^\top \mathbf{f}(y')$, and run the update loop on the left over all features. Also, for comparison, to implement perceptron, remove the sparse update and use UPDATE-ACTIVE $=$ **return** $w + g$.

2.1 Margin

Cutting Plane (Tsochantaridis et al., 2004) Solves a sequence of quadratic programs (QP), each of which is an approximation to the dual formulation of the margin-based learning problem. At each iteration, the current QP is refined by adding additional active constraints. We solve each approximate QP using Sequential Minimal Optimization (Platt, 1999; Taskar et al., 2004).

Online Cutting Plane (Chang and Yih, 2013) A modified form of cutting plane that only partially solves the QP on each iteration, operating in the dual space and optimizing a single dual variable on each iteration. We use a variant of Chang and Yih (2013) for the L_1 loss margin objective.

Online Primal Subgradient (Ratliff et al., 2007) Computes the subgradient of the margin objective on each instance by performing a loss-augmented decode, then uses these instance-wise subgradients to optimize the global objective using AdaGrad (Duchi et al., 2011) with either L_1 or L_2 regularization. The simplest implementation of AdaGrad touches every weight when doing the update for a batch. To save time, we distinguish between two different types of update. When the subgradient is nonzero, we apply the usual update. When the subgradient is zero, we apply a numerically equivalent update later, at the next time the weight is queried. This saves time, as we only touch the weights corresponding to the (usually sparse) nonzero directions in the current batch's subgradient. Algorithm 1 gives pseudocode for our implementation, which was based on Dyer (2013).

2.2 Likelihood

Stochastic Gradient Descent The built-in training method for many of the systems was softmax-margin likelihood optimization (Gimpel and Smith, 2010) via subgradient descent with either AdaGrad or AdaDelta (Duchi et al., 2011; Zeiler, 2012). We include results with each system's default settings as a point of comparison.

2.3 Mistake Driven

Averaged Perceptron (Freund and Schapire, 1999; Collins, 2002) On a mistake, weights for features on the system output are decremented and weights for features on the gold output are incre-

mented. Weights are averaged over the course of training, and decoding is not loss-augmented.

Margin Infused Relaxed Algorithm (Crammer and Singer, 2003) A modified form of the perceptron that uses loss-augmented decoding and makes the smallest update necessary to give a margin at least as large as the loss of each solution. MIRA is generally presented as being related to the perceptron because it does not explicitly optimize a global objective, but it also has connections to margin methods, as explored by Chiang (2012). We consider one-best decoding, where the quadratic program for determining the magnitude of the update has a closed form.

3 Tasks and Systems

We considered tasks covering a range of structured output spaces, from sequences to non-projective trees. Most of the corresponding systems use models designed for likelihood-based structured prediction. Some use sparse indicator features, while others use dense continuous-valued features.

Named Entity Recognition This task provides a case of sequence prediction. We used the NER component of Durrett and Klein (2014)'s entity stack, training it independently of the other components. We define the loss as the number of incorrectly labelled words, and train on the CoNLL 2012 division of OntoNotes (Pradhan et al., 2007).

Coreference Resolution This gives an example of training when there are multiple gold outputs for each instance. The system we consider uses latent links between mentions in the same cluster, marginalizing over the possibilities during learning (Durrett and Klein, 2013). Since the model decomposes across mentions, we train by treating them as independent predictions with multiple gold outputs, comparing the inferred link with the gold link that is scored highest under the current model. We use the system's weighted loss function, and the same data as for NER.

Constituency Parsing We considered two different systems. The first uses only sparse indicator features (Hall et al., 2014), while the second is parameterized via a neural network and adds dense features derived from word vectors (Durrett and Klein, 2015).[2] We define the loss as the number of incorrect rule productions, and use the standard Penn Treebank division (Marcus et al., 1993).

Dependency Parsing We used the first-order MST parser in two modes, Eisner's algorithm for projective trees (Eisner, 1996; McDonald et al., 2005b), and the Chu-Liu-Edmonds algorithm for non-projective trees (Chu and Liu, 1965; Edmonds, 1967; McDonald et al., 2005a). The loss function was the number of arcs with an incorrect parent or label, and we used the standard division of the English Universal Dependencies (Agić et al., 2015). The built-in training method for MST parser is averaged, 1-best MIRA, which we include for comparison purposes.

Summarization With this task, we explore a case in which there is relatively little training data and the model uses a small number of dense features. The system uses a linear model with features considering counts of bigrams in the input document collection. The system forms the output summary by selecting a subset of the sentences in the input collection that does not exceed a fixed word-length limit (Berg-Kirkpatrick et al., 2011). Inference involves solving an integer linear program, the loss function is bigram recall, and the data is from the TAC shared tasks (Dang and Owczarzak, 2008; Dang and Owczarzak, 2009).

3.1 Tuning

For each method we tuned hyperparameters by considering a grid of values and measuring dev set performance over five training iterations, except for constituency parsing, where we took five measurements, 4k instances apart. For the cutting plane methods we cached constraints in memory to save time, but the memory cost was too great to run batch cutting plane on constituency parsing (over 60 Gb), and so is not included in the results.

4 Observations

From the results in Figure 1 and during tuning, we can make several observations about these optimization methods' performance on these tasks.

Observation 1: Margin methods generally perform best As expected given prior work, margin methods equal or surpass the performance of likelihood and perceptron methods across almost all of these tasks. Coreference resolution is an exception, but that model has latent variables that likelihood may treat more effectively,

[2] Our results are slightly lower as we save time by only using the dense features and a reduced n-gram context.

Summarization

Margin	Cutting Plane
	Online Cutting Plane
	Online Primal Subgradient & L_1
	Online Primal Subgradient & L_2
Mistake Driven	Averaged Perceptron
	MIRA
	Averaged MIRA (MST built-in)
Llhood	Stochastic Gradient Descent

Figure 1: Variation in dev set performance (y) across training iterations (x). To show all variation, the scale of the y-axis changes partway, as indicated. Lines that stop early had converged.

	Time per iteration relative to averaged perceptron						
Method	NER	Coref	Span Parser	Neural Parser	MST Proj.	MST Non-Proj.	Summ.
AP	1.0	1.0	1.0	-	1.0	1.0	1.0
MIRA	1.9	1.0	1.0	1.0	1.0	1.0	1.0
CP	60.8	2.7	-	-	6.8	8.4	0.6
OCP	2.7	1.7	0.9	0.9	1.5	1.6	1.1
OPS	3.9	1.3	1.1	1.0	1.8	2.0	0.9
Decoding	0.6	0.2	0.9	0.7	0.7	0.6	0.7

Table 1: Comparison of time per iteration relative to the perceptron (or MIRA for the Neural Parser). Decoding shows the time spent on inference. Times were averaged across the entire run. OPS uses batch size 10 for NER to save time, but performs just as well as with batch size 1 in Figure 1.

and has a weighted loss function tuned for likelihood (softmax-margin).

Observation 2: Dual cutting plane methods appear to learn more slowly Both cutting plane methods took more iterations to reach peak performance than the other methods. In addition, for batch cutting plane, accuracy varied so drastically that we extended tuning to ten iterations, and even then choosing the best parameters was sometimes difficult. Table 1 shows that the online cutting plane method did take slightly less time per iteration than OPS, but not enough to compensate for the slower learning rate.

Observation 3: Learning with real-valued features is difficult for perceptron methods Learning models for tasks such as NER, which are driven by sparse indicator features, often roughly amounts to tallying the features that are contrastively present in correct hypotheses. In such cases, most learning methods work fairly well. However, when models use real-valued features, learning may involve determining a more delicate balance between features. In the models we consider that have real-valued features, summarization and parsing with a neural model, we can see that perceptron methods indeed have difficulty.[3]

Observation 4: Online Primal Subgradient is robust and effective All of the margin based methods, and gradient descent on likelihood, require tuning of a regularization constant and a step size (or convergence requirements for SMO). The dual methods were particularly sensitive to these hyperparameters, performing poorly if they were not chosen carefully. In contrast, performance for the primal methods remained high over a broad range of values.

Our implementation of sparse updates for AdaGrad was crucial for high-speed performance, decreasing time by an order of magnitude on tasks with many sparse features, such as NER and dependency parsing.

Observation 5: Other minor properties We found that varying the batch size did not substantially impact performance after a given number of decodes, but did enable a speed improvement as decoding of multiple instances can occur in parallel. Increasing batch sizes leads to a further improvement to OPS, as overall there are fewer updates per iteration. For some tasks, re-tuning the step size was necessary when changing batch size.

5 Conclusion

The effectiveness of max-margin optimization methods is widely known, but the default choice of learning algorithm in NLP is often a form of the perceptron (or likelihood) instead. Our results illustrate some of the pitfalls of perceptron methods and suggest that online optimization of the max-margin objective via primal subgradients is a simple, well-behaved alternative.

6 Acknowledgments

We would like to thank Greg Durrett for assistance running his code, Adam Pauls for advice on dual methods, and the anonymous reviewers for their helpful suggestions. This work was supported by National Science Foundation grant CNS-1237265, Office of Naval Research MURI grant N000140911081, and a General Sir John Monash Fellowship to the first author. Opinions, findings, conclusions and recommendations expressed in this material are those of the authors and do not necessarily reflect the views of sponsors.

[3]For the neural parser, the perceptron took a gradient step for each mistake, but this had dismal performance.

Learning Better Embeddings for Rare Words Using Distributional Representations

Irina Sergienya and **Hinrich Schütze**

University of Munich, Germany
sergienya@cis.lmu.de

Abstract

There are two main types of word representations: low-dimensional embeddings and high-dimensional distributional vectors, in which each dimension corresponds to a context word. In this paper, we initialize an embedding-learning model with distributional vectors. Evaluation on word similarity shows that this initialization significantly increases the quality of embeddings for rare words.

1 Introduction

Standard neural network (NN) architectures for inducing embeddings have an input layer that represents each word as a *one-hot vector* (e.g., Turian et al. (2010), Collobert et al. (2011), Mikolov et al. (2013)). There is no usable information available in this input-layer representation except for the identity of the word. We call this standard initialization method *one-hot initialization*.

Distributional representations (e.g., Schütze (1992), Lund and Burgess (1996), Sahlgren (2008), Turney and Pantel (2010), Baroni and Lenci (2010)) represent a word as a high-dimensional vector in which each dimension corresponds to a context word. They have been successfully used for a wide variety of tasks in natural language processing such as phrase similarity (Mitchell and Lapata, 2010) and sentiment analysis (Turney and Littman, 2003).

In this paper, we investigate *distributional initialization*: the use of distributional vectors as representations of words at the input layer of NN architectures for embedding learning to improve the embeddings of rare words. It is difficult for one-hot initialization to learn good embeddings from only a few examples. In contrast, distributional initialization provides an additional source of information – the global distribution of the word in the corpus – that improves embeddings learned for rare words. We will demonstrate this type of improvement in the experiments reported below.

In summary, we introduce the idea of distributional initialization for embedding learning, an alternative to one-hot initialization that combines distributed representations (or embeddings) with distributional representations (or high-dimensional vectors). We show that distributional initialization significantly improves the quality of embeddings learned for rare words.

We will first describe our methods in Section 2 and the experimental setup in Section 3. Section 4 presents and discusses experimental results. We summarize related work in Section 5 and finish with conclusion in Section 6 and discussion of future work in Section 7.

2 Method

Weighting. We use two different weighting schemes for distributional vectors. Let $v_1, \ldots, v_n$ be the vocabulary of context words. In BINARY weighting, entry $1 \leq i \leq n$ in the distributional vector of target word w is set to 1 iff v_i and w cooccur at a distance of at most ten words in the corpus and to 0 otherwise.

In PPMI weighting, entry $1 \leq i \leq n$ in the distributional vector of target word w is set to the PPMI (positive pointwise mutual information, introduced by Niwa and Nitta (1994)) of w and v_i. We divide PPMI values by their maximum to ensure they are in $[0, 1]$ because we will combine one-hot vectors (whose values are 0/1) with PPMI weights and it is important that they are on the same scale.

We use two different **distributional initializations**, shown in Figure 1: *separate* (left) and *mixed* (right). Combinations of these two initializations with both BINARY and PPMI weighting will be investigated in the experiments.

Recall that n is the dimensionality of the distri-

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 280–285,
Lisbon, Portugal, 17-21 September 2015.

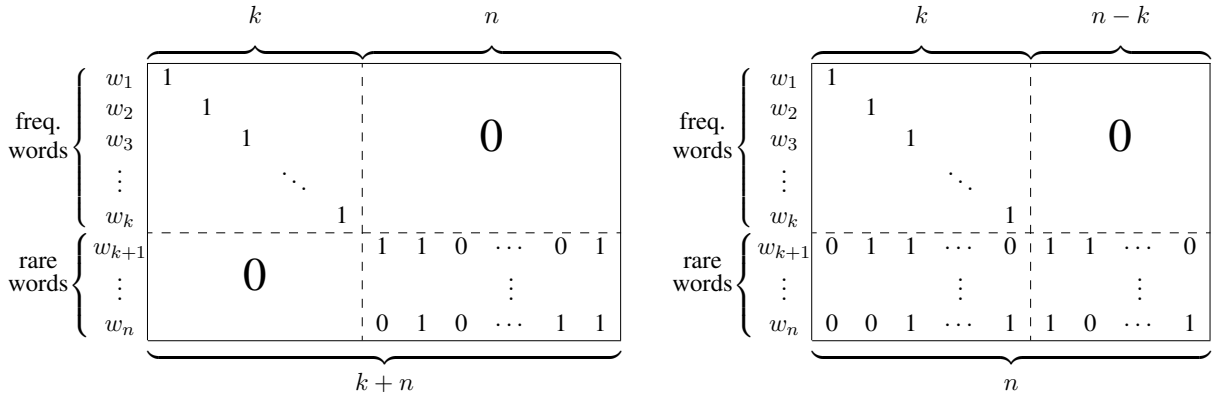

Figure 1: One-hot vectors of frequent words and distributional vectors of rare words are separate in *separate initialization* (left) and overlap in *mixed initialization* (right). This example is for BINARY weighting.

butional vectors. Let k be the number of words with frequency $> \theta$, where the frequency threshold θ is a parameter.

In *separate* initialization, the input representation for a word is the concatenation of a k-dimensional vector and an n-dimensional vector. For a word with frequency $> \theta$, the k-dimensional vector is a one-hot vector and the n-dimensional vector is zero. For a word with frequency $\leq \theta$, the k-dimensional vector is zero and the n-dimensional vector is its distributional vector.

In *mixed* initialization, the input representation for a word is an n-dimensional vector: a one-hot vector for a word with frequency $> \theta$ and a distributional vector for a word with frequency $\leq \theta$.

In summary, separate initialization uses separate representation spaces for frequent words (one-hot space) and rare words (distributional space). Mixed initialization uses the same representation space for all words; and rare words share weights with the frequent words that they cooccur with.

3 Experimental setup

We use ukWaC+WaCkypedia (Baroni et al., 2009), a corpus of 2.4 billion tokens and 6 million word types. Based on (Turian et al., 2010), we preprocess the corpus by removing sentences that are less than 90% lowercase; lowercasing; replacing URLs, email addresses and digits by special tokens; tokenization (Schmid, 2000); replacing words with frequency 1 with <unk>; and adding end-of-sentence tokens. After preprocessing, the size n of the context word vocabulary is 2.7 million.

We evaluate on six word similarity judgment data sets (number of pairs in parentheses): **RG** (Rubenstein and Goodenough (1965), 65) **MC** (Miller and Charles (1991), 30), **MEN**[1] (Bruni et al. (2012), 3000), **W**ord**S**im353[2] (Finkelstein et al. (2001), 353), Stanford **R**are **W**ord[3] (Luong et al. (2013), 2034) and **S**im**L**ex-999[4] (Hill et al. (2014), 999). We exclude from the evaluation the 16 pairs in RW that contain a word that does not occur in our corpus.

Our goal in this paper is to investigate the effect of using distributional initialization vs. one-hot initialization on the quality of embeddings of rare words.

However, except for RW, the six data sets contain only a single word with frequency $\leq$100, all other words are more frequent.

To address this issue, we artificially make all words in the six data sets rare. We do this by keeping only θ randomly chosen occurrences in the corpus (for words with frequency $>\theta$) and replacing all other occurrences with a different token (e.g., "fire" is replaced with "*fire*"). This procedure – *corpus downsampling* – ensures that all words in the six data sets are rare in the corpus and that our setup directly evaluates the impact of distributional initialization on rare words.

Note that we use θ for two different purposes: (i) θ is the frequency threshold that determines which words are classified as rare and which as frequent in Figure 1 – changing θ corresponds to moving the horizontal dashed line in separate and mixed initialization up and down; (ii) θ is the parameter that determines how many occurrences of a word are left in the corpus when we remove oc-

currences to ensure that words from the evaluation data sets are rare in the corpus.

We covary these two parameters in the experiments below; e.g., we apply distributional initialization with $\theta = 20$ to a corpus constructed to have $\theta = 20$ occurrences of words from similarity data sets. We do this to ensure that all evaluation words are rare words for the purpose of distributional initialization and so we can exploit all pairs in the evaluation data sets for evaluating the efficacy of our method for rare words.

We modified word2vec[5] (Mikolov et al., 2013) to accommodate distributional initialization; to support distributional vectors at the input layer, we changed the implementation of activation functions and backpropagation. We use the skipgram model, hierarchical softmax, set the size of the context window to 10 (10 words to the left and 10 to the right), min-count to 1 (train on all tokens), embedding size to 100, sampling rate to 10^{-3} and train models for one epoch.

For four values of the frequency threshold, $\theta \in \{10, 20, 50, 100\}$,[6] we train word2vec models with one-hot initialization and with the four combinations of weighting (BINARY, PPMI) and distributional initialization (mixed, separate), a total of $4 \times (1 + 2 \times 2) = 20$ models. For each training run, we perform corpus downsampling and initialize the parameters of the models randomly. To get a reliable assessment of performance, we train 5 instances of each model and report averages of the 5 runs. One model takes $\sim$3 hours to train on 23 CPU cores, 2.30GHz.

4 Experimental results and discussion

Table 1 shows experimental results, averaged over 5 runs. The evaluation measure is Spearman correlation $\times 100$ between human and machine-generated pair similarity judgments.

Frequency threshold θ. The main result is that for $\theta \in \{10, 20\}$ *distributional initialization is better than one-hot initialization* (see bold numbers): compare lines 1&5 with line 9; and lines 2&6 with line 10. This is true for both mixed and separate initialization, with the exception of WS, for which mixed (column G) is better in only 1 (line 5) of 4 cases.

Looking only at results for $\theta \in \{10, 20\}$, 18 of 24 improvements are significant[7] for mixed initialization and 16 of 24 improvements are significant for separate initialization (lines 1&5 vs 9 and lines

[5] code.google.com/p/word2vec

[6] A reviewer asks whether the value of θ should depend on the size of the training corpus. Our intuition is that it is independent of corpus size. If a certain amount of information – corresponding to a certain number of contexts – is required to learn a meaningful representation of a word, then it should not matter whether that given number of contexts occurs in a small corpus or in a large corpus. However, if the contexts themselves contain many rare words (which is more likely in a small corpus), then corpus size could be an important variable to take into account.

[7] Two-sample t-test, two-tailed, assuming equal variance, $p < .05$

2&6 vs 10).

For $\theta \in \{50, 100\}$, mixed initialization does well for RG, MC and SL, but the gap between mixed and one-hot initializations is generally smaller for these larger values of θ; e.g., the difference is larger than 9 for $\theta = 10$ (A1&A5 vs A/B9, C1&C5 vs C/D9, K1&K5 vs K/L9) and less than 9 for $\theta = 100$ (A4&A8 vs A/B12, C4&C8 vs C/D12, K4&K8 vs K/L12) for these three data sets.

Recall that each value of θ effectively results in a different training corpus – a training corpus in which the number of occurrences of the words in the evaluation data sets has been reduced to $\leq \theta$ (cf. Section 3).

Our results indicate that distributional initialization is beneficial for very rare words – those that occur no more than 20 times in the corpus. Our results for medium rare words – those that occur between 50 and 100 times – are less clear: either there are no improvements or improvements are small.

Thus, our recommendation is to use $\theta = 20$.

Scalability. The time complexity of the basic version of word2vec is $O(ECWD \log V)$ (Mikolov et al., 2013) where E is the number of epochs, C is the corpus size, W is the context window size, D is the number of dimensions of the embedding space, and V is the vocabulary size. Distributional initialization adds a term I, the average number of entries in the distributional vectors, so that time complexity increases to $O(IECWD \log V)$. For rare words, I is small, so that there is no big difference in efficiency between one-hot initialization and distributional initialization of word2vec. However, for frequent words I would be large, so that distributional initialization may not be scalable in that case. So even if our experiments had shown that distributional initialization helps for both rare and frequent words, scalability would be an argument for only using it for rare words.

Binary vs. PPMI. PPMI weighting is almost always better than BINARY, with three exceptions (I8, L7, L8) where the difference between the two is small and not significant. The probable explanation is that the PPMI weights in $[0, 1]$ convey detailed, graded information about the strength of association between two words, taking into account their base frequencies. In contrast, the BINARY weights in $\{0, 1\}$ only indicate if there was any instance of cooccurrence at all – without considering frequency of cooccurrence and without normalizing for base frequencies.

Mixed vs. Separate. Mixed initialization is less variable and more predictable than separate initialization: performance for mixed initialization always goes up as θ increases, e.g., 56.54 $\rightarrow$ 59.08 $\rightarrow$ 63.20 $\rightarrow$ 68.33 (column A, lines 1–4). In contrast, separate initialization performance often decreases, e.g., from 47.06 to 45.31 (column B, lines 1–2) when θ is increased. Since more information (more occurrences of the words that similarity judgments are computed for) should generally not have a negative effect on performance, the only explanation is that separate is more variable than mixed and that this variability sometimes results in decreased performance. Figure 1 explains this difference between the two initializations: in mixed initialization (right panel), rare words are tied to frequent words, so their representations are smoothed by representations learned for frequent words. In separate initialization (left panel), no such links to frequent words exist, resulting in higher variability.

Because of its lower variability, our experiments suggest that mixed initialiation is a better choice than separate initialization.

One-hot vs. Distributional initialization. Our experiments show that distributional representation is helpful for rare words. It is difficult for one-hot initialization to learn good embeddings for such words, based on only a small number of contexts in the corpus. In such cases, distributional initialization makes the learning task easier since in addition to the *contexts of the rare word*, the learner now also has access to the *global distribution of the rare word* and can take advantage of weight sharing with other words that have similar distributional representations to smooth embeddings systematically.

Thus, distributional initialization is a form of smoothing: the embedding of a rare word is tied to the embeddings of other words via the links shown in Figure 1: the 1s in the lower "rare words" part of the illustrations for separate and mixed initialization. As is true for smoothing in general, parameter estimates for frequent events benefit less from smoothing or can even deteriorate. In contrast, smoothing is essential for rare events. Where the boundary lies between rare and frequent events depends on the specifics of the problem and the

smoothing method used and is usually an empirical question. Our results indicate that that boundary lies somewhere between 20 and 50 in our setting.[8]

Variance of results. Table 1 shows averages of five runs. The variance of results was quite high for low-performing models. For higher performing models – those with values ≥ 40 – the ratio of standard deviation divided by mean ranged from .005 to .29. The median was .044. While the variance from run to run is quite high for low-performing models and for a few high-performing models, the significance test takes this into account, so that the relatively high variability does not undermine our results.

In summary, we have shown that distributional initialization improves the quality of word embeddings for rare words. Our recommendation is to use mixed initialization with PPMI weighting and the value $\theta = 20$ of the frequency threshold.

5 Related work

An alternative to using distributional information for initialization is to use syntactic and semantic information for initialization. Approaches along these lines include Botha and Blunsom (2014) who represent a word as a sum of embedding vectors of its morphemes. Cui et al. (2014) use a weighted average of vectors of morphologically similar words. Bian et al. (2014) extend a word's vector with vectors of entity categories and POS tags. This line of work also is partially motivated by improving the embeddings of rare words. Distributional information on the one hand and syntactic/semantic information on the other hand are likely to be complementary, so that a combination of our approach with this prior work is promising.

Le et al. (2010) propose three schemes to address word embedding initialization. *Reinitialization* and *iterative reinitialization* use vectors from prediction space to initialize the context space during training. This approach is both more complex and less efficient than ours. *One-vector initialization* initializes all word embeddings with the same random vector to keep rare words close to each other. This approach is also less efficient than ours since the initial embedding is much denser than in our approach.

6 Conclusion

We have introduced distributional initialization of neural network architectures for learning better embeddings for rare words. Experimental results on a word similarity judgment task demonstrate that embeddings of rare words learned with distributional initialization perform better than embeddings learned with traditional one-hot initialization.

7 Future work

Our work is the first exploration of the utility of distributional representations as initialization for embedding learning algorithms like word2vec. There are a number of research questions we would like to investigate in the future.

First, we showed that distributional representation is beneficial for words with very low frequency. It was not beneficial in our experiments for more frequent words. A more extensive analysis of the factors that are responsible for the positive effect of distributional representation is in order.

Second, to simplify our experimental setup and make the number of runs mangeable, we used the parameter θ both for corpus processing (only θ occurrences of a particular word were left in the corpus) and as the separator between rare words that are distributionally initialized and frequent words that are not. It remains to be investigated whether there are interactions between these two properties of our model, e.g., a high rare-frequent separator may work well for words whose corpus frequency is much smaller than the separator.

Third, while we have shown that distributional initialization improves the quality of representations of rare words, we did not investigate whether distributional initialization for rare words has any adverse effect on the quality of representations of frequent words for which one-hot initialization is applied. Since rare and frequent words are linked in the mixed model, this possibility cannot be dismissed and we plan to investigate it in future work.

Acknowledgments. This work was supported by Deutsche Forschungsgemeinschaft (grant DFG SCHU 2246/10-1, FADeBaC).

[8] A reviewer asks: "If a word is rare, its distributional vector should also be sparse and less informative, which does not guarantee to be a good starting point." This is true and it suggests that it may not be possible to learn a very high-quality representation for a rare word. But this it not our goal. Our goal is simply to learn a *better* representation than the one that is learned by standard word2vec. Our explanation for our positive experimental results is that distributional initialization implements a form of smoothing.

Abstract

Performing link prediction in Knowledge Bases (KBs) with embedding-based models, like with the model TransE (Bordes et al., 2013) which represents relationships as translations in the embedding space, have shown promising results in recent years. Most of these works are focused on modeling single relationships and hence do not take full advantage of the graph structure of KBs. In this paper, we propose an extension of TransE that learns to explicitly model composition of relationships via the addition of their corresponding translation vectors. We show empirically that this allows to improve performance for predicting single relationships as well as compositions of pairs of them.

1 Introduction

Performing link prediction on multi-relational data is becoming essential in order to complete the huge amount of missing information of the knowledge bases. These knowledge can be formalized as directed multi-relation graphs, whose node correspond to entities connected with edges encoding various kind of relationships. We denote these connections via triples *(head, label, tail)*. Link prediction consists in filling in incomplete triples like *(head, label, ?)* or *(?, label, tail)*.

In this context, embedding models (Wang et al., 2014; Lin et al., 2015; Jenatton et al., 2012; Socher et al., 2013) that attempt to learn low-dimensional vector or matrix representations of entities and relationships have shown promising performance in recent years. In particular, the basic model TRANSE (Bordes et al., 2013) has been proved to be very powerful. This model treats each relationship as a translation vector operating on the embedding representing the entities. Hence, for a triple *(head, label, tail)*, the vector embeddings of *head* and *tail* are learned so that they are connected through a translation parameterized by the vector associated with *label*. Many extensions have been proposed to improve the representation power of TRANSE while still keeping its simplicity, by adding some projections steps before the translation (Wang et al., 2014; Lin et al., 2015).

In this paper, we propose an extension of TRANSE [1] that focuses on improving its representation of the underlying graph of multi-relational data by trying to learn compositions of relationships as sequences of translations in the embedding space. The idea is to train the embeddings by learning simple reasonings, such as the relationship *people/nationality* should give a similar result as the composition *people/city_of_birth* and *city/country*. In our approach, called RTRANSE, the training set is augmented with relevant examples of such compositions by performing constrained walks in the knowledge graph, and training so that sequences of translations lead to the desired result. The idea of compositionality to model multi-relational data was previously introduced in (Neelakantan et al., 2015). That work composes relationships by means of recurrent neural networks (RNN) (one per relationship) with non-linearities. However, we show that there is a natural way to compose relationships by simply adding translation vectors and not requiring additional parameters, which makes it specially appealing because of its scalability.

We present experimental results that show the superiority of RTRANSE over TRANSE in terms of link prediction. A detailed evaluation, in which test examples are classified as *easy* or *hard* depending on their similarity with training data, highlights the improvement of RTRANSE on both categories. Our experiments include a new evaluation protocol, in which the model is directly

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 286–290,
Lisbon, Portugal, 17-21 September 2015.

asked to answer questions related to compositions of relations, such as *(head, label$_1$, label$_2$, ?)*. RTRANSE also achieves significantly better performances than TRANSE on this new dataset.

We describe RTRANSE in the next section, and present our experiments in Section 3.

2 Model

The model we propose is inspired by TRANSE (Bordes et al., 2013). In TRANSE, entities and relationships of a KB are mapped to low dimensional vectors, called embeddings. These embeddings are learnt so that for each fact (h, ℓ, t) in the KB, we have $h + \ell \approx t$ in the embedding space.

Using translations for relationships naturally leads to embed the composition of two relationships as the sum of their embeddings: on a path $(h, \ell, t), (t, \ell', t')$, we should have $h+\ell+\ell' \approx t'$ in the embedding space. The original TRANSE does not enforce that the embeddings accurately reproduce such compositions. The *recurrent* TRANSE we propose here has a modified training stage to include such compositions. This should allow to model simple reasonings in the KB, such as *people/nationality* is similar to the composition of *people/city_of_birth* and *city/country*.

2.1 Recurrent TransE

We describe in this section our model in its full generality, which allows to deal with compositions of an arbitrary number of relationships, even though in this first work we experimented only with compositions of two relationships.

Triples that are the result of a compositions are denoted by $(h, \{\ell_i\}_{i=1}^p, t)$, where p is the number of relationships that are composed to go from h to t. Such a path means that there exist entities $e_1, ..., e_{p+1}$, with $e_1 = h$ and $e_{p+1} = t$ such that for all k, (e_k, ℓ_k, e_{k+1}) is a fact in the KB. Our model, RTRANSE for *recurrent* TRANSE, represents each step $s_k(h, \{\ell_i\}_{i=1}^p, t)$ along the path in the KB with the recurrence relationship (boldface characters denote embedding vectors i.e. $\mathbf{h}$ is the embedding vector of the entity h):

$$\begin{aligned} \boldsymbol{s}_1(h, \{\ell_i\}_{i=1}^p, t) &= \boldsymbol{h} \\ \boldsymbol{s}_{k+1}(h, \{\ell_i\}_{i=1}^p, t) &= \boldsymbol{s}_k(h, \{\ell_i\}_{i=1}^p, t) + \boldsymbol{\ell}_k \,. \end{aligned}$$

Then, the energy of a triple is computed as

$$d(h, \{\ell_i\}_{i=1}^p, t) = ||\boldsymbol{s}_p(h, \{\ell_i\}_{i=1}^p, t) - \boldsymbol{t}||_2 \,.$$

2.2 Path construction and filtering

The experience of the paper is motivated by learning simple reasonings in the KB through the compositions of relationships. Therefore, we restricted our analysis to paths of length 2 created as follows.

First, for each fact (h, ℓ, t), retrieve all paths $(h, \{\ell_1, \ell_2\}, t)$ such that there is e such that both (h, ℓ_1, e) and (e, ℓ_2, t) are in the KB. Then, we filter out paths where $(h, \ell_1, e) = (h, \ell, t)$ or $(e, \ell_2, t) = (h, \ell, t)$, as well as the paths with $\ell_1 = \ell_2$ and $h = e = t$.

We focused on "unambiguous" paths, so that the reasoning might actually make sense. In particular, we considered only paths where ℓ_1 is either a 1-to-1 or a 1-to-many relationship, and where ℓ_2 is either a 1-to-1 or a many-to-1 relationship. In our experiments, the paths created for training only consider the training subset of facts.

In the remainder of the paper, such paths of length 2 are called *quadruples*.

2.3 Training and regularization

Our training objective is decomposed in two parts: the first one is the ranking criterion on triples of TRANSE, ignoring quadruples. Paths are then taken into account through additional regularization terms.

Denoting by $\mathcal{S}$ the set of facts in the KB, the first part of the training objective is the following ranking criterion that operates on triples

$$\sum_{\substack{(h,\ell,t)\in\mathcal{S} \\ (h',\ell,t')\in\mathcal{S}_{(h,\ell,t)}}} \left[\gamma + d(h,\ell,t) - d(h',\ell,t')\right]_+ ,$$

where $[x]_+ = \max(x, 0)$ is the positive part of x, γ is a margin hyperparameter and $\mathcal{S}_{(h,\ell,t)}$ is the set of corrupted triples created from (h, ℓ, t) by replacing either h or t with another KB entity.

This ranking loss effectively trains so that the embedding of the tail is the nearest neighbor of the translated head, but it does not guarantee that the distance between the tail and the translated head is small. The nearest neighbor criterion is sufficient to make inference over simple triples, but making sure that the distance is small is necessary for the composition rule to be accurate. In order to account for the compositionality of relationships, we add two additional regularization terms:

- $\lambda \sum_{(h,\ell,t)\in\mathcal{S}} d(h,\ell,t)^2$
- $\alpha \sum_{(h,\{\ell_1,\ell_2\},t)\in\mathcal{S}} N_{\ell\to\{\ell_1,\ell_2\}} d(h,\{\ell_1,\ell_2\},t)^2$.

DATA SET	FAMILY	FB15K

Table 1: Statistics of the datasets.

MODEL	TRANSE		RTRANSE	
	MR	H@10	MR	H@10
EASY	17.7	76.8	**12.5**	**82.2**
HARD	**191.0**	48.9	205.7	**51.0**
EASY W. COMP.	16.4	78.8	**11.6**	**83.0**
EASY W/O COMP.	21.6	71.3	**16.0**	**75.3**
HARD W. COMP.	**208.1**	46.8	212.2	**49.3**
HARD W/O COMP.	**122.9**	**57.0**	123.8	**57.5**
OVERALL	50.7	71.5	**49.5**	**76.2**

Table 2: **Detailed performances on FB15k** of TRANSE and RTRANSE. H@10 are in %. W. COMP. indicates examples for which there exist quadruplets in train matching their relationship.

The first criterion only applies to original facts of the KB, while the second term applies to quadruples. $N_{\ell \to \{\ell_1,\ell_2\}}$, which involves both the relationships of the quadruple and the relationship ℓ from which it was created, is the number of paths involving relationships $\{\ell_1, \ell_2\}$ created from a fact involving ℓ, normalized by the total number of quadruples created from facts involving ℓ. This criterion puts more weight on paths that are reliable as an alternative for a relationship, for instance {*people/city_of_birth*, *city/country*} is likely a better alternative to *people/nationality* than {*people/writer_of_the_film*, *film/film_release_region*}. Finally, a regularization term $\mu||\mathbf{e}||_2^2$ is added for each entity embedding $\mathbf{e}$.

3 Experiments

This section presents experiments on the benchmark FB15K introduced in (Bordes et al., 2013) and on FAMILY, a slightly extended version of the artificial database described in (García-Durán et al., 2014). Table 1 gives their statistics.

3.1 Experimental Protocol

Data FB15K is a subset of Freebase, a very large database of generic facts gathering more than 1.2 billion triples and 80 million entities. Inspired by (Hinton, 1986), FAMILY is a database that contains triples expressing family relationships (cousin_of, has_ancestor, married_to, parent_of, related_to, sibling_of, uncle_of) among the members of 5 families along 6 generations. This dataset is artificial and each family is organized in a layered tree structure where each layer refers to a generation. Families are connected among them by marriage links between two members, randomly sampled from the same layer of different families. Interestingly on this dataset, there are obvious compositional relationships like *uncle_of* $\approx$ *sibling_of* + *parent_of* or *parent_of* $\approx$ *married_to* + *parent_of*, among others.

Setting Our main comparison is TRANSE so we followed the same experimental setting as in (Bordes et al., 2013), using ranking metrics for evaluation. For each test triple we replaced the head by each of the entities in turn, and then computed the score of each of these candidates and sorted them. Since other positive candidates (i.e. entities forming true triples) can be ranked higher than the target one, we filtered out all the positive candidates existing in either the training, validation and test set, except the target one, from the ranking and then we kept the rank of the target entity. The same procedure is repeated but removing the tail instead of the head. The filtered mean rank (mean rank in the rest) is the average of these ranks, and the filtered Hits@10 (H@10 in the rest) is the proportion of target entities in the top 10 predictions.

The embedding dimensions were set to 20 for FAMILY and 100 for FB15K. Training was performed by stochastic gradient descent, stopping after for 500 epochs. On FB15K, we used the embeddings of TRANSE to initialize RTRANSE, and we set a learning rate of 0.001 to fine-tune RTRANSE. On FAMILY, both algorithms were initialized randomly and used a learning rate of 0.01. The mean rank was used as a validation criterion, and the values of γ, λ, α and μ were chosen respectively among $\{0.25, 0.5, 1\}$, $\{1e^{-4}, 1e^{-5}, 0\}$, $\{0.1, 0.05, 0.1, 0.01, 0.005\}$ and $\{1e^{-4}, 1e^{-5}, 0\}$.

3.2 Results

Overall performances Experiments on FAMILY show a quantitative improvement of the performance of RTRANSE : where TRANSE gets a mean rank of 6.7 and a H@5 of 68.7, RTRANSE get a performance of 6.3 and 72.3 respectively.

Similarly, on FB15K, Table 2 (last row) shows that training on longer paths (length 2 here) actually consistently improves the performance while predicting heads and tails of triples only: the overall H@10 improves by almost 5% from 71.5 for

The correct answer is in **bold**.

TRANSE to 76.2 for RTRANSE.

Detailed results In order to better understand the gains of RTRANSE, we performed a detailed evaluation on FB15K, by classifying the test triples along two axes: *easy* vs *hard* and *with composition* vs *without composition*. A test triple (h, ℓ, t) is *easy* if its head and tail are connected by a triple in the training set, i.e. if either (h, ℓ', t) or (t, ℓ', h) is seen in train for some relationship ℓ'. Otherwise, the triple is *hard*. Orthogonally, the test triple (h, ℓ, t) is *with composition* if there is at least one path $\{\ell_1, \ell_2\}$ for the relationship ℓ, regardless of the existence of that specific path between the entities h and t. If no such path exists, (h, ℓ, t) is *without composition*.

The detailed results are shown in Table 2. We can see that comparatively to TRANSE, RTANSE particularly improves performances in terms of H@10 on triples *with composition*, improving on *easy* triples by 4.2% (from 78.8% to 83,0%) and *hard* triples by 2.5% (from 46.8% to 49.3%). The main gains are still on *easy* triples, and in fact the H@10 on *easy* triples *without composition* increases by 4%, from 71.3% to 75.3%. The mean rank also considerably improves on *easy triples*, and stays somehow still on *hard* ones. All in all, the results show that considering paths during training very significantly improves performances, and the results on triples *with composition* suggest that RTRANSE is indeed capable of capturing the evidence of links that exist in longer paths.

3.3 Results on quadruples

While usual evaluations for link prediction in KBs focus on predicting a missing element of a test triple, we propose here to extend the evaluation to answering more complex questions, such as $(h, \{\ell_1, \ell_2\}, ?)$ or $(?, \{\ell_1, \ell_2\}, t)$.

Examples Table 3 presents examples of predictions of both TRANSE and our model RTRANSE on such quadruples. The two first examples try to predict the origin of two TV series from the nationality of the actors that regularly appear in them (regular_tv_appearance). In the first one, the american actor phil_lamarr is the only entity connected to the american TV show madtv through the relationship regular_tv_appearance. RTRANSE is able to correctly infer the country of origin from this information since it forces country_of_origin $\approx$ regular_tv_appearance + nationality. On the other side TRANSE is affected by the cascading error since the ranking loss does not guarantee that the distance between $h + l_1$ and phil_lamarr is small, so when summing l_2 it eventually ends up closer to Ireland rather than USA. In contrast, the second

example shows that answering that question by using that path is sometimes difficult: the members of the cast of that TV show have different nationalities, so RTRANSE lists the nationalities of these ones and the correct one is ranked third. TRANSE is again more affected than RTRANSE by the cascading error. In the third one, RTRANSE deducts the main region where malay is spoken from the continent of the country with the most number of speakers of that language. In the last two examples, our model infers the location of those universities by forcing an equivalence between their location and the location of their respective campus.

Prediction performance For a more quantitative analysis, we have generated a new test dataset of link prediction on quadruples on FB15K. This test set was created by generating the paths from the usual test set (the triple test set) and removing those quadruples that are used for training. We obtain 1,852 quadruples. The overall experimental protocol is the same as before, trying to predict the head or tail of these quadruple in turn.

On that evaluation protocol, RTRANSE has a mean rank of 114.0 and a H@10 of 68.2%, while TRANSE obtains a mean rank of 159.9 and a H@10 of 65.2% (using the same models as in the previous subsection). We can see that learning on paths improves performances on both metrics, with a gain of 3% in terms of H@10 and an important gain of about 46 in mean rank, which corresponds to a relative improvement of about 30%.

4 Conclusion

We have proposed to learn embeddings of compositions of relationships in the translation model for link prediction in KBs. Our experimental results show that this approach is promising.

We considered in this work a restricted set of small paths of length two. We leave the study of more general paths to future work.

Noise or additional information? Leveraging crowdsource annotation item agreement for natural language tasks.

Abstract

In order to reduce noise in training data, most natural language crowdsourcing annotation tasks gather redundant labels and aggregate them into an integrated label, which is provided to the classifier. However, aggregation discards potentially useful information from linguistically ambiguous instances.

For five natural language tasks, we pass item agreement on to the task classifier via soft labeling and low-agreement filtering of the training dataset. We find a statistically significant benefit from low item agreement training filtering in four of our five tasks, and no systematic benefit from soft labeling.

1 Introduction

Crowdsourcing is a cheap and increasingly-utilized source of annotation labels. In a typical annotation task, five or ten labels are collected for an instance, and are aggregated together into an *integrated label*. The high number of labels is used to compensate for worker bias, task misunderstanding, lack of interest, incompetance, and malicious intent (Wauthier and Jordan, 2011).

Majority voting for label aggregation has been found effective in filtering noisy labels (Nowak and Rüger, 2010). Labels can be aggregated under weighted conditions reflecting the reliability of the annotator (Whitehill et al., 2009; Welinder et al., 2010). Certain classifiers are also robust to random (unbiased) label noise (Tibshirani and Manning, 2014; Beigman and Beigman Klebanov, 2009). However, minority label information is discarded by aggregation, and when the labels were gathered under controlled circumstances, these labels may reflect linguistic intuition and contain useful information (Plank et al., 2014b). Two alternative strategies that allow the classifier to learn from the item agreement include training instance *filtering* and *soft labeling*. Filtering training instances by item agreement removes low agreement instances from the training set. Soft labeling assigns a classifier weight to a training instance based on the item agreement.

Consider two Affect Recognition instances and their Krippendorff (1970)'s α *item agreement* :

Text: *India's Taj Mahal gets facelift*
Sadness Rating (0-100): 8.0
α **Agreement (-1.0 – 1.0):** 0.7

Figure 1: Affect Recognition Easy Case.

Text: *After Iraq trip, Clinton proposes war limits*
Sadness Rating (0-100): 12.5
α **Agreement (-1.0 – 1.0):** -0.1

Figure 2: Affect Recognition Hard Case.

In Figure 1, annotators mostly agreed that the headline expresses little sadness. But in Figure 2, the low item agreement may be caused by instance difficulty (i.e., *Is a war zone* sad *or just bad?*): a *Hard Case* (Zeman, 2010). Previous work (Beigman Klebanov and Beigman, 2014; Beigman and Beigman Klebanov, 2009) has shown that training strategy may affect Hard and Easy Case test instances differently.

In this work, for five natural language tasks, we examine the impact of passing crowdsource item agreement on to the task classifier, by means of training instance *filtering* and *soft labeling*. We construct classifiers for Biased Text Detection, Stemming Classification, Recognizing Textual Entailment, Twitter POS Tagging, and Affect Recognition, and evaluate the effect of our different training strategies on the accuracy of each

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 291–297,
Lisbon, Portugal, 17-21 September 2015.

task. These tasks represent a wide range of machine learning tasks typical in NLP: sentence-level SVM regression using n-grams; word pairs with character-based features and binary SVM classification; pairwise sentence binary SVM classification with similarity score features; CRF sequence word classification with a range of feature types; and sentence-level regression using a token-weight averaging, respectively. We use pre-existing, freely-available crowdsourced datasets and post all our experiment code on GitHub[1].

Contributions This is the first work (1) to apply item-agreement-weighted soft labeling from crowdsourced labels to multiple real natural language tasks; (2) to filter training instances by item agreement from crowdsourced labels, for multiple natural language tasks; (3) to evaluate classifier performance on high item agreement (*Easy Case*) instances and low item agreement (*Hard Case*) instances across multiple natural language tasks.

2 Related Work

Dekel and Shamir (2009) calculated integrated labels for an information retrieval crowdsourced dataset, and identified low-quality workers by deviation from the integrated label. Removal of these workers' labels improved classifier performance on data that was not similarly filtered. While much work (Dawid and Skene, 1979; Ipeirotis et al., 2010; Dalvi et al., 2013) has explored techniques to model worker ability, bias, and instance difficulty while aggregating labels, there is no evaluation comparing classifiers trained on the new integrated labels with other options, on their respective NLP tasks.

Training instance filtering aims to remove mislabeled instances from the training dataset. Sculley and Cormack (2008) learned a logistic regression classifier to identify and filter noisy labels in a spam email filtering task. They also proposed a label correcting technique that replaces identified noisy labels with "corrected" labels, at the risk of introducing noise into the corpus. Rebbapragada et al. (2009) developed a label noise detection technique to cluster training instances and remove label outliers. Raykar et al. (2010) jointly learned a classifier/regressor, annotator accuracy, and the integrated label on datasets with multiple noisy labels, outperforming Smyth et al. (1995)'s model of estimating ground truth labels.

Soft labeling, or the association of one training instance with multiple, weighted, conflicting labels, is a technique to model noisy training data. Thiel (2008) found that soft labeled training data produced more accurate classifiers than hard labeled training data, with both Radial Basis Function Networks and Fuzzy-Input Fuzzy-Output SVMs. Shen and Lapata (2007) used soft labeling to model their semantic frame structures in a question answering task, to represent that the semantic frames can bear multiple sematic roles.

Previous research has found that, for a few individual NLP tasks, training while incorporating label noise weight may produce a better model. Martínez Alonso et al. (2015) show that informing a parser of annotator disagreement via loss function reduced error in labeled attachments by 6.4%. Plank et al. (2014a) incorporate annotator disagreement in POS tags into the loss function of a POS-tag machine learner, resulting in improved performance on downstream chunking. Beigman Klebanov and Beigman (2014) observed that, on a task classifying text as semantically *old* or *new*, the inclusion of Hard Cases in training data resulted in reduced classifier performance on Easy Cases.

3 Overview of Experiments

We built systems for the five NLP tasks, and trained them using aggregation, soft labeling, and instance screening strategies. When labels were numeric, the integrated label was the average[2]. When labels were nominal, the integrated label was majority vote. Krippendorff (1970)'s α item agreement was used to filter ambiguous training instances. For soft labeling, percentage item agreement was used to assign instance weights. We followed Sheng et al. (2008)'s suggested *Multiplied Examples* procedure: for each unlabeled instance x_i and each existing label $y_i \in L_i = \{y_{ij}\}$ (as annotated by worker j), we create one replica of x_i, assign it y_i, and weight the instance according to the count of y_i in L_i (i.e., the percentage item agrement). For each training strategy (*Soft-Label*, etc), the *training* instances were changed by the strategy, but the *test* instances were unaffected. For the division of test instances into Hard

[1] github.com/EmilyKJamison/crowdsourcing

[2] We followed Yano et al. (2010) and Strapparava and Mihalcea (2007) in using *mean* as gold standard. Although another aggregation such as as *median* might be more representative, such discussion is beyond the scope of this paper.

and Easy Cases, the training instances were unaffected, but the test instances were filtered by α item agreement. Hard/Easy Case parameters were chosen to divide the corpus by item agreement into roughly equal portions[3], relative to the corpus, for post-hoc error analysis.

All systems except Affect Recognition were constructed using DKPro Text Classification (Daxenberger et al., 2014), and used Weka's *SMO* (Platt, 1999) or *SMOreg* (Shevade et al., 2000) implementations with default parameters, with 10-fold (or 5-fold, for computationally-intensive POS Tagging) cross-validation. More details are available in the Supplemental Notes document.

Agreement Parameters Training strategies *HighAgree* and *VeryHigh* utilize agreement cutoff parameters that vary per corpus. These strategies are a discretized approximation of the gradual effect of filtering low agreement instances from the training data. For any given corpus, we could not use a cutoff value equal to no filtering, or that eliminated a class. If there were only 2 remaining cutoffs, we used these. If there were more candidate cutoff values, we trained and evaluated a classifier on a development set and chose the value for *HighAgree* that maximized Hard Case performance on the development set.

Percentage Agreement In this paper, we follow Beigman Klebanov and Beigman (2014) in using the nominal agreement categories *Hard Cases* and *Easy Cases* to separate instances by item agreement. However, unlike Beigman Klebanov and Beigman (2014) who use simple *percentage agreement*, we calculate item-specific agreement via Krippendorff (1970)'s α item agreement[4], with Nominal, Ordinal, or Ratio distance metrics as appropriate. The agreement is expressed in the range (-1.0 – 1.0); 1.0 is perfect agreement.

3.1 Biased Language Detection

This task detects the use of bias in political text. The corpus (Yano et al., 2010)[5] consists of 1,041 sentences from American political blogs. For each sentence, five crowdsource annotators chose a label *no bias*, *some bias*, and *very biased*. We follow Yano et al. (2010) in representing the amount of bias on a numerical scale (1-3). Hard/Easy Case cutoffs were <-.21 and >.20. Of 1041 total instances, 161 were Hard Cases (<-.21) and 499 were Easy Cases (>.20).

We built an SVM regression task using unigrams, to predict the numerical amount of bias. The gold standard was the integrated labels. Item-specific agreement was calculated with Ordinal Distance Function (Krippendorff, 1980).

We used the following training strategies:
VeryHigh Filtered for agreement >0.4.
HighAgree Filtered for agreement >-0.2.
SoftLabel One training instance is generated for each label from a text, and weighted by how many times that label occurred with the text.
SLLimited SoftLabel, except that training instances with a label distance >1.0 from the original text label average are discarded.

3.2 Morphological Stemming

The goal of this binary classification task is to predict, given an original word and a stemmed version of the word, whether the stemmed version has been correctly stemmed. The word pair was correct if: the stemmed word contained one less affix; or if the original word was a compound, the stemmed word had a space inserted between the components; or if the original word was misspelled, the stemmed word was deleted; or if the original word had no affixes and was not a compound and was not misspelled, then the stemmed word had no changes.

This dataset was compiled by Carpenter et al. (2009)[6]. The dataset contains 6679 word pairs; most pairs have 5 labels each. In the cross-validation division, no pairs with the same original word could be split across training and test data. The gold standard was the integrated label, with 4898 positive and 1781 negative pairs. Hard/Easy Case cutoffs were <-.5 and >.5. Of 6679 total instances, 822 were Hard Cases (<-.5) and 3615 were Easy Cases (>.5). Features used are combinations of the characters after the removal of the longest common substring between the word pair, including 0-2 additional characters from the substring; word boundaries are marked.

Stemming-new training strategies include:
HighAgree Filtered for agreement >-0.1.
SLLimited MajVote with instances weighted by the frequency of the label for the text pair.

[3]Limited by the discrete nature of our agreement.

3.3 Recognising Textual Entailment

Recognizing textual entailment is the process of determining if, given two sentences *text* and *hypothesis*, the meaning of the hypothesis can be inferred from the text.

We used the dataset from the PASCAL RTE-1, which contains 800 sentence pairs. The crowdsource annotations of 10 labels per pair were obtained by Snow et al. (2008)[7]. We reproduced the basic system described in (Dagan et al., 2006) of TF-IDF weighted Cosine Similarity between lemmas of the text and hypothesis. The weight of each word$_i$ in $document_j$, n total documents, is the log-plus-one term$_i$ frequency normalized by raw term$_i$ document frequency, with Euclidean normalization.

$$\text{weight}(i,j) = \begin{cases} (1+\log(\text{tf}_{i,j}))\frac{N}{\text{df}_i} & \text{if tf}_{i,j} \geq 1 \\ 0 & \text{if tf}_{i,j} = 0 \end{cases}$$

Additionally, we used features including the difference in noun chunk character and token length, the difference in number of tokens, shared named entities, and subtask names. The gold standard was the original labels from Dagan et al. (2006). Hard/Easy Case cutoffs were <0.0 and >.3. Training strategies are from Biased Language (*VeryHigh*) and Stem (others) experiments, except the *HighAgree* cutoff was 0.0 and the *VeryHigh* cutoff was 0.3. Of 800 total instances, 230 were Hard Cases (<0.0) and 207 were Easy Cases (>.30).

3.4 POS tagging

We built a POS-tagger for Twitter posts. We used the training section of the dataset from Gimpel et al. (2011). The POS tagset was the universal tag set (Petrov et al., 2012); we converted Gimpel et al. (2011)'s tags to the universal tagset using Hovy et al. (2014)'s mapping. Crowdsource labels for this data came from Hovy et al. (2014)[8], who obtained 5 labels for each tweet. After aligning and cleaning, our dataset consisted of 953 tweets of 14,439 tokens.

We followed Hovy et al. (2014) in constructing a CRF classifier (Lafferty et al., 2001), using a list of English affixes, Hovy et al. (2014)'s set of orthographic features, and word clusters (Owoputi et al., 2013). In the cross-validation division, individual tweets were assigned to folds. The gold standard was the integrated label. Hard/Easy Case cutoffs were <0.0 and >.49. Of 14,439 tokens, 649 were Hard Cases (<0.0) and 10830 were Easy Cases (>.49).

We used the following strategies:

VeryHigh For each token t in sequence s where $agreement(t)$ <0.5, s is broken into two separate sequences s_1 and s_2 and t is deleted (i.e. filtered).

HighAgree *VeryHigh* with agreement <0.2.

SoftLabel For each proto-sequence s, we generate 5 sequences $\{s_0, s_1, ..., s_i\}$, in which each token t is assigned a crowdsource label drawn at random: $l_{t,s_i} \in L_t$.

SLLimited, Each token t in sequence s is assigned its MajVote label. Then s is given a weight representing the average item agreement for all $t \in s$.

3.5 Affect Recognition

Our Affect Recognition experiments are based on the affective text annotation task in Strapparava and Mihalcea (2007), using the *Sadness* dataset. Each headline is rated for "sadness" using a scale of 0-100. Examples are in Figures 1 and 2. We use the crowdsourced annotation for a 100-headline sample of this dataset provided by Snow et al. (2008)[9], with 10 annotations per emotion per headline. Of 100 total instances, 20 were Hard Cases (<0.0) and 49 were Easy Cases (>.30).

Our system design is identical to Snow et al. (2008), which is similar to the SWAT system (Katz et al., 2007), a top-performing system on the SemEval Affective Text task. Hard/Easy Case cutoffs were <0.0 and >.3.

Training strategies are the same as for the Biased Language experiments, except:

VeryHigh Filtered for agreement >0.3.

HighAgree Filtered for agreement >0.

SLLimited SoftLabel, except that instances with a label distance >20.0 from the original label average are discarded.

4 Results

Our results on all five tasks, using each of the training strategies and variously evaluating on all, Easy, or Hard Cases, can be seen in Table 1. Systems outputing numeric values show results in Pearson correlation, and systems outputing nominal labels show micro F_1. Soft labeling (*SoftLabel*) failed to outperform integrated labels for 4 of the 5 complete test sets. Likewise, *SLLimited*

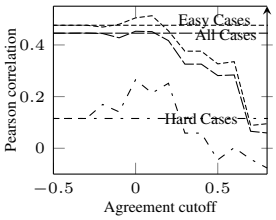

Figure 6: Affective Text.

did not significantly outperform *Integrated*. However, HighAgree does outperform *Integrated* on 4 or the 5 tasks, especially for Hard Cases: Hard Case improvements for Biased Language and POS Tagging, and Affective Text, and overall improvements for RTE, POS Tagging, and Affective Text were significant (Paired TTest, $p < 0.05$, for numerical output, or McNemar's Test[10] (McNemar, 1947), $p < 0.05$, for nominal classes). The fifth task, Stemming, had the lowest number of item agreement categories of the five tasks, preventing fine-grained agreement training filtering, which explains why filtering shows no benefit.

All training strategies used the same amount of annotated data as input, and for filtering strategies such as *HighAgree*, a reduced number of strategy-output instances are used to train the model. As a higher cutoff is used for *HighAgree*, the lack of training data results in a worse model; this can be seen in the downward curves of Figures 3 – 6, where the curved line is *HighAgree* and the matching pattern straight line is *Integrated*. (Due to the low number of item agreement categories, Stemming results are not displayed in an item agreement cutoff table.) However, Figures 4 – 6 show the overall performance boost, and Figure 3 shows the Hard Case performance boost, right before the downward curves from too little training data, using *HighAgree*.

Comparability We found the accuracy of our systems was similar to that reported in previous literature. Dagan et al. (2006) report performance of the RTE system, on a different data division, with accuracy=0.568. Hovy et al. (2014) report majority vote results (from acc=0.805 to acc=0.837 on a different data section) similar to our results of 0.790 micro-F_1. For Affective Text, Snow et al. (2008) report results on a different data section of r=0.174, a merged result from systems trained on combinations of crowdsource labels and evaluated against expert-trained systems. The SWAT system (Katz et al., 2007), which also used lexical resources and additional training data, acheived r=0.3898 on a different section of data. These results are comparable with ours, which range from r=0.326 to r=0.453.

[10] See Japkowicz and Shah (2011) for usage description.

5 Conclusions and Future Work

In this work, for five natural langauge tasks, we have examined the impact of informing the classifier of crowdsource item agreement, by means of soft labeling and removal of low-agreement training instances. We found a statistically significant benefit from low-agreement training filtering in four of our five tasks, and strongest improvements for Hard Cases. Previous work (Beigman Klebanov and Beigman, 2014) found a similar effect, but only evaluated a single task, so generalizability was unknown. We also found that soft labeling was not beneficial compared to aggregation. Our findings suggest that the best crowdsource label training strategy is to remove low item agreement instances from the training set.

Abstract

We present a comprehensive study of evaluation methods for unsupervised embedding techniques that obtain meaningful representations of words from text. Different evaluations result in different orderings of embedding methods, calling into question the common assumption that there is one single optimal vector representation. We present new evaluation techniques that directly compare embeddings with respect to specific queries. These methods reduce bias, provide greater insight, and allow us to solicit data-driven relevance judgments rapidly and accurately through crowdsourcing.

1 Introduction

Neural word embeddings represent meaning via geometry. A good embedding provides vector representations of words such that the relationship between two vectors mirrors the linguistic relationship between the two words. Despite the growing interest in vector representations of semantic information, there has been relatively little work on direct evaluations of these models. In this work, we explore several approaches to measuring the quality of neural word embeddings. In particular, we perform a comprehensive analysis of evaluation methods and introduce novel methods that can be implemented through crowdsourcing, providing better insights into the relative strengths of different embeddings.

Existing schemes fall into two major categories: extrinsic and intrinsic evaluation. In extrinsic evaluation, we use word embeddings as input features to a downstream task and measure changes in performance metrics specific to that task. Examples include part-of-speech tagging and named-entity recognition (Pennington et al., 2014). Extrinsic evaluation only provides one way to specify the goodness of an embedding, and it is not clear how it connects to other measures.

Intrinsic evaluations directly test for syntactic or semantic relationships between words (Mikolov et al., 2013a; Baroni et al., 2014). These tasks typically involve a pre-selected set of query terms and semantically related target words, which we refer to as a *query inventory*. Methods are evaluated by compiling an aggregate score for each method such as a correlation coefficient, which then serves as an absolute measure of quality. Query inventories have so far been collected opportunistically from prior work in psycholinguistics, information retrieval (Finkelstein et al., 2002), and image analysis (Bruni et al., 2014). Because these inventories were not constructed for word embedding evaluation, they are often idiosyncratic, dominated by specific types of queries, and poorly calibrated to corpus statistics.

To remedy these problems, this paper makes the following contributions. First, this is the first paper to conduct a comprehensive study covering a wide range of evaluation criteria and popular embedding techniques. In particular, we study how outcomes from three different evaluation criteria are connected: word relatedness, coherence, downstream performance. We show that using different criteria results in different relative orderings of embeddings. These results indicate that embedding methods should be compared in the context of a specific task, e.g., linguistic insight or good downstream performance.

Second, we study the connections between direct evaluation with real users and pre-collected offline data. We propose a new approach to evaluation that focuses on direct comparison of embeddings with respect to individual queries rather than overall summary scores. Because we phrase all tasks as choice problems rather than ordinal relevance tasks, we can ease the burden of the an-

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 298–307,
Lisbon, Portugal, 17-21 September 2015.

notators. We show that these evaluations can be gathered efficiently from crowdsourcing. Our results also indicate that there is in fact strong correlation between the results of automated similarity evaluation and direct human evaluation. This result justifies the use of offline data, at least for the similarity task.

Third, we propose a model- and data-driven approach to constructing query inventories. Rather than picking words in an *ad hoc* fashion, we select query words to be diverse with respect to their frequency, parts-of-speech and abstractness. To facilitate systematic evaluation and comparison of new embedding models, we release a new frequency-calibrated query inventory along with all user judgments at `http://www.cs.cornell.edu/~schnabts/eval/`.

Finally, we observe that word embeddings encode a surprising degree of information about word frequency. We found this was true even in models that explicitly reserve parameters to compensate for frequency effects. This finding may explain some of the variability across embeddings and across evaluation methods. It also casts doubt on the common practice of using the vanilla cosine similarity as a similarity measure in the embedding space.

It is important to note that this work is a survey of *evaluation* methods not a survey of *embedding* methods. The specific example embeddings presented here were chosen as representative samples only, and may not be optimal.

2 Word embeddings

We refer to a word embedding as a mapping $V \rightarrow \mathbb{R}^D : w \mapsto \vec{w}$ that maps a word w from a vocabulary V to a real-valued vector $\vec{w}$ in an embedding space of dimensionality D.

Following previous work (Collobert et al., 2011; Mikolov et al., 2013a) we use the commonly employed cosine similarity, defined as $\text{similarity}(w_1, w_2) = \frac{\vec{w_1} \cdot \vec{w_2}}{\|\vec{w_1}\| \|\vec{w_2}\|}$, for all similarity computations in the embedding space. The list of nearest neighbors of a word w are all words $v \in V \setminus \{w\}$, sorted in descending order by $\text{similarity}(w, v)$. We will denote w as the *query word* in the remainder of this paper.

All experiments in this paper are carried out on six popular unsupervised embedding methods. These embeddings form a representative but incomplete subset; and since we are studying evaluation methods and not embeddings themselves, no attempt has been made to optimize these embeddings. The first two embedding models, the CBOW model of word2vec (Mikolov et al., 2013a) and C&W embeddings (Collobert et al., 2011) both are motivated by a probabilistic prediction approach. Given a number of context words around a target word w, these models formulate the embedding task as that of finding a representation that is good at predicting w from the context representations.

The second group of models, Hellinger PCA (Lebret and Collobert, 2014), GloVe (Pennington et al., 2014), TSCCA (Dhillon et al., 2012) and Sparse Random Projections (Li et al., 2006) follow a reconstruction approach: word embeddings should be able to capture as much relevant information from the original co-occurrence matrix as possible.

Training corpus. We tried to make the comparison as fair as possible. As the C&W embeddings were only available pretrained on a November 2007 snapshot of Wikipedia, we chose the closest available Wikipedia dump (2008-03-01) for training the other models. We tokenized the data using the Stanford tokenizer (Manning et al., 2014). Like Collobert et al. (2011), we lower-cased all words and replaced digits with zeros.

Details. All models embedded words into a 50-dimensional space ($D = 50$). As implemented, each method uses a different vocabulary, so we computed the intersection of the six vocabularies and used the resulting set of 103,647 words for all nearest-neighbor experiments.

3 Relatedness

We begin with intrinsic evaluation of relatedness using both pre-collected human evaluations and a novel online user study. Section 3.1 introduces the list of datasets that is commonly used as a benchmark for embedding methods. There, embeddings are evaluated individually and only their final scores are compared, hence we refer to this scenario as *absolute intrinsic* evaluation. We present a new scenario, *comparative intrinsic* evaluation, in which we ask people directly for their preferences among different embeddings. We demonstrate that we can achieve the same results as offline, absolute metrics using online, comparative metrics.

3.1 Absolute intrinsic evaluation

For the absolute intrinsic evaluation, we used the same datasets and tasks as Baroni et al. (2014). While we present results on all tasks for completeness, we will mainly focus on relatedness in this section. There are four broad categories:

- **Relatedness**: These datasets contain relatedness scores for pairs of words; the cosine similarity of the embeddings for two words should have high correlation (Spearman or Pearson) with human relatedness scores.
- **Analogy**: This task was popularized by Mikolov et al. (2013a). The goal is to find a term x for a given term y so that $x : y$ best resembles a sample relationship $a : b$.
- **Categorization**: Here, the goal is to recover a clustering of words into different categories. To do this, the corresponding word vectors of all words in a dataset are clustered and the purity of the returned clusters is computed with respect to the labeled dataset.
- **Selectional preference**: The goal is to determine how typical a noun is for a verb either as a subject or as an object (e.g., people eat, but we rarely eat people). We follow the procedure that is outlined in Baroni et al. (2014).

Several important design questions come up when designing reusable datasets for evaluating relatedness. While we focus mainly on challenges that arise in the relatedness evaluation task, many of the questions discussed also apply to other scenarios.

Query inventory. How we pick the word pairs to evaluate affects the results of the evaluation. The commonly-used WordSim-353 dataset (Finkelstein et al., 2002), for example, only tries to have word pairs with a diverse set of similarity scores. The more recent MEN dataset (Bruni et al., 2014) follows a similar strategy, but restricts queries to words that occur as annotations in an image dataset. However, there are more important criteria that should be considered in order to create a diverse dataset: (i) the frequency of the words in the English language (ii) the parts of speech of the words and (iii) abstractness vs. concreteness of the terms. Not only is frequency important because we want to test the quality of embeddings on rare words, but also because it is related with distance in the embedding space as we show later and should be explicitly considered.

Metric aggregation. The main conceptual shortcoming of using correlation-based metrics is that they aggregate scores of different pairs — even though these scores can vary greatly in the embedding space. We can view the relatedness task as the task of evaluating a set of rankings, similar to ranking evaluation in Information Retrieval. More specifically, we have one query for each unique query word w and rank all remaining words v in the vocabulary accordingly. The problem now is that we usually cannot directly compare scores from different rankings (Aslam and Montague, 2001) as their scores are not guaranteed to have the same ranges. An even worse case is the following scenario. Assume we use rank correlation as our metric. As a consequence, we need our gold ranking to define an order on all the word pairs. However, this also means that we somehow need to order completely unrelated word pairs; for example, we have to decide whether (dog, cat) is more similar than (banana, apple).

3.2 Absolute results

Table 1 presents the results on 14 different datasets for the six embedding models. We excluded examples from datasets that contained words not in our vocabulary. For the relatedness and selective preference tasks, the numbers in the table indicate the correlation coefficient of human scores and the cosine similarity times 100. The numbers for the categorization tasks reflect the purities of the resulting clusters. For the analogy task, we report accuracy.

CBOW outperforms other embeddings on 10 of 14 datasets. CBOW especially excels at the relatedness and analogy tasks, but fails to surpass other models on the selective preferences tasks. Random projection performs worst in 13 out of the 14 tasks, being followed by Hellinger PCA. C&W and TSCCA are similar on average, but differ across datasets. Moreover, although TSCCA and GloVe perform similarly on most tasks, TSCCA suffers disproportionally on the analogy tasks.

3.3 Comparative intrinsic evaluation

In comparative evaluation, users give direct feedback on the embeddings themselves, so we do not have to define a metric that compares scored word pairs. Rather than defining both query and target words, we need only choose query words since the

Table 1: Results on absolute intrinsic evaluation. The best result for each dataset is highlighted in bold. The second row contains the names of the corresponding datasets.

embeddings themselves will be used to define the comparable target words.

Query inventory. We compiled a diverse inventory of 100 query words that balance frequency, part of speech (POS), and concreteness. First, we selected 10 out of 45 broad categories from WordNet (Miller, 1995). We then chose an equal number of categories that mostly contained abstract concepts and categories that referred to concrete concepts. Among those categories, we had one for adjectives and adverbs each, and four for nouns and verbs each. From each category, we drew ten random words with the restriction that there be exactly three rare words (i.e., occurring fewer than 2500 times in the training corpus) among the ten.

Details. Our experiments were performed with users from Amazon Mechanical Turk (MTurk) that were native speakers of English with sufficient experience and positive feedback on the Amazon Mechanical Turk framework.

For each of the 100 query words in the dataset, the nearest neighbors at ranks $k \in \{1, 5, 50\}$ for the six embeddings were retrieved. For each query word and k, we presented the six words along with the query word to the users. Each Turker was requested to evaluate between 25 and 50 *items* per task, where an item corresponds to the query word and the set of 6 retrieved neighbor words from each of the 6 embeddings. The payment was between \$0.01 and \$0.02 per item. The users were then asked to pick the word that is most similar according to their perception (the instructions were almost identical to the WordSim-353 dataset instructions). Duplicate words were consolidated, and a click was counted for all embeddings that returned that word. An option "I don't know the meaning of one (or several) of the words" was also provided as an alternative. Table 2 shows an example instance that was given to the Turkers.

Query:	**skillfully**			
	(a)	swiftly	(b)	expertly
	(c)	cleverly	(d)	pointedly

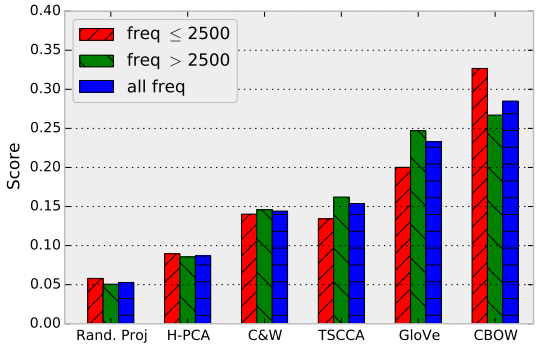
Table 2: Example instance of comparative intrinsic evaluation task. The presented options in this example are nearest neighbors to the query word according to (a) C&W, (b) CBOW, GloVe, TSCCA (c) Rand. Proj. and (d) H-PCA.

The combination of 100 query words and 3 ranks yielded 300 items on which we solicited judgements by a median of 7 Turkers (min=5, max=14). We compare embeddings by average win ratio, where the win ratio was how many times raters chose embedding e divided by the number of total ratings for item i.

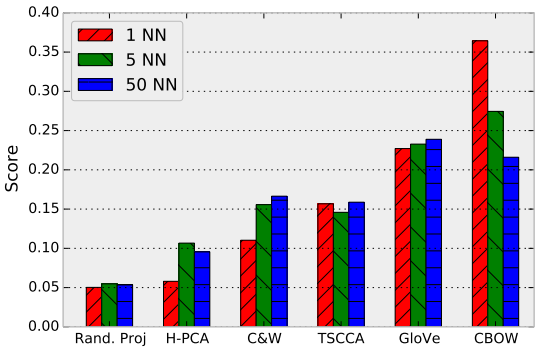
3.4 Comparative results

Overall comparative results replicate previous results. Figure 1(a) shows normalized win ratio scores for each embedding across 3 conditions corresponding to the frequency of the query word in the training corpus. The scores were normalized to sum to one in each condition to emphasize relative differences. CBOW in general performed the best and random projection the worst (p-value < 0.05 for all pairs except H-PCA and C&W in comparing un-normalized score differences for the ALL-FREQ condition with a randomized permutation test). The novel comparative evaluations correspond both in rank and in relative margins to those shown in Table 1.

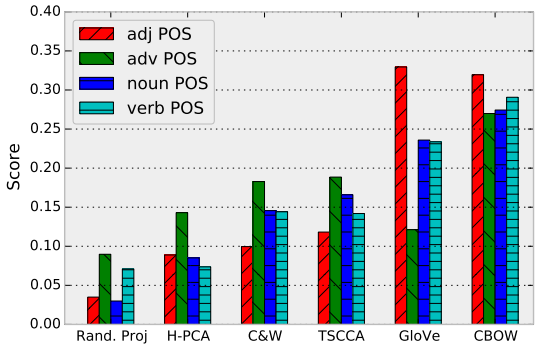
Unlike previous results, we can now show differences beyond the nearest neighbors. Figure 1(b) presents the same results, but this time



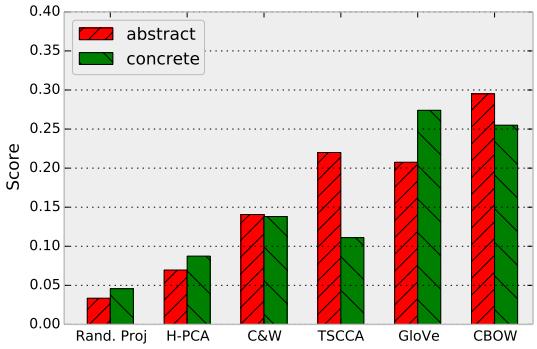
(a) Normalized scores by global word frequency.



(b) Normalized scores by nearest neighbor rank k.



(c) Normalized scores by part of speech.



(d) Normalized scores by category.

Figure 1: Direct comparison task

broken up by the rank k of the neighbors that were compared. CBOW has its strengths especially at rank $k = 1$. For neighbors that appear after that, CBOW does not necessarily produce better embeddings. In fact, it even does worse for $k = 50$ than GloVe. It is important to note, however, that we cannot make absolute statements about how performance behaves across different values of k since each assessment is always relative to the quality of all other embeddings.

We balanced our query inventory also with respect to parts of speech and abstractness vs. concreteness. Figure 1(c) shows the relative performances of all embeddings for the four POS classes (adjectives, adverbs, nouns and verbs). While most embeddings show relatively homogeneous behaviour across the four classes, GloVe suffers disproportionally on adverbs. Moving on to Figure 1(d), we can see a similar behavior for TSCCA: Its performance is much lower on concrete words than on abstract ones. This difference may be important, as recent related work finds that simply differentiating between general and specific terms explains much of the observed variation between embedding methods in hierarchical classification tasks (Levy et al., 2015b). We take the two observations above as evidence that a more fine-grained analysis is necessary in discerning different embedding methods.

As a by-product, we observed that there was no embedding method that consistently performed best on all of the four different absolute evaluation tasks. However, we would like to reiterate that our goal is not to identify one best method, but rather point out that different evaluations (e.g., changing the rank k of the nearest neighbors in the comparison task) result in different outcomes.

4 Coherence

In the relatedness task we measure whether a pair of semantically similar words are near each other in the embedding space. In this novel coherence task we assess whether *groups* of words in a small neighborhood in the embedding space are mutually related. Previous work has used this property for qualitative evaluation using visualizations of 2D projections (Turian et al., 2010), but we are not aware of any work using local neighborhoods for

quantitative evaluation. Good embeddings should have coherent neighborhoods for each word, so inserting a word not belonging to this neighborhood should be easy to spot. Similar to Chang et al. (2009), we presented Turkers with four words, three of which are close neighbors and one of which is an "intruder." For each of the 100 words in our query set of Section 3.3, we retrieved the two nearest neighbors. These words along with the query word defined the set of (supposedly) good options. Table 3 shows an example instance that was given to the Turkers.

(a)	finally	(b)	eventually
(c)	immediately	(d)	put

Table 3: Example instance of intrusion task. The query word is option (a), intruder is (d).

To normalize for frequency-based effects, we computed the average frequency avg of the three words in this set and chose the intruder word to be the first word that had a frequency of $avg \pm 500$ starting at rank 100 of the list of nearest neighbors.

Results. In total, we solicited judgments on 600 items (100 query words for each of the 6 embeddings) from a median of 7 Turkers (min=4, max=11) per item, where each Turker evaluated between 25 and 50 items per task. Figure 2 shows the results of the intrusion experiment. The evaluation measure is micro-averaged precision for an embedding across 100 query words, where per-item precision is defined as the number of raters that discovered the intruder divided the total number of raters of item i. Random guessing would achieve an average precision of 0.25.

All embeddings perform better than guessing, indicating that there is at least some coherent structure captured in all of them. However, the best performing embeddings at this task are TSCCA, CBOW and GloVe (the precision mean differences were not significant under a random permutation test), while TSCCA attains greater precision ($p < 0.05$) in relation to C&W, H-PCA and random projection embeddings. These results are in contrast to the direct comparison study, where the performance of TSCCA was found to be significantly worse than that of CBOW. However, the order of the last three embeddings remains unchanged, implying that performance on the intrusion task and performance on the direct comparison task are correlated. CBOW and C&W seem to do equally well on rare and frequent words, whereas the other models' performance suffers on rare words.

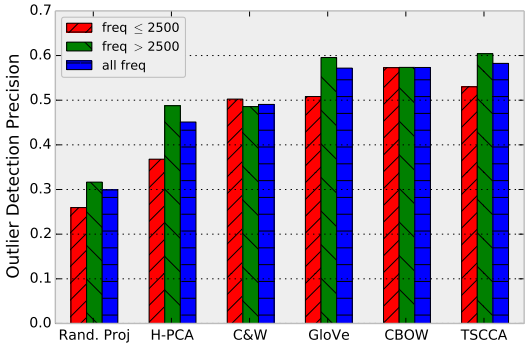


Figure 2: Intrusion task: average precision by global word frequency.

Discussion. Evaluation of set-based properties of embeddings may produce different results from item-based evaluation: rankings we got from the intrusion task did not match the rankings we obtained from the relatedness task. Pairwise similarities seem to be only part of the information that is encoded in word embeddings, so looking at more global measures is necessary for a better understanding of differences between embeddings.

We choose intruder words based on similar but lower-ranked words, so an embedding could score well on this task by doing an unusually bad job at returning less-closely related words. However, the results in Figure 1(b) suggest that there is little differences at higher ranks (rank 50) between embeddings.

5 Extrinsic Tasks

Extrinsic evaluations measure the contribution of a word embedding model to a specific task. There is an implicit assumption in the use of such evaluations that there is a consistent, global ranking of word embedding quality, and that higher quality embeddings will necessarily improve results on any downstream task. We find that this assumption does not hold: different tasks favor different embeddings. Although these evaluations are useful in characterizing the relative strengths of different models, we do not recommend that they be used as a proxy for a general notion of embedding quality.

	dev	test	p-value

TSCCA	75.02	$7.28{\cdot}10^{-4}$

Table 5: F1 sentiment analysis results using different word embeddings as features. The p-values are with respect to the best performing embedding.

Noun phrase chunking. First we use a noun phrase chunking task similar to that used by Turian et al. (2010). The only difference is that we normalize all word vectors to unit length, rather than scaling them with some custom factor, before giving them to the conditional random field (CRF) model as input. We expect that this task will be more sensitive to syntactic information than to semantic information.

Sentiment classification. Second we use a recently released dataset for binary sentiment classification by Maas et al. (2011). The dataset contains 50K movie reviews with a balanced distribution of binary polarity labels. We evaluate the relative performance of word embeddings at this task as follows: we generate embedding-only features for each review by computing a linear combination of word embeddings weighted by the number of times that the word appeared in the review (using the same bag-of-words features as Maas et al. (2011)). A LIBLINEAR logistic regression model (Fan et al., 2008) with the default parameters is trained and evaluated using 10 fold cross-validation. A vanilla bag of words feature set is the baseline (denoted as BOW here). We expect that this task will be more sensitive to semantic information than syntactic information.

Results. Table 4 shows the average F1-scores for the chunking task. The p-values were computed using randomization (Yeh, 2000) on the sentence level. First, we can observe that adding word vectors as features results in performance lifts with all embeddings when compared to the baseline. The performance of C&W and TSCCA is statistically not significant, and C&W does better than all the remaining methods at the $p = 0.05$ level. Surprisingly, although the performance of Random Projections is still last, the gap to GloVe and CBOW is now very small. Table 5 shows results on the sentiment analysis task. We recover a similar order of embeddings as in the absolute intrinsic evaluation, however, the order of TSCCA and GloVe is now reversed.

Discussion. Performance on downstream tasks is not consistent across tasks, and may not be consistent with intrinsic evaluations. Comparing performance across tasks may provide insight into the information encoded by an embedding, but we should not expect any specific task to act as a proxy for abstract quality. Furthermore, if good downstream performance is really the goal of an embedding, we recommend that embeddings be trained specifically to optimize a specific objective (Lebret and Collobert, 2014).

6 Discussion

We find consistent differences between word embeddings, despite the fact that they are operating on the same input data and optimizing arguably very similar objective functions (Pennington et al., 2014; Levy and Goldberg, 2014). Recent work suggests that many apparent performance differences on specific tasks are due to a lack of hyperparameter optimization (Levy et al., 2015a). Different algorithms are, in fact, encoding surprisingly different information that may or may not align with our desired use cases. For example, we find that embeddings encode differing degrees of information about word frequency, even after length normalization. This result is surprising for two reasons. First, many algorithms reserve distinct "intercept" parameters to absorb frequency-based effects. Second, we expect that the geometry of the embedding space will be primar-

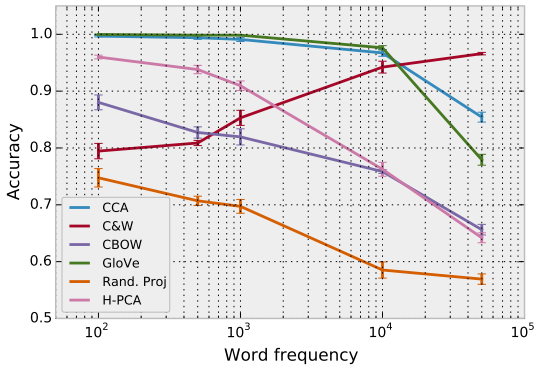

Figure 3: Embeddings can accurately predict whether a word is frequent or rare.

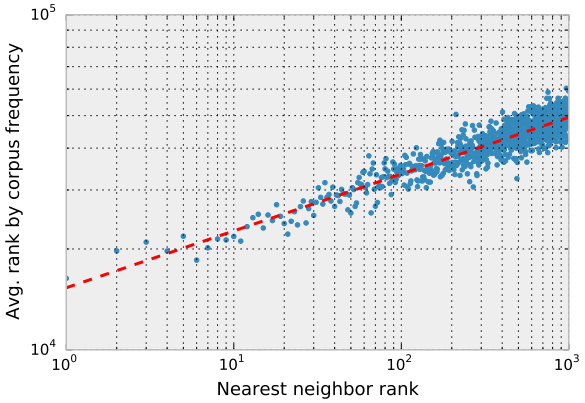

Figure 4: Avg. word rank by frequency in training corpus vs. nearest-neighbor rank in the C&W embedding space.

ily driven by semantics: the relatively small number of frequent words should be evenly distributed through the space, while large numbers of rare, specific words should cluster around related, but more frequent, words.

We trained a logistic regression model to predict word frequency categories based on word vectors. The linear classifier was trained to put words either in a frequent or rare category, with thresholds varying from 100 to 50,000. At each threshold frequency, we sampled the training sets to ensure a consistent balance of the label distribution across all frequencies. We used length-normalized embeddings, as rare words might have shorter vectors resulting from fewer updates during training (Turian et al., 2010). We report the mean accuracy and standard deviation (1σ) using five-fold cross-validation at each threshold frequency in Figure 3.

All word embeddings do better than random, suggesting that they contain some frequency information. GloVe and TSCCA achieve nearly 100% accuracy on thresholds up to 1000. Unlike all other embeddings, accuracy for C&W embeddings increases for larger threshold values. Further investigation revealed that the weight vector direction changes gradually with the threshold frequency — indicating that frequency seems to be encoded in a smooth way in the embedding space.

Although GloVe and CBOW are the two best performing embeddings on the intrinsic tasks, they differ vastly in the amount of frequency information they encode. As a consequence, we can conclude that most of the differences in frequency prediction are not due to intrinsic properties of natural language: it is not the case that frequent words naturally have only frequent neighbors.

Word frequency information in the embedding space also affects cosine similarity. For each of the words in the WordSim-353 dataset, we queried for the $k = 1000$ nearest neighbors. We then looked up their frequency ranks in the training corpus and averaged those ranks over all the query words. We found a strong correlation between the frequency of a word and its position in the ranking of nearest neighbors in our experiments. Figure 4 shows a power law relationship for C&W embeddings between a word's nearest neighbor rank (w.r.t. a query) and the word's frequency rank in the training corpus (nn-rank $\sim$ 1000 $\cdot$ corpus-rank$^{0.17}$). This is a concern: the frequency of a word in the language plays a critical role in word processing of humans as well (Cattell, 1886). As a consequence, we need to explicitly consider word frequency as a factor in the experiment design. Also, the above results mean that the commonly-used cosine similarity in the embedding space for the intrinsic tasks gets polluted by frequency-based effects. We believe that further research should address how to better measure linguistic relationships between words in the embedding space, e.g., by learning a custom metric.

7 Related work

Mikolov et al. (2013b) demonstrate that certain linguistic regularities exist in the embedding space. The authors show that by doing simple vector arithmetic in the embedding space, one can solve various syntactic and semantic analogy tasks. This is different to previous work, which phrased the analogy task as a classification problem (Turney, 2008). Surprisingly, word embed-

dings seem to capture even more complex linguistic properties. Chen et al. (2013) show that word embeddings even contain information about regional spellings (UK vs. US), noun gender and sentiment polarity.

Previous work in evaluation for word embeddings can be divided into intrinsic and extrinsic evaluations. Intrinsic evaluations measure the quality of word vectors by directly measuring correlation between semantic relatedness and geometric relatedness, usually through inventories of query terms. Focusing on intrinsic measures, Baroni et al. (2014) compare word embeddings against distributional word vectors on a variety of query inventories and tasks. Faruqui and Dyer (2014) provide a website that allows the automatic evaluation of embeddings on a number of query inventories. Gao et al. (2014) publish an improved query inventory for the analogical reasoning task. Finally, Tsvetkov et al. (2015) propose a new intrinsic measure that better correlates with extrinsic performance. However, all these evaluations are done on precollected inventories and mostly limited to local metrics like relatedness.

Extrinsic evaluations use embeddings as features in models for other tasks, such as semantic role labeling or part-of-speech tagging (Collobert et al., 2011), and improve the performance of existing systems (Turian et al., 2010). However, they have been less successful at other tasks such as parsing (Andreas and Klein, 2014).

More work has been done in unsupervised semantic modeling in the context of topic models. One example is the *word intrusion* task (Chang et al., 2009), in which annotators are asked to identify a random word inserted into the set of high probability words for a given topic. Word embeddings do not produce interpretable dimensions, so we cannot directly use this method, but we present a related task based on nearest neighbors. Manual evaluation is expensive and time-consuming, but other work establishes that automated evaluations can closely model human intuitions (Newman et al., 2010).

8 Conclusions

There are many factors that affect word embedding quality. Standard aggregate evaluations, while useful, do not present a complete or consistent picture. Factors such as word frequency play a significant and previously unacknowledged role. Word frequency also interferes with the commonly-used cosine similarity measure. We present a novel evaluation framework based on direct comparisons between embeddings that provides more fine-grained analysis and supports simple, crowdsourced relevance judgments. We also present a novel *Coherence* task that measures our intuition that neighborhoods in the embedding space should be semantically or syntactically related. We find that extrinsic evaluations, although useful for highlighting specific aspects of embedding performance, should not be used as a proxy for generic quality.

Abstract

Latent Dirichlet allocation (LDA) is a popular topic modeling technique for exploring hidden topics in text corpora. Increasingly, topic modeling needs to scale to larger topic spaces and use richer forms of prior knowledge, such as word correlations or document labels. However, inference is cumbersome for LDA models with prior knowledge. As a result, LDA models that use prior knowledge only work in small-scale scenarios. In this work, we propose a factor graph framework, Sparse Constrained LDA (SC-LDA), for efficiently incorporating prior knowledge into LDA. We evaluate SC-LDA's ability to incorporate word correlation knowledge and document label knowledge on three benchmark datasets. Compared to several baseline methods, SC-LDA achieves comparable performance but is significantly faster.

1 Challenge: Leveraging Prior Knowledge in Large-scale Topic Models

Topic models, such as Latent Dirichlet Allocation (Blei et al., 2003, LDA), have been successfully used for discovering hidden topics in text collections. LDA is an unsupervised model—it requires no annotation—and discovers, without any supervision, the thematic trends in a text collection. However, LDA's lack of supervision can lead to disappointing results. Often, the hidden topics learned by LDA fail to make sense to end users. Part of the problem is that the objective function of topic models does not always correlate with human judgments of topic quality (Chang et al., 2009). Therefore, it's often necessary to incorporate prior knowledge into topic models to improve the model's performance. Recent work has also shown that by interactive human feedback can improve the quality and stability of topics (Hu and Boyd-Graber, 2012; Yang et al., 2015). Information about documents (Ramage et al., 2009) or words (Boyd-Graber et al., 2007) can improve LDA's topics.

In addition to its occasional inscrutability, scalability can also hamper LDA's adoption. Conventional Gibbs sampling—the most widely used inference for LDA—scales linearly with the number of topics. Moreover, accurate training usually takes many sampling passes over the dataset. Therefore, for large datasets with millions or even billions of tokens, conventional Gibbs sampling takes too long to finish. For standard LDA, recently introduced fast sampling methods (Yao et al., 2009; Li et al., 2014; Yuan et al., 2015) enable industrial applications of topic modeling to search engines and online advertising, where capturing the "long tail" of infrequently used topics requires large topic spaces. For example, while typical LDA models in academic papers have up to 10^3 topics, industrial applications with 10^5–10^6 topics are common (Wang et al., 2014). Moreover, scaling topic models to many topics can also reveal the hierarchical structure of topics (Downey et al., 2015).

Thus, there is a need for topic models that can both benefit from rich prior information and that can scale to large datasets. However, existing methods for improving scalability focus on topic models without prior information. To rectify this, we propose a factor graph model that encodes a potential function over the hidden topic variables, encouraging topics consistent with prior knowledge. The factor model representation admits an efficient sampling algorithm that takes advantage of the model's sparsity. We show that our method achieves comparable performance but runs significantly faster than baseline methods, enabling mod-

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 308–317,
Lisbon, Portugal, 17-21 September 2015.

els to discover models with many topics enriched by prior knowledge.

2 Efficient Algorithm for Incorporating Knowledge into LDA

In this section, we introduce the factor model for incorporating prior knowledge and show how to efficiently use Gibbs sampling for inference.

2.1 Background: LDA and SparseLDA

A statistical topic model represents words in documents in a collection D as mixtures of T topics, which are multinomials over a vocabulary of size V. In LDA, each document d is associated with a multinomial distribution over topics, θ_d. The probability of a word type w given topic z is $\phi_{w|z}$. The multinomial distributions θ_d and ϕ_z are drawn from Dirichlet distributions: α and β are the hyperparameters for θ and ϕ. We represent the document collection D as a sequence of words $\mathbf{w}$, and topic assignments as $\mathbf{z}$. We use symmetric priors α and β in the model and experiment, but asymmetric priors are easily encoded in the models (Wallach et al., 2009).

Discovering the latent topic assignments $\mathbf{z}$ from observed words $\mathbf{w}$ requires inferring the the posterior distribution $P(\mathbf{z}|\mathbf{w})$. Griffiths and Steyvers (2004) propose using collapsed Gibbs sampling. The probability of a topic assignment $z = t$ in document d given an observed word type w and the other topic assignments z_- is

$$P(z = t|\mathbf{z}_-, w) \propto (n_{d,t} + \alpha)\frac{n_{w,t} + \beta}{n_t + V\beta} \quad (1)$$

where $\mathbf{z}_-$ are the topic assignments of all other tokens. This conditional probability is based on cumulative counts of topic assignments: $n_{d,t}$ is the number of times topic t is used in document d, $n_{w,t}$ is the number of times word type w is used in topic t, and n_t is the marginal count of the number of tokens assigned to topic t.

Unfortunately, explicitly computing the conditional probability is quite for models with many topics. The time complexity of drawing a sample by Equation 1 is linear to the number of topics. Yao et al. (2009) propose a clever factorization of Equation 1 so that the complexity is typically sublinear by breaking the conditional probability into three "buckets":

$$\sum_t P(z = t|\mathbf{z}_-, w) = \underbrace{\sum_t \frac{\alpha\beta}{n_t + V\beta}}_{\text{s}} + \underbrace{\sum_{t,n_{d,t}>0} \frac{n_{d,t}\beta}{n_t + V\beta}}_{\text{r}} + \underbrace{\sum_{t,n_{w,t}>0} \frac{(n_{d,t} + \alpha)n_{w,t}}{n_t + V\beta}}_{\text{q}}. \quad (2)$$

The first term s is the "smoothing only" bucket—constant for all documents. The second term r is the "document only" bucket that is shared by a document's tokens. Both s and r have simple constant time updates. The last term q has to be computed specifically for each token, only for the few types with non-zero counts in a topic, due to the sparsity of word-topic count. Since q often has the largest mass and few non-zero terms, we start the sampling from bucket q.

2.2 A Factor Model for Incorporating Prior Knowledge

With SparseLDA, inferring LDA models over large topic spaces becomes tractable. However, existing methods for incorporating prior knowledge use conventional Gibbs sampling, which hinders inference. We address this limitation in this section by adding a factor graph to encode prior knowledge.

LDA assumes that the hidden topic assignment of a word is independent from other hidden topics, given the document's topic distribution θ. While this assumption facilitates computational efficiency, it loses the rich correlation between words. In many scenarios, users have external knowledge regarding word correlation, document labels, or document relations, which can reshape topic models and improve coherence.

Prior knowledge can constrain what models discover. A correlation between two words v and w indicates that they have a similar topic distribution, i.e., $p(z|v) \approx p(z|w)$.[1] Therefore, the posterior topic assignments v and w will be correlated. In contrast, if v and w are uncorrelated, nothing—other than the Dirichlet's rich get richer effect—prevents the topics from diverging. Similarly, if two documents share a label, then it is reasonable

[1] In (Andrzejewski et al., 2009) two correlated words are taken to indicate that $p(v|z) \approx p(w|z)$. However, for word types that have very different frequencies, these two quantities would never be close, and thus $p(z|v) \approx p(z|w)$ is a more intuitive constraint.

to assume that they are more likely than two random documents to share topics.

We denote the set of prior knowledge as M. Each prior knowledge $m \in M$ defines a potential function $f_m(z, w, d)$ of the hidden topic z of word type w in document d with which m is associated. Therefore, the complete prior knowledge M defines a score on the current topic assignments $\mathbf{z}$:

$$\psi(\mathbf{z}, M) = \prod_{z \in \mathbf{z}} \exp f_m(z, w, d) \tag{3}$$

If m is knowledge about word type w, then $f_m(z, w, d)$ applies to all hidden topics of word w. If m is knowledge about document d, then $f_m(z, w, d)$ applies to all topics that are in document d. The potential function assigns large values to the topics that accord with prior knowledge but penalizes the topic assignments that disagree with the prior knowledge. In an extreme case, if a prior knowledge m says word type w in document d is Topic 3, then the potential function $f_m(z, w, d)$ is zero for all topics but Topic 3.

Since the potential function ψ is a function of $\mathbf{z}$, and it is only a real-value score of current topic assignments, the potential can be factored out of the marginalized joint:

$$\begin{aligned} &P(\mathbf{w}, \mathbf{z}|\alpha, \beta, M) = P(\mathbf{w}|\mathbf{z}, \beta) P(\mathbf{z}|\alpha) \psi(\mathbf{z}, M) \qquad (4) \\ &= \int_\theta \int_\phi p(\mathbf{w}|\mathbf{z}, \phi) p(\phi|\beta) p(\mathbf{z}|\theta) p(\theta|\alpha) \psi(\mathbf{z}, M) d\theta d\phi \\ &= \psi(\mathbf{z}, M) \int_\theta \int_\phi p(\mathbf{w}|\mathbf{z}, \phi) p(\phi|\beta) p(\mathbf{z}|\theta) p(\theta|\alpha) d\theta d\phi. \end{aligned}$$

Given the joint likelihood and observed data, the goal is evaluate the posterior $P(\mathbf{z}|\mathbf{w})$. Computing $P(\mathbf{z}|\mathbf{w})$ involves evaluating a probability distribution on a large discrete state space: $P(\mathbf{z}|\mathbf{w}) = P(\mathbf{z}, \mathbf{w}) / \sum_{\mathbf{z}} P(\mathbf{z}, \mathbf{w})$. Griffiths and Steyvers (2004)—mirroring the original inspirations for Gibbs sampling (Geman and Geman, 1990)—draw an analogy to statistical physics, viewing standard LDA as a system that favors configurations $\mathbf{z}$ that compromise between having few topics per document and having few words per topic, with the terms of this compromise being set by the hyperparameters α and β. Our factor model representation of prior knowledge adds a further constraint that asks the model to also consider ensembles of topic assignments $\mathbf{z}$ that are compatible with a standard LDA model *and* the given prior knowledge.

The collapsed Gibbs Sampling for inferring topic assignment z of word w in document d is:

$$\begin{aligned} &P(z = t|w, \mathbf{z}_-, M) \qquad (5) \\ &= \frac{P(\mathbf{w}, \mathbf{z}_-, z = t|\alpha, \beta, M)}{P(\mathbf{w}, \mathbf{z}_-|\alpha, \beta, M)} \\ &= \frac{P(\mathbf{w}, \mathbf{z}_-, z = t)}{P(\mathbf{w}, \mathbf{z}_-)} \frac{\psi(\mathbf{z}_-, z = t, M)}{\psi(\mathbf{z}_-, M)} \\ &\propto \left\{ (n_{d,t} + \alpha) \frac{n_{w,t} + \beta}{n_t + W\beta} \right\} \frac{\psi(\mathbf{z}_-, z = t, M)}{\psi(\mathbf{z}_-, M)} \\ &\propto \left\{ (n_{d,t} + \alpha) \frac{n_{w,t} + \beta}{n_t + W\beta} \right\} \exp f_m(z = t, w, d). \end{aligned}$$

The first term is identical to standard LDA, and admits efficient computation using SparseLDA. However, if the second term, $\exp f_m(z, w, d)$, is dense, we still need to compute it explicitly T times (once for each topic) because we need the summation of $P(z = t)$ for sampling. Therefore, the critical part of speeding up the sampler is finding a sparse representation of the second term. In the following sections, we show that natural, sparse prior knowledge representations are possible. We first present an efficient sparse representation of word correlation prior knowledge and then one for document-label knowledge.

2.3 Word Correlation Prior Knowledge

We now illustrate how we can encode word correlation knowledge as a set of sparse constraints $f_m(z, w, d)$ in our model. In previous work (Andrzejewski et al., 2009; Hu et al., 2011; Xie et al., 2015), word correlation prior knowledge is represented as word must-link constraints and cannot-link constraints. A must-link relation between two words indicates that the two words tend to be related to the same topics, i.e. their topic probabilities are correlated. In contrast, a cannot-link relation between two words indicates that these two words are not topically similar, and they should not both be prominent within the same topic. For example, "quarterback" and "fumble" are both related to American football, so they can share a must-link relation. But "fumble" and "bank" imply two different topics, so they share a cannot-link.

Let us say word w is associated with a set of prior knowledge correlations M_w. Each prior knowledge $m \in M_w$ is a word pair (w, w'), and it has "topic preference" of w given its correlation word w'. The must-link set of w is M_w^m, and the cannot-link set of w is M_w^c, i.e., $M_w = M_w^c \bigcup M_w^m$. In the example above, $M_{fumble}^m =$

$\{quarterback\}$, and $M^c_{fumble} = \{bank\}$, so $M_{fumble} = \{quarterback, bank\}$. The topic assignment of word "fumble" has higher conditional probability for the same topics as "quarterback" but lower probability for topics containing "bank".

The potential score of sampling topic t for word type w—if M_w is not empty—is

$$f_m(z, w, d) = \sum_{u \in M^m_w} \log \max(\lambda, n_{u,z}) + \sum_{v \in M^c_w} \log \frac{1}{\max(\lambda, n_{v,z})}. \quad (6)$$

where λ is a hyperparameter, which we call the correlation strength. The intuitive explanation of Equation 6 is that the prior knowledge about the word type w will make an impact on the conditional probability of sampling the hidden topic z. Unlike standard LDA where every word's hidden topic is independent of other words given θ, Equation 6 instead increases the probability that a word w will be drawn from the same topics as those of w's must-link word set, and decreases its probability of being drawn from the same topics as those of w's cannot-link word set.

The hyperparameter λ controls the strength of each piece of prior knowledge. The smaller λ is, the stronger this correlation is. For large λ, the constraint is inactive for topics except those with the large counts. As λ decreases, the constraint becomes active for topics with lesser counts. We can adjust the value of λ for each piece of prior knowledge based on our confidence. In our experiments, for simplicity, we use the same value λ for all knowledge and set $\lambda = 1$.

From Equation 6 and Equation 5, the conditional probability of a topic z in document d given an observed word type w is:

$$P(z = t|w, \mathbf{z}_-, M) \propto \left\{ \frac{\alpha\beta}{n_t + V\beta} + \frac{n_{d,t}\beta}{n_t + V\beta} + \frac{(n_{d,t} + \alpha)n_{w,t}}{n_t + V\beta} \right\} \left\{ \prod_{u \in M^m_w} \max(\lambda, n_{u,t}) \prod_{v \in M^c_w} \frac{1}{\max(\lambda, n_{v,t})} \right\} \quad (7)$$

As explained above, λ controls the "strength" of the prior knowledge term. If λ is large, the prior knowledge has little impact on the conditional probability of topic assignments.

Let's return to the question whether Equation 6 is sparse, allowing efficient computation of Equation 7. Fortunately, $n_{u,t}$ and $n_{v,t}$, which are the topic counts for must-link word u and cannot-link word v, are often sparse. For example, in a 100-topic model trained on the NIPS dataset, 87.2% of word types have fewer than ten topics with nonzero counts. In a 500-topic model trained on a larger dataset like the New York Times News (Sandhaus, 2008), 81.9% of word types have fewer than 50 topics with nonzero counts. Moreover, the model becomes increasingly sparse with additional Gibbs iterations. Figure 1 shows the word frequency histogram of nonzero topic counts of NYT-News dataset.

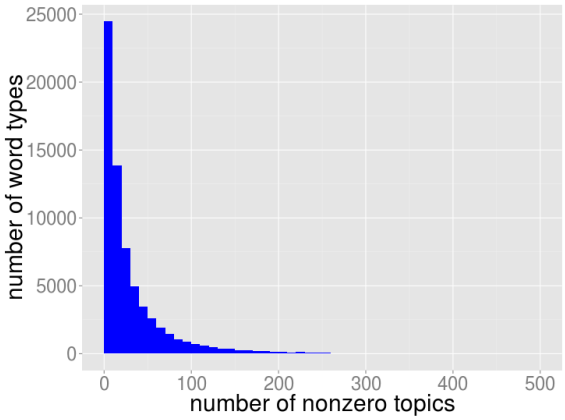

Figure 1: Histogram of nonzero topic counts for word types in NYT-News dataset after inference. 81.9% word types have fewer than 50 topics with nonzero counts. This sparsity allows our sparse constraints to speed inference.

Therefore, the computational cost of Equation 7 can be reduced. SparseLDA efficiently computes the s, r, q bins as in Equation 3. Then for words that are associated with prior knowledge, we update s, r, q with an additional potential term. We only need to compute the potential term for the topics whose counts are greater than λ. The collapsed Gibbs sampling procedure is summarized in Algorithm 1.

Algorithm 1 Gibbs Sampling for word type w in document d, given w's correlation set M_w

1: compute s_t, r_t, q_t with SparseLDA, (see Eq. 3)
2: **for** $t \leftarrow 0$ **to** T **do**
3: update s_t, r_t, q_t. $\forall u \in M_w$ if $n_{u,t} > \lambda$
4: **end for**
5: $p(t) = s_t + r_t + q_t$
6: sample new topic assignment for w from $p(t)$

2.4 Other Types of Prior Knowledge

The factor model framework can also handle other types of prior knowledge, such as document labels, sentence labels, and document link relations. We briefly describe document labels here.

Ramage et al. (2009) propose Labeled-LDA, which improves LDA with document labels. It assumes that there is a one-to-one mapping between topics and labels, and it restricts each document's topics to be sampled only from those allowed by the documents label set. Therefore, Labeled-LDA can be expressed in our model. We define

$$f_m(z, w, d) = \begin{cases} 1, & \text{if } z \in m_d \\ -\infty, & \text{else} \end{cases} \quad (8)$$

where m_d specifies document d's label set converted to corresponding topic labels. Since $f_m(z, w, d)$ is sparse, we can speed up the training as well. Sentence-level prior knowledge (e.g., for sentiment or aspect models (Paul and Girju, 2010)) can be defined in a similar way.

Documents can be associated with other useful metadata. For example, a scientific paper and the prior work it cites might have similar topics (Dietz et al., 2007) or friends in a social network might talk about the same topics (Chang and Blei, 2009). To model link relations, we can use Equation 6 and replace the word-topic counts $n_{v,z}$ with document-topic counts $n_{d,z}$. By doing so, we encourage related documents to have similar topic structures. Moreover, the document-topic count is also sparse, which fits into the efficient learning framework.

Therefore, for different types of prior knowledge, as long as we can define $\psi(\mathbf{z}, M)$ appropriately so that $f(z, w, d)$ are sparse, we are able to speed up learning.

3 Experiments

In this section, we demonstrate the effectiveness of our SC-LDA by comparing it with several baseline methods on three benchmark datasets. We first evaluate the convergence rate of each method and then evaluate the learned model parameter ϕ—the topic-word distribution—in terms of topic coherence. We show that SC-LDA can achieve results comparable to the baseline models but is significantly faster. We set up all experiments on a 8-Core 2.8GHz CPU, 16GB RAM machine.[2]

[2]Our implementation of SC-LDA is available at `https://github.com/yya518/sparse-constrained-lda`.

DATASET	DOCS	TYPE	TOKEN(APPROX)
NIPS	1,500	12,419	1,900,000
NYT-NEWS	3,000,000	102,660	100,000,000
20NG	18,828	21,514	1,946,000

Table 1: Characteristics of benchmark datasets. We use NIPS and NYT for word correlation experiments and 20NG for document label experiments.

3.1 Dataset

We use the NIPS and NYT-News datasets from the UCI bag of words data collections.[3] These two datasets have no document labels, and we use them for word correlation experiments. We also use the 20Newsgroup (20NG) dataset,[4] which has document labels, for document label experiments. Table 1 shows the characteristics of each dataset. Since NIPS and NYT-News have already been preprocessed, to ensure repeatability, we use the data "as they are" from the sources. For 20NG, we perform tokenization and stopword removal using Mallet (McCallum, 2002) and remove words that appear fewer than 10 times.

3.2 Prior Knowledge Generation

Word Correlation Prior Knowledge Previous work proposes two methods to automatically generate prior word correlation knowledge from external sources. Hu and Boyd-Graber (2012) use WordNet 3.0 to obtain synsets for word types, and then if a synset is also in the vocabulary, they add a must-link correlation between the word type and the synset. Xie et al. (2015) use a different method that takes advantage of an existing pretrained word embedding. Each word embedding is a real-valued vector capturing the word's semantic meaning based on distributional similarity. If the similarity between the embeddings of two word types in the vocabulary exceeds a threshold, they generate a must-link between the two words.

In our experiments, we adopt a hybrid method that combines the above two methods. For a noun word type, we first obtain its synsets from WordNet 3.0. We also obtain the embeddings of each word from word2vec (Mikolov et al., 2013). If the synset is also in the vocabulary, and the similarity between the synset and the word is higher than a threshold, which in our experiment is 0.2, we generate a must-link between thee words. Empir-

[3]https://archive.ics.uci.edu/ml/datasets/Bag+of+Words

[4]http://qwone.com/ jason/20Newsgroups/

ically, this hybrid method is able to obtain high quality correlated words. For example, for the NIPS dataset, the must-links we obtain for *randomness* are {noise, entropy, stochasticity}.

Document Label Prior Knowledge Since documents in the 20NG dataset are associated with labels, we use the labels directly as prior knowledge.

3.3 Baselines

The baseline methods for incorporating word correlation prior knowledge in our experiments are as follows:

DF-LDA: incorporates word must-links and cannot-links using a Dirichlet Forest prior in LDA (Andrzejewski et al., 2009). Here we use Hu and Boyd-Graber (2012)'s efficient implementation *FAST-RB-SDW* for DF-LDA.

Logic-LDA: encodes general domain knowledge as first-order logic and incorporates it in LDA (Andrzejewski et al., 2011). Logic-LDA has been used for word correlations and document label knowledge.

MRF-LDA: encodes word correlations in LDA as a Markov random field (Xie et al., 2015).

We also use Mallet's SparseLDA implementation for vanilla LDA in the topic coherence experiment. We use a symmetric Dirichlet prior for all models. We set $\alpha = 1.0$, $\beta = 0.01$. For DF-LDA, $\eta = 100$. For Logic-LDA, we use the default parameter setting in the package: a sample rate of 1.0 and step rate of 10.0. For MRF-LDA, we use the default setting with $\gamma = 1.0$. (Parameter semantics can be found in the original papers.)

3.4 Convergence

The main advantage of our method over other existing methods is efficiency. In this experiment, we show the change of our model's log likelihood over time. In topic models, the log likelihood change is a good indicator of whether a model has converged or not. Figure 2 shows the log likelihood change over time for SC-LDA and three baseline methods on NIPS and NYT-News dataset. SC-LDA converges faster than all the other methods.

We also conduct experiments on SC-LDA with varying numbers of word correlations. Table 2 shows the Gibbs sampling iteration time on the 1st, 50th, 100th and the 200th iteration. We also incorporate different numbers of word correlations

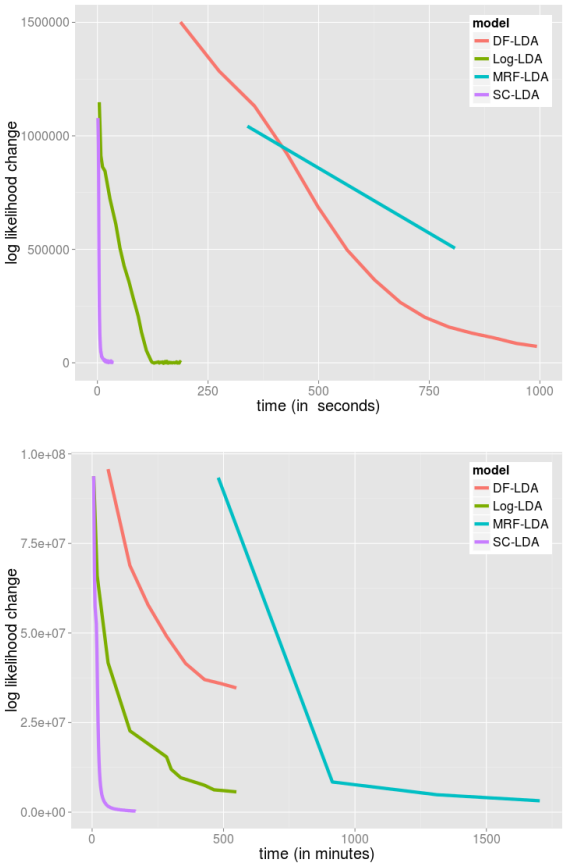

Figure 2: Models' log likelihood convergence on NIPS dataset (above) and NYT-News dataset (below). For NIPS, a 100-topic model with 100 must-links is trained. For NYT-News, a 500-topic model with 100 must-links is trained. SC-LDA reaches likelihood convergence much more rapidly than the other methods.

	# Word Correlations			
round	C0	C100	C500	C1000
1st iteration	2.02	2.14	2.30	2.50
50th iteration	0.53	0.56	0.58	0.62
100th iteration	0.48	0.50	0.53	0.56
200th iteration	0.48	0.49	0.52	0.56

Table 2: SC-LDA runtime (in seconds) in the 1st, 50th, 100th, and 200th iteration with different numbers of correlations.

in SC-LDA. SC-LDA runs faster as sampling proceeds as the sparsity increases, but additional correlations slow the model.

3.5 Topic Coherence

Topic models are often evaluated using perplexity on held-out test data, but this evaluation is of-

ten at odds with human evaluations (Chang et al., 2009). Following Mimno et al. (2011), we employ Topic Coherence—a metric that is consistent with human judgment—to measure a topic model's quality. Topic t's coherence is defined as $C(t : V^{(t)}) = \sum_{m=2}^{M} \sum_{l=1}^{m-1} \log \frac{F(v_m^{(t)}, v_l^{(t)}) + \epsilon}{F(v_l^{(t)})}$, where $F(v)$ is the document frequency of word type v, $F(v, v')$ is the co-document frequency of word type v and v', and $V^{(t)} = (v_1^{(t)}, ..., v_M^{(t)})$ is a list of the M most probable words in topic t. In our experiments, we choose the ten words with highest probability in the topic to compute topic coherence, i.e., $M = 10$. Mimno et al. (2011) use $\epsilon = 1$, but Röder et al. (2015) show smaller ϵ (such as 10^{-12}) improves coherence stability, so we set $\epsilon = 10^{-12}$. Larger topic coherence scores imply more coherent topics.

We train a 500-topic model on the NIPS dataset with different methods and compare the average topic coherence score and the average of the top twenty topic coherence scores. Since the topics learned by topic model often contain "bad" topics (Mimno et al., 2011) which do not make sense to end users, evaluating the top twenty topics reflects the model's performance. We let each model train for one hour. Figure 3 shows the topic coherence of each method. SC-LDA has about the same average topic coherence with LDA but has higher coherence score (-36.6) for the top 20 topics than LDA (-39.1). This is because incorporating word correlation knowledge encourages correlated words to have high probability under the same topic, thus improving the coherence score. For the other methods, however, because they cannot converge within an hour, their topic coherence scores are much worse than SC-LDA and LDA. This again demonstrates the efficiency of SC-LDA over other baselines.

3.6 Document Label Prior Knowledge

SC-LDA can also handle other types of prior knowledge. We compare it with Labeled-LDA (Ramage et al., 2009). Labeled-LDA also uses Gibbs sampling for inference, allowing direct computation time comparisons.

Table 3 shows the average running time per iteration for Labeled-LDA and SC-LDA. Because document labels apply sparsity to the document-topic counts, the average running time per iteration decreases as the number of labeled document increases. SC-LDA exhibits greater speedup with more topics; when $T = 500$,[5] SC-LDA runs more than ten times faster than Labeled-LDA.

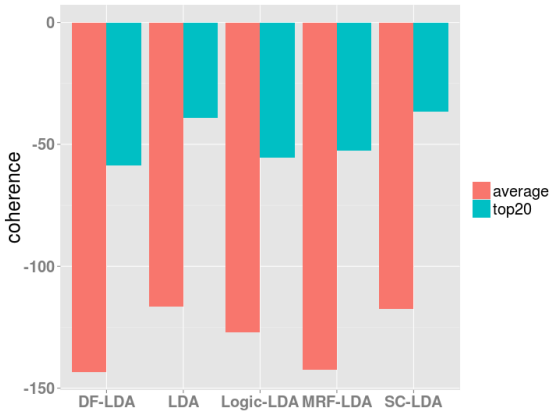

Figure 3: Average topic coherence and average top 20 topic coherence. The models are trained on NIPS dataset with 500-topic and 100 word correlations. SC-LDA achieves higher topic coherence than other methods.

# Topics				
	T50	T100	T200	T500
Labeled-LDA	0.93	1.89	3.60	8.05
SC-LDA	0.38	0.45	0.51	0.72
# Labeled Documents				
	C500	C1000	C2000	C5000
Labeled-LDA	1.95	1.88	1.75	1.48
SC-LDA	0.51	0.45	0.41	0.31

Table 3: The average running time per iteration over 100 iterations, averaged over 5 seeds, on 20NG dataset. Experiments begin with 100 topics, 1000 labeled documents, and then vary one dimension: number of topics (top), or number of labeled documents (bottom).

4 Related Work

This works brings together two lines of research: incorporating rich knowledge into probabilistic models and efficient inference of probabilistic models on large datasets. Both are common areas of interest across many machine learning formalisms: probabilistic logic (Bach et al., 2015), graph algorithms (Low et al., 2012), and probabilistic grammars (Cohen et al., 2008). However, our focus in this paper is the intersection of these lines of research with topic models.

[5]For 20NG dataset, it may overfit the data with 500 topics, but here we use it to demonstrate the scalability.

Adding knowledge and metadata to topic models makes the models richer, more understandable, and more domain-specific. A common distinction is upstream (conditioning on metadata) vs. downstream models (conditioning on variables already present in a topic model to predict metadata) (Mimno et al., 2008). Downstream models are typically better at prediction tasks such as predicting sentiment (Blei and McAuliffe, 2007), ideology (Nguyen et al., 2014a), or links in a social network (Chang and Blei, 2009). In contrast, our approach—an upstream model—is often easier to implement and leads to more interpretable topics. Upstream models at the document level have been used to understand the labels in large document collections (Ramage et al., 2009; Nguyen et al., 2014b) and capture relationships in document networks using Markov random fields (Daumé III, 2009). At the word level, Xie et al. (2015) incorporate word correlation to LDA by building a Markov Random Field regularization, similar to Newman et al. (2011), who use regularization to improve topic coherence. However, despite these exciting applications, the experiments in the above work are typically on small datasets.

In contrast, there is a huge interest in improving the scalability of topic models to large numbers of documents, numbers of topics, and vocabularies. Attempts to scale inference for topic models have started from both variational inference and Gibbs sampling—two popular learning inference techniques for topic modeling. Gibbs sampling is a popular technique because of its simplicitly and low latency. However, for large numbers of topics, Gibbs sampling can become unwieldy. Porteous et al. (2008) address this issue by creating an upper bound approximation that produces accurate results, while SparseLDA (Yao et al., 2009) present an effective factorization that speeds inference without sacrificing accuracy. Just as our model builds on SparseLDA's insights, SparseLDA has been incorporated into commercial deployments (Wang et al., 2014) and improved using alias tables (Li et al., 2014). Yuan et al. (2015) also presents an efficient constant time sampling algorithm for building big topic models. Variational inference can easily be parallelized (Nallapati et al., 2007; Zhai et al., 2012), but has high latency, which has been addressed by performing online updates (Hoffman et al., 2010) and taking stochastic gradients estimated by MCMC inference (Mimno et al., 2012). In this paper, we only focus on single-processor learning, but existing parallelization techniques (Newman et al., 2009) are applicable to our model.

At the intersection lies models that improve the scalability of upstream topic model inference. In addition to our SC-LDA, Hu and Boyd-Graber (2012) speed Gibbs sampling in tree-based topic models using SparseLDA's factorization strategy, and Hu et al. (2014) extend this approach by parallelizing global parameter updates using variational inference. Our work is more general (also encompassing document-based constraints) and is faster. In contrast to these upstream models, Zhu et al. (2013) and Nguyen et al. (2015) improve inference of downstream models.

5 Conclusion

We present a factor graph framework for incorporating prior knowledge into topic models. By expressing the prior knowledge as sparse constraints on the hidden topic variables, we are able to take advantage of the sparsity to speed up training. We demonstrate in experiments that our model runs significantly faster than the other alternative models and achieves comparable performance in terms of topic coherence. Efficient algorithms for incorporating prior knowledge with large topic models will benefit several downstream applications. For example, interactive topic modeling becomes feasible because fast model updates reduce the user's waiting time and thus improve the user experience. Personalized topic modeling is also an interesting future direction in which the model will generate a personalized topic structure based on the user's preferences or interests. For all these applications, an efficient learning algorithm is a crucial prerequisite.

Abstract

Path queries on a knowledge graph can be used to answer compositional questions such as "*What languages are spoken by people living in Lisbon?*". However, knowledge graphs often have missing facts (edges) which disrupts path queries. Recent models for knowledge base completion impute missing facts by embedding knowledge graphs in vector spaces. We show that these models can be recursively applied to answer path queries, but that they suffer from cascading errors. This motivates a new "compositional" training objective, which dramatically improves all models' ability to answer path queries, in some cases more than doubling accuracy. On a standard knowledge base completion task, we also demonstrate that compositional training acts as a novel form of structural regularization, reliably improving performance across all base models (reducing errors by up to 43%) and achieving new state-of-the-art results.

1 Introduction

Broad-coverage knowledge bases such as Freebase (Bollacker et al., 2008) support a rich array of reasoning and question answering applications, but they are known to suffer from incomplete coverage (Min et al., 2013). For example, as of May 2015, Freebase has an entity Tad Lincoln (Abraham Lincoln's son), but does not have his ethnicity. An elegant solution to incompleteness is using vector space representations: Controlling the dimensionality of the vector space forces generalization to new facts (Nickel et al., 2011; Nickel et al., 2012; Socher et al., 2013; Riedel et al., 2013; Neelakantan et al., 2015). In the example, we would hope to infer Tad's ethnicity from the ethnicity of his parents.

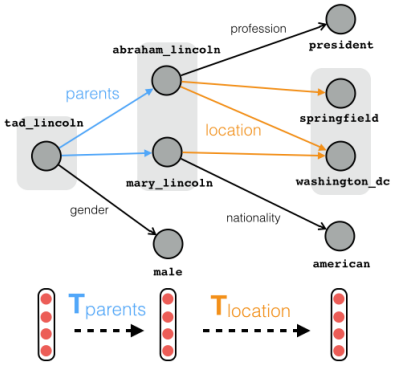

Figure 1: We propose performing path queries such as `tad_lincoln/parents/location` ("*Where are Tad Lincoln's parents located?*") in a parallel low-dimensional vector space. Here, entity sets (boxed) are represented as real vectors, and edge traversal is driven by vector-to-vector transformations (e.g., matrix multiplication).

However, what is missing from these vector space models is the original strength of knowledge bases: the ability to support compositional queries (Ullman, 1985). For example, we might ask what the ethnicity of Abraham Lincoln's daughter would be. This can be formulated as a path query on the knowledge graph, and we would like a method that can answer this efficiently, while generalizing over missing facts and even missing or hypothetical entities (Abraham Lincoln did not in fact have a daughter).

In this paper, we present a scheme to answer path queries on knowledge bases by "compositionalizing" a broad class of vector space models that have been used for knowledge base completion (see Figure 1). At a high level, we interpret the base vector space model as implementing a soft edge traversal operator. This operator can then be recursively applied to predict paths. Our interpretation suggests a new *compositional training* objective that encourages better modeling of

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 318–327,
Lisbon, Portugal, 17-21 September 2015.

paths. Our technique is applicable to a broad class of *composable* models that includes the bilinear model (Nickel et al., 2011) and TransE (Bordes et al., 2013).

We have two key empirical findings: First, we show that compositional training enables us to answer path queries up to at least length 5 by substantially reducing cascading errors present in the base vector space model. Second, we find that somewhat surprisingly, compositional training also improves upon state-of-the-art performance for knowledge base completion, which is a special case of answering unit length path queries. Therefore, compositional training can also be seen as a new form of structural regularization for existing models.

2 Task

We now give a formal definition of the task of answering path queries on a knowledge base. Let $\mathcal{E}$ be a set of entities and $\mathcal{R}$ be a set of binary relations. A knowledge graph $\mathcal{G}$ is defined as a set of triples of the form (s, r, t) where $s, t \in \mathcal{E}$ and $r \in \mathcal{R}$. An example of a triple in Freebase is $(\texttt{tad\_lincoln}, \texttt{parents}, \texttt{abraham\_lincoln})$.

A path query q consists of an initial *anchor entity,* s, followed by a sequence of relations to be traversed, $p = (r_1, \ldots, r_k)$. The answer or denotation of the query, $[\![q]\!]$, is the set of all entities that can be reached from s by traversing p. Formally, this can be defined recursively:

$$[\![s]\!] \stackrel{\text{def}}{=} \{s\}, \tag{1}$$

$$[\![q/r]\!] \stackrel{\text{def}}{=} \{t : \exists s \in [\![q]\!], (s, r, t) \in \mathcal{G}\}. \tag{2}$$

For example, `tad_lincoln/parents/location` is a query q that asks: "*Where did Tad Lincoln's parents live?*".

For evaluation (see Section 5 for details), we define the set of candidate answers to a query $\mathcal{C}(q)$ as the set of all entities that "type match", namely those that participate in the final relation of q at least once; and let $\mathcal{N}(q)$ be the incorrect answers:

$$\mathcal{C}\left(s/r_1/\cdots/r_k\right) \stackrel{\text{def}}{=} \{t \mid \exists e, (e, r_k, t) \in \mathcal{G}\} \tag{3}$$

$$\mathcal{N}\left(q\right) \stackrel{\text{def}}{=} \mathcal{C}\left(q\right) \setminus [\![q]\!]. \tag{4}$$

Knowledge base completion. Knowledge base completion (KBC) is the task of predicting whether a given edge (s, r, t) belongs in the graph or not. This can be formulated as a path query $q = s/r$ with candidate answer t.

3 Compositionalization

In this section, we show how to compositionalize existing KBC models to answer path queries. We start with a motivating example in Section 3.1, then present the general technique in Section 3.2. This suggests a new compositional training objective, described in Section 3.3. Finally, we illustrate the technique for several more models in Section 3.4, which we use in our experiments.

3.1 Example

A common vector space model for knowledge base completion is the *bilinear model* (Nickel et al., 2011). In this model, we learn a vector $x_e \in \mathbb{R}^d$ for each entity $e \in \mathcal{E}$ and a matrix $W_r \in \mathbb{R}^{d \times d}$ for each relation $r \in \mathcal{R}$. Given a query s/r (asking for the set of entities connected to s via relation r), the bilinear model scores how likely $t \in [\![s/r]\!]$ holds using

$$\text{score}(s/r, t) = x_s^\top W_r x_t. \tag{5}$$

To motivate our compositionalization technique, take $d = |\mathcal{E}|$ and suppose W_r is the adjacency matrix for relation r and entity vector x_e is the indicator vector with a 1 in the entry corresponding to entity e. Then, to answer a path query $q = s/r_1/\ldots/r_k$, we would then compute

$$\text{score}(q, t) = x_s^\top W_{r_1} \ldots W_{r_k} x_t. \tag{6}$$

It is easy to verify that the score counts the number of unique paths between s and t following relations $r_1/\ldots/r_k$. Hence, any t with positive score is a correct answer ($[\![q]\!] = \{t : \text{score}(q, t) > 0\}$).

Let us interpret (6) recursively. The model begins with an entity vector x_s, and sequentially applies *traversal operators* $\mathbb{T}_{r_i}(v) = v^\top W_{r_i}$ for each r_i. Each traversal operation results in a new "set vector" representing the entities reached at that point in traversal (corresponding to the nonzero entries of the set vector). Finally, it applies the *membership operator* $\mathbb{M}(v, x_t) = v^\top x_t$ to check if $t \in [\![s/r_1/\ldots/r_k]\!]$. Writing graph traversal in this way immediately suggests a useful generalization: take d much smaller than $|\mathcal{E}|$ and learn the parameters W_r and x_e.

3.2 General technique

The strategy used to extend the bilinear model of (5) to the compositional model in (6) can be applied to any *composable* model: namely, one that

has a scoring function of the form:

$$\text{score}(s/r, t) = \mathbb{M}(\mathbb{T}_r(x_s), x_t) \tag{7}$$

for some choice of membership operator $\mathbb{M} : \mathbb{R}^d \times \mathbb{R}^d \to \mathbb{R}$ and traversal operator $\mathbb{T}_r : \mathbb{R}^d \to \mathbb{R}^d$.

We can now define the *vector denotation* of a query $[\![q]\!]_{\text{V}}$ analogous to the definition of $[\![q]\!]$ in (1) and (2):

$$[\![s]\!]_{\text{V}} \stackrel{\text{def}}{=} x_s, \tag{8}$$

$$[\![q/r]\!]_{\text{V}} \stackrel{\text{def}}{=} \mathbb{T}_r\left([\![q]\!]_{\text{V}}\right). \tag{9}$$

The score function for a compositionalized model is then

$$\text{score}(q, t) = \mathbb{M}([\![q]\!]_{\text{V}}, [\![t]\!]_{\text{V}}). \tag{10}$$

We would like $[\![q]\!]_{\text{V}}$ to approximately represent the set $[\![q]\!]$ in the sense that for every $e \in [\![q]\!]$, $\mathbb{M}\left([\![q]\!]_{\text{V}}, [\![e]\!]_{\text{V}}\right)$ is larger than the values for $e \notin [\![q]\!]$. Of course it is not possible to represent all sets perfectly, but in the next section, we present a training objective that explicitly optimizes $\mathbb{T}$ and $\mathbb{M}$ to preserve path information.

3.3 Compositional training

The score function in (10) naturally suggests a new compositional training objective. Let $\{(q_i, t_i)\}_{i=1}^N$ denote a set of path query training examples with path lengths ranging from 1 to L. We minimize the following max-margin objective:

$$J(\Theta) = \sum_{i=1}^{N} \sum_{t' \in \mathcal{N}(q_i)} \left[1 - \text{margin}(q_i, t_i, t')\right]_+,$$

$$\text{margin}(q, t, t') = \text{score}(q, t) - \text{score}(q, t'),$$

where the parameters are the membership operator, the traversal operators, and the entity vectors:

$$\Theta = \{\mathbb{M}\} \cup \{\mathbb{T}_r : r \in \mathcal{R}\} \cup \left\{x_e \in \mathbb{R}^d : e \in \mathcal{E}\right\}.$$

This objective encourages the construction of "set vectors": because there are path queries of different lengths and types, the model must learn to produce an accurate set vector $[\![q]\!]_{\text{V}}$ after any sequence of traversals. Another perspective is that each traversal operator is trained such that its transformation preserves information in the set vector which might be needed in subsequent traversal steps.

In contrast, previously proposed training objectives for knowledge base completion only train on queries of path length 1. We will refer to this special case as *single-edge training*.

In Section 5, we show that compositional training leads to substantially better results for both path query answering and knowledge base completion. In Section 6, we provide insight into why.

3.4 Other composable models

There are many possible candidates for $\mathbb{T}$ and $\mathbb{M}$. For example, $\mathbb{T}$ could be one's favorite neural network mapping from $\mathbb{R}^d$ to $\mathbb{R}^d$. Here, we focus on two composable models that were both recently shown to achieve state-of-the-art performance on knowledge base completion.

TransE. The TransE model of Bordes et al. (2013) uses the scoring function

$$\text{score}(s/r, t) = -\|x_s + w_r - x_t\|_2^2. \tag{11}$$

where x_s, w_r and x_t are all d-dimensional vectors.

In this case, the model can be expressed using membership operator

$$\mathbb{M}(v, x_t) = -\|v - x_t\|_2^2 \tag{12}$$

and traversal operator $\mathbb{T}_r(x_s) = x_s + w_r$. Hence, TransE can handle a path query $q = s/r_1/r_2/\cdots/r_k$ using

$$\text{score}(q, t) = -\|x_s + w_{r_1} + \cdots + w_{r_k} - x_t\|_2^2.$$

We visualize the compositional TransE model in Figure 2.

Bilinear-Diag. The Bilinear-Diag model of Yang et al. (2015) is a special case of the bilinear model with the relation matrices constrained to be diagonal. Alternatively, the model can be viewed as a variant of TransE with multiplicative interactions between entity and relation vectors.

Not all models can be compositionalized. It is important to point out that some models are not naturally composable—for example, the latent feature model of Riedel et al. (2013) and the neural tensor network of Socher et al. (2013). These approaches have scoring functions which combine s, r and t in a way that does not involve an intermediate vector representing s/r alone without t, so they do not decompose according to (7).

	Test	46,577	109,557

Table 1: WordNet and Freebase statistics for base and path query datasets.

3.5 Implementation

We use AdaGrad (Duchi et al., 2010) to optimize $J(\Theta)$, which is in general non-convex. Initialization scale, mini-batch size and step size were cross-validated for all models. We initialize all parameters with i.i.d. Gaussians of variance 0.1 in every entry, use a mini-batch size of 300 examples, and a step size in $[0.001, 0.1]$ (chosen via cross-validation) for all of the models. For each example q, we sample 10 negative entities $t' \in \mathcal{N}(q)$. During training, all of the entity vectors are constrained to lie on the unit ball, and we clipped the gradients to the median of the observed gradients if the update exceeded 3 times the median.

We first train on path queries of length 1 until convergence and then train on all path queries until convergence. This guarantees that the model masters basic edges before composing them to form paths. When training on path queries, we explicitly parameterize inverse relations. For the bilinear model, we initialize $W_{r^{-1}}$ with $W_r^\top$. For TransE, we initialize $w_{r^{-1}}$ with $-w_r$. For Bilinear-Diag, we found initializing $w_{r^{-1}}$ with the exact inverse $1/w_r$ is numerically unstable, so we instead randomly initialize $w_{r^{-1}}$ with i.i.d Gaussians of variance 0.1 in every entry. Additionally, for the bilinear model, we replaced the sum over $\mathcal{N}(q_i)$ in the objective with a max since it yielded slightly higher accuracy. Our models are implemented using Theano (Bastien et al., 2012; Bergstra et al., 2010).

4 Datasets

In Section 4.1, we describe two standard knowledge base completion datasets. These consist of single-edge queries, so we call them *base datasets*. In Section 4.2, we generate path query datasets from these base datasets.

4.1 Base datasets

Our experiments are conducted using the subsets of WordNet and Freebase from Socher et al. (2013). The statistics of these datasets and their splits are given in Table 1.

The WordNet and Freebase subsets exhibit substantial differences that can influence model performance. The Freebase subset is almost bipartite with most of the edges taking the form (s, r, t) for some *person* s, relation r and property t. In WordNet, both the source and target entities are arbitrary words.

Both the raw WordNet and Freebase contain many relations that are almost perfectly correlated with an inverse relation. For example, WordNet contains both `has_part` and `part_of`, and Freebase contains both `parents` and `children`. At test time, a query on an edge (s, r, t) is easy to answer if the inverse triple (t, r^{-1}, s) was observed in the training set. Following Socher et al. (2013), we account for this by excluding such "trivial" queries from the test set.

4.2 Path query datasets

Given a base knowledge graph, we generate path queries by performing random walks on the graph. If we view compositional training as a form of regularization, this approach allows us to generate extremely large amounts of auxiliary training data. The procedure is given below.

Let $\mathcal{G}_{\text{train}}$ be the training graph, which consists only of the edges in the training set of the base dataset. We then repeatedly generate training examples with the following procedure:

1. Uniformly sample a path length $L \in \{1, \ldots, L_{\max}\}$, and uniformly sample a starting entity $s \in \mathcal{E}$.

2. Perform a random walk beginning at entity s and continuing L steps.

   (a) At step i of the walk, choose a relation r_i uniformly from the set of relations incident on the current entity e.

   (b) Choose the next entity uniformly from the set of entities reachable via r_i.

3. Output a query-answer pair, (q, t), where $q = s/r_1/\cdots/r_L$ and t is the final entity of the random walk.

In practice, we do not sample paths of length 1 and instead directly add all of the edges from $\mathcal{G}_{\text{train}}$ to the path query dataset.

To generate a path query test set, we repeat the above procedure except using the graph $\mathcal{G}_{\text{full}}$, which is $\mathcal{G}_{\text{train}}$ plus all of the test edges from the base dataset. Then we remove any queries from the test set that also appeared in the training set. The statistics for the path query datasets are presented in Table 1.

5 Main results

We evaluate the models derived in Section 3 on two tasks: path query answering and knowledge base completion. On both tasks, we show that the compositional training strategy proposed in Section 3.3 leads to substantial performance gains over standard single-edge training. We also compare directly against the KBC results of Socher et al. (2013), demonstrating that previously inferior models now match or outperform state-of-the-art models after compositional training.

Evaluation metric. Numerous metrics have been used to evaluate knowledge base queries, including hits at 10 (percentage of correct answers ranked in the top 10) and mean rank. We evaluate on hits at 10, as well as a normalized version of mean rank, *mean quantile*, which better accounts for the total number of candidates. For a query q, the quantile of a correct answer t is the fraction of incorrect answers ranked after t:

$$\frac{|\{t' \in \mathcal{N}(q) : \text{score}(q, t') < \text{score}(q, t)\}|}{|\mathcal{N}(q)|} \quad (13)$$

The quantile ranges from 0 to 1, with 1 being optimal. Mean quantile is then defined to be the average quantile score over all examples in the dataset. To illustrate why normalization is important, consider a set of queries on the relation `gender`. A model that predicts the incorrect gender on every query would receive a mean rank of 2 (since there are only 2 candidate answers), which is fairly good in absolute terms, whereas the mean quantile would be 0, rightfully penalizing the model.

As a final note, several of the queries in the Freebase path dataset are "type-match trivial" in the sense that all of the type matching candidates $\mathcal{C}(q)$ are correct answers to the query. In this case, mean quantile is undefined and we exclude such queries from evaluation.

Overview. The upper half of Table 2 shows that compositional training improves path querying performance across all models and metrics on both datasets, reducing error by up to 76.2%.

The lower half of Table 2 shows that surprisingly, compositional training also improves performance on knowledge base completion across almost all models, metrics and datasets. On WordNet, TransE benefits the most, with a 43.3% reduction in error. On Freebase, Bilinear benefits the most, with a 38.8% reduction in error.

In terms of mean quantile, the best overall model is TransE (COMP). In terms of hits at 10, the best model on WordNet is Bilinear (COMP), while the best model on Freebase is TransE (COMP).

Deduction and Induction. Table 3 takes a deeper look at performance on path query answering. We divided path queries into two subsets: *deduction* and *induction*. The *deduction* subset consists of queries $q = s/p$ where the source and target entities $[\![q]\!]$ are connected via relations p in the training graph $\mathcal{G}_{\text{train}}$, but the specific query q was never seen during training. Such queries can be answered by performing explicit traversal on the training graph, so this subset tests a model's ability to approximate the underlying training graph and predict the existence of a path from a collection of single edges. The *induction* subset consists of all other queries. This means that at least one edge was missing on all paths following p from source to target in the training graph. Hence, this subset tests a model's generalization ability and its robustness to missing edges.

Performance on the *deduction* subset of the dataset is disappointingly low for models trained with single-edge training: they struggle to answer path queries even when *all edges in the path query have been seen at training time.* Compositional training dramatically reduces these errors, sometimes doubling mean quantile. In Section 6, we analyze how this might be possible. After compositional training, performance on the harder *induction* subset is also much stronger. Even when edges are missing along a path, the models are able to infer them.

Interpretable queries. Although our path datasets consists of random queries, both datasets contain a large number of useful, interpretable queries. Results on a few illustrative examples are shown in Table 4.

Table 2: **Path query answering and knowledge base completion.** We compare the performance of single-edge training (SINGLE) vs compositional training (COMP). MQ: mean quantile, H@10: hits at 10, %red: percentage reduction in error.

Interpretable Queries	Bilinear SINGLE	Bilinear COMP
`X/institution/institution`$^{-1}$`/profession`	50.0	**93.6**
`X/parents/religion`	81.9	**97.1**
`X/nationality/nationality`$^{-1}$`/ethnicity`$^{-1}$	68.0	**87.0**
`X/has_part/has_instance`$^{-1}$	92.6	**95.1**
`X/type_of/type_of/type_of`	72.8	**79.4**

Table 4: Path query performance (mean quantile) on a selection of interpretable queries. We compare Bilinear SINGLE and Bilinear COMP. Meanings of each query (descending): "What professions are there at X's institution?"; "What is the religion of X's parents?"; "What are the ethnicities of people from the same country as X?"; "What types of parts does X have?"; and the transitive "What is X a type of?". (Note that a relation r and its inverse r^{-1} do not necessarily cancel out if r is not a one-to-one mapping. For example, `X/institution/institution`$^{-1}$ denotes the set of all people who work at the institution X works at, which is not just X.)

Path query task		**WordNet**		**Freebase**	
		Ded.	Ind.	Ded.	Ind.
Bilinear	SINGLE	96.9	66.0	49.3	49.4
	COMP	**98.9**	**75.6**	**82.1**	**70.6**
Bi-Diag	SINGLE	56.3	51.6	49.3	50.2
	COMP	**98.5**	**78.2**	**84.5**	**72.8**
TransE	SINGLE	92.6	71.7	85.3	72.4
	COMP	**99.0**	**87.4**	**87.5**	**76.3**

Table 3: **Deduction and induction.** We compare mean quantile performance of single-edge training (SINGLE) vs compositional training (COMP). Length 1 queries are excluded.

Comparison with Socher et al. (2013). Here, we measure performance on the KBC task in terms of the accuracy metric of Socher et al. (2013). This evaluation involves sampled negatives, and is hence noisier than mean quantile, but makes our results directly comparable to Socher et al. (2013). Our results show that previously inferior models such as the bilinear model can outperform state-of-the-art models after compositional training.

Socher et al. (2013) proposed parametrizing each entity vector as the average of vectors of words in the entity ($w_{\texttt{tad\_lincoln}} = \frac{1}{2}(w_{\texttt{tad}} + w_{\texttt{lincoln}})$, and pretraining these word vectors using the method of Turian et al. (2010). Table 5 reports results when using this approach in conjunction with compositional training. We initialized all models with word vectors from Pennington et al. (2014). We found that compositionally trained models outperform the neural tensor network (NTN) on WordNet, while being only slightly behind on Freebase. (We did not use word vectors in any of our other experiments.)

When the strategy of averaging word vectors to form entity vectors is not applied, our compositional models are significantly better on WordNet and slightly better on Freebase. It is worth noting that in many domains, entity names are not lexically meaningful, so word vector averaging is not

Accuracy	WordNet		Freebase	
	EV	WV	EV	WV
NTN	70.6	86.2	87.2	**90.0**
Bilinear COMP	77.6	**87.6**	86.1	89.4
TransE COMP	**80.3**	84.9	**87.6**	89.6

Table 5: Model performance in terms of accuracy. EV: entity vectors are separate (initialized randomly); WV: entity vectors are average of word vectors (initialized with pretrained word vectors).

always meaningful.

6 Analysis

In this section, we try to understand why compositional training is effective. For concreteness, everything is described in terms of the bilinear model. We will refer to the compositionally trained model as COMP, and the model trained with single-edge training as SINGLE.

6.1 Why does compositional training improve path query answering?

It is tempting to think that if SINGLE has accurately modeled individual edges in a graph, it should accurately model the paths that result from those edges. This intuition turns out to be incorrect, as revealed by SINGLE's relatively weak performance on the path query dataset. We hypothesize that this is due to cascading errors along the path. For a given edge (s, r, t) on the path, single-edge training encourages x_t to be closer to $x_s^\top W_r$ than any other incorrect $x_{t'}$. However, once this is achieved by a margin of 1, it does not push x_t any closer to $x_s^\top W_r$. The remaining discrepancy is noise which gets added at each step of path traversal. This is illustrated schematically in Figure 2.

To observe this phenomenon empirically, we examine how well a model handles each *intermediate* step of a path query. We can do this by measuring the *reconstruction quality* (RQ) of the set vector produced after each traversal operation. Since each intermediate stage is itself a valid path query, we define RQ to be the average quantile over all entities that belong in $[\![q]\!]$:

$$\text{RQ}(q) = \frac{1}{|[\![q]\!]|} \sum_{t \in [\![q]\!]} \text{quantile}(q, t) \qquad (14)$$

When all entities in $[\![q]\!]$ are ranked above all incorrect entities, RQ is 1. In Figure 3, we illustrate how RQ changes over the course of a query.

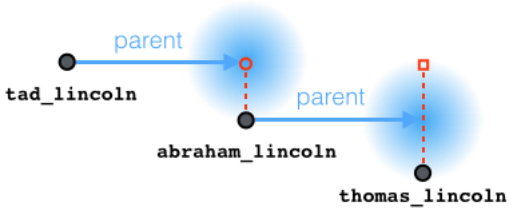

Figure 2: **Cascading errors visualized for TransE.** Each node represents the position of an entity in vector space. The relation `parent` is ideally a simple horizontal translation, but each traversal introduces noise. The red circle is where we expect Tad's parent to be. The red square is where we expect Tad's grandparent to be. Dotted red lines show that error grows larger as we traverse farther away from Tad. Compositional training pulls the entity vectors closer to the ideal arrangement.

Given the nature of cascading errors, it might seem reasonable to address the problem by adding a term to our objective which explicitly encourages $x_s^\top W_r$ to be as close as possible to x_t. With this motivation, we tried adding $\lambda \|x_s^\top W_r - x_t\|_2^2$ term to the objective of the bilinear model and a $\lambda \|x_s + w_r - x_t\|_2^2$ term to the objective of TransE. We experimented with different settings of λ over the range $[0.001, 100]$. In no case did this additional ℓ_2 term improve SINGLE's performance on the path query or single edge dataset. These results suggest that compositional training is a more effective way to combat cascading errors.

6.2 Why does compositional training improve knowledge base completion?

Table 2 reveals that COMP also performs better on the single-edge task of knowledge base completion. This is somewhat surprising, since SINGLE is trained on a training set which distributionally matches the test set, whereas COMP is not. However, COMP's better performance on path queries suggests that there must be another factor at play. At a high level, training on paths must be providing some form of structural regularization which reduces cascading errors. Indeed, paths in a knowledge graph have proven to be important features for predicting the existence of single edges (Lao et al., 2011; Neelakantan et al., 2015). For example, consider the following Horn clause:

$$\text{parents}(x, y) \wedge \text{location}(y, z) \Rightarrow \text{place\_of\_birth}(x, z),$$

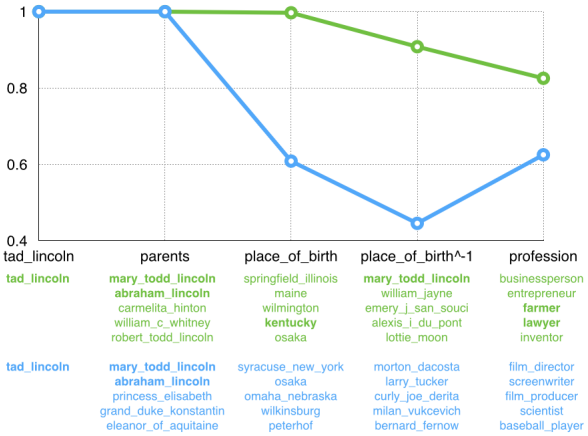

Figure 3: Reconstruction quality (RQ) at each step of the query `tad_lincoln/parents/place_of_birth/place_of_birth`$^{-1}$`/profession`. COMP experiences significantly less degradation in RQ as path length increases. Correspondingly, the set of 5 highest scoring entities computed at each step using COMP (green) is significiantly more accurate than the set given by SINGLE (blue). Correct entities are bolded.

which states that if x has a parent with location z, then x has place of birth z. The body of the Horn clause expresses a path from x to z. If COMP models the path better, then it should be better able to use that knowledge to infer the head of the Horn clause.

More generally, consider Horn clauses of the form $p \Rightarrow r$, where $p = r_1/\ldots/r_k$ is a path type and r is the relation being predicted. Let us focus on Horn clauses with high precision as defined by:

$$\text{prec}(p) = \frac{|[\![p]\!] \cap [\![r]\!]|}{|[\![p]\!]|}, \tag{15}$$

where $[\![p]\!]$ is the set of entity pairs connected by p, and similarly for $[\![r]\!]$.

Intuitively, one way for the model to implicitly learn and exploit such a Horn clause would be to satisfy the following two criteria:

1. The model should ensure a *consistent* spatial relationship between entity pairs that are related by the path type p; that is, keeping $x_s^\top W_{r_1} \ldots W_{r_k}$ close to x_t for *all* valid (s,t) pairs.

2. The model's representation of the path type p and relation r should capture that spatial relationship; that is, $x_s^\top W_{r_1} \ldots W_{r_k} \approx x_t$ implies $x_s^\top W_r \approx x_t$, or simply $W_{r_1} \ldots W_{r_k} \approx W_r$.

We have already seen empirically that SINGLE does not meet criterion 1, because cascading errors cause it to put incorrect entity vectors $x_{t'}$ closer to $x_s^\top W_{r_1} \ldots W_{r_k}$ than the correct entity. COMP mitigates these errors.

To empirically verify that COMP also does a better job of meeting criterion 2, we perform the following: for a path type p and relation r, define $\text{dist}(p,r)$ to be the angle between their corresponding matrices (treated as vectors in $\mathbb{R}^{d^2}$). This is a natural measure because $x_s^\top W_r x_t$ computes the matrix inner product between W_r and $x_s x_t^\top$. Hence, any matrix with small distance from W_r will produce nearly the same scores as W_r for the same entity pairs.

If COMP is better at capturing the correlation between p and r, then we would expect that when $\text{prec}(p)$ is high, compositional training should shrink $\text{dist}(p,r)$ more. To confirm this hypothesis, we enumerated over all 676 possible paths of length 2 (including inverted relations), and examined the proportional reduction in $\text{dist}(p,r)$ caused by compositional training,

$$\Delta\text{dist}(p,r) = \frac{\text{dist}_{\text{COMP}}(p,r) - \text{dist}_{\text{SINGLE}}(p,r)}{\text{dist}_{\text{SINGLE}}(p,r)}. \tag{16}$$

Figure 4 shows that higher precision paths indeed correspond to larger reductions in $\text{dist}(p,r)$.

7 Related work

Knowledge base completion with vector space models. Many models have been proposed for knowledge base completion, including those reviewed in Section 3.4 (Nickel et al., 2011; Bordes et al., 2013; Yang et al., 2015; Socher et al., 2013). Dong et al. (2014) demonstrated that KBC models can improve the quality of relation extraction by serving as graph-based priors. Riedel et al. (2013) showed that such models can be also be directly used for open-domain relation extraction. Our compositional training technique is an orthogonal improvement that could help any composable model.

Distributional compositional semantics. Previous works have explored compositional vector space representations in the context of logic and sentence interpretation. In Socher et al. (2012), a matrix is associated with each word of a sentence, and can be used to recursively modify the meaning of nearby constituents. Grefenstette (2013) ex-

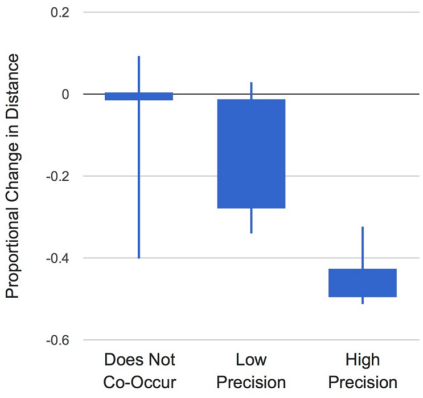

Figure 4: We divide paths of length 2 into high precision (> 0.3), low precision (≤ 0.3), and not co-occuring with r. Here $r =$ `nationality`. Each box plot shows the min, max, and first and third quartiles of $\Delta\text{dist}(p, r)$. As hypothesized, compositional training results in large decreases in $\text{dist}(p, r)$ for high precision paths p, modest decreases for low precision paths, and little to no decreases for irrelevant paths.

plored the ability of tensors to simulate logical calculi. Bowman et al. (2014) showed that recursive neural networks can learn to distinguish important semantic relations. Socher et al. (2014) found that compositional models were powerful enough to describe and retrieve images.

We demonstrate that compositional representations are also useful in the context of knowledge base querying and completion. In the aforementioned work, compositional models produce vectors which represent truth values, sentiment or image features. In our approach, vectors represent sets of entities constituting the denotation of a knowledge base query.

Path modeling. Numerous methods have been proposed to leverage path information for knowledge base completion and question answering. Nickel et al. (2014) proposed combining low-rank models with sparse path features. Lao and Cohen (2010) used random walks as features and Gardner et al. (2014) extended this approach by using vector space similarity to govern random walk probabilities. Neelakantan et al. (2015) addressed the problem of path sparsity by embedding paths using a recurrent neural network. Perozzi et al. (2014) sampled random walks on social networks as training examples, with a different goal to classify nodes in the network. Bordes et al. (2014) embed paths as a sum of relation vectors for question answering. Our approach is unique in modeling the denotation of each intermediate step of a path query, and using this information to regularize the spatial arrangement of entity vectors.

8 Discussion

We introduced the task of answering path queries on an incomplete knowledge base, and presented a general technique for compositionalizing a broad class of vector space models. Our experiments show that compositional training leads to state-of-the-art performance on both path query answering and knowledge base completion.

There are several key ideas from this paper: regularization by augmenting the dataset with paths, representing sets as low-dimensional vectors in a context-sensitive way, and performing function composition using vectors. We believe these three could all have greater applicability in the development of vector space models for knowledge representation and inference.

Reproducibility Our code, data, and experiments are available on the CodaLab platform at `https://www.codalab.org/worksheets/0xfcace41fdeec45f3bc6ddf31107b829f`.

Density-Driven Cross-Lingual Transfer of Dependency Parsers

Mohammad Sadegh Rasooli and **Michael Collins***
Department of Computer Science, Columbia University
New York, NY 10027, USA
{rasooli,mcollins}@cs.columbia.edu

Abstract

We present a novel method for the cross-lingual transfer of dependency parsers. Our goal is to induce a dependency parser in a target language of interest without any direct supervision: instead we assume access to parallel translations between the target and one or more source languages, and to supervised parsers in the source language(s). Our key contributions are to show the utility of *dense* projected structures when training the target language parser, and to introduce a novel learning algorithm that makes use of dense structures. Results on several languages show an absolute improvement of 5.51% in average dependency accuracy over the state-of-the-art method of (Ma and Xia, 2014). Our average dependency accuracy of 82.18% compares favourably to the accuracy of fully supervised methods.

1 Introduction

In recent years there has been a great deal of interest in dependency parsing models for natural languages. Supervised learning methods have been shown to produce highly accurate dependency-parsing models; unfortunately, these methods rely on human-annotated data, which is expensive to obtain, leading to a significant barrier to the development of dependency parsers for new languages. Recent work has considered unsupervised methods (e.g. (Klein and Manning, 2004; Headden III et al., 2009; Gillenwater et al., 2011; Mareček and Straka, 2013; Spitkovsky et al., 2013; Le and Zuidema, 2015; Grave and Elhadad, 2015)), or methods that transfer linguistic structures across languages (e.g. (Cohen et al., 2011; McDonald et al., 2011; Ma and Xia, 2014; Tiedemann, 2015; Guo et al., 2015; Zhang and Barzilay, 2015; Xiao and Guo, 2015)), in an effort to reduce or eliminate the need for annotated training examples. Unfortunately the accuracy of these methods generally lags quite substantially behind the performance of fully supervised approaches.

This paper describes novel methods for the transfer of syntactic information between languages. As in previous work (Hwa et al., 2005; Ganchev et al., 2009; McDonald et al., 2011; Ma and Xia, 2014), our goal is to induce a dependency parser in a target language of interest without any direct supervision (i.e., a treebank) in the target language: instead we assume access to parallel translations between the target and one or more source languages, and to supervised parsers in the source languages. We can then use alignments induced using tools such as GIZA++ (Och and Ney, 2000), to transfer dependencies from the source language(s) to the target language (example projections are shown in Figure 1). A target language parser is then trained on the projected dependencies.

Our contributions are as follows:

- We demonstrate the utility of *dense* projected structures when training the target-language parser. In the most extreme case, a "dense" structure is a sentence in the target language where the projected dependencies form a fully projective tree that includes all words in the sentence (we will refer to these structures as "full" trees). In more relaxed definitions, we might include sentences where at least some proportion (e.g., 80%) of the words participate as a modifier in some dependency, or where long sequences (e.g., 7 words or more) of words all participate as modifiers in some dependency. We give empirical evidence that dense structures give particularly high accuracy for their projected dependencies.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 328–338,
Lisbon, Portugal, 17-21 September 2015.

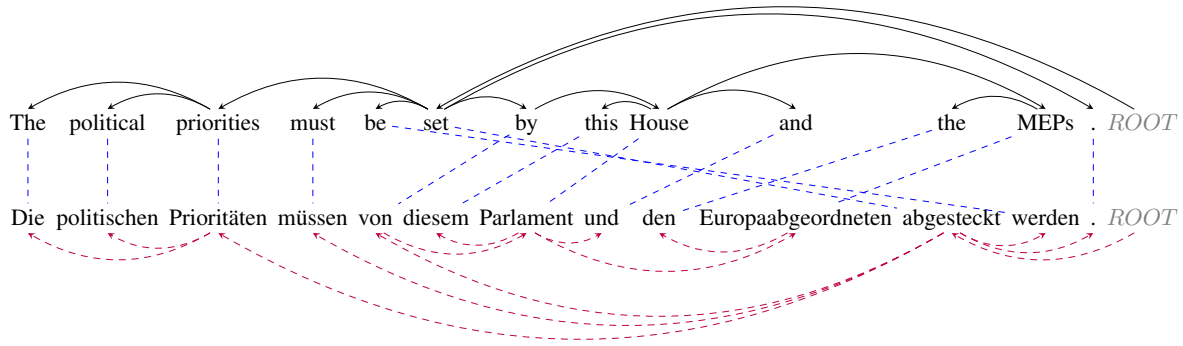

Figure 1: An example projection from English to German in the EuroParl data (Koehn, 2005). The English parse tree is the output from a supervised parser, while the German parse tree is projected from the English parse tree using translation alignments from GIZA++.

- We describe a training algorithm that builds on the definitions of dense structures. The algorithm initially trains the model on full trees, then iteratively introduces increasingly relaxed definitions of density. The algorithm makes use of a training method that can leverage partial (incomplete) dependency structures, and also makes use of confidence scores from a perceptron-trained model.

In spite of the simplicity of our approach, our experiments demonstrate significant improvements in accuracy over previous work. In experiments on transfer from a single source language (English) to a single target language (German, French, Spanish, Italian, Portuguese, and Swedish), our average dependency accuracy is 78.89%. When using multiple source languages, average accuracy is improved to 82.18%. This is a 5.51% absolute improvement over the previous best results reported on this data set, 76.67% for the approach of (Ma and Xia, 2014). To give another perspective, our accuracy is close to that of the fully supervised approach of (McDonald et al., 2005), which gives 84.29% accuracy on this data. To the best of our knowledge these are the highest accuracy parsing results for an approach that makes no use of treebank data for the language of interest.

2 Related Work

A number of researchers have considered the problem of projecting linguistic annotations from the source to the target language in a parallel corpus (Yarowsky et al., 2001; Hwa et al., 2005; Ganchev et al., 2009; Spreyer and Kuhn, 2009; McDonald et al., 2011; Ma and Xia, 2014). The projected annotations are then used to train a model in the target language. This prior work involves various innovations such as the use of posterior regularization (Ganchev et al., 2009), the use of entropy regularization and parallel guidance (Ma and Xia, 2014), the use of a simple method to transfer delexicalized parsers across languages (McDonald et al., 2011), and a method for training on partial annotations that are projected from source to target language (Spreyer and Kuhn, 2009). There is also recent work on treebank translation via a machine translation system (Tiedemann et al., 2014; Tiedemann, 2015). The work of (McDonald et al., 2011) and (Ma and Xia, 2014) is most relevant to our own work, for two reasons: first, these papers consider dependency parsing, and as in our work use the latest version of the Google universal treebank for evaluation;[1] second, these papers represent the state of the art in accuracy. The results in (Ma and Xia, 2014) dominate the accuracies for all other papers discussed in this related work section: they report an average accuracy of 76.67% on the languages German, Italian, Spanish, French, Swedish and Portuguese; this evaluation includes all sentence lengths.

Other work on unsupervised parsing has considered various methods that transfer information from source to target languages, where parsers are available in the source languages, but without the use of parallel corpora (Cohen et al., 2011; Dur-

[1]The original paper of (McDonald et al., 2011) does not use the Google universal treebank, however (Ma and Xia, 2014) reimplemented the model and report results on the Google universal treebank.

rett et al., 2012; Naseem et al., 2012; Täckström et al., 2013; Duong et al., 2015; Zhang and Barzilay, 2015). These results are somewhat below the performance of (Ma and Xia, 2014).[2]

3 Our Approach

This section describes our approach, giving definitions of parallel data and of dense projected structures; describing preliminary exploratory experiments on transfer from German to English; describing the iterative training algorithm used in our work; and finally describing a generalization of the method to transfer from multiple languages.

3.1 Parallel Data Definitions

We assume that we have parallel data in two languages. The source language, for which we have a supervised parser, is assumed to be English. The target language, for which our goal is to learn a parser, will be referred to as the "foreign" language. We describe the generalization to more than two languages in §3.5.

We use the following notation. Our parallel data is a set of examples $(e^{(k)}, f^{(k)})$ for $k = 1 \ldots n$, where each $e^{(k)}$ is an English sentence, and each $f^{(k)}$ is a foreign sentence. Each $e^{(k)} = e_1^{(k)} \ldots e_{s_k}^{(k)}$ where $e_i^{(k)}$ is a word, and s_k is the length of k'th source sentence. Similarly, $f^{(k)} = f_1^{(k)} \ldots f_{t_k}^{(k)}$ where $f_j^{(k)}$ is a word, and t_k is the length of k'th foreign sentence.

A **dependency** is a four-tuple (l, k, h, m) where $l \in \{e, f\}$ is the language, k is the sentence number, h is the head index, m is the modifier index. Note that if $l = e$ then we have $0 \leq h \leq s_k$ and $1 \leq m \leq s_k$, conversely if $l = f$ then $0 \leq h \leq t_k$ and $1 \leq m \leq t_k$. We use $h = 0$ when h is the root of the sentence.

For any $k \in \{1 \ldots n\}$, $j \in \{0 \ldots t_k\}$, $A_{k,j}$ is an integer specifying which word in $e_1^{(k)} \ldots e_{s_k}^{(k)}$, word $f_j^{(k)}$ is aligned to. It is `NULL` if $f_j^{(k)}$ is not aligned to anything. We have $A_{k,0} = 0$ for all k: that is, the root in one language is always aligned to the root in the other language.

In our experiments we use intersected alignments from GIZA++ (Och and Ney, 2000) to provide the $A_{k,j}$ values.

[2]With one exception: on Spanish, using the CoNLL definition of dependencies. The good results from (Ma and Xia, 2014) on the universal dependencies for Spanish may show that the result on the CONLL data is an anomaly, perhaps due to the annotation scheme in Spanish being different from other languages.

3.2 Projected Dependencies

We now describe various sets of projected dependencies. We use $\mathcal{D}$ to denote the set of all dependencies in the source language: these dependencies are the result of parsing the English side of the translation data using a supervised parser. Each dependency $(l, k, h, m) \in \mathcal{D}$ is a four-tuple as described above, with $l = e$. We will use $\mathcal{P}$ to denote the set of all projected dependencies from the source to target language. The set $\mathcal{P}$ is constructed from $\mathcal{D}$ and the alignment variables $A_{k,j}$ as follows:

$$\mathcal{P} = \{(l, k, h, m) : l = f \wedge (e, k, A_{k,h}, A_{k,m}) \in \mathcal{D}\}$$

We say the k'th sentence receives a *full* parse under the dependencies $\mathcal{P}$ if the dependencies (f, k, h, m) for k form a projective tree over the entire sentence: that is, each word has exactly one head, the root symbol is the head of the entire structure, and the resulting structure is a projective tree. We use $\mathcal{T}_{100} \subseteq \{1 \ldots n\}$ to denote the set of all sentences that receive a full parse under $\mathcal{P}$. We then define the following set,

$$\mathcal{P}_{100} = \{(l, k, h, m) \in \mathcal{P} : k \in \mathcal{T}_{100}\}$$

We say the k'th sentence receives a *dense* parse under the dependencies $\mathcal{P}$ if the dependencies of the form (f, k, h, m) for k form a projective tree over at least 80% of the words in the sentence. We use $\mathcal{T}_{80} \subseteq \{1 \ldots n\}$ to denote the set of all sentences that receive a dense parse under $\mathcal{P}$. We then define the following set,

$$\mathcal{P}_{80} = \{(l, k, h, m) \in \mathcal{P} : k \in \mathcal{T}_{80}\}$$

We say the k'th sentence receives a *span-s* parse where s is an integer if there is a sequence of at least s consecutive words in the target language that are all seen as a modifier in the set $\mathcal{P}$. We use $\mathcal{S}_s$ to refer to the set of all sentences with a span-s parse. We define the sets

$$\mathcal{P}_{\geq 7} = \{(l, k, h, m) \in \mathcal{P} : k \in \mathcal{S}_7\}$$

$$\mathcal{P}_{\geq 5} = \{(l, k, h, m) \in \mathcal{P} : k \in \mathcal{S}_5\}$$

$$\mathcal{P}_{\geq 1} = \{(l, k, h, m) \in \mathcal{P} : k \in \mathcal{S}_1\}$$

Finally, we also create datasets that only include projected dependencies that are consistent with respect to part-of-speech (POS) tags for the head and

modifier words in source and target data. We assume a function $\text{POS}(k, j, i)$ which returns TRUE if the POS tags for words $f_j^{(k)}$ and $e_i^{(k)}$ are consistent. The definition of POS-consistent projected dependencies is then as follows:

$$\bar{\mathcal{P}} = \{(l, k, h, m) \in \mathcal{P} : \text{POS}(k, h, A_{k,h}) \wedge \text{POS}(k, m, A_{k,m})\}$$

We experiment with two definitions for the POS function. The first imposes a hard constraint, that the POS tags in the two languages must be identical. The second imposes a soft constraint, that the two POS tags must fall into the same equivalance class: the equivalence classes used are listed in §4.1.

Given this definition of $\bar{\mathcal{P}}$, we can create sets $\bar{\mathcal{P}}_{100}$, $\bar{\mathcal{P}}_{80}$, $\bar{\mathcal{P}}_{\geq 7}$, $\bar{\mathcal{P}}_{\geq 5}$, and $\bar{\mathcal{P}}_{\geq 1}$, using analogous definitions to those given above.

3.3 Preliminary Experiments with Transfer from English to German

Throughout the experiments in this paper, we used German as the target language for development of our approach. Table 1 shows some preliminary results on transferring dependencies from English to German. We can estimate the accuracy of dependency subsets such as $\mathcal{P}_{100}$, $\mathcal{P}_{80}$, $\mathcal{P}_{\geq 7}$ and so on by comparing these dependencies to the dependencies from a supervised German parser on the same data. That is, we use a supervised parser to provide gold standard annotations. The full set of dependencies $\mathcal{P}$ give 74.0% accuracy under this measure; results for $\mathcal{P}_{100}$ are considerably higher in accuracy, ranging from 83.0% to 90.1% depending on how POS constraints are used.

As a second evaluation method, we can test the accuracy of a model trained on the $\mathcal{P}_{100}$ data. The benefit of the soft-matching POS definition is clear. The hard match definition harms performance, presumably because it reduces the number of sentences used to train the model.

Throughout the rest of this paper, we use the soft POS constraints in all projection algorithms.[3]

3.4 The Training Procedure

We now describe the training procedure used in our experiments. We use a perceptron-trained shift-reduce parser, similar to that of (Zhang and Nivre, 2011). We assume that the parser is able to operate in a "constrained" mode, where it returns the highest scoring parse that is consistent with a given subset of dependencies. This can be achieved via zero-cost dynamic oracles (Goldberg and Nivre, 2013).

Inputs: Sets $\mathcal{P}_{100}$, $\mathcal{P}_{80}$, $\mathcal{P}_{\geq 7}$, $\mathcal{P}_{\geq 5}$, $\mathcal{P}_{\geq 1}$ as defined in §3.2.

Definitions: Functions TRAIN, CDECODE, TOP as defined in §3.4.

Algorithm:

1. $\theta^1 = \text{TRAIN}(\mathcal{P}_{100})$
2. $\mathcal{P}^1_{100} = \text{CDECODE}(\mathcal{P}_{80} \cup \mathcal{P}_{\geq 7}, \theta^1)$
3. $\theta^2 = \text{TRAIN}(\mathcal{P}_{100} \cup \text{TOP}(\mathcal{P}^1_{100}, \theta^1))$
4. $\mathcal{P}^2_{100} = \text{CDECODE}(\mathcal{P}_{80} \cup \mathcal{P}_{\geq 5}, \theta^2)$
5. $\theta^3 = \text{TRAIN}(\mathcal{P}_{100} \cup \text{TOP}(\mathcal{P}^2_{100}, \theta^2))$
6. $\mathcal{P}^3_{100} = \text{CDECODE}(\mathcal{P}_{\geq 1}, \theta^3)$
7. $\theta^4 = \text{TRAIN}(\mathcal{P}_{100} \cup \text{TOP}(\mathcal{P}^3_{100}, \theta^3))$

Output: Parameter vectors $\theta^1, \theta^2, \theta^3, \theta^4$.

Figure 2: The learning algorithm.

We assume the following definitions:

- $\text{TRAIN}(\mathcal{D})$ is a function that takes a set of dependency structures $\mathcal{D}$ as input, and returns a model θ as its output. The dependency structures are assumed to be full trees: that is, they correspond to fully projected trees with the root symbol as their root.
- $\text{CDECODE}(\mathcal{P}, \theta)$ is a function that takes a set of partial dependency structures $\mathcal{P}$, and a model θ as input, and as output returns a set of full trees $\mathcal{D}$. It achieves this by constrained decoding of the sentences in $\mathcal{P}$ under the model θ, where for each sentence we use beam search to search for the highest scoring projective full tree that is consistent with the dependencies in $\mathcal{P}$.
- $\text{TOP}(\mathcal{D}, \theta)$ takes as input a set of full trees $\mathcal{D}$, and a model θ. It returns the top m highest scoring trees in $\mathcal{D}$ (in our experiments we used $m = 200,000$), where the score for each tree is the perceptron-based score normalized by the sentence length. Thus we return the

[3] The hard constraint is also used by Ma and Xia (2014).

POS Constraints	$\mathcal{P}$		$dense$		$\mathcal{P}_{100}$		Train on $\mathcal{P}_{100}$
	#sen	Acc.	#sen	Acc.	#sen	Acc.	
No Restriction	$968k$	74.0	$65k$	81.4	$23k$	83.0	69.5
Hard match	$927k$	80.1	$26k$	88.0	$8k$	90.1	68.0
Soft match	$904k$	80.0	$52k$	84.9	$18k$	85.8	70.6

Table 1: Statistics showing the accuracy for various definitions of projected trees: see §3.2 for definitions of $\mathcal{P}$, $\mathcal{P}_{100}$ etc. Columns labeled "Acc." show accuracy when the output of a supervised German parser is used as gold standard data. Columns labeled "#sen" show number of sentences. "dense" shows $\mathcal{P}_{100} \cup \mathcal{P}_{80} \cup \mathcal{P}_{\geq 7}$ and "Train" shows accuracy on test data of a model trained on the $\mathcal{P}_{100}$ trees.

200,000 trees that the perceptron is most confident on.[4]

Figure 2 shows the learning algorithm. It generates a sequence of parsing models, $\theta^1 \ldots \theta^4$. In the first stage of learning, the model is initialized by training on $\mathcal{P}_{100}$. The method then uses this model to fill in the missing dependencies on $\mathcal{P}_{80} \cup \mathcal{P}_{\geq 7}$ using the CDECODE method; this data is added to $\mathcal{P}_{100}$ and the model is retrained. The method is iterated, at each point adding in additional partial structures (note that $\mathcal{P}_{\geq 7} \subseteq \mathcal{P}_{\geq 5} \subseteq \mathcal{P}_{\geq 1}$, hence at each stage we expand the set of training data that is parsed using CDECODE).

3.5 Generalization to Multiple Languages

We now consider the generalization to learning from multiple languages. We again assume that the task is to learn a parser in a single target language, for example German. We assume that we now have multiple source languages. For example, in our experiments with German as the target, we used English, French, Spanish, Portuguese, Swedish, and Italian as source languages. We assume that we have fully supervised parsers for all source languages. We will consider two methods for combining information from the different languages:

Method 1: Concatenation In this approach, we form sets $\mathcal{P}$, $\mathcal{P}_{100}$, $\mathcal{P}_{80}$, $\mathcal{P}_{\geq 7}$ etc. from each of the languages separately, and then concatenate[5] the data to give new definitions of $\mathcal{P}$, $\mathcal{P}_{100}$,$\mathcal{P}_{80}$, $\mathcal{P}_{\geq 7}$ etc.

Method 2: Voting In this case, we assume that each target language sentence is aligned to a source language sentence in each of the source languages. This is the case, for example, in the Europarl data, where we have translations of the same material into multiple languages. We can then create the set $\mathcal{P}$ of projected dependencies using a voting scheme. For any word (k, j) seen in the target language, each source language will identify a headword (this headword may be NULL if there is no alignment giving a dependency). We simply take the most frequent headword chosen by the languages. After creating the set $\mathcal{P}$, we can create subsets such as $\mathcal{P}_{100}$, $\mathcal{P}_{80}$, $\mathcal{P}_{\geq 7}$ in exactly the same way as before.

Once the various projected dependency training sets have been created, we train the dependency parsing model using the algorithm given in §3.4.

4 Experiments

We now describe experiments using our approach. We first describe data and tools used in the experiments, and then describe results.

4.1 Data and Tools

Data We use the EuroParl data (Koehn, 2005) as our parallel data and the Google universal treebank (v2; standard data) (McDonald et al., 2013) as our evaluation data, and as our training data for the supervised source-language parsers. We use seven languages that are present in both Europarl and the Google universal treebank: English (used only as the source language), and German, Spanish, French, Italian, Portuguese and Swedish.

Word Alignments We use Giza++[6] (Och and Ney, 2000) to induce word alignments. Sentences with length greater than 100 and single-word sentences are removed from the parallel data. We follow common practice in training Giza++ for both translation directions, and taking the intersection of the two sets as our final alignment. Giza++ de-

[4] In cases where $|\mathcal{D}| < m$, the entire set $\mathcal{D}$ is returned.

[5] That is, dependency structures projected from different languages are taken to be entirely separate from each other.

Table 2: Parsing accuracies of different methods on the test data using the gold standard POS tags. The models $\theta^1 \ldots \theta^4$ are described in §3.4. "en→trgt" is the single-source setting with English as the source language. "concat→trgt" and "voting→trgt" are results with multiple source languages for the concatenation and voting methods

fault alignment model is used in all of our experiments.

The Parsing Model For all parsing experiments we use the Yara parser[7] (Rasooli and Tetreault, 2015), a reimplementation of the k-beam arc-eager parser of Zhang and Nivre (2011). We use a beam size of 64, and Brown clustering features[8] (Brown et al., 1992; Liang, 2005). The parser gives performance close to the state of the art: for example on section 23 of the Penn WSJ treebank (Marcus et al., 1993), it achieves 93.32% accuracy, compared to 92.9% accuracy for the parser of (Zhang and Nivre, 2011).

POS Consistency As mentioned in §3.2, we define a soft POS consistency constraint to prune some projected dependencies. A source/target language word pair satisifies this constraint if one of the following conditions hold: 1) the POS tags for the two words are identical; 2) the word forms for the two words are identical (this occurs frequently for numbers, for example); 3) both tags are in one of the following equivalence classes: {ADV ↔ ADJ} {ADV ↔ PRT} {ADJ ↔ PRON} {DET ↔ NUM} {DET ↔ PRON} {DET ↔ NOUN} {PRON ↔ NOUN} {NUM ↔ X} {X ↔ .}. These rules were developed primarily on German, with some additional validation on Spanish. These rules required a small amount of human engineering, but we view this as relatively negligible.

Parameter Tuning We used German as a target language in the development of our approach, and in setting hyper-parameters. The parser is trained using the averaged structured perceptron algorithm (Collins, 2002) with max-violation updates (Huang et al., 2012). The number of iterations over the training data is 5 when training model θ^1 in any setting, and 2, 1 and 4 when training models $\theta^2, \theta^3, \theta^4$ respectively. These values are chosen by observing the performance on German. We use θ^4 as the final output from the training process: this is found to be optimal in English to German projections.

4.2 Results

This section gives results of our approach for the single source, multi-source (concatenation) and multi-source (voting) methods. Following previous work (Ma and Xia, 2014) we use gold-standard part-of-speech (POS) tags on test data. We also provide results with automatic POS tags.

Results with a Single Source Language The first set of results are with a single source language; we use English as the source in all of these experiments. Table 2 shows the accuracy of parameters $\theta^1 \ldots \theta^4$ for transfer into German, Spanish, French, Italian, Portuguese, and Swedish. Even the lowest performing model, θ^1, which is trained only on full trees, has a performance of 75.88%, close to the 76.15% accuracy for the method of (Ma and Xia, 2014). There are clear gains as we move from θ^1 to θ^4, on all languages. The average accuracy for θ^4 is 78.89%.

Results with Multiple Source Languages, using Concatenation Table 2 shows results using multiple source languages, using the concatenation method. In these experiments for a given target language we use all other languages in our

Table 4: Comparison to previous work: ge15 (Grave and Elhadad, 2015, Figure 4), zb15 (Zhang and Barzilay, 2015), zb_s15 (Zhang and Barzilay, 2015, semi-supervised with 50 annotated sentences), mph11 (McDonald et al., 2011) and mx14 (Ma and Xia, 2014) on the Google universal treebank v2. The mph11 results are copied from (Ma and Xia, 2014, Table 4). All results are reported on gold part of speech tags. The numbers in parentheses are absolute improvements over (Ma and Xia, 2014). Sup (1st) is the supervised first-order dependency parser used by (Ma and Xia, 2014) and sup(ae) is the Yara arc-eager supervised parser (Rasooli and Tetreault, 2015).

data as source languages. The performance of θ^1 improves from an average of 75.88% for a single source language, to 79.76% for multiple languages. The performance of θ^4 gives an additional improvement to 81.23%.

Results with Multiple Source Languages, using Voting The final set of results in Table 2 are for multiple languages using the voting strategy. There are further improvements: model θ^1 has average accuracy of 80.95%, and model θ^4 has average accuracy of 82.18%.

Results with Automatic POS Tags We use our final θ^4 models to parse the treebank with automatic tags provided by the same POS tagger used for tagging the parallel data. Table 3 shows the results for the transfer methods and the supervised parsing models of (McDonald et al., 2011) and (Rasooli and Tetreault, 2015). The first-order supervised method of (McDonald et al., 2005) gives only a 1.7% average absolute improvement in accuracy over the voting method. For one language (Swedish), our method actually gives improved accuracy over the 1st order parser.

Comparison to Previous Results Table 4 gives a comparison of the accuracy on the six languages, using the single source and multiple source methods, to previous work. As shown in the table, our model outperforms all models: among them, the results of (McDonald et al., 2011) and (Ma and Xia, 2014) are directly comparable to us because they use the same training and evaluation data. The recent work of (Xiao and Guo, 2015) uses the same parallel data but evaluates on CoNLL treebanks but their results are lower than Ma and Xia (2014). The recent work of (Guo et al., 2015) evaluates on the same data as ours but uses different parallel corpora. They only reported on three languages (German: 60.35, Spanish: 71.90 and French: 72.93) which are all far bellow our results. The work of (Grave and Elhadad, 2015) is the state-of-the-art fully unsupervised model with

Table 5: Table showing statistics on projected dependencies for the target languages, for the single-source, multi-source (concat) and multi-source (voting) methods. "sen#" is the number of sentences. "dep#" is the average number of dependencies per sentence. "len" is the average sentence length. "acc." is the percentage of projected dependencies that agree with the output from a supervised parser.

minimal linguistic prior knowledge. The model of (Zhang and Barzilay, 2015) does not use any parallel data but uses linguistic information across languages. Their semi-supervised model selectively samples 50 annotated sentences but our model outperforms their model.

Compared to the results of (McDonald et al., 2011) and (Ma and Xia, 2014) which are directly comparable, there are clear improvements across all languages; the highest accuracy, 82.18%, is a 5.51% absolute improvement over the average accuracy for (Ma and Xia, 2014).

5 Analysis

We conclude with some analysis of the accuracy of the projected dependencies for the different languages, for different definitions ($\mathcal{P}_{100}$, $\mathcal{P}_{80}$ etc.), and for different projection methods. Table 5 gives a summary of statistics for the various languages. Recall that German is used as the development language in our experiments; the other languages can be considered to be test languages. In all cases the accuracy reported is the percentage match to a supervised parser used to parse the same data.

There are some clear trends. The accuracy of the $\mathcal{P}_{100}$ datasets is high, with an average accuracy of 84.7% for the single source method, 88.3% for the concatenation method, and 89.0% for the voting method. The voting method not only increases accuracy over the single source method, but also increases the number of sentences (from an average 17k to 77k) and the average number of dependencies per sentence (from 6.8 to 10.4).

The accuracy of the $\mathcal{P}_{80} \cup \mathcal{P}_{\geq 7}$ datasets is slightly lower, with around 83-87% accuracy for the single source, concatenation and voting methods. The voting method gives a significant increase in the number of sentences—from an average of 140k to 243k. The average sentence length for this data is around 28 words, considerably longer than the $\mathcal{P}_{100}$ data; the addition of longer sentences is very likely beneficial to the model. For the voting method the average number of dependencies is 13.7, giving an average density of 50% on these sentences.

The accuracy for the different languages, in particular for the voting data, is surprisingly uniform, with a range of 85.8-91.4% for the $\mathcal{P}_{100}$ data, and 81.3-87.4% for the $\mathcal{P}_{80} \cup \mathcal{P}_{\geq 7}$ data. The number of sentences for each language, the average length of those sentences, and average number of dependencies per sentence is also quite uniform, with the exception of German, which is a clear outlier. German has fewer sentences, and fewer dependencies per sentence: this may account for it having the lowest accuracy for our models. Future work should investigate why this is the case: one hypothesis is that German has quite different word order from the other languages (it is V2, and verb final), which may lead to a degradation in the quality of the alignments from GIZA++, or in the projection process.

Finally, figure 3 shows some randomly selected examples from the $\mathcal{P}_{100}$ data for Spanish, giving a qualitative feel for the data obtained using the voting method.

6 Conclusions

We have described a density-driven method for the induction of dependency parsers using parallel data and source-language parsers. The key ideas are a series of increasingly relaxed definitions of density, together with an iterative training procedure that makes use of these definitions. The method gives a significant gain over previous methods, with dependency accuracies approach-

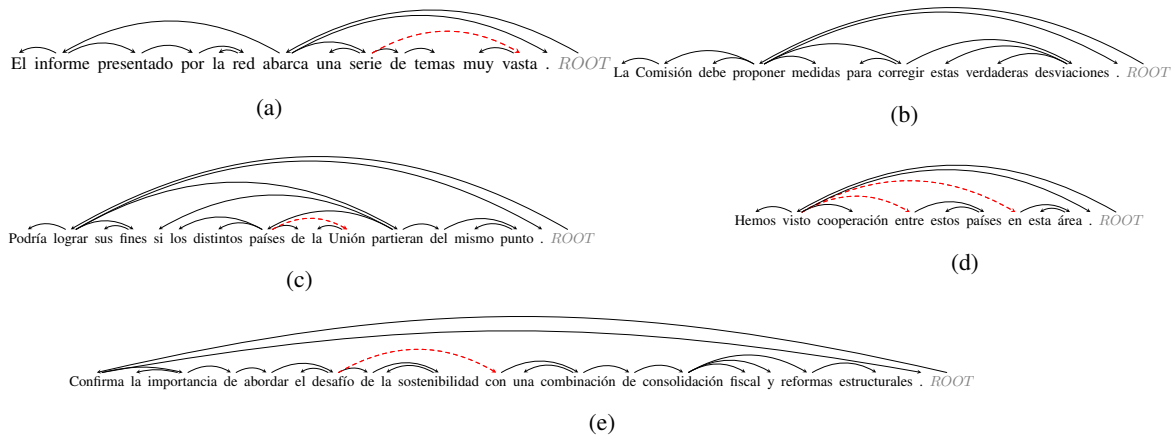

Figure 3: Randomly selected examples of Spanish dependency structures derived using the *voting* method. Dashed/red dependencies are mismatches with the output of a supervised Spanish parser; all other dependencies match the supervised parser. In these examples, 92.4% of dependencies match the supervised parser; this is close to the average match rate on Spanish of 89.2% for the voting method.

ing the level of fully supervised methods. Future work should consider application of the method to a broader set of languages, and application of the method to transfer of information other than dependency structures.

Abstract

Accurate dependency parsing requires large treebanks, which are only available for a few languages. We propose a method that takes advantage of shared structure across languages to build a mature parser using less training data. We propose a model for learning a shared "universal" parser that operates over an inter-lingual continuous representation of language, along with language-specific mapping components. Compared with supervised learning, our methods give a consistent 8-10% improvement across several treebanks in low-resource simulations.

1 Introduction

Dependency parsing is an important task for Natural Language Processing (NLP) with application to text classification (Özgür and Güngör, 2010), relation extraction (Bunescu and Mooney, 2005), question answering (Cui et al., 2005), statistical machine translation (Xu et al., 2009), and sentiment analysis (Socher et al., 2013). A mature parser normally requires a large treebank for training, yet such resources are rarely available and are costly to build. Ideally, we would be able to construct a high quality parser with less training data, thereby enabling accurate parsing for low-resource languages.

In this paper we formalize the dependency parsing task for a low-resource language as a domain adaptation task, in which a *target* resource-poor language treebank is treated as *in-domain*, while a much larger treebank in a high-resource language forms the *out-of-domain* data. In this way, we can apply well-understood domain adaptation techniques to the dependency parsing task. However, a crucial requirement for domain adaptation is that the in-domain and out-of-domain data have compatible representations. In applying our approach to data from several languages, we must learn such a cross-lingual representation. Here we frame this representation learning as part of a neural network training. The underlying hypothesis for the joint learning is that there are some shared-structures across languages that we can exploit. This hypothesis is motivated by the excellent results of the cross-lingual application of unlexicalised parsing (McDonald et al., 2011), whereby a delexicalized parser constructed on one language is applied directly to another language.

Our approach works by jointly training a neural network dependency parser to model the syntax in both a source and target language. Many of the parameters of the source and target language parsers are shared, except for a small handful of language-specific parameters. In this way, the information can flow back and forth between languages, allowing for the learning of a compatible cross-lingual syntactic representation, while also allowing the parsers to mutually correct one another's errors. We include some language-specific components, in order to better model the lexicon of each language and allow learning of the syntactic idiosyncrasies of each language. Our experiments show that this outperforms a purely supervised setting, on both small and large data conditions, with a gain as high as 10% for small training sets. Our proposed joint training method also out-performs the conventional cascade approach where the parameters between source and target languages are related together through a regularization term (Duong et al., 2015).

Our model is flexible, allowing easy incorporation of peripheral information. For example, assuming the presence of a small bilingual dictionary is befitting of a low-resource setting, as this is prototypically one of the first artifacts generated by field linguists. We incorporate a bilingual dictionary as a set of soft constraints on the

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 339–348,
Lisbon, Portugal, 17-21 September 2015.

model, such that it learns similar representations for each word and its translation(s). For example, the representation of *house* in English should be close to *haus* in German. We empirically show that adding a bilingual dictionary improves parser performance, particularly when target data is limited.

The final contribution of the paper concerns the learned word embeddings. We demonstrate that these encode meaningful syntactic phenomena, both in terms of the observable clusters and through a verb classification task. The code for this paper is published as an open source project.[1]

2 Related Work

This work is motivated by the idea of delexicalized parsing, in which a parser is built without any lexical features and trained on a treebank for a resource-rich source language (Zeman et al., 2008). It is then applied directly to parse sentences in the target resource-poor languages. Delexicalized parsing relies on the fact that identical part-of-speech (POS) inventories are highly informative of dependency relations, and that there exists shared dependency structures across languages.

Building a dependency parser for a resource-poor language usually starts with the delexicalized parser and then uses other resources to refine the model. McDonald et al. (2011) and Ma and Xia (2014) exploited parallel data as the bridge to transfer constraints from the source resource-rich language to the target resource-poor languages. Täckström et al. (2012) also used parallel data to induce cross-lingual word clusters which added as features for their delexicalized parser. Durrett et al. (2012) constructed the set of language-independent features and used a bilingual dictionary as the bridge to transfer these features from source to target language. Täckström et al. (2013) additionally used high-level linguistic features extracted from the World Atlas of Language Structures (WALS) (Dryer and Haspelmath, 2013).

For low-resource languages, no large parallel corpus is available. Some linguists are dependency-annotating small amounts of field data, e.g. for Karuk, a nearly-extinct language of Northwest California (Garrett et al., 2013). Accordingly, we adopt a different resource requirement: a small treebank in the target low-resource language.

Domain adaptation or joint-training is a different branch of research, and falls outside the scope of this paper. Nevertheless, we would like to contrast our work with Senna (Collobert et al., 2011), a neural network framework to perform a variety of NLP tasks such as part-of-speech (POS) tagging, named entity recognition (NER), chunking, and so forth. Both approaches exploit common linguistic properties of the data through joint learning. However, Collobert et al's goal is to find a single input representation that can work well for many tasks. Our goal is different: we allow the joint-training inputs to be different but constrain the parameter weights in the upper layer to be identical. Consequently, our method applies to the task where inputs are different, possibly from different languages or domains. Their method applies for different tasks in the same language/domain where the inputs are fairly similar.

2.1 Supervised Neural Network Parser

This section describes the monolingual neural network dependency parser structure of Chen and Manning (2014). This parser achieves excellent performance, and has a highly flexible formulation allowing auxilliary inputs. The model is based on a transition-based dependency parser (Nivre, 2006) formulated as a neural-network classifier to decide which transition to apply to each parsing state configuration.[2] That is, for each configuration, the selected list of words, POS tags and labels from the Stack, Queue and Arcs are extracted. Each word, POS and label is mapped into a low-dimension vector representation using an embedding matrix, which is then fed into a two-layer neural network classifier to predict the next parsing action. The set of parameters for the model is $E = \{E^{word}, E^{\text{pos}}, E^{\text{arc}}\}$ for the embedding layer, W_1 for the fully connected cubic hidden layer and W_2 for the softmax output layer. The model prediction function is

$$P(Y|X = \vec{x}, W_1, W_2, E) = \text{softmax}\Big(W_2 \times \text{cube}(W_1 \times \Phi\left[\vec{x}, E\right])\Big) \quad (1)$$

[1] http://github.com/longdt219/universal_dependency_parser

[2] Our approach is focused on a technique for transfer learning which can be more widely applied to other types of dependency parser (and models, generally) regardless of whether they are transition-based or graph-based.

where cube is a non-linear activation function, Φ is the embedding function that returns a vector representation of parsing state x using an embedding matrix E. We refer the reader to Chen and Manning (2014) for a more detailed description.

3 A Joint Interlingual Model

We assume a small treebank in a target resource-poor language, as well as a larger treebank in the source language. Our objective is to learn a model of both languages, subject to the constraint that both models are similar overall, while allowing for some limited language variability. Instead of just training two different parsers on source and then on target, we train them jointly, in order to learn an interlingual parser. This allows the method to take maximum advantage of the limited treebank data available, resulting in highly accurate predicted parses.

Training a monolingual parser as described in section 2.1 requires optimizing the simple cross-entropy learning objective, $\mathcal{L} = -\sum_{i=1}^{|D|} \log P(Y = \vec{y}^{(i)} | X = \vec{x}^{(i)})$, where $P(Y|X)$ is given by equation 1 and $D = \{\vec{x}^{(i)}, \vec{y}^{(i)}\}_{i=1}^{n}$ is the training data. Joint training of a parser over the source and target languages can be achieved by simply adding two such cross-entropy objectives, i.e.,

$$\mathcal{L}_{\text{joint}} = -\sum_{i=1}^{|D_s|} \log P(Y_s = \vec{y}_s^{(i)} | X_s = \vec{x}_s^{(i)}) - \sum_{i=1}^{|D_t|} \log P(Y_t = \vec{y}_t^{(i)} | X_t = \vec{x}_t^{(i)}) \,, \quad (2)$$

where the training data, $D = D_s \cup D_t$, comprises data in both the source and target language. However training the model according to equation 2 will result in two independent parsers. To enforce similarity between the two parsers, we adopt parameter sharing: the neural network parameters, W_1 and W_2, are identical in both parsers. Thereby

$$P(Y_\alpha | X_\alpha = \vec{x}) = P(Y | X = \vec{x}, W_1, W_2, E_\alpha) \,,$$

where the subscript $\alpha \in \{s, t\}$ denotes the source or target language. We allow the embedding matrix E_α to differ in order to accommodate language-specific features, in terms of the representations of lexical types, E_s^{word}, part-of-speech, E_s^{pos} and dependency arc labels E_s^{arc}. This reflects the fact that different languages have different lexicon, parts-of-speech often exhibit different roles, and dependency edges serve different functions, e.g. in Korean a *static verb* can serve as an *adjective* (Kim, 2001). During training, the language-specific errors are back propagated through different branches according to the language, guiding learning towards an interlingual representation that informs parsing decisions in both languages. The set of parameters for the model is W_1, W_2, E_s, E_t where E_s, E_t are the embedding matrices for the source and target languages.

Generally speaking, we can understand the model as building the universal dependency parser that parses the universal language. Specifically, the model is the combination of two parts: the universal part (W_1, W_2) that is shared between the languages, and the conversion part (E_s, E_t) that maps a language-specific representation into the universal language. Naturally, we could stack several non-linear layers in the conversion components such that the model can better transform the input into the universal representation; we leave this exploration for future work. Currently, our cross-lingual word embeddings are meaningful for a pair of source and target languages. However, our model can easily be used for joint training over $k > 2$ languages. We also leave this avenue of enquiry for future work

One concern from equation 2 is that when the source language treebank D_s is much bigger than the target language treebank D_t, it is likely to dominate, and consequently, learning will mainly focus on optimizing the source language parser. We adjust for this disparity by balancing the two datasets, D_s and D_t, during training. When selecting mini-batches for online gradient updates, we select an equal number of classification instances from the source and target languages. Thus, for each step $|D_s| = |D_t|$, effectively reweighting the cross-entropy components in (2) to ensure parity between the languages.

The other concern is over-fitting, especially when we only have a small treebank in the target language. As suggested by Chen and Manning (2014), we apply drop-out, a form of regularization for both source and target language. That is, we randomly drop some of the activation units from both hidden layer and input layer. Following Srivastava et al. (2014), we randomly dropout 20% of the input layer and 50% of the hid-

den layer. Empirically, we observe a substantial improvement applying dropout to the model over MLE or l_2 regularization.

3.1 Incorporating a Dictionary

Our model is flexible, enabling us to freely add additional components. In this section, we assume the presence of a bilingual dictionary between the source and target language. We seek to incorporate this dictionary as a part of model learning, to encode the intuition that if two lexical items are translations of one another, the parser should treat them similarly.[3] Recall that the mapping layer is the combination of word, pos and arc embeddings, i.e., $E_\alpha = \{E_\alpha^{\text{word}}, E_\alpha^{\text{pos}}, E_\alpha^{\text{arc}}\}$. We can easily add bilingual dictionary constraints to the model in the form of regularization to minimize the l_2 distance between word representations, i.e., $\sum_{\langle i,j\rangle \in \mathcal{D}} \|E_s^{\text{word}(i)} - E_t^{\text{word}(j)}\|_F^2$, where $\mathcal{D}$ comprises translation pairs, word(i) and word(j).

When the languages share the same POS tagset and arc set,[4] we can also add further constraints such as their language-specific embeddings be close together. This results a regularised training objective,

$$\mathcal{L}_{\text{dict}} = \mathcal{L}_{\text{joint}} - \lambda \Bigg(\sum_{\langle i,j\rangle \in \mathcal{D}} \|E_s^{\text{word}(i)} - E_t^{\text{word}(j)}\|_F^2 + \|E_s^{\text{pos}} - E_t^{\text{pos}}\|_F^2 + \|E_s^{\text{arc}} - E_t^{\text{arc}}\|_F^2 \Bigg), \quad (3)$$

where $\lambda \in [0, \infty]$ controls to what degree we bind these words or pos tags or arc labels together, with high λ tying the parameters and small λ allowing independent learning. We expect the best value of λ to fall somewhere between these extremes. Finally, we use a mini-batch size of 1000 instance pairs and adaptive learning rate trainer, `adagrad` (Duchi et al., 2011) to build our two separate models corresponding to equations 2 and 3.

4 Experiments

In this section, we compare our joint training approach with baseline methods of supervised learning in the target language, and cascaded learning of source and target parsers.

[3] However, this is not always the case. For example, modal or auxiliary verbs in English often have no translations in different languages or map to words with different syntactic functions.

[4] As was the case for our experiments.

4.1 Dataset

We experiment with the Universal Dependency Treebank (UDT) V1.0 (Nivre et al., 2015), simulating low resource settings.[5] This treebank has many desirable properties for our model: the dependency types (arc labels set) and coarse POS tagset are the same across languages. This removes the need for mapping the source and target language tagsets to a common tagset. Moreover, the dependency types are also common across languages allowing evaluation of the labelled attachment score (LAS). The treebank covers 10 languages,[6] with some languages very highly resourced—Czech, French and Spanish have 400k tokens—and only modest amounts of data for other languages—Hungarian and Irish have only around $25k$ tokens. Cross-lingual models assume English as the source language, for which we have a large treebank, and only a small treebank of 3k tokens exists in each target language, simulated by subsampling the corpus.

4.2 Baseline Cascade Model

We compare our approach to a baseline interlingual model based on the same parsing algorithm as presented in section 2.1, but with cascaded training (Duong et al., 2015). This works by first learning the source language parser, and then training the target language parser using a regularization term to minimise the distance between the parameters of the target parser and the source parser (which is fixed). In this way, some structural information from the source parser can be used in the target parser, however it is likely that the representation will be overly biased towards the source language and consequently may not prove as useful for modelling the target.

4.3 Monolingual Word Embeddings

While the E^{pos} and E^{arc} are randomly initialized, we initialize both the source and target language word embeddings $E_s^{\text{word}}, E_t^{\text{word}}$ of our neural network models with pre-trained embeddings. This is an advantage since we can incorporate the monolingual data which is often available, even for

[5] Evaluating on truly resource-poor languages would be preferable to simulation. However for ease of training and evaluation, which requires a small treebank in the target language, we simulate the low-resource setting using a small part of the UDT.

[6] Czech (cs), English (en), Finnish (fi), French (fr), German (de), Hungarian (hu), Irish (ga), Italian (it), Spanish (es), Swedish (sv).

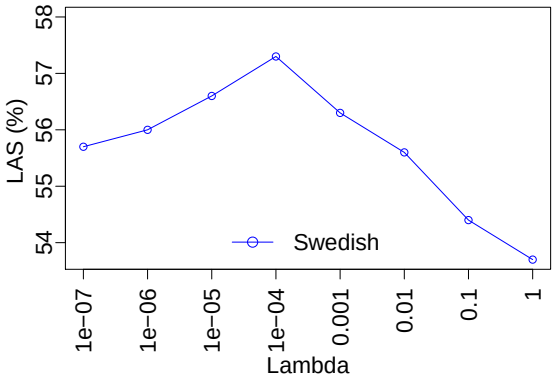

Figure 1: Sensitivity of regularization parameter λ against the LAS measured on the Swedish development set trained on 1000 (tokens).

resource-poor languages. We collect monolingual data for each language from the Machine Translation Workshop (WMT) data,[7] Europarl (Koehn, 2005) and EU Bookshop Corpus (Skadiņš et al., 2014). The size of monolingual data also varies significantly, with as much as 400 million tokens for English and German, and as few as 4 million tokens for Irish. We use the skip-gram model (Mikolov et al., 2013b) to induce 50-dimensional word embeddings.

4.4 Bilingual Dictionary

For the extended model as described in section 3.1, we also need a bilingual dictionary. We extract dictionaries from PanLex (Kamholz et al., 2014) which currently covers around 1300 language varieties and about 12 million expressions. This dataset is growing and aims at covering all languages in the world and up to 350 million expressions. The translations in PanLex come from various sources such as glossaries, dictionaries, automatic inference from other languages, etc. Naturally, the bilingual dictionary size varies greatly among resource-poor and resource-rich languages.

4.5 Regularization Parameter Tuning

Joint training with a dictionary (see equation 3) includes a regularization sensitivity parameter λ. This parameter controls to what extent we should bind the source words and their target translation, common POS tags and arcs together. In this section we measure the sensitivity of our approach with respect to this parameter. In a real world scenario, getting development data to tune this parameter is difficult. Thus, we want a parameter that can work well cross-lingually. To simulate this, we only tune the parameter on one language and apply it directly to different languages. We trained on a small Swedish treebank with 1k tokens, testing several different values of λ. We evaluated on the Swedish development dataset. Figure 1 shows the labelled attachment score (LAS) for different λ. It's clearly visible that $\lambda = 0.0001$ gives the maximum LAS on the development set. Thus, we use this value for all the experiments involving a dictionary hereafter.

4.6 Results

For our initial experiments we assume that we have only a small target treebank with 3000 tokens (around 200 sentences). Ideally the much larger source language (English) treebank should be able to improve parser performance versus simple supervised learning on such a small collection. We apply the joint model (equation 2) and joint model with the dictionary constraints (equation 3) for each target language,

The results are reported in Table 1. The supervised neural network dependency parser performed worst, as expected, and the baseline cascade model consistently outperformed the supervised model on all languages by an average margin of 5.6% (absolute).[8] The joint model also consistently out-performed both baselines giving a further 1.9% average improvement over the cascade. This was despite the fact that the cascaded model had the benefit of tuning for the regularization parameters on a development corpus, while the joint model had no parameter tuning. Note that the improvement varies substantially across languages, and is largest for Czech but is only minor for Swedish. The joint model with the bilingual dictionary outperforms the joint model, however, the improvement is modest (0.7%). Nevertheless, this model gives substantial improvements compared with the cascaded and the supervised model (2.6% and 8.2%).

5 Analysis

5.1 Learning Curve

In section 4.6, we used a 3k token treebank in the target language. What if we have more or less

target language data? Figure 2 shows the learning curve with respect to various models on different data sizes averaged over all target languages. For small datasets of 1k training tokens, the cascaded model, joint model and joint + dict model performed similarly well, out-performing the supervised model by about 10% (absolute). With more training data, we see interesting changes to the relative performance of the different models. While the baseline cascade model still outperforms the supervised model, the improvement is diminishing, and by 15k, the difference is only 2.9%. On the other hand, compared with the supervised model, the joint and joint + dict models perform consistently well at all sizes, maintaining an 8% lead at 15k. This shows the superiority of joint training compared with single language training.

To understand this pattern of performance differences for the cascade versus the joint model, one needs to consider the cascade model formulation. In this approach, the target language parameters are tied (softly) with the source language parameters through regularization. This is a benefit for small datasets, providing a smoothing function to limit overtraining. However, when we have more training data, these constraints limit the capacity of the model to describe the target data. This is compounded by the problem that the source representation may not be appropriate for modelling the target language, and there is no way to correct for this. In contrast the joint model learns a mutually compatible representation automatically during joint training.

The performance results for the joint model with and without the dictionary are similar overall. Only on small datasets (1k, 3k), is the difference notable. From 5k tokens, the bilingual dictionary doesn't confer additional information, presumably as there is sufficient data for learning syntactic word representations. Moreover, translation entries exist between syntactically related word types as well as semantically related pairs, with the latter potentially limiting the beneficial effect of the dictionary.

When training on all the target language data, the supervised model does well, surpassing the cascade model. Surprisingly, the joint models outperform slightly, yielding a 0.4% improvement. This is an interesting observation suggesting that our method has potential for use not only for low resource problems, but also high resource settings.

5.2 Different Tagsets

In the above experiments, we used the universal POS tagset for all the languages in the corpus. However, for some languages,[9] the UDT also provides language specific POS tags. We use this data to test the relative performance of the model using a universal tagset cf. language specific tagsets. In this experiment, we applied the same joint model (see §3) but with a language specific tagset instead of UPOS for these languages. We expect the joint

model to automatically learn to project the different tagsets into a common space, i.e., implicitly learn a tagset mapping between languages. Figure 3 shows the learning curve comparing the joint model with the two types of POS tagsets. For the small dataset, it is clear that the data is insufficient for the model to learn a good tagset mapping, especially for a morphologically rich language like Czech. However, with more data, the model is better able to learn the tagset mapping as part of joint training. Beyond 15k tokens, the joint model using the language specific POS tagset outperforms UPOS. Clearly there is some information lost in the UPOS tagset, although the UPOS mapping simultaneously provides implicit linguistic supervision. This explains why the UPOS might be useful in small data scenarios, but detrimental at scale. Using all the target data ("All") the language specific POS provides a 1% (absolute) gain over UPOS.

5.3 Universal Representation

As described in section 3, we can consider our joint model as the combination of two parts: a universal parser and a language-specific embedding E_s or E_t that converts the source and target language into the universal representation. We now seek to analyse qualitatively this universal representation through visualization. For this purpose we use a joint model of English and French, using all the available French treebank (more than 350k tokens) as well as a bilingual dictionary.[10] Figure 4 shows the t-SNE (Van Der Maaten, 2014) projection of the 50 dimensional word embeddings in both languages. We can see that English and French are mixed nicely together. The colouring denotes the POS tag, showing clearly that the words with similar POS tags are grouped together regardless of languages. This is partially understandable since word embeddings for dependency parsing need to convey the dependency context rather than surrounding words, as in most distributional embedding models. Words having similar dependency relation should be grouped together as they are treated similarly by the parser.

Some of the learned cross-lingual word-embeddings are shown in Table 2, which includes the five nearest neighbours to selected English words according to the monolingual word embedding (section 4.3) and our cross-lingual dependency word embeddings, trained using PanLex. The monolingual sets appear to be strongly characterised by distributional similarity. The cross-lingual embeddings display greater semantic similarity, while being more variable morphosyntactically. In many cases, the top five words of English and French are translations of each other, but with varying inflectional endings in the French forms. For example, "*buy*" vs "*vendez*" or "*invest*" vs "*in-*

[10] We also visualized the cross-lingual word embeddings without the dictionary, however the results were rather odd. Although we saw coherent POS clusters, the two languages were largely disjoint. We speculate that many components of the embeddings are use for only one language, and these outnumber the shared components, and thus more careful projection is needed for meaningful visualisation.

vestir". This is a direct consequence of incorporating the bilingual lexicon. Moreover, the top five closest words of both English and French mostly have the same part of speech. This is consistent with the finding in Figure 4.

Levin (1993) has shown that there is a strong connection between a verb's meaning and its syntactic behaviour. We compare the English side of our cross-lingual dependency based word embeddings with various other pre-trained monolingual English word embeddings and our monolingual embedding (section 4.3) on Verb-143 dataset (Baker et al., 2014). This dataset contains 143 pairs of verbs that are manually given score from 1 to 10 according to the meaning similarity. Table 3 shows the Pearson correlation

with human judgment for our embeddings and other pre-trained embeddings. As expected, our cross-lingual embeddings out-perform others embeddings on this dataset. This is partly because the syntactic behaviour is well encoded in our word embeddings through dependency relation.

Our embeddings encode not just cross-lingual correspondences, but also capture dependency relations which we expect might be beneficial for other NLP tasks based on dependency parsing, e.g., cross-lingual semantic role labelling where long-distance relationship can be captured by word embedding.

6 Conclusion

In this paper, we present a training method for building a dependency parser for a resource-poor language using a larger treebank in a high-resource language. Our approach takes advantage of the shared structure among languages to learn a universal parser and language-specific mappings to the lexicon, parts of speech and dependency arcs. Compared with supervised learning, our joint model gives a consistent 8-10% improvement over several different datasets in simulation low-resource scenarios. Interestingly, some small but consistent gains are still realised by joint cross-lingual training even on large complete treebanks. This suggests that our approach has utility not just in low resource settings. Our joint model is flexible, allowing the incorporation of a bilingual dictionary, which results in small improvements particularly for tiny training scenarios.

As the side-effect of training our joint model, we obtain cross-lingual word embeddings specialized for dependency parsing. We expect these embeddings to be beneficial to other syntatic and se-

mantic tasks. In future work, we plan to extend joint training to several languages, and further explore the idea of learning and exploiting cross-lingual embeddings.

Abstract

We present extensions to a continuous-state dependency parsing method that makes it applicable to morphologically rich languages. Starting with a high-performance transition-based parser that uses long short-term memory (LSTM) recurrent neural networks to learn representations of the parser state, we replace lookup-based word representations with representations constructed from the orthographic representations of the words, also using LSTMs. This allows statistical sharing across word forms that are similar on the surface. Experiments for morphologically rich languages show that the parsing model benefits from incorporating the character-based encodings of words.

1 Introduction

At the heart of natural language parsing is the challenge of representing the "state" of an algorithm—what parts of a parse have been built and what parts of the input string are not yet accounted for—as it incrementally constructs a parse. Traditional approaches rely on independence assumptions, decomposition of scoring functions, and/or greedy approximations to keep this space manageable. **Continuous-state** parsers have been proposed, in which the state is embedded as a vector (Titov and Henderson, 2007; Stenetorp, 2013; Chen and Manning, 2014; Dyer et al., 2015; Zhou et al., 2015; Weiss et al., 2015). Dyer et al. reported state-of-the-art performance on English and Chinese benchmarks using a transition-based parser whose continuous-state embeddings were constructed using LSTM recurrent neural networks (RNNs) whose parameters were estimated to maximize the probability of a gold-standard sequence of parse actions.

The primary contribution made in this work is to take the idea of continuous-state parsing a step further by making the word embeddings that are used to construct the parse state sensitive to the morphology of the words.[1] Since it it is well known that a word's form often provides strong evidence regarding its grammatical role in morphologically rich languages (Ballesteros, 2013, *inter alia*), this has promise to improve accuracy and statistical efficiency relative to traditional approaches that treat each word type as opaque and independently modeled. In the traditional parameterization, words with similar grammatical roles will only be embedded near each other if they are observed in similar contexts with sufficient frequency. Our approach reparameterizes word embeddings using the same RNN machinery used in the parser: a word's vector is calculated based on the sequence of orthographic symbols representing it (§3).

Although our model is provided no supervision in the form of explicit morphological annotation, we find that it gives a large performance increase when parsing morphologically rich languages in the SPMRL datasets (Seddah et al., 2013; Seddah and Tsarfaty, 2014), especially in agglutinative languages and the ones that present extensive case systems (§4). In languages that show little morphology, performance remains good, showing that the RNN composition strategy is capable of capturing both morphological regularities and arbitrariness in the sense of Saussure (1916). Finally, a particularly noteworthy result is that we find that character-based word embeddings in some cases obviate explicit POS information, which is usually found to be indispensable for accurate parsing.

A secondary contribution of this work is to show that the continuous-state parser of Dyer et al. (2015) can learn to generate nonprojective trees. We do this by augmenting its transition operations

[1]Software for replicating the experiments is available from `https://github.com/clab/lstm-parser`.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 349–359,
Lisbon, Portugal, 17-21 September 2015.

with a SWAP operation (Nivre, 2009) (§2.4), enabling the parser to produce nonprojective dependencies which are often found in morphologically rich languages.

2 An LSTM Dependency Parser

We begin by reviewing the parsing approach of Dyer et al. (2015) on which our work is based.

Like most transition-based parsers, Dyer et al.'s parser can be understood as the sequential manipulation of three data structures: a buffer B initialized with the sequence of words to be parsed, a stack S containing partially-built parses, and a list A of actions previously taken by the parser. In particular, the parser implements the arc-standard parsing algorithm (Nivre, 2004).

At each time step t, a transition action is applied that alters these data structures by pushing or popping words from the stack and the buffer; the operations are listed in Figure 1.

Along with the discrete transitions above, the parser calculates a vector representation of the states of B, S, and A; at time step t these are denoted by $\mathbf{b}_t$, $\mathbf{s}_t$, and $\mathbf{a}_t$, respectively. The total parser state at t is given by

$$\mathbf{p}_t = \max\{\mathbf{0}, \mathbf{W}[\mathbf{s}_t; \mathbf{b}_t; \mathbf{a}_t] + \mathbf{d}\} \quad (1)$$

where the matrix $\mathbf{W}$ and the vector $\mathbf{d}$ are learned parameters. This continuous-state representation $\mathbf{p}_t$ is used to decide which operation to apply next, updating B, S, and A (Figure 1).

We elaborate on the design of $\mathbf{b}_t$, $\mathbf{s}_t$, and $\mathbf{a}_t$ using RNNs in §2.1, on the representation of partial parses in S in §2.2, and on the parser's decision mechanism in §2.3. We discuss the inclusion of SWAP in §2.4.

2.1 Stack LSTMs

RNNs are functions that read a sequence of vectors incrementally; at time step t the vector $\mathbf{x}_t$ is read in and the hidden state $\mathbf{h}_t$ computed using $\mathbf{x}_t$ and the previous hidden state $\mathbf{h}_{t-1}$. In principle, this allows retaining information from time steps in the distant past, but the nonlinear "squashing" functions applied in the calcluation of each $\mathbf{h}_t$ result in a decay of the error signal used in training with backpropagation. LSTMs are a variant of RNNs designed to cope with this "vanishing gradient" problem using an extra memory "cell" (Hochreiter and Schmidhuber, 1997; Graves, 2013).

Past work explains the computation within an LSTM through the metaphors of deciding how much of the current input to pass into memory ($\mathbf{i}_t$) or forget ($\mathbf{f}_t$). We refer interested readers to the original papers and present only the recursive equations updating the memory cell $\mathbf{c}_t$ and hidden state $\mathbf{h}_t$ given $\mathbf{x}_t$, the previous hidden state $\mathbf{h}_{t-1}$, and the memory cell $\mathbf{c}_{t-1}$:

$$\begin{aligned}
\mathbf{i}_t &= \sigma(\mathbf{W}_{ix}\mathbf{x}_t + \mathbf{W}_{ih}\mathbf{h}_{t-1} + \mathbf{W}_{ic}\mathbf{c}_{t-1} + \mathbf{b}_i) \\
\mathbf{f}_t &= \mathbf{1} - \mathbf{i}_t \\
\mathbf{c}_t &= \mathbf{f}_t \odot \mathbf{c}_{t-1} + \\
&\qquad \mathbf{i}_t \odot \tanh(\mathbf{W}_{cx}\mathbf{x}_t + \mathbf{W}_{ch}\mathbf{h}_{t-1} + \mathbf{b}_c) \\
\mathbf{o}_t &= \sigma(\mathbf{W}_{ox}\mathbf{x}_t + \mathbf{W}_{oh}\mathbf{h}_{t-1} + \mathbf{W}_{oc}\mathbf{c}_t + \mathbf{b}_o) \\
\mathbf{h}_t &= \mathbf{o}_t \odot \tanh(\mathbf{c}_t),
\end{aligned}$$

where σ is the component-wise logistic sigmoid function and $\odot$ is the component-wise (Hadamard) product. Parameters are all represented using $\mathbf{W}$ and $\mathbf{b}$. This formulation differs slightly from the classic LSTM formulation in that it makes use of "peephole connections" (Gers et al., 2002) and defines the forget gate so that it sums with the input gate to $\mathbf{1}$ (Greff et al., 2015). To improve the representational capacity of LSTMs (and RNNs generally), they can be stacked in "layers." In these architectures, the input LSTM at higher layers at time t is the value of $\mathbf{h}_t$ computed by the lower layer (and $\mathbf{x}_t$ is the input at the lowest layer).

The **stack LSTM** augments the left-to-right sequential model of the conventional LSTM with a stack pointer. As in the LSTM, new inputs are added in the right-most position, but the stack pointer indicates which LSTM cell provides $\mathbf{c}_{t-1}$ and $\mathbf{h}_{t-1}$ for the computation of the next iterate. Further, the stack LSTM provides a pop operation that moves the stack pointer to the previous element. Hence each of the parser data structures (B, S, and A) is implemented with its own stack LSTM, each with its own parameters. The values of $\mathbf{b}_t$, $\mathbf{s}_t$, and $\mathbf{a}_t$ are the $\mathbf{h}_t$ vectors from their respective stack LSTMs.

2.2 Composition Functions

Whenever a REDUCE operation is selected, two tree fragments are popped off of S and combined to form a new tree fragment, which is then popped back onto S (see Figure 1). This tree must be embedded as an input vector $\mathbf{x}_t$.

To do this, Dyer et al. (2015) use a recursive neural network g_r (for relation r) that composes

$\textbf{Stack}_t$	$\textbf{Buffer}_t$	Action	$\textbf{Stack}_{t+1}$	$\textbf{Buffer}_{t+1}$	Dependency
$(\mathbf{u}, u), (\mathbf{v}, v), S$	B	REDUCE-RIGHT(r)	$(g_r(\mathbf{u}, \mathbf{v}), u), S$	B	$u \xrightarrow{r} v$
$(\mathbf{u}, u), (\mathbf{v}, v), S$	B	REDUCE-LEFT(r)	$(g_r(\mathbf{v}, \mathbf{u}), v), S$	B	$u \xleftarrow{r} v$
S	$(\mathbf{u}, u), B$	SHIFT	$(\mathbf{u}, u), S$	B	—
$(\mathbf{u}, u), (\mathbf{v}, v), S$	B	SWAP	$(\mathbf{u}, u), S$	$(\mathbf{v}, v), B$	—

Figure 1: Parser transitions indicating the action applied to the stack and buffer and the resulting stack and buffer states. Bold symbols indicate (learned) embeddings of words and relations, script symbols indicate the corresponding words and relations. Dyer et al. (2015) used the SHIFT and REDUCE operations in their continuous-state parser; we add SWAP.

the representations of the two subtrees popped from S (we denote these by $\mathbf{u}$ and $\mathbf{v}$), resulting in a new vector $g_r(\mathbf{u}, \mathbf{v})$ or $g_r(\mathbf{v}, \mathbf{u})$, depending on the direction of attachment. The resulting vector embeds the tree fragment in the same space as the words and other tree fragments. This kind of composition was thoroughly explored in prior work (Socher et al., 2011; Socher et al., 2013b; Hermann and Blunsom, 2013; Socher et al., 2013a); for details, see Dyer et al. (2015).

2.3 Predicting Parser Decisions

The parser uses a probabilistic model of parser decisions at each time step t. Letting $\mathcal{A}(S, B)$ denote the set of allowed transitions given the stack S and buffer S (i.e., those where preconditions are met; see Figure 1), the probability of action $z \in \mathcal{A}(S, B)$ defined using a log-linear distribution:

$$p(z \mid \mathbf{p}_t) = \frac{\exp\left(\mathbf{g}_z^\top \mathbf{p}_t + q_z\right)}{\sum_{z' \in \mathcal{A}(S,B)} \exp\left(\mathbf{g}_{z'}^\top \mathbf{p}_t + q_{z'}\right)} \quad (2)$$

(where $\mathbf{g}_z$ and q_z are parameters associated with each action type z).

Parsing proceeds by always choosing the most probable action from $\mathcal{A}(S, B)$. The probabilistic definition allows parameter estimation for all of the parameters ($\mathbf{W}_*$, $\mathbf{b}_*$ in all three stack LSTMs, as well as $\mathbf{W}$, $\mathbf{d}$, $\mathbf{g}_*$, and q_*) by maximizing the conditional likelihood of each correct parser decisions given the state.

2.4 Adding the SWAP Operation

Dyer et al. (2015)'s parser implemented the most basic version of the arc-standard algorithm, which is capable of producing only projective parse trees. In order to deal with nonprojective trees, we also add the SWAP operation which allows nonprojective trees to be produced.

The SWAP operation, first introduced by Nivre (2009), allows a transition-based parser to produce nonprojective trees. Here, the inclusion of the SWAP operation requires breaking the linearity of the stack by removing tokens that are not at the top of the stack. This is easily handled with the stack LSTM. Figure 1 shows how the parser is capable of moving words from the stack (S) to the buffer (B), breaking the linear order of words. Since a node that is swapped may have already been assigned as the head of a dependent, the buffer (B) can now also contain tree fragments.

3 Word Representations

The main contribution of this paper is to change the word representations. In this section, we present the standard word embeddings as in Dyer et al. (2015), and the improvements we made generating word embeddings designed to capture morphology based on orthographic strings.

3.1 Baseline: Standard Word Embeddings

Dyer et al.'s parser generates a word representation for each input token by concatenating two vectors: a vector representation for each word type ($\mathbf{w}$) and a representation ($\mathbf{t}$) of the POS tag of the token (if it is used), provided as auxiliary input to the parser.[2] A linear map ($\mathbf{V}$) is applied to the resulting vector and passed through a component-wise ReLU:

$$\mathbf{x} = \max\{\mathbf{0}, \mathbf{V}[\mathbf{w}; \mathbf{t}] + \mathbf{b}\}$$

For out-of-vocabulary words, the parser uses an "UNK" token that is handled as a separate word during parsing time. This mapping can be shown schematically as in Figure 2.

[2] Dyer et al. (2015), included a third input representation learned from a neural language model ($\tilde{\mathbf{w}}_{\text{LM}}$). We do not include these pretrained representations in our experiments, focusing instead on character-based representations.

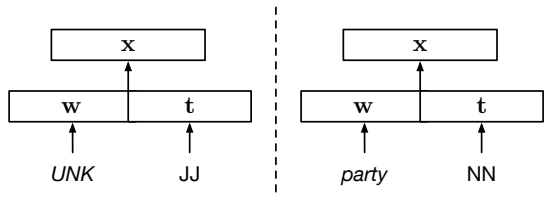

Figure 2: Baseline model word embeddings for an in-vocabulary word that is tagged with POS tag NN (right) and an out-of-vocabulary word with POS tag JJ (left).

3.2 Character-Based Embeddings of Words

Following Ling et al. (2015), we compute character-based continuous-space vector embeddings of words using bidirectional LSTMs (Graves and Schmidhuber, 2005). When the parser initiates the learning process and populates the buffer with all the words from the sentence, it reads the words character by character from left to right and computes a continuous-space vector embedding the character sequence, which is the $\mathbf{h}$ vector of the LSTM; we denote it by $\overrightarrow{\mathbf{w}}$. The same process is also applied in reverse (albeit with different parameters), computing a similar continuous-space vector embedding starting from the last character and finishing at the first ($\overleftarrow{\mathbf{w}}$); again each character is represented with an LSTM cell. After that, we concatenate these vectors and a (learned) representation of their tag to produce the representation $\mathbf{w}$. As in §3.1, a linear map ($\mathbf{V}$) is applied and passed through a component-wise ReLU.

$$\mathbf{x} = \max\left\{\mathbf{0}, \mathbf{V}[\overrightarrow{\mathbf{w}}; \overleftarrow{\mathbf{w}}; \mathbf{t}] + \mathbf{b}\right\}$$

This process is shown schematically in Figure 3.

Note that under this representation, out-of-vocabulary words are treated as bidirectional LSTM encodings and thus they will be "close" to other words that the parser has seen during training, ideally close to their more frequent, syntactically similar morphological relatives. We conjecture that this will give a clear advantage over a single "UNK" token for all the words that the parser does not see during training, as done by Dyer et al. (2015) and other parsers without additional resources. In §4 we confirm this hypothesis.

4 Experiments

We applied our parsing model and several variations of it to several parsing tasks and report results below.

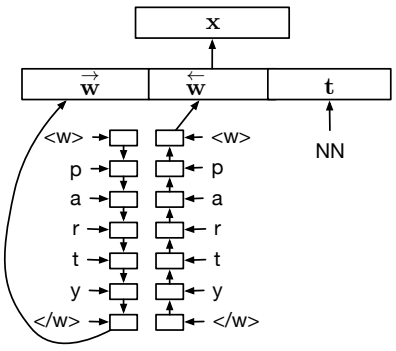

Figure 3: Character-based word embedding of the word *party*. This representation is used for both in-vocabulary and out-of-vocabulary words.

4.1 Data

In order to find out whether the character-based representations are capable of learning the morphology of words, we applied the parser to morphologically rich languages specifically the treebanks of the SPMRL shared task (Seddah et al., 2013; Seddah and Tsarfaty, 2014): Arabic (Maamouri et al., 2004), Basque (Aduriz et al., 2003), French (Abeillé et al., 2003), German (Seeker and Kuhn, 2012), Hebrew (Sima'an et al., 2001), Hungarian (Vincze et al., 2010), Korean (Choi, 2013), Polish (Świdziński and Woliński, 2010) and Swedish (Nivre et al., 2006b). For all the corpora of the SPMRL Shared Task we used predicted POS tags as provided by the shared task organizers.[3] For these datasets, evaluation is calculated using `eval07.pl`, which includes punctuation.

We also experimented with the Turkish dependency treebank[4] (Oflazer et al., 2003) of the CoNLL-X Shared Task (Buchholz and Marsi, 2006). We used gold POS tags, as is common with the CoNLL-X data sets.

To put our results in context with the most recent neural network transition-based parsers, we run the parser in the same Chinese and English

[3]The POS tags were calculated with the MarMot tagger (Müller et al., 2013) by the best performing system of the SPMRL Shared Task (Björkelund et al., 2013). Arabic: 97.38. Basque: 97.02. French: 97.61. German: 98.10. Hebrew: 97.09. Hungarian: 98.72. Korean: 94.03. Polish: 98.12. Swedish: 97.27.

[4]Since the Turkish dependency treebank does not have a development set, we extracted the last 150 sentences from the 4996 sentences of the training set as a development set.

setups as Chen and Manning (2014) and Dyer et al. (2015). For Chinese, we use the Penn Chinese Treebank 5.1 (CTB5) following Zhang and Clark (2008b),[5] with gold POS tags. For English, we used the Stanford Dependency (SD) representation of the Penn Treebank[6] (Marcus et al., 1993; Marneffe et al., 2006).[7]. Results for Turkish, Chinese, and English are calculated using the CoNLL-X `eval.pl` script, which ignores punctuation symbols.

4.2 Experimental Configurations

In order to isolate the improvements provided by the LSTM encodings of characters, we run the stack LSTM parser in the following configurations:

- **Words**: words only, as in §3.1 (but without POS tags)
- **Chars**: character-based representations of words with bidirectional LSTMs, as in §3.2 (but without POS tags)
- **Words + POS**: words and POS tags (§3.1)
- **Chars + POS**: character-based representations of words with bidirectional LSTMs plus POS tags (§3.2)

None of the experimental configurations include pretrained word-embeddings or any additional data resources. All experiments include the SWAP transition, meaning that nonprojective trees can be produced in any language.

Dimensionality. The full version of our parsing model sets dimensionalities as follows. LSTM hidden states are of size 100, and we use two layers of LSTMs for each stack. Embeddings of the parser actions used in the composition functions have 20 dimensions, and the output embedding size is 20 dimensions. The learned word representations embeddings have 32 dimensions when used, while the character-based representations have 100 dimensions, when used. Part of speech embeddings have 12 dimensions. These dimensionalities were chosen after running several tests with different values, but a more careful selection of these values would probably further improve results.

[5]Training: 001–815, 1001–1136. Development: 886–931, 1148–1151. Test: 816–885, 1137–1147.

[6]Training: 02–21. Development: 22. Test: 23.

[7]The POS tags are predicted by using the Stanford Tagger (Toutanova et al., 2003) with an accuracy of 97.3%.

4.3 Training Procedure

Parameters are initialized randomly—refer to Dyer et al. (2015) for specifics—and optimized using stochastic gradient descent (without minibatches) using derivatives of the negative log likelihood of the sequence of parsing actions computed using backpropagation. Training is stopped when the learned model's UAS stops improving on the development set, and this model is used to parse the test set. No pretraining of any parameters is done.

4.4 Results and Discussion

Tables 1 and 2 show the results of the parsers for the development sets and the final test sets, respectively. Most notable are improvements for agglutinative languages—Basque, Hungarian, Korean, and Turkish—both when POS tags are included and when they are not. Consistently, across all languages, **Chars** outperforms **Words**, suggesting that the character-level LSTMs are learning representations that capture similar information to parts of speech. On average, **Chars** is on par with **Words + POS**, and the best average of labeled attachment scores is achieved with **Chars + POS**.

It is common practice to encode morphological information in treebank POS tags; for instance, the Penn Treebank includes English number and tense (e.g., NNS is plural noun and VBD is verb in past tense). Even if our character-based representations are capable of encoding the same kind of information, existing POS tags suffice for high accuracy. However, the POS tags in treebanks for morphologically rich languages do not seem to be enough.

Swedish, English, and French use suffixes for the verb tenses and number,[8] while Hebrew uses prepositional particles rather than grammatical case. Tsarfaty (2006) and Cohen and Smith (2007) argued that, for Hebrew, determining the correct morphological segmentation is dependent on syntactic context. Our approach sidesteps this step, capturing the same kind of information in the vectors, and learning it from syntactic context. Even for Chinese, which is not morphologically rich, **Chars** shows a benefit over **Words**, perhaps by capturing regularities in syllable structure within words.

[8]Tense and number features provide little improvement in a transition-based parser, compared with other features such as case, when the POS tags are included (Ballesteros, 2013).

Boldface shows the better result comparing **Words** vs. **Chars** and comparing **Words + POS** vs. **Chars + POS**.

4.4.1 Learned Word Representations

Figure 4 visualizes a sample of the character-based bidirectional LSTMs's learned representations (**Chars**). Clear clusters of past tense verbs, gerunds, and other syntactic classes are visible. The colors in the figure represent the most common POS tag for each word.

4.4.2 Out-of-Vocabulary Words

The character-based representation for words is notably beneficial for out-of-vocabulary (OOV) words. We tested this specifically by comparing **Chars** to a model in which all OOVs are replaced by the string "UNK" during parsing. This always has a negative effect on LAS (average -4.5 points, -2.8 UAS). Figure 5 shows how this drop varies with the development OOV rate across treebanks; most extreme is Korean, which drops 15.5 LAS. A similar, but less pronounced pattern, was observed for models that include POS.

Interestingly, this artificially impoverished model is still consistently better than **Words** for all languages (e.g., for Korean, by 4 LAS). This implies that not all of the improvement is due to OOV words; statistical sharing across orthographically close words is beneficial, as well.

4.4.3 Computational Requirements

The character-based representations make the parser slower, since they require composing the character-based bidirectional LSTMs for each

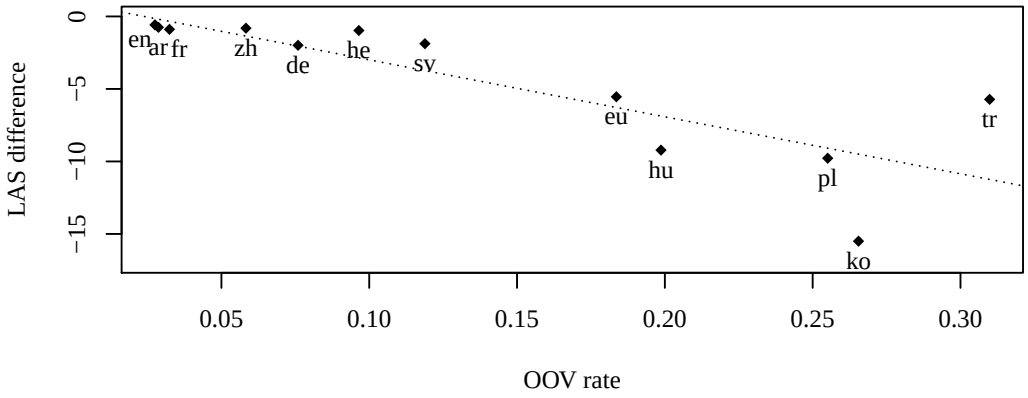

Figure 5: On the x-axis is the OOV rate in development data, by treebank; on the y-axis is the difference in development-set LAS between **Chars** model as described in §3.2 and one in which all OOV words are given a single representation.

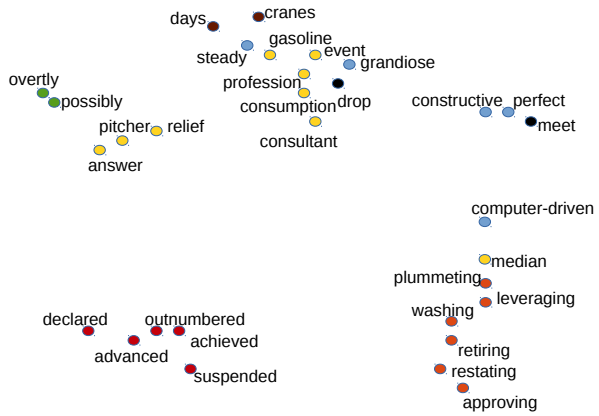

Figure 4: Character-based word representations of 30 random words from the English development set (**Chars**). Dots in red represent past tense verbs; dots in orange represent gerund verbs; dots in black represent present tense verbs; dots in blue represent adjectives; dots in green represent adverbs; dots in yellow represent singular nouns; dots in brown represent plural nouns. The visualization was produced using t-SNE; see `http://lvdmaaten.github.io/tsne/`.

word of the input sentence; however, at test time these results could be cached. On average, **Words** parses a sentence in 44 ms, while**Chars** needs 130 ms.[9] Training time is affected by the same constant, needing some hours to have a competitive model. In terms of memory, **Words** requires on average 300 MB of main memory for both training and parsing, while **Chars** requires 450 MB.

4.4.4 Comparison with State-of-the-Art

Table 3 shows a comparison with state-of-the-art parsers. We include greedy transition-based parsers that, like ours, do not apply a beam search (Zhang and Clark, 2008b) or a dynamic oracle (Goldberg and Nivre, 2013). For all the SPMRL languages we show the results of Ballesteros (2013), who reported results after carrying out a careful automatic morphological feature selection experiment. For Turkish, we show the results of Nivre et al. (2006a) which also carried out a careful manual morphological feature selection. Our parser outperforms these in most cases. Since those systems rely on morphological features, we believe that this comparison shows even more that the character-based representations are capturing morphological information, though without explicit morphological features. For English and Chinese, we report (Dyer et al., 2015) which is **Words + POS** but with pretrained word embeddings.

We also show the best reported results on these datasets. For the SPMRL data sets, the best performing system of the shared task is either Björkelund et al. (2013) or Björkelund et al. (2014), which are consistently better than our sys-

[9] We are using a machine with 32 Intel Xeon CPU E5-2650 at 2.00GHz; the parser runs on a single core.

Table 3: Test-set performance of our best results (according to UAS or LAS, whichever has the larger difference), compared to state-of-the-art greedy transition-based parsers ("Best Greedy Result") and best results reported ("Best Published Result"). All of the systems we compare against use explicit morphological features and/or one of the following: pretrained word embeddings, unlabeled data and a combination of parsers; our models do not. B'13 is Ballesteros (2013); N+'06a is Nivre et al. (2006a); D+'15 is Dyer et al. (2015); B+'13 is Björkelund et al. (2013); B+'14 is Björkelund et al. (2014); K+'10 is Koo et al. (2010); W+'15 is Weiss et al. (2015).

tem for all languages. Note that the comparison is harsh to our system, which does not use unlabeled data or explicit morphological features nor any combination of different parsers. For Turkish, we report the results of Koo et al. (2010), which only reported unlabeled attachment scores. For English, we report (Weiss et al., 2015) and for Chinese, we report (Dyer et al., 2015) which is **Words + POS** but with pretrained word embeddings.

5 Related Work

Character-based representations have been explored in other NLP tasks; for instance, dos Santos and Zadrozny (2014) and dos Santos and Guimarães (2015) learned character-level neural representations for POS tagging and named entity recognition, getting a large error reduction in both tasks. Our approach is similar to theirs. Others have used character-based models as features to improve existing models. For instance, Chrupała (2014) used character-based recurrent neural networks to normalize tweets.

Botha and Blunsom (2014) show that stems, prefixes and suffixes can be used to learn useful word representations but relying on an external morphological analyzer. That is, they learn the morpheme-meaning relationship with an additive model, whereas we do not need a morphological analyzer. Similarly, Chen et al. (2015) proposed joint learning of character and word embeddings for Chinese, claiming that characters contain rich information.

Methods for joint morphological disambiguation and parsing have been widely explored Tsarfaty (2006; Cohen and Smith (2007; Goldberg and Tsarfaty (2008; Goldberg and Elhadad (2011). More recently, Bohnet et al. (2013) presented an arc-standard transition-based parser that performs competitively for joint morphological tagging and dependency parsing for richly inflected languages, such as Czech, Finnish, German, Hungarian, and Russian. Our model seeks to achieve a similar benefit to parsing without explicitly reasoning about the internal structure of words.

Zhang et al. (2013) presented efforts on Chinese parsing with characters showing that Chinese can be parsed at the character level, and that Chinese word segmentation is useful for predicting the correct POS tags (Zhang and Clark, 2008a).

To the best of our knowledge, previous work has not used character-based embeddings to improve dependency parsers, as done in this paper.

6 Conclusion

We have presented several interesting findings. First, we add new evidence that character-based representations are useful for NLP tasks. In this paper, we demonstrate that they are useful for transition-based dependency parsing, since they are capable of capturing morphological information crucial for analyzing syntax.

The improvements provided by the character-based representations using bidirectional LSTMs are strong for agglutinative languages, such as

Basque, Hungarian, Korean, and Turkish, comparing favorably to POS tags as encoded in those languages' currently available treebanks. This outcome is important, since annotating morphological information for a treebank is expensive. Our finding suggests that the best investment of annotation effort may be in dependencies, leaving morphological features to be learned implicitly from strings.

The character-based representations are also a way of overcoming the out-of-vocabulary problem; without any additional resources, they enable the parser to substantially improve the performance when OOV rates are high. We expect that, in conjunction with a pretraing regime, or in conjunction with distributional word embeddings, further improvements could be realized.

Sentence Compression by Deletion with LSTMs

{katjaf,ealfonseca,crcarlos,lukaszkaiser,vinyals}@google.com

Abstract

We present an LSTM approach to deletion-based sentence compression where the task is to translate a sentence into a sequence of zeros and ones, corresponding to token deletion decisions. We demonstrate that even the most basic version of the system, which is given no syntactic information (no PoS or NE tags, or dependencies) or desired compression length, performs surprisingly well: around 30% of the compressions from a large test set could be regenerated. We compare the LSTM system with a competitive baseline which is trained on the same amount of data but is additionally provided with all kinds of linguistic features. In an experiment with human raters the LSTM-based model outperforms the baseline achieving 4.5 in readability and 3.8 in informativeness.

1 Introduction

Sentence compression is a standard NLP task where the goal is to generate a shorter paraphrase of a sentence. Dozens of systems have been introduced in the past two decades and most of them are deletion-based: generated compressions are token subsequences of the input sentences (Jing, 2000; Knight & Marcu, 2000; McDonald, 2006; Clarke & Lapata, 2008; Berg-Kirkpatrick et al., 2011, to name a few).

Existing compression systems heavily use syntactic information to minimize chances of introducing grammatical mistakes in the output. A common approach is to use only some syntactic information (Jing, 2000; Clarke & Lapata, 2008, among others) or use syntactic features as signals in a statistical model (McDonald, 2006). It is probably even more common to operate on syntactic trees directly (dependency or constituency) and generate compressions by pruning them (Knight & Marcu, 2000; Berg-Kirkpatrick et al., 2011; Filippova & Altun, 2013, among others). Unfortunately, this makes such systems vulnerable to error propagation as there is no way to recover from an incorrect parse tree. With the state-of-the-art parsing systems achieving about 91 points in labeled attachment accuracy (Zhang & McDonald, 2014), the problem is not a negligible one. To our knowledge, there is no competitive compression system so far which does not require any linguistic preprocessing but tokenization.

In this paper we research the following question: can a robust compression model be built which only uses tokens and has no access to syntactic or other linguistic information? While phenomena like long-distance relations may seem to make generation of grammatically correct compressions impossible, we are going to present an evidence to the contrary. In particular, we will present a model which benefits from the very recent advances in deep learning and uses word embeddings and Long Short Term Memory models (LSTMs) to output surprisingly readable and informative compressions. Trained on a corpus of less than two million automatically extracted parallel sentences and using a standard tool to obtain word embeddings, in its best and most simple configuration it achieves 4.5 points out of 5 in readability and 3.8 points in informativeness in an extensive evaluation with human judges. We believe that this is an important result as it may suggest a new direction for sentence compression research which is less tied to modeling linguistic

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 360–368,
Lisbon, Portugal, 17-21 September 2015.

structures, especially syntactic ones, than the compression work so far.

The paper is organized as follows: Section 3 presents a competitive baseline which implements the system of McDonald (2006) for large training sets. The LSTM model and its three configurations are introduced in Section 4. The evaluation set-up and a discussion on wins and losses with examples are presented in Section 5 which is followed by the conclusions.

2 Related Work

The problem formulation we adopt in this paper is very simple: for every token in the input sentence we ask whether it should be kept or dropped, which translates into a sequence labeling problem with just two labels: one and zero. The deletion approach is a standard one in compression research, although the problem is often formulated over the syntactic structure and not the raw token sequence. That is, one usually drops constituents or prunes dependency edges (Jing, 2000; Knight & Marcu, 2000; McDonald, 2006; Clarke & Lapata, 2008; Berg-Kirkpatrick et al., 2011; Filippova & Altun, 2013). Thus, the relation to existing compression work is that we also use the deletion approach.

Recent advances in machine learning made it possible to escape the typical paradigm of mapping a fixed dimensional input to a fixed dimensional output to mapping an input sequence onto an output sequence. Even though many of these models were proposed more than a decade ago, it is not until recently that they have empirically been shown to perform well. Indeed, core problems in natural language processing such as translation (Cho et al., 2014; Sutskever et al., 2014; Luong et al., 2014), parsing (Vinyals et al., 2014), image captioning (Vinyals et al., 2015; Xu et al., 2015), or learning to execute small programs (Zaremba & Sutskever, 2014) employed virtually the same principles—the use of Recurrent Neural Networks (RNNs). Thus, with regard to this line of research, our work comes closest to the recent machine translation work. An important difference is that we do not aim at building a model that generates compressions directly but rather a model which generates a sequence of deletion decisions.

A more complex translation model is also conceivable and may significantly advance work on compression by paraphrasing, of which there have not been many examples yet (Cohn & Lapata, 2008). However, in this paper our goal is to demonstrate that a simple but robust deletion-based system can be built without using any linguistic features other than token boundaries. We leave experiments with paraphrasing models to future work.

3 Baseline

We compare our model against the system of McDonald (2006) which also formulates sentence compression as a binary sequence labeling problem. In contrast to our proposal, it makes use of a large set of syntactic features which are treated as soft evidence. The presence or absence of these features is treated as signals which do not condition the output that the model can produce. Therefore the model is robust against noise present in the precomputed syntactic structures of the input sentences.

The system was implemented based on the description by McDonald (2006) with two changes which were necessary due to the large size of the training data set used for model fitting. The first change was related to the learning procedure and the second one to the family of features used.

Regarding the learning procedure, the original model uses a large-margin learning framework, namely MIRA (Crammer & Singer, 2003), but with some minor changes as presented by McDonald et al. (2005). In this set-up, online learning is performed, and at each step an optimization procedure is made where K constraints are included, which correspond to the top-K solutions for a given training observation. This optimization step is equivalent to a Quadratic Programming problem if $K > 1$, which is time-costly to solve, and therefore not adequate for the large amount of data we used for training the model. Furthermore, in his publication McDonald states clearly that different values of K did not actually have a major impact on the final performance of the model. Consequently, and for the sake of being able to successfully train the model with large-scale data, the learning procedure is implemented as a distributed structured perceptron with iterative parameter mixing (McDonald et al., 2010), where each shard is processed with MIRA and K is set to 1.

Setting $K = 1$ will only affect the weight update described on line 4 of Figure 3 of McDonald

(2006), which is now expressed as:

$$\boldsymbol{w}^{(i+1)} \leftarrow \boldsymbol{w}^{(i)} + \tau \times \boldsymbol{e}_{\boldsymbol{y}_t,\boldsymbol{y}'}$$
$$\text{where } \tau = \max\left(0, \frac{L(\boldsymbol{y}_t, \boldsymbol{y}') - \boldsymbol{w} \cdot \boldsymbol{e}_{\boldsymbol{y}_t,\boldsymbol{y}'}}{||\boldsymbol{e}_{\boldsymbol{y}_t,\boldsymbol{y}'}||^2}\right)$$
$$\boldsymbol{e}_{\boldsymbol{y}_t,\boldsymbol{y}'} = \boldsymbol{F}(\boldsymbol{x}_t, \boldsymbol{y}_t) - \boldsymbol{F}(\boldsymbol{x}_t, \boldsymbol{y}')$$
$$\boldsymbol{y}' = \text{best}(\boldsymbol{x}; \boldsymbol{w}^{(i)})$$
$$\boldsymbol{F}(\boldsymbol{x}, \boldsymbol{y}) = \sum_{j=2}^{|\boldsymbol{y}|} \boldsymbol{f}(\boldsymbol{x}, I(y_{j-1}), I(y_j))$$

The second change concerns the feature set used. While McDonald's original model contains deep syntactic features coming from both dependency and constituency parse trees, we use only dependency-based features. Additionally, and to better compare the baseline with the LSTM models, we have included as an optional feature a 256-dimension embedding-vector representation of each input word and its syntactic parent. The vectors are pre-trained using the Skipgram model[1] (Mikolov et al., 2013). Ultimately, our implementation of McDonald's model contained 463,614 individual features, summarized in three categories:

- **PoS features:** Joint PoS tags of selected tokens. Unigram, bigram and trigram PoS context of selected and dropped tokens. All the previous features conjoined with one indicating if the last two selected tokens are adjacent.
- **Deep syntactic features:** Dependency labels of taken and dropped tokens and their parent dependencies. Boolean features indicating syntactic relations between selected tokens (*i.e.*, siblings, parents, leaves, etc.). Dependency label of the least common ancestor in the dependency tree between a batch of dropped tokens. All the previous features conjoined with the PoS tag of the involved tokens.
- **Word features:** Boolean features indicating if a group of dropped nodes contain a complete or incomplete parenthesization. Word-embedding vectors of selected and dropped tokens and their syntactic parents.

The model is fitted over ten epochs on the whole training data, and for model selection a small development set consisting of 5,000 previously unseen sentences is used (none of them belonging to the evaluation set). The automated metric used for this selection was accuracy@1 which is the proportion of golden compressions which could be fully reproduced. The performance on the development set plateaus when getting close to the last epoch.

4 The LSTM model

Our approach is largely based on the sequence to sequence paradigm proposed in Sutskever et al. (2014). We train a model that maximizes the probability of the correct output given the input sentence. Concretely, for each training pair (X, Y), we will learn a parametric model (with parameters θ), by solving the following optimization problem:

$$\theta^* = \arg\max_{\theta} \sum_{X,Y} \log p(Y|X;\theta) \quad (1)$$

where the sum is assumed to be over all training examples. To model the probability p, we use the same architecture described by Sutskever et al. (2014). In particular, we use a RNN based on the Long Short Term Memory (LSTM) unit (Hochreiter & Schmidhuber, 1997), designed to avoid vanishing gradients and to remember some long-distance dependences from the input sequence. Figure 1 shows a basic LSTM architecture. The RNN is fed with input words X_i (one at a time), until we feed a special symbol "GO". It is now a common practice (Sutskever et al., 2014; Li & Jurafsky, 2015) to start feeding the input in reversed order, as it has been shown to perform better empirically. During the first pass over the input, the network is expected to learn a compact, distributed representation of the input sentence, which will allow it to start generating the right predictions when the second pass starts, after the "GO" symbol is read.

We can apply the chain rule to decompose Equation (1) as follows:

$$p(Y|X;\theta) = \prod_{t=1}^{T} p(Y_t|Y_1, \ldots, Y_{t-1}, X; \theta) \quad (2)$$

noting that we made no independence assumptions. Once we find the optimal θ^*, we construct our estimated compression $\hat{Y}$ as:

$$\hat{Y} = \arg\max_{Y} p(Y|X;\theta^*) \quad (3)$$

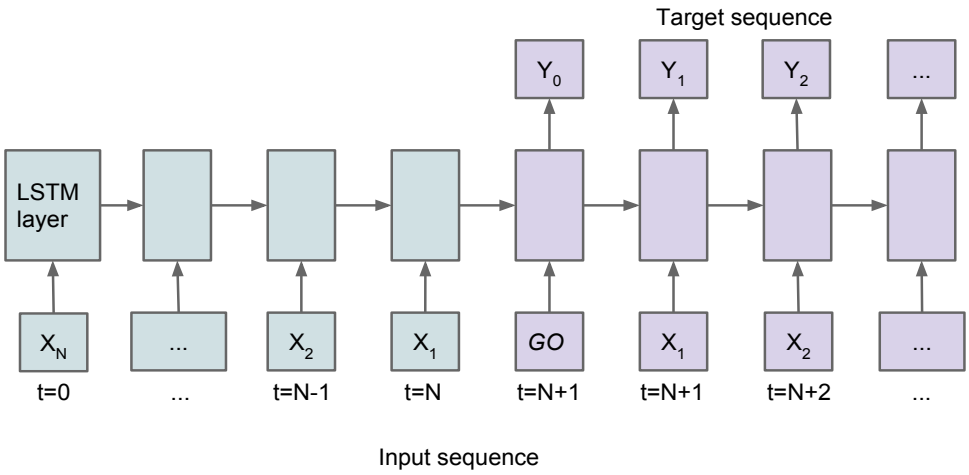

Figure 1: High-level overview of an LSTM unrolled through time.

LSTM cell: Let us review the sequence-to-sequence LSTM model. The Long Short Term Memory model of Hochreiter & Schmidhuber (1997) is defined as follows. Let x_t, h_t, and m_t be the input, control state, and memory state at timestep t. Then, given a sequence of inputs $(x_1, \ldots, x_T)$, the LSTM computes the h-sequence $(h_1, \ldots, h_T)$ and the m-sequence $(m_1, \ldots, m_T)$ as follows

$$\begin{aligned} i_t &= \text{sigm}(W_1 x_t + W_2 h_{t-1}) \\ i'_t &= \tanh(W_3 x_t + W_4 h_{t-1}) \\ f_t &= \text{sigm}(W_5 x_t + W_6 h_{t-1}) \\ o_t &= \text{sigm}(W_7 x_t + W_8 h_{t-1}) \\ m_t &= m_{t-1} \odot f_t + i_t \odot i'_t \\ h_t &= m_t \odot o_t \end{aligned}$$

The operator $\odot$ denotes element-wise multiplication, the matrices $W_1, \ldots, W_8$ and the vector h_0 are the parameters of the model, and all the non-linearities are computed element-wise.

Stochastic gradient descent is used to maximize the training objective (Eq. (1)) w.r.t. all the LSTM parameters.

Network architecture: In these experiments we have used the architecture depicted in Figure 3. Following Vinyals et al. (2014), we have used three stacked LSTM layers to allow the upper layers to learn higher-order representations of the input, interleaved with dropout layers to prevent overfitting (Srivastava et al., 2014). The output layer is a SoftMax classifier that predicts, after the "GO" symbol is read, one of the following three

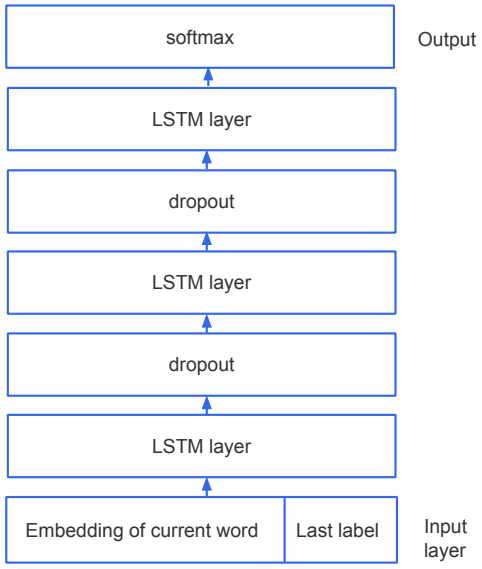

Figure 3: Architecture of the network used for sentence compression. Note that this basic structure is then unrolled 120 times, with the standard dependences from LSTM networks (Hochreiter & Schmidhuber, 1997).

labels: **1**, if a word is to be retained in the compression, **0** if a word is to be deleted, or **EOS**, which is the output label used for the "GO" input and the end-of-sentence final period.

Input representation: In the simplest implementation, that we call LSTM, the input layer has 259 dimensions. The first 256 contain the embedding-vector representation of the current in-

    return TOP(Beam)
end function
```

Figure 2: Pseudocode of the beam-search algorithm for compressing an input sentence.

put word, pre-trained using the Skipgram model[2] (Mikolov et al., 2013). The final three dimensions contain a one-hot-spot representation of the gold-standard label of the previous word (during training), or the generated label of the previous word (during decoding).

For the LSTM+PAR architecture we first parse the input sentence, and then we provide as input, for each input word, the embedding-vector representation of that word and its parent word in the dependency tree. If the current input is the root node, then a special parent embedding is constructed with all nodes set to zero except for one node. In these settings we want to test the hypothesis whether knowledge about the parent node can be useful to decide if the current constituent is relevant or not for the compression. The dimensionality of the input layer in this case is 515. Similarly to McDonald (2006), syntax is used here as a soft feature in the model.

For the LSTM+PAR+PRES architecture, we again parse the input sentence, and use a 518-sized embedding vector, that includes:

- The embedding vector for the current word (256 dimensions).
- The embedding vector for the parent word (256 dimensions).
- The label predicted for the last word (3 dimensions).
- A bit indicating whether the parent word has already been seen and kept in the compression (1 dimension).
- A bit indicating whether the parent word has already been seen but discarded (1 dimension).
- A bit indicating whether the parent word comes later in the input (1 dimension).

Decoding: Eq. (3) involves searching through all possible output sequences (given X). Contrary to the baseline, in the case of LSTMs the complete previous history is taken into account for each prediction and we cannot simplify Eq. (2) with a Markov assumption. Therefore, the search space at decoding time is exponential on the length of the input, and we have used a beam-search procedure as described in Figure 2.

Fixed parameters: For training, we unfold the network 120 times and make sure that none of our training instances is longer than that. The learning rate is initialized at 2, with a decay factor of 0.96 every 300,000 traning steps. The dropping probability for the dropout layers is 0.2. The number of nodes in each LSTM layer is always identical to the number of nodes in the input layer. We have not tuned these parameters nor the number of stacked layers.

5 Evaluation

5.1 Data

Both the LSTM systems we introduced and the baseline require a training set of a considerable size. In particular, the LSTM model uses 256-dimensional embeddings of token sequences and cannot be expected to perform well if trained on a thousand parallel sentences, which is the size of the commonly used data sets (Knight & Marcu, 2000; Clarke & Lapata, 2006). Following the method of Filippova & Altun (2013), we collect a much larger corpus of about two million parallel sentence-compression instances from the news where every compression is a subsequence of tokens from the input. For testing, we use the publicly released set of 10,000 sentence-compression pairs[3]. We take the first 200 sentences from this set for the manual evaluation with human raters, and the first 1,000 sentences for the automatic evaluation.

5.2 Experiments

We evaluate the baseline and our systems on the 200-sentence test set in an experiment with human raters. The raters were asked to rate *readability* and *informativeness* of compressions given the input which are the standard evaluation metrics for compression. The former covers the grammatical correctness, comprehensibility and fluency of the output while the latter measures the amount of important content preserved in the compression.

Additionally, for experiments on the development set, we used two metrics for automatic evaluation: *per-sentence accuracy* (i.e., how many compressions could be fully reproduced) and *word-based F1-score*. The latter differs from the RASP-based relation F-score by Riezler et al. (2003) in that we simply compute the recall and precision in terms of tokens kept in the golden and the generated compressions. We report these results for completeness although it is the results of the human evaluation from which we draw our conclusions.

Compression ratio: The three versions of our system (LSTM*) and the baseline (MIRA) have comparable compression ratios (CR) which are defined as the length of the compression in characters divided over the sentence length. Since the ratios are very close, a comparison of the systems' scores is justified (Napoles et al., 2011).

Automatic evaluation: A total of 1,000 sentence pairs from the test set[4] were used in the automatic evaluation. The results are summarized in Table 1.

	F1	*Acc*	*CR*
MIRA	0.75	0.21	0.37
LSTM	0.80	0.30	0.39
LSTM+PAR	0.81	0.31	0.38
LSTM+PAR+PRES	0.82	0.34	0.38

Table 1: F1-score, per-sentence accuracy and compression ratio for the baseline and the systems

There is a significant difference in performance of the MIRA baseline and the LSTM models, both in terms of F1-score and in accuracy. More than 30% of golden compressions could be fully regenerated by the LSTM systems which is in sharp contrast with the 20% of MIRA. The differences in F-score between the three versions of LSTM are not significant, all scores are close to 0.81.

Evaluation with humans: The first 200 sentences from the set of 1,000 used in the automatic evaluation were compressed by each of the four systems. Every sentence-compression pair was rated by three raters who were asked to select a rating on a five-point Likert scale, ranging from one to five. In very few cases (around 1%) the ratings were inconclusive (i.e., *1, 3, 5* were given to the same pair) and had to be skipped. Table 2 summarizes the results.

	read	*info*
MIRA	4.31	3.55
LSTM	4.51†	3.78†
LSTM+PAR	4.40	3.73
LSTM+PAR+PRES	4.37	3.79†

Table 2: Readability and informativeness for the baseline and the systems: † stands for *significantly better than MIRA with 0.95 confidence*.

The results indicate that the LSTM models produce more readable and more informative compressions. Interestingly, there is no benefit in using the syntactic information, at least not with

the amount of parallel data we had at our disposal. The simple LSTM model which only uses token embeddings to generate a sequence of deletion decisions significantly outperforms the baseline which was given not only embeddings but also syntactic and other features.

Discussion: What are the wins and losses of the LSTM systems? Figure 4 presents some of the evaluated sentence-compression pairs. In terms of readability, the basic LSTM system performed surprisingly well. Only in a few cases (out of 200) did it get an average score of two or three. Sentences which pose difficulty to the model are the ones with quotes, intervening commas, or other uncommon punctuation patterns. For example, in the second sentence in Figure 4, if one removes from the input the age modifiers and the preceding commas, the words *and Chris Martin* are not dropped and the output compression is grammatical, preserving both conjoined elements.

With regard to informativeness, the difficult cases are those where there is very little to be removed and where the model still removed more than a half to achieve the compression ratio it observed in the training data. For example, the only part that can be removed from the fourth sentence in Figure 4 is the modifier of *police*, everything else being important content. Similarly, in the fifth sentence the context of the event must be retained in the compression for the event to be interpreted correctly.

Arguably, such cases would also be difficult for other systems. In particular, recognizing when the context is crucial is a problem that can be solved only by including deep semantic and discourse features which has not been attempted yet. And

sentences with quotes (direct speech, a song or a book title, etc.) are challenging for parsers which in turn provide important signals for most compression systems.

The bottom of Figure 4 contains examples of good compressions. Even though for a significant number of input sentences the compression was a continuous subsequence of tokens, there are many discontinuous compressions. In particular, the LSTM model learned to drop appositions, no matter how long they are, temporal expressions, optional modifiers, introductory clauses, etc.

Our understanding of why the extended model (LSTM+PAR+PRES) performed worse in the human evlauation than the base model is that, in the absence of syntactic features, the basic LSTM learned a model of syntax useful for compression, while LSTM++, which was given syntactic information, learned to optimize for the particular way the "golden" set was created (tree pruning). While the automatic evaluation penalized all deviations from the single golden variant, in human evals there was no penalty for readable alternatives.

6 Conclusions

We presented, to our knowledge, a first attempt at building a competitive compression system which is given no linguistic features from the input. The two important components of the system are (1) word embeddings, which can be obtained by anyone either pre-trained, or by running `word2vec` on a large corpus, and (2) an LSTM model which draws on the very recent advances in research on RNNs. The training data of about two million sentence-compression pairs was collected automatically from the Internet.

Our results clearly indicate that a compression model which is not given syntactic information explicitly in the form of features may still achieve competitive performance. The high readability and informativeness scores assigned by human raters support this claim. In the future, we are planning to experiment with more "interesting" paraphrasing models which translate the input not into a zero-one sequence but into words.

Abstract

Syntactic language models and *N*-gram language models have both been used in word ordering. In this paper, we give an empirical comparison between *N*-gram and syntactic language models on word order task. Our results show that the quality of automatically-parsed training data has a relatively small impact on syntactic models. Both of syntactic and *N*-gram models can benefit from large-scale raw text. Compared with *N*-gram models, syntactic models give overall better performance, but they require much more training time. In addition, the two models lead to different error distributions in word ordering. A combination of the two models integrates the advantages of each model, achieving the best result in a standard benchmark.

1 Introduction

N-gram language models have been used in a wide range of the generation tasks, such as machine translation (Koehn et al., 2003; Chiang, 2007; Galley et al., 2004), text summarization (Barzilay and McKeown, 2005) and realization (Guo et al., 2011). Such models are trained from large-scale raw text, capturing distributions of local word *N*-grams, which can be used to improve the fluency of synthesized text.

More recently, syntactic language models have been used as a complement or alternative to *N*-gram language models for machine translation (Charniak et al., 2003; Shen et al., 2008; Schwartz et al., 2011), syntactic analysis (Chen et al., 2012) and tree linearization (Song et al., 2014). Compared with *N*-gram models, syntactic models capture rich structural information, and can be more effective in improving the fluency of large constituents, long-range dependencies and overall sentential grammaticality. However, Syntactic models require annotated syntactic structures for training, which are expensive to obtain manually. In addition, they can be slower compared to *N*-gram models.

In this paper, we make an empirical comparison between syntactic and *N*-gram language models on the task of word ordering (Wan et al., 2009; Zhang and Clark, 2011a; De Gispert et al., 2014), which is to order a set of input words into a grammatical and fluent sentence. The task can be regarded as an abstract language modeling problem, although methods have been explored extending it for tree linearization (Zhang, 2013), broader text generation (Song et al., 2014) and machine translation (Zhang et al., 2014).

We choose the model of Liu et al.(2015) as the syntactic language model. There has been two main types of syntactic language models in the literature, the first being relatively more oriented to syntactic structure, without an explicit emphasis on word orders (Shen et al., 2008; Chen et al., 2012). As a result, this type of syntactic language models are typically used jointly with *N*-gram model for text-to-text tasks. The second type models syntactic structures incrementally, thereby can be used to directly score surface orders (Schwartz et al., 2011; Liu et al., 2015). We choose the discriminative model of Liu et al. (2015), which gives state-of-the-art results for word ordering.

We try to answer the following research questions by comparing the syntactic model and the *N*-gram model using the same search algorithm.

• **What is the influence of automatically-parsed training data on the performance of syntactic models.** Because manual syntactic annotations are relatively limited and highly expensive, it is necessary to use large-scale automatically-parsed sentences for training syntactic language models. As a result, the syntactic structures that a word ordering system learns can be inaccurate. However, this might not affect

the quality of the synthesized output, which is a string only. We quantitatively study the influence of parsing accuracy of syntactic training data on word ordering output.

• **What is the influence of data scale on the performance.** *N*-gram language models can be trained efficiently over large numbers of raw sentences. In contrast, syntactic language models can be much slower to train due to rich features. We compare the output quality of the two models on different scales of training data, and also on different amounts of training time.

• **What are the errors characteristics of each model.** Syntactic language models can potentially be better in capturing larger constituents and overall sentence structures. However, compared with *N*-gram models, little work has been done to quantify the difference between the two models. We characterise the outputs using a set of different measures, and show empirically the relative strength and weakness of each model.

• **What is the effect of model combination.** Finally, because the two models make different types of errors, they can be combined to give better outputs. We develop a combined model by discretizing probability from *N*-gram model, and using them as features in the syntactic model. The combined model gives the best results in a standard benchmark.

2 Systems

2.1 Syntactic word ordering

Syntactic word ordering algorithms take a multi-set of input words constructing an output sentence and its syntactic derivation simultaneously. Transition-based syntactic word ordering can be modelled as an extension to transition-based parsing (Liu et al., 2015), with the main difference being that the order of words is not given in the input, which leads to a much larger search space.

We take the system of Liu, et al.[1], which gives state-of-the-art performance and efficiencies in standard word ordering benchmark. It maintains outputs in stack σ, and orders the unprocessed incoming words in a set ρ. Given an input bag of words, ρ is initialized to the input and σ is initialized as empty. The system repeatedly applies transition actions to consume words from ρ and construct output on σ.

Figure 1 shows the deduction system, where ρ is unordered and any word in ρ can be shifted onto the stack σ. The set of actions are SHIFT, L-ARC and R-ARC. The SHIFT actions add a word to the stack. For the L-ARC and R-ARC actions, new arcs $\{j \leftarrow i\}$ and $\{j \rightarrow i\}$ are constructed respectively. Under these possible actions, the unordered word set "*potatoes*$_0$ *Tom*$_1$ *likes*$_2$" is generated as shown in Figure 2, and the result is "*Tom*$_1$ ←*likes*$_2$→*potatoes*$_0$".

We apply the learning and search framework of Zhang and Clark (2011a). Pseudocode of the search algorithm is shown in Algorithm 1. [] refers to an empty stack, and $set(1...n)$ represents the full set of input words W and n is the number of distinct words. $candidates$ stores possible states, and $agenda$ stores temporary states transited from possible actions. GETACTIONS generates a set of possible actions depending on the current state s. APPLY generates a new state by applying action on the current state s. N-BEST produces the top k candidates in $agenda$. Finally, the algorithm returns the highest-score state $best$ in the $agenda$.

A global linear model is used to score search hypotheses. Given a hypothesis h, its score is calculated by:

$$Score(h) = \Phi(h) \cdot \vec{\theta},$$

[1] http://sourceforge.net/projects/zgen/

Algorithm 1 Transition-based linearisation

Input: *W*, a set of input word
Output: the highest-scored final state

$candidates \leftarrow ([], set(1..n), \emptyset)$
$agenda \leftarrow \emptyset$
$N \leftarrow 2n$
for $i \leftarrow 1..N$ **do**

    for $action$ **in** GETACTIONS(s) **do**
      $agenda \leftarrow$ APPLY($s, action$)
    end for
  end for
  $candidates \leftarrow$ N-BEST($agenda$)
  $agenda \leftarrow \emptyset$
end for
$best \leftarrow$ BEST($candidates$)
return $best$

where $\Phi(h)$ is the feature vector of h, extracted by using the same feature templates as Liu et al.(2015), which are shown in Table 1 and $\vec{\theta}$ is the parameter vector of the model. The feature templates essentially represents a syntactic language model. As shown in Figure 2, from the hypotheses produced in steps 2 and 4, the features "$Tom_1 \leftarrow likes_2$" and "$likes_2 \rightarrow potatoes_0$" are extracted, which corresponds to $P(Tom_1|likes_2)$ and $P(potatoes_0|likes_2)$ respectively in the dependency language model of Chen et al.,(2012).

Training. We apply perceptron with early-update (Collins and Roark, 2004), and iteratively tune related parameters on a set of development data. For each iteration, we measure the performance on the development data, and choose best parameters for final tests.

2.2 *N*-gram word ordering

We build an *N*-gram word ordering system under the same beam-search framework as the syntactic word ordering system. In particular, search is performed incrementally, from left to right, adding one word at each step. The decoding process can be regarded as a simplified version of Algorithm 1, with only SHIFT being returned by GETACTIONS, and the score of each transition is given by a standard *N*-gram language model. We use the same beam size for both *N*-gram and the syntactic word ordering. Compared with the syntactic model, the *N*-gram model has less information for disambiguation, but also has less structural ambiguities, and therefore a smaller search space.

cus et al., 1993), and the Agence France-Presse (AFP) and Xinhua News Agency (XIN) subsets of the English Giga Word Fifth Edition (Parker et al., 2011). As the development data, we use WSJ section 0 for parameter tuning. For testing, we use data from various domain, which consist of WSJ section 23, Washington Post/Bloomberg(WPB) subsets of the English Giga Word Fifth Edition and SANCL blog data, as shown in Table 2. Example sentence in various test domains are shown in Table 3.

3.2 Evaluation metrics

We follow previous work and use the BLEU metric (Papineni et al., 2002) for evaluation. Since BLEU only scores *N*-gram precisions, it can be in favour of *N*-gram language models. We additionally use METEOR[3](Denkowski and Lavie, 2010) to evaluate the system performances. The BLEU metric measures the fluency of generated sentence without considering long range ordering. The METEOR metric can potentially fix this problem using a set of mapping between generated sentences and references to evaluate distortion. The following example illustrates the difference between BLEU and METEOR on long range reordering, where the reference is

(1) *[The document is necessary for developer ,]$_0$ [so you can not follow this document to get right options .]$_1$*

and the generated output sentence is

(2) *[so you can not follow this document to get right options .]$_1$ [The document is necessary for developer ,]$_0$.*

There is a big distortion in the output. The BLEU metric gives a score of 90.09 out of 100, while the METEOR gives a score of 61.34 out of 100. This is because that METEOR is based on explicit word-to-word matches over the whole sentence. For word ordering, word-to-word matches are unique, which facilitates METEOR evaluation between generated sentences and references. As can bee seen from the example, long range distortion can highly influence the METEOR scores making the METEOR metric more suitable for evaluating word ordering distortions.

set88	all	30	88.10

Table 4: Parsing accuracy settings.

3.3 Data preparation

For all the experiments, we assume that the input is a bag of words without order, and the output is a fully ordered sentence. Following previous work (Wan et al., 2009; Zhang, 2013; Liu et al., 2015), we treat base noun phrases (i.e. noun phrases do not contains other noun phrases, such as '*Pierre Vinken*' and '*a big cat*') as a single word. This avoids unnecessary ambiguities in combination between their subcomponents.

The syntactic model requires that the training sentences have syntactic dependency structure. However, only the WSJ data contains gold-standard annotations. In order to obtain automatically annotated dependency trees, we train a constituent parser using the gold-standard bracketed sentences from WSJ, and automatically parse the Giga Word data. The results are turned into dependency trees using Penn2Malt[4], after base noun phrases are extracted. In our experiments, we use ZPar[5] (Zhu et al., 2013) for automatic constituent parsing.

In order to study the influence of parsing accuracy of the training data, we also use ten-fold jackknifing to construct WSJ training data with different accuracies. The data is randomly split into ten equal-size subsets, and each subset is automatically parsed with a parser trained on the other

Table 5: Influence result of parsing accuracy.

nine subset. In order to obtain datasets with different parsing accuracies, we randomly sample a small number of sentences from each training subset, as shown in Table 4. The dependency trees of each set are derived from these bracketed sentences using Penn2Malt after base noun phrase are extracted as a single word.

4 Influence of parsing accuracy

4.1 In-domain word ordering

We train the syntactic models on the WSJ training parsing data with different accuracies. The WSJ development data are used to find out the optimal number of training iterations for each experiments, and the WSJ test results are shown in Table 5.

Table 5 shows that the parsing accuracy can affect the performance of the syntactic model. A higher parsing accuracy can lead to a better syntactic language model. It conforms to the intuition that syntactic quality affects the fluency of surface texts. On the other hand, the influence is not huge, the BLEU scores decrease by 1.0 points as the parsing accuracy decreases from 88.10% to 57.31%

4.2 Cross-domain word ordering

The influence of parsing accuracy of the training data on cross-domain word ordering is measured by using the same training settings, but testing on the WPB and SANCL test sets. Table 5 shows that the performance on cross-domain word ordering cannot reach that of in-domain word ordering using the syntactic models. Compared with the cross-domain experiments, the influence of parsing accuracy becomes smaller. In the WPB test, the fluctuation of performance decline to about 0.9 BLEU points, and in the SANCL test, the fluctuation is about 1.1 BLEU points.

In conclusion, the experiments show that parsing accuracies have a relatively small influence on the syntactic models. This suggests that it is possible to use large automatically-parsed data to train syntactic models. On the other hand, when the training data scale increases, syntactic models can become much slower to train compared with *N*-gram models. The influence on data scale, which includes output quality and training time, is further studied in the next section.

5 Influence of data scale

We use the AFP news data as the training data for the experiments of this section. The syntactic models are trained using automatically-parsed trees derived from ZPar, as described in Section 3.3. The WPB test data is used to measure in-domain performance, and the SANCL blog data is used to measure cross-domain performance.

5.1 Influence on BLEU and METEOR

The Figure 3 and 4 shows that using both the BLEU and the METEOR metrics, the performance of the syntactic model is better than that of the *N*-gram models. It suggests that sentences generated by the syntactic model have both better fluency and better ordering. The performance of the syntactic models is not highly weakened in cross-domain tests.

The grey dot in each figure shows the performance of the syntactic model trained on the gold WSJ training data, and evaluated on the same WPB and SANCL test data sets. A comparison between the grey dots and the dashed lines shows that the syntactic model trained on the WSJ data perform better than the syntactic model trained on similar amounts of AFP data. This again shows the effect of syntactic quality of the training data.

On the other hand, as the scale of automatically-parsed AFP data increases, the performance of the

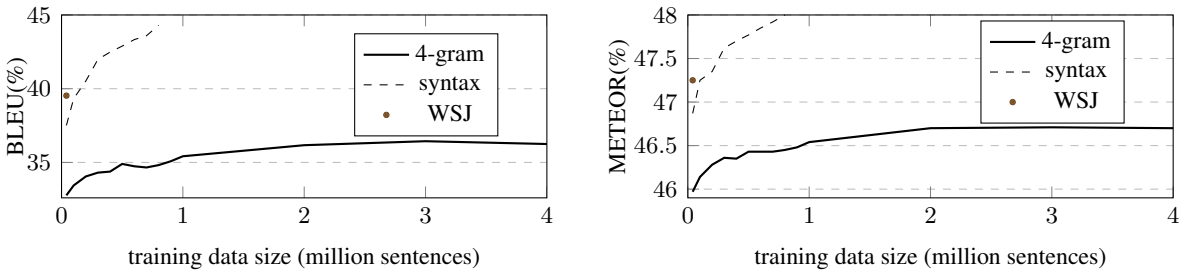

Figure 3: In-domain results on different training data size.

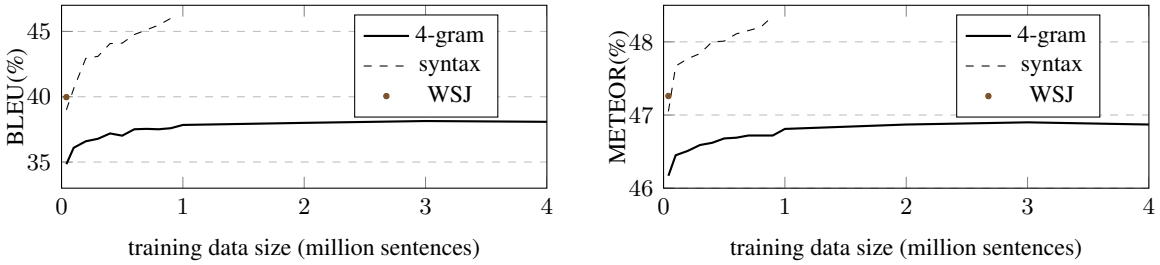

Figure 4: Cross-domain results on different training data sizes.

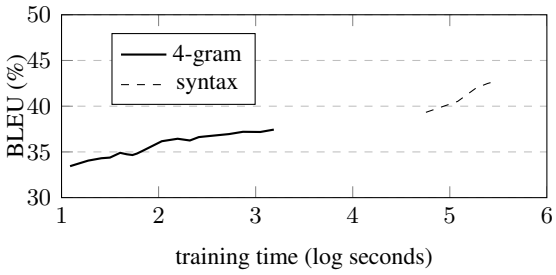

Figure 5: BLEU on different training times.

syntactic model rapidly increases, surpassing the syntactic model trained on the high-quality WSJ data. This observation is important, showing that large-scale data can be used to alleviate the problem of lower syntactic quality in automatically-parsed data, which can be leveraged to address the scarcity issue of manually annotated data in both in-domain and cross-domain settings.

5.2 Influence on training time

The training time of both syntactic models and *N*-gram models increases as the size of training data increases. Figure 5 shows the BLEU of the two systems under different amounts of training time. There is no result reported for the syntactic model beyond 1 million training sentences, because training becomes infeasibly slow [6]. On the other hand, the *N*-gram model can be trained using all the WSJ, AFP, XIN training sentences, which are 53 millions, within $10^{3.2}$ seconds. As a result, there is no overlap between the syntactic model and the *N*-gram model curves.

As can be seen from the figure, the syntactic model is much slower to train. However, it benefits more from the scale of the training data, with the slope of the dashed curve being steeper than that of the solid curve. The *N*-gram model can be trained with more data thanks to the fast training speed. However, the performance of the *N*-gram model flattens when the training data size reaches beyond 3 million. Projection of the solid curve suggests that the performance of the *N*-gram model may not surpass that of the syntactic model even if sufficiently large data is available for training the *N*-gram model in more time.

6 Error analysis

Although giving overall better performance, the syntactic model does not perform better than the *N*-gram model in all cases. Here we analyze the strength of each model via more fine-grained comparison.

In this set of experiments, the syntactic model is trained using gold-standard annotated WSJ training parse trees, and the *N*-gram model is trained using the data containing WSJ training data, AFP and XIN. The WSJ test data, which contains

[6] Our experiments are carried on a single thread of 3.60GHz CPU. If the training time is over 90 hours for a model, we consider it infeasible.

golden constituent trees, is used to analyze errors in different aspects.

6.1 Sentence length

The BLEU and METEOR scores of the two systems on various sentence lengths are shown in Figure 6. The results are measured by binning sentences according to their lengths, so that each bin contains about the same number of sentences. As shown by the figure, the *N*-gram model performs better on short sentences (less than 8 tokens), and the syntactic model performs better on longer sentences. This can be explained by the fact that longer sentences have richer underlying syntactic structures, which can better captured by the syntactic model. In contrast, for shorter sentences, the syntactic structure is relatively simple, and therefore the *N*-gram model can give better performance based on string patterns, which form smaller search spaces.

6.2 Distortion range

We measure the average distortion rate of output word w using the following metric:

$$distortion(w) = \frac{|i_w - i'_w|}{len(S_w)},$$

where i_w is index of word w in the output sentence S_w, i'_w is the index of the word w in the reference sentence. $len(S_w)$ is the number of tokens in sentence S_w. Figure 7 shows distributions of distortion respectively by the syntactic and *N*-gram model. The *N*-gram model makes relatively fewer short-range distortions, but more long-range distortions. This can be explained by the local scoring nature of the *N*-gram model. In contrast, the syntactic model makes less long-range distortions, which can suggest better sentence structure.

6.3 Constituent span

We further evaluate sentence structure correctness by evaluating the recalls of discovered constituent span in output two systems, respectively. As shown in Figure 8. The syntactic model performs better in most constituent labels. However, the *N*-gram model performs better in WHPP, SBARQ and WHNP.

In the test data, WHPP, SBARQ and WHNP are much less than PP, NP, VP, ADJP, ADVP and CONJP, on which the syntactic model gives better recalls. WHNP spans are small and most of them consist of a question word (WP$) and one or two nouns (e.g. “whose (WP$) parents (NNS)”). WHPP spans are also small and usually consist of a preposition (IN) and a WHNP span (e.g “at (IN) what level (WHNP)”). The *N*-gram model performs better on these small spans. The syntactic model also performs better on S, which covers the whole sentence structure. This verifies the hypothesis introduce that syntactic language models better capture overall sentential grammaticality.

Table 7: Final results on various domains.

7 Combining the syntactic and *N*-gram models

The results above show the respective error characteristics of each model, which are complimentary. This suggests that better results can be achieved by model combination.

7.1 *N*-gram language model feature

We integrate the two types of models by using *N*-gram language model probabilities as features in the syntactic model. *N*-gram language model probabilities, which ranges from 0 to 1. Direct use of real value probabilities as features does not work well in our experiments, and we use discretized features instead. For the L-ARC and R-ARC actions, because no words are pushed onto the stack, The NLM feature is set to NULL by default. For the SHIFT action, different feature values are extracted depending on the NLM from 0 to 1.

In order to measure the *N*-gram probabilities on our data, we train the 4-gram language model WSJ, AFP and XIN data, and randomly sample 4-gram probabilities from the syntactic model output on the WSJ development data, finding that most of 4-gram probabilities p are larger than $10^{-12.5}$. In this way, if p lower than $10^{-12.5}$, NLM feature value is set to LOW. As for p larger than $10^{-12.5}$, we extract the discrete features by assigning them into different bins. We bin the 4-gram probabilities with different granularities without overlap features. As shown in Table 6, NLM-20, NLM-10, NLM-5 and NLM-2 respectively use 20, 10, 5 and 2 bins to capture NLM feature values.

7.2 Final results

We use the WSJ, AFP and XIN for training the *N*-gram model[7]. The same WSJ, WPB and SANCL test data are used to measure performances on different domains.

The experimental results are shown in Tables 7 and 8. In both in-domain and cross-domain test data, the combined system outperforms all other systems, with a BLEU score of 52.38 been achieved in the WSJ domain. It would be overly expensive to obtain a human oracle on discusses. However, according to Papineni (2002), a BLEU

[7]For the combined model, we used the WSJ training data for training, because the syntactic model is slower to train using large data. However, we did a set of experiments to scale up the training data by sampling 900k sentences from AFP. Results show that the combined model gives BLEU scores of 42.86 and 44.44 on the WPB and SANCL tests, respectively. Cross-domain BLEU on WSJ, however falls to 49.84.

Table 9: Output samples.

score of over 52.38 indicate an easily understood sentence. Some sample outputs with different BLEU scores are shown in Table 9

In addition, Table 7 shows that the *N*-gram model is the fastest among the models due to its small search space. The running time of the combined system is larger than the pure syntactic system, because of *N*-gram probability computation. Table 8 compare our results with different previous methods on word ordering. Our combined model gives the best reported performance on this standard benchmarks.

8 Conclusion

We empirically compared the strengths and error distributions of syntactic and *N*-gram language models on word ordering, showing that both can benefit from large-scale raw text. The influence of parsing accuracies has relatively small impact on the syntactic language model trained on automatically-parsed data, which enables scaling up of training data for syntactic language models. However, as the size of training data increases, syntactic language models can become intolerantly slow to train, making them benefit less from the scale of training data, as compared with *N*-gram models.

Syntactic models give better performance compared with *N*-gram models, despite trained with less data. On the other hand, the two models lead to different error distributions in word ordering. As a result, we combined the advantages of both systems by integrating a syntactic model trained with relatively small data and an *N*-gram model trained with relatively large data. The resulting model gives better performance than both single models and achieves the best reported scores in a standard benchmark for word ordering.

We release our code under GPL at `https://github.com/SUTDNLP/ZGen`. Future work includes application of the system on text-to-text problem such as machine translation.

Abstract

Summarization based on text extraction is inherently limited, but generation-style abstractive methods have proven challenging to build. In this work, we propose a fully data-driven approach to abstractive sentence summarization. Our method utilizes a local attention-based model that generates each word of the summary conditioned on the input sentence. While the model is structurally simple, it can easily be trained end-to-end and scales to a large amount of training data. The model shows significant performance gains on the DUC-2004 shared task compared with several strong baselines.

1 Introduction

Summarization is an important challenge of natural language understanding. The aim is to produce a condensed representation of an input text that captures the core meaning of the original. Most successful summarization systems utilize *extractive* approaches that crop out and stitch together portions of the text to produce a condensed version. In contrast, *abstractive* summarization attempts to produce a bottom-up summary, aspects of which may not appear as part of the original.

We focus on the task of sentence-level summarization. While much work on this task has looked at deletion-based sentence compression techniques (Knight and Marcu (2002), among many others), studies of human summarizers show that it is common to apply various other operations while condensing, such as paraphrasing, generalization, and reordering (Jing, 2002). Past work has modeled this abstractive summarization problem either using linguistically-inspired constraints (Dorr et al., 2003; Zajic et al., 2004) or with syntactic transformations of the input text (Cohn and Lapata, 2008; Woodsend et al., 2010). These approaches are described in more detail in Section 6.

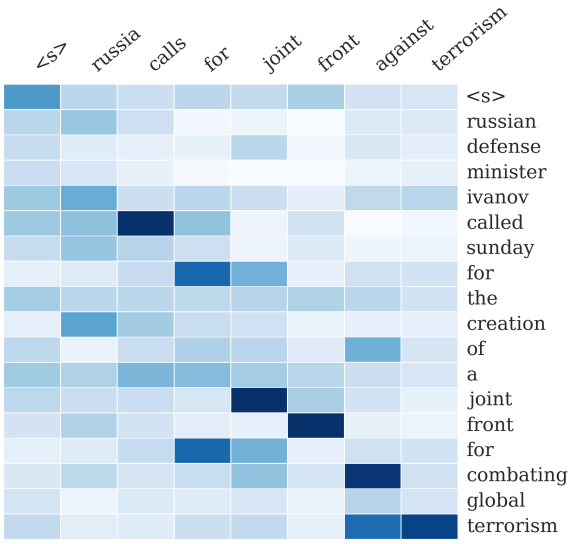

Figure 1: Example output of the attention-based summarization (ABS) system. The heatmap represents a soft alignment between the input (right) and the generated summary (top). The columns represent the distribution over the input after generating each word.

We instead explore a fully data-driven approach for generating abstractive summaries. Inspired by the recent success of neural machine translation, we combine a neural language model with a contextual input encoder. Our encoder is modeled off of the attention-based encoder of Bahdanau et al. (2014) in that it learns a latent soft alignment over the input text to help inform the summary (as shown in Figure 1). Crucially both the encoder and the generation model are trained jointly on the sentence summarization task. The model is described in detail in Section 3. Our model also incorporates a beam-search decoder as well as additional features to model extractive elements; these aspects are discussed in Sections 4 and 5.

This approach to summarization, which we call Attention-Based Summarization (ABS), incorporates less linguistic structure than comparable abstractive summarization approaches, but can easily

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 379–389,
Lisbon, Portugal, 17-21 September 2015.

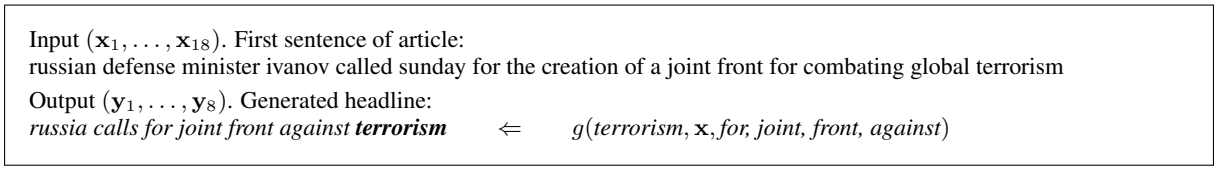

Figure 2: Example input sentence and the generated summary. The score of generating $\mathbf{y}_{i+1}$ (`terrorism`) is based on the context $\mathbf{y}_c$ (`for ... against`) as well as the input $\mathbf{x}_1 \ldots \mathbf{x}_{18}$. Note that the summary generated is abstractive which makes it possible to *generalize* (`russian defense minister` to `russia`) and *paraphrase* (`for combating` to `against`), in addition to *compressing* (dropping `the creation of`), see Jing (2002) for a survey of these editing operations.

scale to train on a large amount of data. Since our system makes no assumptions about the vocabulary of the generated summary it can be trained directly on any document-summary pair.[1] This allows us to train a summarization model for headline-generation on a corpus of article pairs from Gigaword (Graff et al., 2003) consisting of around 4 million articles. An example of generation is given in Figure 2, and we discuss the details of this task in Section 7.

To test the effectiveness of this approach we run extensive comparisons with multiple abstractive and extractive baselines, including traditional syntax-based systems, integer linear program-constrained systems, information-retrieval style approaches, as well as statistical phrase-based machine translation. Section 8 describes the results of these experiments. Our approach outperforms a machine translation system trained on the same large-scale dataset and yields a large improvement over the highest scoring system in the DUC-2004 competition.

2 Background

We begin by defining the sentence summarization task. Given an input sentence, the goal is to produce a condensed summary. Let the input consist of a sequence of M words $\mathbf{x}_1, \ldots, \mathbf{x}_M$ coming from a fixed vocabulary $\mathcal{V}$ of size $|\mathcal{V}| = V$. We will represent each word as an indicator vector $\mathbf{x}_i \in \{0,1\}^V$ for $i \in \{1, \ldots, M\}$, sentences as a sequence of indicators, and $\mathcal{X}$ as the set of possible inputs. Furthermore define the notation $\mathbf{x}_{[i,j,k]}$ to indicate the sub-sequence of elements i, j, k.

A summarizer takes $\mathbf{x}$ as input and outputs a shortened sentence $\mathbf{y}$ of length $N < M$. We will assume that the words in the summary also come from the same vocabulary $\mathcal{V}$ and that the output is a sequence $\mathbf{y}_1, \ldots, \mathbf{y}_N$. Note that in contrast to related tasks, like machine translation, we will assume that the output length N is fixed, and that the system knows the length of the summary before generation.[2]

Next consider the problem of generating summaries. Define the set $\mathcal{Y} \subset (\{0,1\}^V, \ldots, \{0,1\}^V)$ as all possible sentences of length N, i.e. for all i and $\mathbf{y} \in \mathcal{Y}$, $\mathbf{y}_i$ is an indicator. We say a system is *abstractive* if it tries to find the optimal sequence from this set $\mathcal{Y}$,

$$\arg\max_{\mathbf{y} \in \mathcal{Y}} s(\mathbf{x}, \mathbf{y}), \tag{1}$$

under a scoring function $s : \mathcal{X} \times \mathcal{Y} \mapsto \mathbb{R}$. Contrast this to a fully *extractive* sentence summary[3] which transfers words from the input:

$$\arg\max_{m \in \{1,\ldots M\}^N} s(\mathbf{x}, \mathbf{x}_{[m_1,\ldots,m_N]}), \tag{2}$$

or to the related problem of sentence *compression* that concentrates on deleting words from the input:

$$\arg\max_{m \in \{1,\ldots M\}^N, m_{i-1} < m_i} s(\mathbf{x}, \mathbf{x}_{[m_1,\ldots,m_N]}). \tag{3}$$

While abstractive summarization poses a more difficult generation challenge, the lack of hard constraints gives the system more freedom in generation and allows it to fit with a wider range of training data.

In this work we focus on factored scoring functions, s, that take into account a fixed window of previous words:

$$s(\mathbf{x}, \mathbf{y}) \approx \sum_{i=0}^{N-1} g(\mathbf{y}_{i+1}, \mathbf{x}, \mathbf{y}_c), \tag{4}$$

[1] In contrast to a large-scale sentence compression systems like Filippova and Altun (2013) which require monotonic aligned compressions.

[2] For the DUC-2004 evaluation, it is actually the number of *bytes* of the output that is capped. More detail is given in Section 7.

[3] Unfortunately the literature is inconsistent on the formal definition of this distinction. Some systems self-described as abstractive would be extractive under our definition.

where we define $\mathbf{y}_c \triangleq \mathbf{y}_{[i-C+1,\ldots,i]}$ for a window of size C.

In particular consider the conditional log-probability of a summary given the input, $s(\mathbf{x}, \mathbf{y}) = \log p(\mathbf{y}|\mathbf{x}; \theta)$. We can write this as:

$$\log p(\mathbf{y}|\mathbf{x}; \theta) \approx \sum_{i=0}^{N-1} \log p(\mathbf{y}_{i+1}|\mathbf{x}, \mathbf{y}_c; \theta),$$

where we make a Markov assumption on the length of the context as size C and assume for $i < 1$, $\mathbf{y}_i$ is a special start symbol $\langle S \rangle$.

With this scoring function in mind, our main focus will be on modelling the local conditional distribution: $p(\mathbf{y}_{i+1}|\mathbf{x}, \mathbf{y}_c; \theta)$. The next section defines a parameterization for this distribution, in Section 4, we return to the question of generation for factored models, and in Section 5 we introduce a modified factored scoring function.

3 Model

The distribution of interest, $p(\mathbf{y}_{i+1}|\mathbf{x}, \mathbf{y}_c; \theta)$, is a conditional language model based on the input sentence $\mathbf{x}$. Past work on summarization and compression has used a noisy-channel approach to split and independently estimate a language model and a conditional summarization model (Banko et al., 2000; Knight and Marcu, 2002; Daumé III and Marcu, 2002), i.e.,

$$\arg\max_{\mathbf{y}} \log p(\mathbf{y}|\mathbf{x}) = \arg\max_{\mathbf{y}} \log p(\mathbf{y}) p(\mathbf{x}|\mathbf{y})$$

where $p(y)$ and $p(x|y)$ are estimated separately. Here we instead follow work in neural machine translation and directly parameterize the original distribution as a neural network. The network contains both a neural probabilistic language model and an encoder which acts as a conditional summarization model.

3.1 Neural Language Model

The core of our parameterization is a language model for estimating the contextual probability of the next word. The language model is adapted from a standard feed-forward neural network language model (NNLM), particularly the class of NNLMs described by Bengio et al. (2003). The full model is:

$$\begin{aligned} p(\mathbf{y}_{i+1}|\mathbf{y}_c, \mathbf{x}; \theta) &\propto \exp(\mathbf{V}\mathbf{h} + \mathbf{W}\mathrm{enc}(\mathbf{x}, \mathbf{y}_c)), \\ \tilde{\mathbf{y}}_c &= [\mathbf{E}\mathbf{y}_{i-C+1}, \ldots, \mathbf{E}\mathbf{y}_i], \\ \mathbf{h} &= \tanh(\mathbf{U}\tilde{\mathbf{y}}_c). \end{aligned}$$

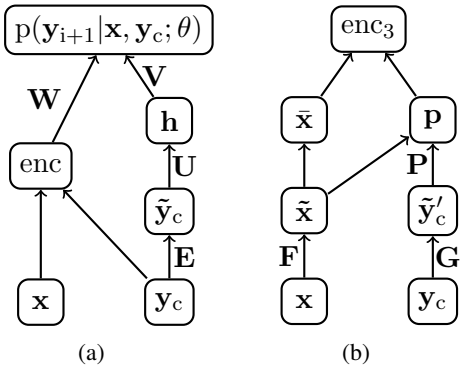

Figure 3: (a) A network diagram for the NNLM decoder with additional encoder element. (b) A network diagram for the attention-based encoder enc_3.

The parameters are $\theta = (\mathbf{E}, \mathbf{U}, \mathbf{V}, \mathbf{W})$ where $\mathbf{E} \in \mathbb{R}^{D \times V}$ is a word embedding matrix, $\mathbf{U} \in \mathbb{R}^{(CD) \times H}$, $\mathbf{V} \in \mathbb{R}^{V \times H}$, $\mathbf{W} \in \mathbb{R}^{V \times H}$ are weight matrices,[4] D is the size of the word embeddings, and $\mathbf{h}$ is a hidden layer of size H. The black-box function enc is a contextual encoder term that returns a vector of size H representing the input and current context; we consider several possible variants, described subsequently. Figure 3a gives a schematic representation of the decoder architecture.

3.2 Encoders

Note that without the encoder term this represents a standard language model. By incorporating in enc and training the two elements jointly we crucially can incorporate the input text into generation. We discuss next several possible instantiations of the encoder.

Bag-of-Words Encoder Our most basic model simply uses the bag-of-words of the input sentence embedded down to size H, while ignoring properties of the original order or relationships between neighboring words. We write this model as:

$$\begin{aligned} \mathrm{enc}_1(\mathbf{x}, \mathbf{y}_c) &= \mathbf{p}^\top \tilde{\mathbf{x}}, \\ \mathbf{p} &= [1/M, \ldots, 1/M], \\ \tilde{\mathbf{x}} &= [\mathbf{F}\mathbf{x}_1, \ldots, \mathbf{F}\mathbf{x}_M]. \end{aligned}$$

Where the input-side embedding matrix $\mathbf{F} \in \mathbb{R}^{H \times V}$ is the only new parameter of the encoder and $\mathbf{p} \in [0, 1]^M$ is a uniform distribution over the input words.

[4] Each of the weight matrices $\mathbf{U}$, $\mathbf{V}$, $\mathbf{W}$ also has a corresponding bias term. For readability, we omit these terms throughout the paper.

For summarization this model can capture the relative importance of words to distinguish content words from stop words or embellishments. Potentially the model can also learn to combine words; although it is inherently limited in representing contiguous phrases.

Convolutional Encoder To address some of the modelling issues with bag-of-words we also consider using a deep convolutional encoder for the input sentence. This architecture improves on the bag-of-words model by allowing local interactions between words while also not requiring the context $\mathbf{y}_{\mathrm{c}}$ while encoding the input.

We utilize a standard time-delay neural network (TDNN) architecture, alternating between temporal convolution layers and max pooling layers.

$$\forall j,\ \mathrm{enc}_2(\mathbf{x}, \mathbf{y}_{\mathrm{c}})_j = \max_i \tilde{\mathbf{x}}^L_{i,j}, \quad (5)$$

$$\forall i, l \in \{1, \dots L\},\ \tilde{\mathbf{x}}^l_j = \tanh(\max\{\bar{\mathbf{x}}^l_{2i-1}, \bar{\mathbf{x}}^l_{2i}\}), \quad (6)$$

$$\forall i, l \in \{1, \dots L\},\ \bar{\mathbf{x}}^l_i = \mathbf{Q}^l \tilde{\mathbf{x}}^{l-1}_{[i-Q,\dots,i+Q]}, \quad (7)$$

$$\tilde{\mathbf{x}}^0 = [\mathbf{F}\mathbf{x}_1, \dots, \mathbf{F}\mathbf{x}_M]. \quad (8)$$

Where $\mathbf{F}$ is a word embedding matrix and $\mathbf{Q}^{L \times H \times 2Q+1}$ consists of a set of filters for each layer $\{1, \dots L\}$. Eq. 7 is a temporal (1D) convolution layer, Eq. 6 consists of a 2-element temporal max pooling layer and a pointwise non-linearity, and final output Eq. 5 is a max over time. At each layer $\tilde{x}$ is one half the size of $\bar{x}$. For simplicity we assume that the convolution is padded at the boundaries, and that M is greater than 2^L so that the dimensions are well-defined.

Attention-Based Encoder While the convolutional encoder has richer capacity than bag-of-words, it still is required to produce a single representation for the entire input sentence. A similar issue in machine translation inspired Bahdanau et al. (2014) to instead utilize an attention-based contextual encoder that constructs a representation based on the generation context. Here we note that if we exploit this context, we can actually use a rather simple model similar to bag-of-words:

$$\begin{aligned}
\mathrm{enc}_3(\mathbf{x}, \mathbf{y}_{\mathrm{c}}) &= \mathbf{p}^\top \bar{\mathbf{x}}, \\
\mathbf{p} &\propto \exp(\tilde{\mathbf{x}} \mathbf{P} \tilde{\mathbf{y}}'_{\mathrm{c}}), \\
\tilde{\mathbf{x}} &= [\mathbf{F}\mathbf{x}_1, \dots, \mathbf{F}\mathbf{x}_M], \\
\tilde{\mathbf{y}}'_{\mathrm{c}} &= [\mathbf{G}\mathbf{y}_{i-C+1}, \dots, \mathbf{G}\mathbf{y}_i], \\
\forall i\ \ \bar{\mathbf{x}}_i &= \sum_{q=i-Q}^{i+Q} \tilde{\mathbf{x}}_i / Q.
\end{aligned}$$

Where $\mathbf{G} \in \mathbb{R}^{D \times V}$ is an embedding of the context, $\mathbf{P} \in \mathbb{R}^{H \times (CD)}$ is a new weight matrix parameter mapping between the context embedding and input embedding, and Q is a smoothing window. The full model is shown in Figure 3b.

Informally we can think of this model as simply replacing the uniform distribution in bag-of-words with a learned soft alignment, $\mathbf{P}$, between the input and the summary. Figure 1 shows an example of this distribution $\mathbf{p}$ as a summary is generated. The soft alignment is then used to weight the smoothed version of the input $\bar{\mathbf{x}}$ when constructing the representation. For instance if the current context aligns well with position i then the words $\mathbf{x}_{i-Q}, \dots, \mathbf{x}_{i+Q}$ are highly weighted by the encoder. Together with the NNLM, this model can be seen as a stripped-down version of the attention-based neural machine translation model.[5]

3.3 Training

The lack of generation constraints makes it possible to train the model on arbitrary input-output pairs. Once we have defined the local conditional model, $p(\mathbf{y}_{i+1} | \mathbf{x}, \mathbf{y}_{\mathrm{c}}; \theta)$, we can estimate the parameters to minimize the negative log-likelihood of a set of summaries. Define this training set as consisting of J input-summary pairs $(\mathbf{x}^{(1)}, \mathbf{y}^{(1)}), \dots, (\mathbf{x}^{(J)}, \mathbf{y}^{(J)})$. The negative log-likelihood conveniently factors[6] into a term for each token in the summary:

$$\begin{aligned}
\mathrm{NLL}(\theta) &= -\sum_{j=1}^{J} \log p(\mathbf{y}^{(j)} | \mathbf{x}^{(j)}; \theta), \\
&= -\sum_{j=1}^{J} \sum_{i=1}^{N-1} \log p(\mathbf{y}^{(j)}_{i+1} | \mathbf{x}^{(j)}, \mathbf{y}_{\mathrm{c}}; \theta).
\end{aligned}$$

We minimize NLL by using mini-batch stochastic gradient descent. The details are described further in Section 7.

[5] To be explicit, compared to Bahdanau et al. (2014) our model uses an NNLM instead of a target-side LSTM, source-side windowed averaging instead of a source-side bi-directional RNN, and a weighted dot-product for alignment instead of an alignment MLP.

[6] This is dependent on using the gold standard contexts $\mathbf{y}_{\mathrm{c}}$. An alternative is to use the predicted context within a structured or reenforcement-learning style objective.

4 Generating Summaries

We now return to the problem of generating summaries. Recall from Eq. 4 that our goal is to find,

$$\mathbf{y}^* \quad = \quad \arg\max_{\mathbf{y} \in \mathcal{Y}} \sum_{i=0}^{N-1} g(\mathbf{y}_{i+1}, \mathbf{x}, \mathbf{y}_{\mathrm{c}}).$$

Unlike phrase-based machine translation where inference is NP-hard, it actually is tractable in theory to compute $\mathbf{y}^*$. Since there is no explicit hard alignment constraint, Viterbi decoding can be applied and requires $O(NV^C)$ time to find an exact solution. In practice though V is large enough to make this difficult.

An alternative approach is to approximate the $\arg\max$ with a strictly greedy or deterministic decoder. While decoders of this form can produce very bad approximations, they have shown to be relatively effective and fast for neural MT models (Sutskever et al., 2014).

A compromise between exact and greedy decoding is to use a beam-search decoder (Algorithm 1) which maintains the full vocabulary $\mathcal{V}$ while limiting itself to K potential hypotheses at each position of the summary. The beam-search algorithm is shown here:

Algorithm 1 Beam Search

Input: Parameters θ, beam size K, input $\mathbf{x}$
Output: Approx. K-best summaries

$\pi[0] \leftarrow \{\epsilon\}$
$\mathcal{S} = \mathcal{V}$ if abstractive else $\{\mathbf{x}_i \mid \forall i\}$
for $i = 0$ to $N-1$ **do**
  ▷ Generate Hypotheses
  $\mathcal{N} \leftarrow \left\{ [\mathbf{y}, \mathbf{y}_{i+1}] \quad | \quad \mathbf{y} \in \pi[i], \mathbf{y}_{i+1} \in \mathcal{S} \right\}$
  ▷ Hypothesis Recombination
  $\mathcal{H} \leftarrow \left\{ \mathbf{y} \in \mathcal{N} \quad | \quad \begin{array}{c} s(\mathbf{y}, \mathbf{x}) > s(\mathbf{y}', \mathbf{x}) \\ \forall \mathbf{y}' \in \mathcal{N} \text{ s.t. } \mathbf{y}_{\mathrm{c}} = \mathbf{y}'_{\mathrm{c}} \end{array} \right\}$
  ▷ Filter K-Max
  $\pi[i+1] \leftarrow \underset{\mathbf{y} \in \mathcal{H}}{\text{K-arg max}}\, g(\mathbf{y}_{i+1}, \mathbf{y}_{\mathrm{c}}, \mathbf{x}) + s(\mathbf{y}, \mathbf{x})$
end for
return $\pi[N]$

As with Viterbi this beam search algorithm is much simpler than beam search for phrase-based MT. Because there is no explicit constraint that each source word be used exactly once there is no need to maintain a bit set and we can simply move from left-to-right generating words. The beam search algorithm requires $O(KNV)$ time. From a computational perspective though, each round of beam search is dominated by computing $p(\mathbf{y}_i | \mathbf{x}, \mathbf{y}_{\mathrm{c}})$ for each of the K hypotheses. These can be computed as a mini-batch, which in practice greatly reduces the factor of K.

5 Extension: Extractive Tuning

While we will see that the attention-based model is effective at generating summaries, it does miss an important aspect seen in the human-generated references. In particular the abstractive model does not have the capacity to find extractive word matches when necessary, for example transferring unseen proper noun phrases from the input. Similar issues have also been observed in neural translation models particularly in terms of translating rare words (Luong et al., 2014).

To address this issue we experiment with tuning a very small set of additional features that tradeoff the abstractive/extractive tendency of the system. We do this by modifying our scoring function to directly estimate the probability of a summary using a log-linear model, as is standard in machine translation:

$$p(\mathbf{y} | \mathbf{x}; \theta, \alpha) \quad \propto \quad \exp(\alpha^\top \sum_{i=0}^{N-1} f(\mathbf{y}_{i+1}, \mathbf{x}, \mathbf{y}_{\mathrm{c}})).$$

Where $\alpha \in \mathbb{R}^5$ is a weight vector and f is a feature function. Finding the best summary under this distribution corresponds to maximizing a factored scoring function s,

$$s(\mathbf{y}, \mathbf{x}) \quad = \quad \sum_{i=0}^{N-1} \alpha^\top f(\mathbf{y}_{i+1}, \mathbf{x}, \mathbf{y}_{\mathrm{c}}).$$

where $g(\mathbf{y}_{i+1}, \mathbf{x}, \mathbf{y}_{\mathrm{c}}) \triangleq \alpha^\top f(\mathbf{y}_{i+1}, \mathbf{x}, \mathbf{y}_{\mathrm{c}})$ to satisfy Eq. 4. The function f is defined to combine the local conditional probability with some additional indicator featrues:

$$\begin{aligned} f(\mathbf{y}_{i+1}, \mathbf{x}, \mathbf{y}_{\mathrm{c}}) = [\ & \log p(\mathbf{y}_{i+1} | \mathbf{x}, \mathbf{y}_{\mathrm{c}}; \theta), \\ & \mathbb{1}\{\exists j.\ \mathbf{y}_{i+1} = \mathbf{x}_j\ \}, \\ & \mathbb{1}\{\exists j.\ \mathbf{y}_{i+1-k} = \mathbf{x}_{j-k}\ \forall k \in \{0, 1\}\}, \\ & \mathbb{1}\{\exists j.\ \mathbf{y}_{i+1-k} = \mathbf{x}_{j-k}\ \forall k \in \{0, 1, 2\}\}, \\ & \mathbb{1}\{\exists k > j.\ \mathbf{y}_i = \mathbf{x}_k, \mathbf{y}_{i+1} = \mathbf{x}_j\}\ ]. \end{aligned}$$

These features correspond to indicators of unigram, bigram, and trigram match with the input as well as reordering of input words. Note that setting $\alpha = \langle 1, 0, \ldots, 0 \rangle$ gives a model identical to standard ABS.

After training the main neural model, we fix θ and tune the α parameters. We follow the statistical machine translation setup and use minimum-error rate training (MERT) to tune for the summarization metric on tuning data (Och, 2003). This tuning step is also identical to the one used for the phrase-based machine translation baseline.

6 Related Work

Abstractive sentence summarization has been traditionally connected to the task of headline generation. Our work is similar to early work of Banko et al. (2000) who developed a statistical machine translation-inspired approach for this task using a corpus of headline-article pairs. We extend this approach by: (1) using a neural summarization model as opposed to a count-based noisy-channel model, (2) training the model on much larger scale (25K compared to 4 million articles), (3) and allowing fully abstractive decoding.

This task was standardized around the DUC-2003 and DUC-2004 competitions (Over et al., 2007). The TOPIARY system (Zajic et al., 2004) performed the best in this task, and is described in detail in the next section. We point interested readers to the DUC web page (`http://duc.nist.gov/`) for the full list of systems entered in this shared task.

More recently, Cohn and Lapata (2008) give a compression method which allows for more arbitrary transformations. They extract tree transduction rules from aligned, parsed texts and learn weights on transfomations using a max-margin learning algorithm. Woodsend et al. (2010) propose a quasi-synchronous grammar approach utilizing both context-free parses and dependency parses to produce legible summaries. Both of these approaches differ from ours in that they directly use the syntax of the input/output sentences. The latter system is W&L in our results; we attempted to train the former system T3 on this dataset but could not train it at scale.

In addition to Banko et al. (2000) there has been some work using statistical machine translation directly for abstractive summary. Wubben et al. (2012) utilize MOSES directly as a method for text simplification.

Recently Filippova and Altun (2013) developed a strictly extractive system that is trained on a relatively large corpora (250K sentences) of article-title pairs. Because their focus is extractive compression, the sentences are transformed by a series of heuristics such that the words are in monotonic alignment. Our system does not require this alignment step but instead uses the text directly.

Neural MT This work is closely related to recent work on neural network language models (NNLM) and to work on neural machine translation. The core of our model is a NNLM based on that of Bengio et al. (2003).

Recently, there have been several papers about models for machine translation (Kalchbrenner and Blunsom, 2013; Cho et al., 2014; Sutskever et al., 2014). Of these our model is most closely related to the attention-based model of Bahdanau et al. (2014), which explicitly finds a soft alignment between the current position and the input source. Most of these models utilize recurrent neural networks (RNNs) for generation as opposed to feed-forward models. We hope to incorporate an RNN-LM in future work.

7 Experimental Setup

We experiment with our attention-based sentence summarization model on the task of headline generation. In this section we describe the corpora used for this task, the baseline methods we compare with, and implementation details of our approach.

7.1 Data Set

The standard sentence summarization evaluation set is associated with the DUC-2003 and DUC-2004 shared tasks (Over et al., 2007). The data for this task consists of 500 news articles from the New York Times and Associated Press Wire services each paired with 4 different human-generated reference summaries (not actually headlines), capped at 75 bytes. This data set is evaluation-only, although the similarly sized DUC-2003 data set was made available for the task. The expectation is for a summary of roughly 14 words, based on the text of a complete article (although we only make use of the first sentence). The full data set is available by request at `http://duc.nist.gov/data.html`.

For this shared task, systems were entered and evaluated using several variants of the recall-oriented ROUGE metric (Lin, 2004). To make recall-only evaluation unbiased to length, output of all systems is cut-off after 75-characters and no bonus is given for shorter summaries.

Unlike BLEU which interpolates various n-gram matches, there are several versions of ROUGE for different match lengths. The DUC evaluation uses ROUGE-1 (unigrams), ROUGE-2 (bigrams), and ROUGE-L (longest-common substring), all of which we report.

In addition to the standard DUC-2014 evaluation, we also report evaluation on single reference headline-generation using a randomly held-out subset of Gigaword. This evaluation is closer to the task the model is trained for, and it allows us to use a bigger evaluation set, which we will include in our code release. For this evaluation, we tune systems to generate output of the average title length.

For training data for both tasks, we utilize the annotated Gigaword data set (Graff et al., 2003; Napoles et al., 2012), which consists of standard Gigaword, preprocessed with Stanford CoreNLP tools (Manning et al., 2014). Our model only uses annotations for tokenization and sentence separation, although several of the baselines use parsing and tagging as well. Gigaword contains around 9.5 million news articles sourced from various domestic and international news services over the last two decades.

For our training set, we pair the headline of each article with its first sentence to create an input-summary pair. While the model could in theory be trained on any pair, Gigaword contains many spurious headline-article pairs. We therefore prune training based on the following heuristic filters: (1) Are there no non-stop-words in common? (2) Does the title contain a byline or other extraneous editing marks? (3) Does the title have a question mark or colon? After applying these filters, the training set consists of roughly $J = 4$ million title-article pairs. We apply a minimal preprocessing step using PTB tokenization, lower-casing, replacing all digit characters with #, and replacing of word types seen less than 5 times with UNK. We also remove all articles from the time-period of the DUC evaluation. release.

The complete input training vocabulary consists of 119 million word tokens and 110K unique word types with an average sentence size of 31.3 words. The headline vocabulary consists of 31 million tokens and 69K word types with the average title of length 8.3 words (note that this is significantly shorter than the DUC summaries). On average there are 4.6 overlapping word types between the headline and the input; although only 2.6 in the first 75-characters of the input.

7.2 Baselines

Due to the variety of approaches to the sentence summarization problem, we report a broad set of headline-generation baselines.

From the DUC-2004 task we include the PREFIX baseline that simply returns the first 75-characters of the input as the headline. We also report the winning system on this shared task, TOPIARY (Zajic et al., 2004). TOPIARY merges a compression system using linguistically-motivated transformations of the input (Dorr et al., 2003) with an unsupervised topic detection (UTD) algorithm that appends key phrases from the full article onto the compressed output. Woodsend et al. (2010) (described above) also report results on the DUC dataset.

The DUC task also includes a set of manual summaries performed by 8 human summarizers each summarizing half of the test data sentences (yielding 4 references per sentence). We report the average inter-annotater agreement score as REFERENCE. For reference, the best human evaluator scores 31.7 ROUGE-1.

We also include several baselines that have access to the same training data as our system. The first is a sentence compression baseline COMPRESS (Clarke and Lapata, 2008). This model uses the syntactic structure of the original sentence along with a language model trained on the headline data to produce a compressed output. The syntax and language model are combined with a set of linguistic constraints and decoding is performed with an ILP solver.

To control for memorizing titles from training, we implement an information retrieval baseline, IR. This baseline indexes the training set, and gives the title for the article with highest BM-25 match to the input (see Manning et al. (2008)).

Finally, we use a phrase-based statistical machine translation system trained on Gigaword to produce summaries, MOSES+ (Koehn et al., 2007). To improve the baseline for this task, we augment the phrase table with "deletion" rules mapping each article word to ϵ, include an additional deletion feature for these rules, and allow for an infinite distortion limit. We also explicitly tune the model using MERT to target the 75-byte capped ROUGE score as opposed to standard

Model	DUC-2004 ROUGE-1	DUC-2004 ROUGE-2	DUC-2004 ROUGE-L	Gigaword ROUGE-1	Gigaword ROUGE-2	Gigaword ROUGE-L	Ext. %
IR	11.06	1.67	9.67	16.91	5.55	15.58	29.2
PREFIX	22.43	6.49	19.65	23.14	8.25	21.73	100

ABS+	28.18	8.49	23.81	31.00	12.65	28.34	91.5
REFERENCE	29.21	8.38	24.46	-	-	-	45.6

Table 1: Experimental results on the main summary tasks on various ROUGE metrics . Baseline models are described in detail in Section 7.2. We report the percentage of tokens in the summary that also appear in the input for Gigaword as `Ext %`.

BLEU-based tuning. Unfortunately, one remaining issue is that it is non-trivial to modify the translation decoder to produce fixed-length outputs, so we tune the system to produce roughly the expected length.

7.3 Implementation

For training, we use mini-batch stochastic gradient descent to minimize negative log-likelihood. We use a learning rate of 0.05, and split the learning rate by half if validation log-likelihood does not improve for an epoch. Training is performed with shuffled mini-batches of size 64. The minibatches are grouped by input length. After each epoch, we renormalize the embedding tables (Hinton et al., 2012). Based on the validation set, we set hyperparameters as $D = 200$, $H = 400$, $C = 5$, $L = 3$, and $Q = 2$.

Our implementation uses the Torch numerical framework (`http://torch.ch/`) and will be openly available along with the data pipeline. Crucially, training is performed on GPUs and would be intractable or require approximations otherwise. Processing 1000 mini-batches with $D = 200$, $H = 400$ requires 160 seconds. Best validation accuracy is reached after 15 epochs through the data, which requires around 4 days of training.

Additionally, as described in Section 5 we apply a MERT tuning step after training using the DUC-2003 data. For this step we use Z-MERT (Zaidan, 2009). We refer to the main model as ABS and the tuned model as ABS+.

8 Results

Our main results are presented in Table 1. We run experiments both using the DUC-2004 evaluation data set (500 sentences, 4 references, 75 bytes) with all systems and a randomly held-out Gigaword test set (2000 sentences, 1 reference). We first note that the baselines COMPRESS and IR do relatively poorly on both datasets, indicating that neither just having article information or language model information alone is sufficient for the task. The PREFIX baseline actually performs surprisingly well on ROUGE-1 which makes sense given the earlier observed overlap between article and summary.

Both ABS and MOSES+ perform better than TOPIARY, particularly on ROUGE-2 and ROUGE-L in DUC. The full model ABS+ scores the best on these tasks, and is significantly better based on the default ROUGE confidence level than TOPIARY on all metrics, and MOSES+ on ROUGE-1 for DUC as well as ROUGE-1 and ROUGE-L for Gigaword. Note that the additional extractive features bias the system towards retaining more input words, which is useful for the underlying metric.

Next we consider ablations to the model and algorithm structure. Table 2 shows experiments for the model with various encoders. For these experiments we look at the perplexity of the system as a language model on validation data, which controls for the variable of inference and tuning. The NNLM language model with no encoder gives a gain over the standard n-gram language model. Including even the bag-of-words encoder reduces perplexity number to below 50. Both the convolutional encoder and the attention-based encoder further reduce the perplexity, with attention giving a value below 30.

We also consider model and decoding ablations on the main summary model, shown in Table 3. These experiments compare to the BoW encoding models, compare beam search and greedy decoding, as well as restricting the system to be com-

Model	Encoder	Perplexity
KN-Smoothed 5-Gram	none	183.2
Feed-Forward NNLM	none	145.9
Bag-of-Word	enc_1	43.6
Convolutional (TDNN)	enc_2	35.9
Attention-Based (ABS)	enc_3	27.1

Table 2: Perplexity results on the Gigaword validation set comparing various language models with C=5 and end-to-end summarization models. The encoders are defined in Section 3.

Decoder	Model	Cons.	R-1	R-2	R-L
Greedy	ABS+	Abs	26.67	6.72	21.70
Beam	BOW	Abs	22.15	4.60	18.23
Beam	ABS+	Ext	27.89	7.56	22.84
Beam	ABS+	Abs	28.48	8.91	23.97

Table 3: ROUGE scores on DUC-2003 development data for various versions of inference. Greedy and Beam are described in Section 4. Ext. is a purely extractive version of the system (Eq. 2)

plete extractive. Of these features, the biggest impact is from using a more powerful encoder (attention versus BoW), as well as using beam search to generate summaries. The abstractive nature of the system helps, but for ROUGE even using pure extractive generation is effective.

Finally we consider example summaries shown in Figure 4. Despite improving on the baseline scores, this model is far from human performance on this task. Generally the models are good at picking out key words from the input, such as names and places. However, both models will reorder words in syntactically incorrect ways, for instance in Sentence 7 both models have the wrong subject. ABS often uses more interesting re-wording, for instance *new nz pm after election* in Sentence 4, but this can also lead to attachment mistakes such a *russian oil giant chevron* in Sentence 11.

9 Conclusion

We have presented a neural attention-based model for abstractive summarization, based on recent developments in neural machine translation. We combine this probabilistic model with a generation algorithm which produces accurate abstractive summaries. As a next step we would like to further improve the grammaticality of the summaries in a data-driven way, as well as scale this system to generate paragraph-level summaries. Both pose additional challenges in terms of efficient alignment and consistency in generation.

Abstract

We propose a summarization approach for scientific articles which takes advantage of citation-context and the document discourse model. While citations have been previously used in generating scientific summaries, they lack the related context from the referenced article and therefore do not accurately reflect the article's content. Our method overcomes the problem of inconsistency between the citation summary and the article's content by providing context for each citation. We also leverage the inherent scientific article's discourse for producing better summaries. We show that our proposed method effectively improves over existing summarization approaches (greater than 30% improvement over the best performing baseline) in terms of ROUGE scores on TAC2014 scientific summarization dataset. While the dataset we use for evaluation is in the biomedical domain, most of our approaches are general and therefore adaptable to other domains.

1 Introduction

Due to the expanding rate at which articles are being published in each scientific field, it has become difficult for researchers to keep up with the developments in their respective fields. Scientific summarization aims to facilitate this problem by providing readers with concise and informative representation of contributions or findings of an article. Scientific summarization is different than general summarization in three main aspects (Teufel and Moens, 2002). First, the length of scientific papers are usually much longer than general articles (e.g newswire). Second, in scientific summarization, the goal is typically to provide a technical summary of the paper which includes important findings, contributions or impacts of a paper to the community. Finally, scientific papers follow a natural discourse. A common organization for scientific paper is the one in which the problem is first introduced and is followed by the description of hypotheses, methods, experiments, findings and finally results and implications. Scientific summarization was recently further motivated by TAC2014 biomedical summarization track[1] in which they planned to investigate this problem in the domain of biomedical science.

There are currently two types of approaches towards scientific summarization. First is the articles' abstracts. While abstracts provide a general overview of the paper, they cannot be considered as an accurate scientific summary by themselves. That is due to the fact that not all the contributions and impacts of the paper are included in the abstract (Elkiss et al., 2008). In addition, the stated contributions are those that the authors deem important while they might be less important to the scientific community. Moreover, contributions are stated in a general and less focused fashion. These problems motivated the other form of scientific summaries, i.e., citation based summaries. Citation based summary is a summary which is formed by utilizing a set of citations to a referenced article (Qazvinian and Radev, 2008; Qazvinian et al., 2013). This set of citations has been previously indicated as a good representation of important findings and contributions of the article. Contributions stated in the citations are usually more focused than the abstract and contain additional information that is not in the abstract (Elkiss et al., 2008).

However, citations may not accurately represent

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 390–400,
Lisbon, Portugal, 17-21 September 2015.

the content of the referenced article as they are biased towards the viewpoint of the citing authors. Moreover, citations may address a contribution or a finding regarding the referenced article without referring to the assumptions and data under which it was obtained.

The problem of inconsistency between the degree of certainty of expressing findings between the citing article and referenced article has been also reported (De Waard and Maat, 2012). Therefore, citations by themselves lack the related "context" from the original article. We call the textual spans in the reference articles that reflect the citation, the citation-context. Figure 1 shows an example of the citation-context in the reference article (green color) for a citation in the citing article (blue color).

We propose an approach to overcome the aforementioned shortcomings of existing scientific summaries. Specifically, we extract citation-context in the reference article for each citation. Then, by using the discourse facets of the citations as well as community structure of the citation-contexts, we extract candidate sentences for the summary. The final summary is formed by maximizing both novelty and informativeness of the sentences in the summary. We evaluate and compare our methods against several well-known summarization methods. Evaluation results on the TAC2014 dataset show that our proposed methods can effectively improve over the well-known existing summarization approaches. That is, we obtained greater than 30% improvement over the highest performing baseline in terms of mean ROUGE scores.

Citing article:

... The general impression that has emerged is that transformation of human cells by Ras requires the inactivation of both the pRb and p53 pathways, typically achieved by introducing DNA tumor virus oncoproteins such as SV40 large tumor antigen (T-Ag) or human papillomavirus E6 and E7 proteins (Serrano et al., 1997).
To address this question, we have been investigating the ...

Reference article (Serrano et al., 1997):

... continued to incorporate BrdU and proliferate following introduction of H-ras V12. In agreement with previous reports (66 and 60), both p53/ and p16/ MEFs expressing H-ras V12 displayed features of oncogenic transformation (e.g., refractile morphology, loss of contact inhibition), which were apparent almost immediately after H-ras V12 was transduced (data not shown). These results indicate that p53 and p16 are essential for ras-induced arrest in MEFs, and that inactivation of either p53 or p16 alone is sufficient to circumvent arrest. In REF52 and IMR90 fibroblasts, a different approach was ...

Figure 1: The blue highlighted span in the citing article (top) shows the citation text, followed by the citation marker (pink span). For this citation, the citation-context is the green highlighted span in the reference article (bottom). The text spans outside the scope of the citation text and citation-context are not highlighted.

2 Related work

Document summarization is a relatively well studied area and various types of approaches for document summarization have been proposed in the past twenty years.

Latent Semantic Analysis (LSA) has been used in text summarization first by (Gong and Liu, 2001). Other variations of LSA based summarization approaches have later been introduced (Steinberger and Jezek, 2004; Steinberger et al., 2005; Lee et al., 2009; Ozsoy et al., 2010). Summarization approaches based on topic modeling and Bayesian models have also been explored (Vanderwende et al., 2007; Haghighi and Vanderwende, 2009; Celikyilmaz and Hakkani-Tur, 2010; Ritter et al., 2010; Celikyilmaz and Hakkani-Tür, 2011; Ma and Nakagawa, 2013; Li and Li, 2014). In these approaches, the content/topic distribution in the final summary is estimated using a graphical probabilistic model. Some approaches have viewed summarization as an optimization task solved by linear programming (Clarke and Lapata, 2008; Berg-Kirkpatrick et al., 2011; Woodsend and Lapata, 2012). Many works have viewed the summarization problem as a supervised classification problem in which several features are used to predict the inclusion of document sentences in the summary. Variations of supervised models have been utilized for summary generation, such as: maximum entropy (Osborne, 2002), HMM (Conroy et al., 2011), CRF (Galley, 2006; Shen et al., 2007; Chali and Hasan, 2012), SVM (Xie and Liu, 2010), logistic regression (Louis et al., 2010) and reinforcement learning (Rioux et al., 2014). Problems with supervised models in context of summarization include the need for large amount of annotated data and domain dependency.

Graph based models have shown promising results for text summarization. In these approaches, the goal is to find the most central sentences in the document by constructing a graph in which nodes are sentences and edges are similarity between these sentences. Examples of these techniques include LexRank (Erkan and Radev, 2004), TextRank (Mihalcea and Tarau, 2004), and the work by (Paul et al., 2010). Maximizing the novelty and preventing

the redundancy in a summary is addressed by greedy selection of content summarization (Carbonell and Goldstein, 1998; Guo and Sanner, 2010; Lin et al., 2010). Rhetorical structure of the documents have also been investigated for automatic summarization. In this line of work, dependency and discourse parsing based on Rhetorical Structure Theory (RST) (Mann and Thompson, 1988) is used for analyzing the structure of the documents (Hirao et al., 2013; Kikuchi et al., 2014; Yoshida et al., 2014). Summarization based on rhetorical structure is better suited for shorter documents and is highly dependent on the quality of the discourse parser that is used. Training the discourse parser requires large amount of training data in the RST framework.

Scientific article summarization was first studied by (Teufel and Moens, 2002) in which they trained a supervised Naive Bayes classifier to select informative content for the summary. Later (Elkiss et al., 2008) argue the benefits of citations to scientific work analysis. (Cohan et al., 2015) use a search oriented approach for finding relevant parts of the reference paper to citations. (Qazvinian and Radev, 2008; Qazvinian et al., 2013) use citations to an article to construct its summary. More specifically, they perform hierarchical agglomerative clustering on citations to maximize purity and select most central sentences from each cluster for the final summary. Our work is closest to (Qazvinian and Radev, 2008) with the difference that they only make use of citations. While citations are useful for summarization, relying solely on them might not accurately capture the original context of the referenced paper. That is, the generated summary lacks the appropriate evidence to reflect the content of the original paper, such as circumstances, data and assumptions under which certain findings were obtained. We address this shortcoming by leveraging the citation-context and the inherent discourse model in the scientific articles.

3 The summarization approach

Our scientific summary generation algorithm is composed of four steps: (1) Extracting the citation-context, (2) Grouping citation-contexts, (3) Ranking the sentences within each group and (4) Selecting the sentences for final summary. We assume that the citation text (the text span in the citing article that references another article) in each citing article is already known. We describe each step in the following sub-sections. Our proposed method generates a summary of an article with the premise that the article has a number of citations to it. We call the article that is being referenced the "reference article". We shall note that we tokenized the articles' text to sentences by using the punkt unsupervised sentence boundary detection algorithm (Kiss and Strunk, 2006). We modified the original sentence boundary detection algorithm to also account for biomedical abbreviations. For the rest of the paper, "sentence" refers to units that are output of the sentence boundary detection algorithm, whereas "text span" or in short "span" can consist of multiple sentences.

3.1 Extracting the citation-context

As described in section 2, one problem with existing citation based summarization approaches is that they lack the context of the referenced paper. Therefore, our goal is to leverage citation-context in the reference article to correctly reflect the reference paper. To find citation-contexts, we consider each citation as an n-gram vector and use vector space model for locating the relevant text spans in the reference article. More specifically, given a citation c, we return the ranked list of text spans $r_1, r_2, ..., r_n$ which have the highest similarity to c. We call the retrieved text spans reference spans. These reference spans are essentially forming the context for each citation. The similarity function is the cosine similarity between the pivoted normalized vectors. We evaluated four different approaches for forming the citation vector.

1. All terms in citation except for stopwords, numeric values and citation markers i.e., name of authors or numbered citations. In figure 1 an example of citation marker is shown.

2. Terms with high inverted document frequency (idf). Idf values of terms have shown to be a good estimate of term informativeness.

3. Concepts that are represented through noun phrases in the citation, for example in the following: " ... typically achieved by introducing DNA tumor virus oncoproteins such a ... " which is part of a citation, the phrase "DNA tumor virus oncoproteins" is a noun phrase.

4. Biomedical concepts and noun phrases expanded by related biomedical concepts: This formation is specific to the biomedical domain. It selects biomedical concepts and noun phrases in the citation and uses related biomedical terminology to expand the citation vector. We used Metamap[1] for extracting biomedical concepts from the citation text (which is a tool for mapping free form text to UMLS[2] concepts). For expanding the citation vector using the related biomedical terminology, we used SNOMED CT[3] ontology by which we added synonyms of the concepts in the citation text to the citation vector.

3.2 Grouping the citation-contexts

After identifying the context for each citation, we use them to form the summary. To capture various important aspects of the reference article, we form groups of citation-contexts that are about the same topic. We use the following two approaches for forming these groups:

Community detection - We want to find diverse key aspects of the reference article. We form the graph of extracted reference spans in which nodes are sentences and edges are similarity between sentences. As for the similarity function, we use cosine similarity between tf-idf vectors of the sentences. Similar to (Qazvinian and Radev, 2008), we want to find subgraphs or communities whose intra-connectivity is high but inter-connectivity is low. Such quality is captured by the modularity measure of the graph (Newman, 2006; Newman, 2012). Graph modularity quantifies the denseness of the subgraphs in comparison with denseness of the graph of randomly distributed edges and is defined as follows:

$$Q = \frac{1}{2m} \sum_{vw} \left[A_{vw} - \frac{k_v \times k_w}{2m} \right] \delta(c_v, c_w)$$

Where A_{vw} is the weigh of the edge (v, w); k_v is the degree of the vertex v; c_v is the community of vertex v; δ is the Kronecker's delta function and $m = \sum_{vw} A_{vw}$ is the normalization factor.

While the general problem of precise partitioning of the graph into highly dense communities that optimizes the modularity is computationally prohibitive (Brandes et al., 2008), many heuristic algorithms have been proposed with reasonable results. To extract communities from the graph of reference spans, we use the algorithm proposed by (Blondel et al., 2008) which is a simple yet accurate and efficient community detection algorithm. Specifically, communities are built in a hierarchical fashion. At first, each node belongs to a separate community. Then nodes are assigned to new communities if there is a positive gain in modularity. This process is applied iteratively until no further improvement in modularity is possible.

Discourse model - A natural discourse model is followed in each scientific article. In this method, instead of finding communities to capture different important aspects of the paper, we try to select reference spans based on the discourse model of the paper. The discourse model is according to the following facets: "hypothesis", "method", "results", "implication", "discussion" and "data-set-used". The goal is to ideally include reference spans from each of these discourse facets of the article in the summary to correctly capture all aspects of the article. We use a one-vs-rest SVM supervised model with linear kernel to classify the reference spans to their respective discourse facets. Training was done on both the citation and reference spans since empirical evaluation showed marginal improvements upon including the reference spans in addition to the citation itself. We use unigram and verb features with tf-idf weighting to train the classifier.

3.3 Ranking model

To identify the most representative sentences of each group, we require a measure of importance of sentences. We consider the sentences in a group as a graph and rank nodes based on their importance. An important node is a node that has many connections with other nodes. There are various ways of measuring centrality of nodes such as nodes degree, betweenness, closeness and eigenvectors. Here, we opt for eigenvectors and we find the most central sentences in each group by using the "power method" (Erkan and Radev, 2004) which iteratively updates the eigenvector until convergence.

[3] *http://www.nlm.nih.gov/research/umls/Snomed/snomed_main.html*

3.4 Selecting the sentences for final summary

After scoring and ranking the sentences in each group which were identified either by discourse model or by community detection algorithm, we employ two strategies for generating the summary within the summary length threshold.

- *Iterative*: We select top sentences iteratively from each group until we reach the summary length threshold. That is, we first pick the top sentence from all groups and if the threshold is not met, we select the second sentence and so forth. In the discourse based method, the following ordering for selecting sentences from groups is used: "hypothesis", "method","results", "implication" and "discussion". In the community detection method, no pre-determined order is specified.
- *Novelty:* We employ a greedy strategy similar to MMR (Carbonell and Goldstein, 1998) in which sentences from each group are selected based on the following scoring formula:

$$\text{score(S)} \stackrel{\text{def}}{=} \lambda Sim_1(\text{S, D}) - (1-\lambda) Sim_2(\text{S,Summary})$$

Where, for each sentence S, the score is a linear interpolation of similarity of sentence with all other sentences (Sim_1) and the similarity of sentence with the sentences already in the summary (Sim_2) and λ is a constant. We empirically set $\lambda = 0.7$ and also selected top 3 central sentences from each group as the candidates for the final summary.

4 Experimental setup

4.1 Data

We used the TAC2014 biomedical summarization dataset for evaluation of our proposed method. The TAC2014 benchmark contains 20 topics each of which consists of one reference article and several articles that have citations to each reference article (the statistics of the dataset is shown in Table 1). All articles are biomedical papers published by Elsevier. For each topic, 4 experts in biomedical domain have written a scientific summary of length not exceeding 250 words for the reference article. The data also contains annotated citation texts as well as the discourse facets. The latter were used to build the supervised discourse model. The distribution of discourse facets is shown in Table 2.

Table 1: Dataset statistics

	mean	std
# of topics (reference articles)	20	0
# of Gold summaries for each topic	4	0
# of citing articles in each topic	15.65	2.70
# of citations to the reference article in each citing article	1.57	1.17
Length of summaries (words)	235.64	31.24
Length of articles (words)	9759.86	2199.48

Table 2: Distribution of annotated discourse facets

Discourse facet	count
Hypothesis	21
Method	155
Results	490
Implication	140
Discussion	446

4.2 Baselines

We compared existing well-known and widely-used approaches discussed in section 2 with our approach and evaluated their effectiveness for scientific summarization. The first three approaches use the scientific article's text and the last approach uses the citations to the article for generating the summary.

- *LSA (Steinberger and Jezek, 2004)* - The LSA summarization method is based on singular value decomposition. In this method, a term document index $\mathbf{A}$ is created in which the values correspond to the tf-idf values of terms in the document. Then, Singular Value Decomposition, a dimension reduction approach, is applied to A. This will yield a singular value matrix $\mathbf{\Sigma}$ and a singular vector matrix $\mathbf{V}^T$. The top singular vectors are selected from $\mathbf{V}^T$ iteratively until length of the summary reaches a predefined threshold.
- *LexRank (Erkan and Radev, 2004)* - LexRank uses a measure called centrality to find the most representative sentences in given sets of sentences. It finds the most central sentences by updating the score of each sentence using an algorithm based on PageRank random walk ranking model (Page et al., 1999). More specifically, the centrality score of each sentence is represented by a centrality matrix $\mathbf{p}$ which is updated iteratively through the following equation using a method called "power method":

$$\mathbf{p} = \mathbf{A}^T \mathbf{p}$$

Where matrix $\mathbf{A}$ is based on the similarity matrix $\mathbf{B}$ of the sentences:

$$\mathbf{A} = [d\mathbf{U} + (1-d)\mathbf{B}]$$

In which $\mathbf{U}$ is a square matrix with values $1/N$ and d is a parameter called the damping factor. We set d to 0.1 which is the default suggested value.

- *MMR (Carbonell and Goldstein, 1998)* - In Maximal Marginal Relevance (MMR), sentences are greedily ranked according to a score based on their relevance to the document and the amount of redundant information they carry. It scores sentences based on the maximization of the linear interpolation of the relevance to the document and diversity:

$$\text{MMR(S,D)} \stackrel{\text{def}}{=} \lambda Sim_1(\text{S, D}) - (1-\lambda) Sim_2(\text{S,Summary})$$

Where S is the sentence being evaluated, D is the document being summarized, Sim_1 and Sim_2 are similarity function, $Summary$ is the summary formed by the previously selected sentences and λ is a parameter. We used cosine similarity as similarity functions and we set λ to 0.3, 0.5 and 0.7 for observing the effect of informativeness vs. novelty.

- *Citation summary (Qazvinian and Radev, 2008)*- In this approach, a network of citations is built and citations are clustered to maximum purity (Zhao and Karypis, 2001) and mutual information. These clusters are then used to generate the final summary by selecting the top central sentences from each cluster in a round-robin fashion. Our approach is similar to this work in that they also use centrality scores on citation network clusters. Since they only focus on citations, comparison of our approach with this work gives a better insight into how beneficial our use of citation-context and article's discourse model can be in generating scientific summaries.

5 Results and discussions

5.1 Evaluation metrics

We use the ROUGE evaluation metrics which has shown consistent correlation with manually evaluated summarization scores (Lin, 2004). More specifically, we use ROUGE-L, ROUGE-1 and ROUGE-2 to evaluate and compare the quality of the summaries generated by our system. While ROUGE-N focuses on n-gram overlaps, ROUGE-L uses the longest common subsequence to measure the quality of the summary. ROUGE-N where N is the n-gram order, is defined as follows:

$$\text{ROUGE-N} = \frac{\sum_{S \in \{\text{Gold summaries}\}} \sum_{W \in S} f_{match}(W)}{\sum_{S \in \{\text{Gold summaries}\}} \sum_{W \in S} f(W)}$$

Where W is the n-gram, $f(.)$ is the count function, $f_{match}(.)$ is the maximum number of n-grams co-occurring in the generated summary and in a set of gold summaries. For a candidate summary C with n words and a gold summary S with u sentences, ROUGE-L is defined as follows:

$$\text{ROUGE-L}_{rec} = \frac{\sum_{i=1}^{u} LCS_{\cup}(r_i, C)}{\sum_{i=1}^{u} |r_i|}$$

$$\text{ROUGE-L}_{prec} = \frac{\sum_{i=1}^{u} LCS_{\cup}(r_i, C)}{n}$$

Where $LCS_{\cup}(.,.)$ is the Longest common subsequence (LCS) score of the union of LCS between gold sentence r_i and the candidate summary C. ROUGE-L f score is the harmonic mean between precision and recall.

5.2 Comparison between summarizers

We generated two sets of summaries using the methods and baselines described in previous sections. We consider short summaries of length 100 words and longer summaries of length 250 words (which corresponds to the length threshold in gold summaries). We also considered the oracle's performance by averaging over the ROUGE scores of all human summaries calculated by considering one human summary against others in each topic. As far as 100 words summaries, since we did not have gold summaries of that length, we considered the first 100 words from each gold summary. Figure 2 shows the box-and-whisker plots with ROUGE scores. For each metric, the scores of each summarizer in comparison with the baselines for 100 word summaries and 250 words summaries are shown. The citation-context for all the methods were identified by the citation text vector method which uses the citation text except for numeric values, stop words and citation markers (first method in section 3.1). In section 5.3, we analyze the effect of various citation-context extraction methods that we discussed in section 3

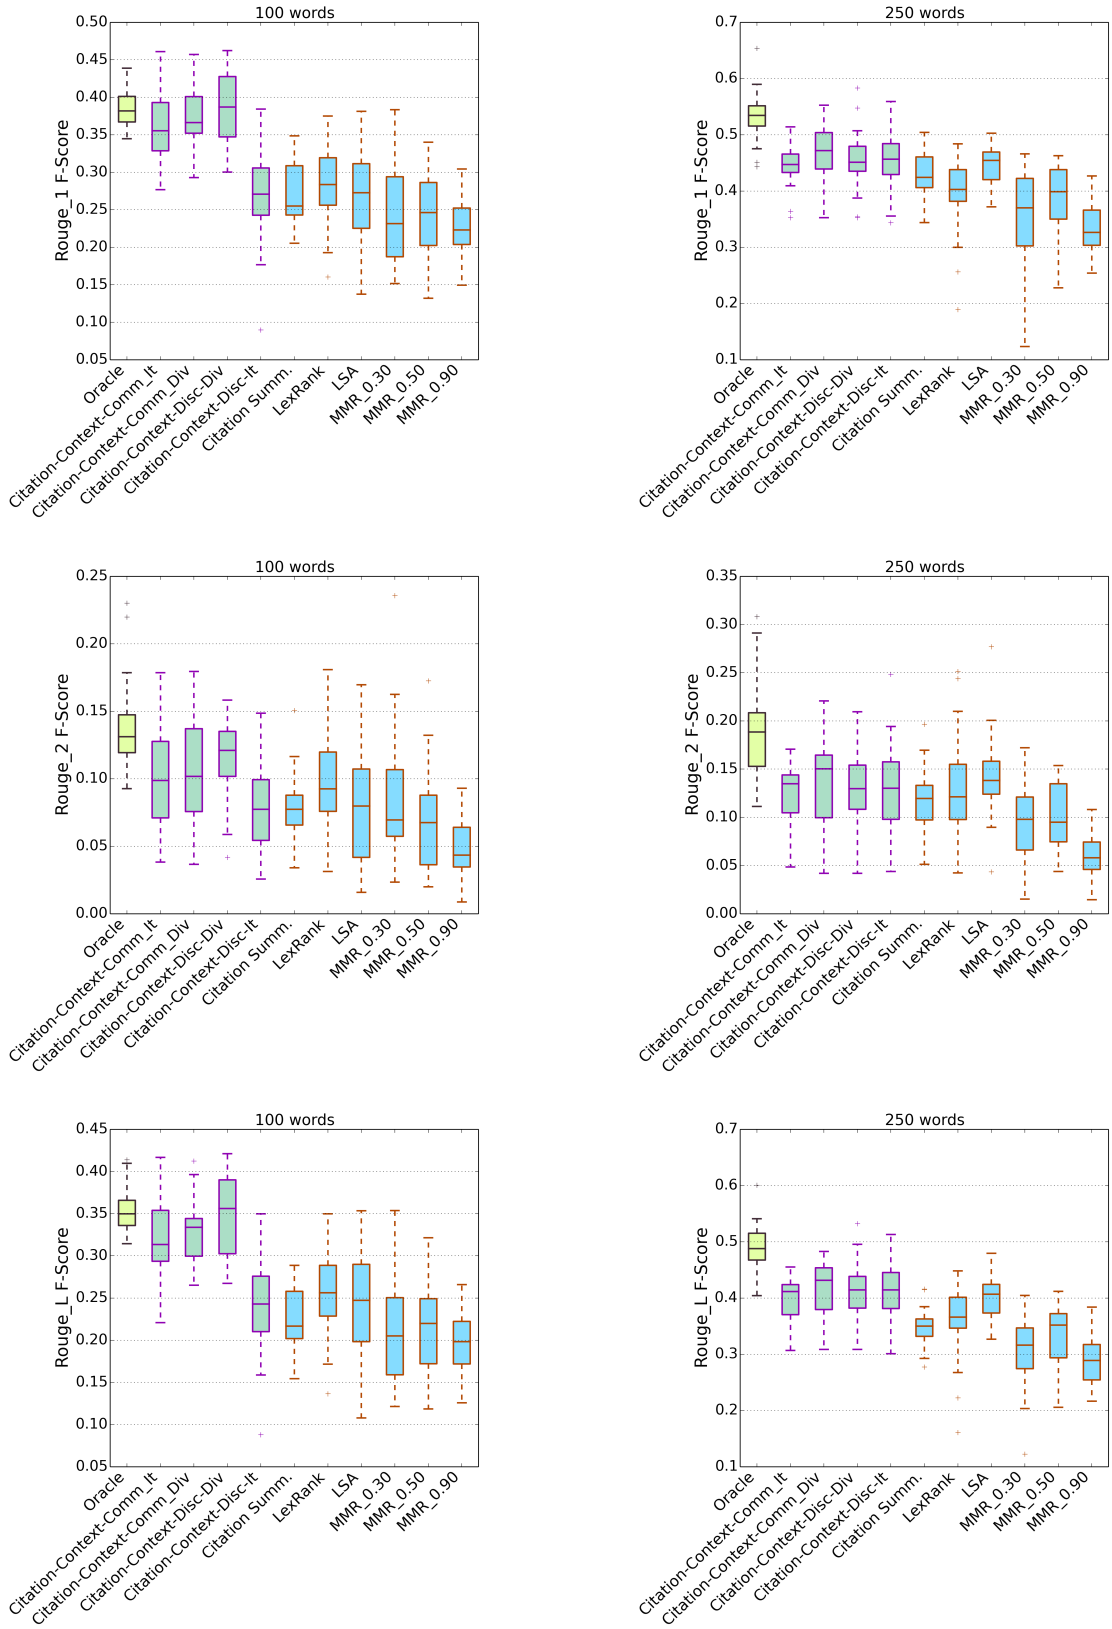

Figure 2: ROUGE-1, ROUGE-2 and ROUGE-L scores for different summarization approaches. Chartreuse (yellowish green) box shows the oracle, green boxes show the proposed summarizers and blue boxes show the baselines; From left, Oracle; Citation-Context-Comm-It: Community detection on citation-context followed by iterative selection; Citation-Context-Community-Div: Community detection on citation-context followed by relevance and diversification in sentence selection; Citation-Context-Discourse-Div: Discourse model on citation-context followed by relevance and diversification; Citation-Context-Discourse-It: Discourse model on citation-context followed by iterative selection; Citation Summ.: Citation summary; MMR_0.3: Maximal marginal relevance with $\lambda = 0.3$.

on the final summary. The name of each of our methods is shortened by the following convention: [Summarization approach]_[Sentence selection strategy]. Summarization approach is based on either community detection (Citation-Context-Comm) or discourse model of the article (Citation-Context-Disc) and sentence selection strategy can be iterative (It) or by relevance and diversification (Div).

We can clearly observe that our proposed methods achieve encouraging results in comparison with existing baselines. Specifically, for 100 words short summaries, the discourse based method (with 34.6% mean ROUGE-L improvement over the best baseline) and for 250 word summaries, the community based method (with 3.5% mean ROUGE-L improvement over the best baseline) are the best performing methods. We observe relative consistency between different rouge scores for each summarization approach. Grouping citation-context based on both the discourse structure and the communities show comparable results. The community detection approach is thus effectively able to identify diverse aspects of the article. The discourse model of the scientific article is also able to diversify selection of citation contexts for the final summary. These results confirm our hypotheses that using the citation context along with the discourse model of the scientific articles can help producing better summaries.

Comparison of performance of methods on individual topics showed that the citation-context methods consistently over perform all other methods in most of the topics (65% of all topics).

While the discourse approach shows encouraging results, we attribute its limitation in achieving higher ROUGE scores to the classification errors that we observed in intrinsic classification evaluation. In evaluating the performance of several classifiers, linear SVM achieved the highest performance with accuracy of 0.788 in comparison with human annotation performance. Many of the citations cannot exactly belong to only one of the discourse facets of the paper and thus some errors in classification are inevitable. This is also observable in disagreements between the annotators in labeling as reported by (Cohan et al., 2014). This fact influences the diversification and finally the summarization quality.

Among baseline summarization approaches, LexRank performs relatively well. Its performance is the best for short summaries among other baselines. This is expected since LexRank tries to find the most central sentences. When the length of the summary is short, the main idea in the summary is usually captured by finding the most representative sentence which LexRank can effectively achieve. However, the sentences that it chooses are usually about the same topic. Hence, the diversity in the gold summaries is not considered. This becomes more visible when we observe 250 word summaries. Our discourse based method can overcome this problem by including important contents for diverse discourse facets (34.6% mean ROUGE-L improvement for 100 words summaries and 13.9% improvement for 250 word summaries). The community based approach achieves the same diversification effect in an unsupervised fashion by forming citation-context communities (27.16% mean ROUGE-L improvement for 100 words summaries and 14.9% improvement for 250 word summaries).

The citation based summarization baseline has somewhat average performance among the baseline methods. This confirms that relying only on the citations can not be optimal for scientific summarization. While LSA approach performs relatively well, we observe lower scores for all variations of MMR approaches. We attribute the low performance of MMR to its sub optimal greedy selection of sentences from relatively long scientific articles.

By comparing the two sentence selection approaches (i.e., iterative and diversification-relevance), we observe that while for shorter length summaries the method based on diversification performs better, for the longer summaries results for the two methods are comparable. This is because when the length threshold is smaller, iterative approach may fail to select best representative sentences from all the groups. It essentially selects one sentence from each group until the length threshold is met, and consequently misses some aspects. Whereas, the diversification method selects sentences that maximize the gain in informativeness and at the same time contributes to the novelty of the summary. In longer summaries, due to larger threshold, iterative approach seems to be able

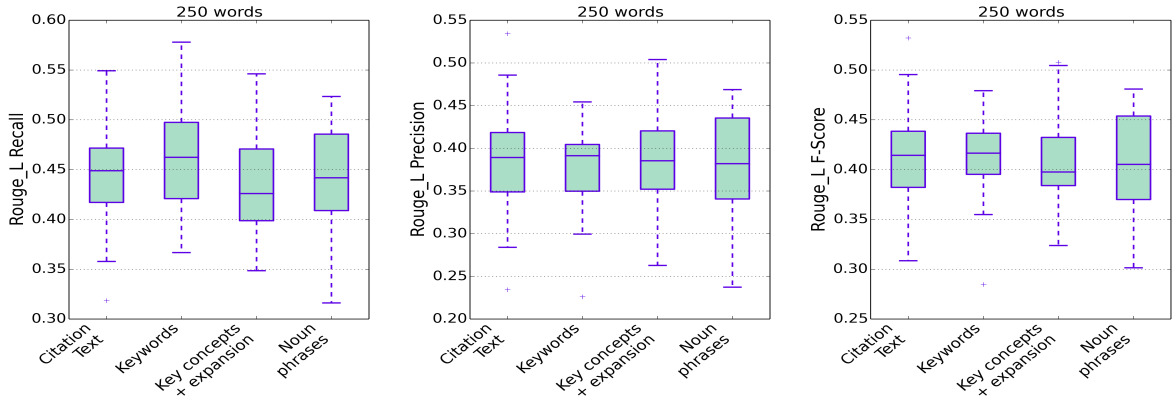

Figure 3: Comparison of the effect of different citation-context extraction methods on the quality of the final summary.

to select the top sentences from each group, enabling it to reflect different aspect of the paper. Therefore, the iterative approach performs comparably well to the diversification approach. This outcome is expected because the number of groups are small. For discourse method, there are 5 different discourse facets and for community method, on average 5.2 communities are detected. Hence, iterative selection can select sentences from most of these groups within 250 words limit summaries.

5.3 Analysis of strategies for citation-context extraction

Figure 3 shows ROUGE-L results for 250 words summaries based on using different citation-context extraction approaches, described in section 3.1. Relatively comparable performance for all the approaches is achieved. Using the citation text for extracting the context is almost as effective as other methods. Keywords approach which uses the terms with high idf values for locating the context achieves slightly higher Rouge-L precision while it has the lowest recall. This is expected since keywords approach chooses only informative terms for extracting citation-contexts. This results in missing terms that may not be keywords by themselves but help providing meaning. Noun phrases has the highest mean F-score and thus suggests the fact that noun phrases are good indicators of important concepts in scientific text. We attribute the high recall of noun phrases to the fact that most important concepts are captured by only selecting noun phrases. Interestingly, introducing biomedical concepts and expanding the citation vector by related concepts does not improve the performance. This approach achieves a relatively higher recall but a lower mean precision. While capturing domain concepts along with noun phrases helps improving the performance, adding related concepts to the citation vector causes drift from the original context as expressed in the reference article. Therefore some decline in performance is incurred.

6 Conclusion

We proposed a pipeline approach for summarization of scientific articles which takes advantage of the article's inherent discourse model and citation-contexts extracted from the reference article[1]. Our approach focuses on the problem of lack of context in existing citation based summarization approaches. We effectively achieved improvement over several well known summarization approaches on the TAC2014 biomedical summarization dataset. That is, in all cases we improved over the baselines; in some cases we obtained greater than 30% improvement for mean ROUGE scores over the best performing baseline. While the dataset we use for evaluation of scientific articles is in biomedical domain, most of our approaches are general and therefore adaptable to other scientific domains.

Abstract

In recent years, the task of recommending hashtags for microblogs has been given increasing attention. Various methods have been proposed to study the problem from different aspects. However, most of the recent studies have not considered the differences in the types or uses of hashtags. In this paper, we introduce a novel nonparametric Bayesian method for this task. Based on the Dirichlet Process Mixture Models (DPMM), we incorporate the type of hashtag as a hidden variable. The results of experiments on the data collected from a real world microblogging service demonstrate that the proposed method outperforms state-of-the-art methods that do not consider these aspects. By taking these aspects into consideration, the relative improvement of the proposed method over the state-of-the-art methods is around 12.2% in F1- score.

1 Introduction

Hashtags are used to mark keywords or topics in a microblog. Over the past few years, social media services have become some of the most important communication channels for people. According to the statistic reported by the Pew Research Centers Internet & American Life Project in Aug 5, 2013, about 72% of adult internet users are also members of at least one social networking site. Hence, microblogs have also been widely used as data sources for public opinion analyses (Bermingham and Smeaton, 2010; Jiang et al., 2011), prediction (Asur and Huberman, 2010; Bollen et al., 2011), reputation management (Pang and Lee, 2008; Otsuka et al., 2012), and many other applications (Sakaki et al., 2010; Becker et al., 2010; Guy et al., 2010; Guy et al., 2013).

In addition to the limited number of characters in the content, microblogs also contain a form of metadata tag (hashtag), which is a string of characters preceded by the symbol (#). Hashtags are used to mark the keywords or topics of a microblog. They can occur anywhere in a microblog, at the beginning, middle, or end. Hashtags have been proven to be useful for many applications, including microblog retrieval (Efron, 2010), query expansion (A.Bandyopadhyay et al., 2011), and sentiment analysis (Davidov et al., 2010; Wang et al., 2011). However, only a small percentages of microblogs contain hashtags provided by their authors. Hence, the task of recommending hashtags for microblogs has become an important research topic and has received considerable attention in recent years. Existing works have studied discriminative models (Ohkura et al., 2006; Heymann et al., 2008) and generative models (Blei and Jordan, 2003; Krestel et al., 2009; Ding et al., 2013; Godin et al., 2013) based on the textual information of a single microblog.

Since microblog users are free to develop and use their own hashtags, they may select hashtags for different purposes. Based on an analysis of the hashtags crawled from a real online service, we observe that hashtags are used for events, conferences, conversation, disasters, memes, recall, quotes, and so on. To illustrate it let us take the following examples:

Example 1:*#Apple_iOS_9 includes music feature, new security and support for older iPhones.*

Example 2:*#BREAKING: Missing cyclist Natalie Donoghue has been found alive after she went missing in the Hunter Valley.*

We can see that the hashtag *#Apple_iOS_9* used in the example summarize the main topics of the corresponding microblog. While, the aim of hashtag *#BREAKING* in the example 2 is used as a label of the microblog. The different uses greatly

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 401–410,
Lisbon, Portugal, 17-21 September 2015.

impact the strategy of hashtag recommendation. However, there has been relatively few studies which take this issue into consideration.

In this paper, we propose a novel nonparametric Bayesian method to perform this problem. Inspired by the methods proposed by Liu et al. (2012), we assume that the hashtags and textual content in the corresponding microblog are parallel descriptions of the same thing in different languages. We adapt a translation model with topic distribution to achieve this task. Because of the ability of Dirichlet Process Mixture Models (DPMM) (Antoniak and others, 1974; Ferguson, 1983) to handle an unbounded number of topics, the proposed method is extended from them. Based on the different uses of hashtags, we incorporate the type of hashtag into the DPMM as a hidden variable.

The main contributions of this work can be summarized as follows:

- Through analyzing the microblogs, we propose the problem of influences of types of hashtags.
- We adopt a nonparametric Bayesian method to perform the hash tag recommendation task, which also takes the types of hashtags into consideration.
- Experimental results on the dataset we construct from a real microblogging service show that the proposed method can achieve significantly better performance than the state-of-the-arts methods.

2 The Proposed Method

In this section, we first give some brief descriptions about the Dirichlet process (DP) and Dirichlet Process Mixture Models (DPMM). Then, we detail the proposed hashtag recommendation method.

2.1 Preliminaries

2.1.1 Dirichlet Process

The Dirichlet process (DP) is a distribution over distributions. A DP, denoted by $G \sim DP(\alpha, H)$, is parameterized by a base measure H, and a concentration parameter α. After a discussion of basic definitions, we present two different perspectives on the Dirichlet process.

A perspective on the Dirichlet process is stick-breaking construction. The stick-breaking construction considers a probability mass function $\{\beta_k\}_{k=1}^{\infty}$ on a countably infinite set, where the discrete probabilities are defined as follows:

$$\begin{aligned} v_k|\alpha &\sim Beta(1,\alpha) \\ \beta_k &= v_k \prod_{l=1}^{k-1}(1-v_l). \end{aligned} \tag{1}$$

The k^{th} weight is a random proportion v_k of the remaining stick after the previous$(k-1)$ weights have been defined. This stick-breaking construction is generally denoted by $\beta \sim GEM(\alpha)$ (GEM stands for Griffiths, Engen and McCloskey). A random draw $G \sim DP(\alpha, H)$ can be expressed as:

$$G = \sum_{k=1}^{\infty} \beta_k \delta_{\theta_k} \quad \theta_k|\alpha, H \sim H, \tag{2}$$

where δ_θ is a probability measure concentrated at θ.

A second perspective on the Dirichlet process is provided by the *Pólya urn scheme* (Blackwell and MacQueen, 1973). It refers to draws from G. Let $\theta_1, \theta_2, ...$ represent a sequence of independent and identically distributed (i.i.d.) random variables distributed according to G. Blackwell and MacQueen (1973) showed that the conditional distributions of θ_i given $\theta_1, ..., \theta_{i-1}$ have the following form:

$$\begin{aligned} &\theta_i|\theta_1, ..., \theta_{i-1}, \alpha, H \\ &\sim \sum_{j=1}^{i-1} \frac{j}{i-1+\alpha}\delta_{\theta_j} + \frac{\alpha}{i-1+\alpha}H. \end{aligned} \tag{3}$$

Eq.(3) shows that θ_i has positive probability of being equal to one of the previous draws. We use $\phi_1, ..., \phi_K$ to represent the distinct values taken on by $\theta_1, ..., \theta_{i-1}$, and Eq.(3) can be re-expressed as:

$$\begin{aligned} &\theta_i|\theta_1, ..., \theta_{i-1}, \alpha, H \\ &\sim \sum_{k=1}^{K} \frac{m_k}{i-1+\alpha}\delta_{\theta_{\phi_k}} + \frac{\alpha}{i-1+\alpha}H, \end{aligned} \tag{4}$$

where m_k is the number of values $\theta_{i'} = \phi_k$ for $1 \leq i' < i$.

2.1.2 Dirichlet Process Mixture Models

In nonparametric Bayesian statistics, DPs are commonly used as prior distributions for mixture

models with an unknown number of components. Let $F(\theta_i)$ denotes the distribution of the observation x_i given θ_i. We can get the observation x_i as follows:

$$\theta_i|G \sim G$$
$$x_i|\theta_i \sim F(\theta_i).$$

Given $G \sim DP(\alpha, H)$, each observation x_i from an exchangeable data set $\mathbf{x}$ is generated by first choosing a parameter $\theta_i \sim G$, and then sampling $x_i \sim F(\theta_i)$. This model is referred to as a Dirichlet process mixture model. This process is often described by a set $\mathbf{z}$ of independently sampled variables $z_i \sim Mult(\beta)$ indicating the component of the mixture $G(\theta)$ associated with each data point $x_i \sim F(\theta_{z_i})$. Then we can get:

$$z_i|\beta \sim Mult(\beta)$$
$$x_i|\{\theta_k\}_{k=1}^{\infty}, z_i \sim F(\theta_{z_i}).$$

2.2 DPMM Based Hashtag Recommendation

2.2.1 The Generation Process

Let D represent the number of microblogs in the given corpus. A microblog contains a bag of words denoted by $w_d = \{w_{d_1}, w_{d_2}, ..., w_{d_{N_d}}\}$, where N_d is the total number of terms in the microblog. A word is defined as an item from a vocabulary with W distinct words indexed by $w = \{w_1, w_2, ..., w_W\}$. Each microblog may have a number of hashtags denoted by $h_d = \{h_{d_1}, h_{d_2}, ..., h_{d_{M_d}}\}$. M_d is the number of hashtags of microblog d. Each hashtag is from the vocabulary with V distinct hashtags indexed by $h = \{h_1, h_2, ..., h_V\}$. Given an unlabeled data set, the task of hashtag recommendation is to discover a list of hashtags for each microblog.

In standard LDA, each document is viewed as a mixture of topics, and each topic has probabilities to generate words. A LDA is a generalization of a finite mixture model. Since DP is the extension of finite mixture models to the nonparametric setting, the appropriate tool for nonparametric topic models is HDP. However, both LDA and HDP are normally suitable for long documents. For microblogs, which have limited number of words, a single microblog is most likely to talk about a single topic. Hence, in this work, we regard that each microblog associates with only one topic. The set of documents are viewed as a mixture of infinite topics. And we use DPs as prior distributions for the mixture of infinite topics.

The main assumptions of our model are as follows. When user u publishes a microblog, he will first generate the content and then generate the hashtags. When constructing the content, he will select a topic based on the topic distribution. Then he will choose a bag of words one by one from the word distribution of the topic or from the background words that captures white noise. Hashtags will be chosen according to the following two situations. In the first situation, hashtags summarize the corresponding microblogs. Hashtags of a microblog can be generated from the content through the topic-specific alignment probability between words and hashtags. In the second situation, hashtag is used as a label of the microblog. We recommend the hashtags using the words in the microblog, which is based on the frequency of words regarded as this type of hashtag.

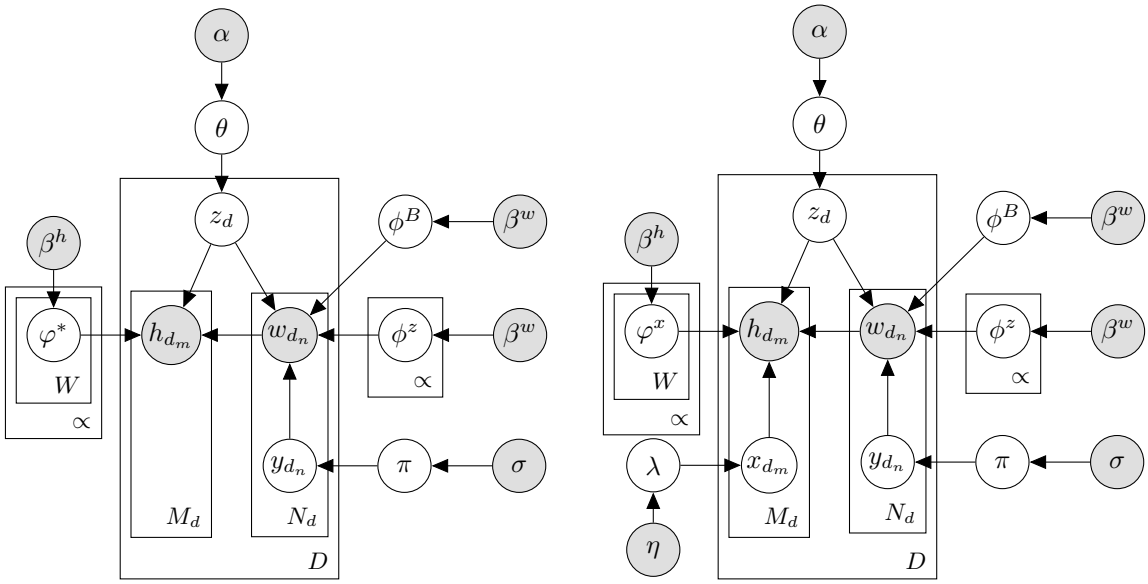
Let π be the probability of choosing a topic word or a background word, and we use $y_d = \{y_{d_n}\}_{n=1}^{N_d}$ to indicate a word to be a topic word or background word. θ denotes the topic distribution, and ϕ^k represents the word distribution for topic k. ϕ^B represents the word distribution for background words. We use x_{d_m} to represent the type of hashtag h_{d_m}, and use z_d to represent the topic of document d. Then each hashtag h_{d_m} is annotated according to the translation possibility $P(h_{d_m}|w_d, z_d, x_{d_m}, \varphi^{x_{d_m}})$, where $\varphi^{x_{d_m}}$ is the probability alignment table between words and hashtags. The generation process is as Algorithm 1.

Figure 1(a) shows the graphical representation of the generation process in Algorithm 1. Figure 1(b) is the graphical model which does not take the types of hashtags into consideration, where $\varphi^* \in \{\varphi^1, \varphi^2\}$. If $\varphi^* = \varphi^1$, the model is just considering the first situation. when $\varphi^* = \varphi^2$, only the second type of hashtag will be considered.

2.2.2 Learning

We use collapsed Gibbs sampling (Griffiths and Steyvers, 2004) to obtain samples of hidden variables assignment and to estimate the model parameters from these samples.

The sampling probability of being a topic/background word for the nth word in the microblog d can be calculated by the following



(a) CNHR (b) NHR*

Figure 1: The graphical representation of the proposed model. Shaded circles are observations or constants. Unshaded ones are hidden variables. *CNHR* represents the proposed hashtag recommendation method. *NHR** represents the model which does not take the types of hashtags into consideration.

Algorithm 1 The generation process of CNHR

Draw $\pi \sim Beta(\sigma)$, $\lambda \sim Beta(\eta)$

    Draw $y_{d_n} \sim Ber(\pi)$
    if $y_{d_n} = 0$ **then**
      Draw a word w_{d_n} from the background-word distribution $w_{d_n} \sim Mul(\phi^B)$
    else
      Draw a word w_{d_n} from the topic-word distribution $w_{d_n} \sim Mul(\phi^{z_d})$
    end if
  end for
  for each hashtag $m = 1, ..., M_d$ **do**
    Draw $x_{d_m} \sim Ber(\lambda)$
    Draw $\varphi^{x_{d_m}} \sim Dir(\beta^h)$
    Draw a hashtag $h_{d_m} \sim P(h_{d_m}|w_d, z_d, x_{d_m}, \varphi^{x_{d_m}})$
  end for
end for

equation:

$$p(y_{d_n}|\mathbf{w}, \mathbf{h}, \mathbf{z}, \mathbf{y}_{\neg \mathbf{d_n}}, \sigma, \beta^w) \propto \frac{N_{\neg n,p} + \sigma}{N_{\neg n,(.)} + 2\sigma} \cdot \frac{N^{w_{d_n}}_{\neg n,l} + \beta^w}{N^{(.)}_{\neg n,l} + \beta^w W}, \quad (5)$$

where $l = B$ when $p = 0$ and $l = z_d$ when $p = 1$, $N_{\neg n,p}$ is a count of words that are assigned to background words and any topic respectively, $N^{w_{d_n}}_{\neg n,B}$ is the number of word w_{d_n} assigned to background words, $N^{w_{d_n}}_{\neg n,z_d}$ is the number of word w_{d_n} that are assigned to topic z_d. All counters are calculated with the current word w_{d_n} excluded.

We sample z_d for the microblog d using the following equation:

$$p(z_d|\mathbf{w}, \mathbf{h}, \mathbf{z}_{\neg \mathbf{d}}, \mathbf{y}, \mathbf{x}, \alpha, \beta^w, \beta^h) \propto p(z_d|\mathbf{z}_{\neg \mathbf{d}}, \alpha) \cdot p(\mathbf{w_d}|\mathbf{z}, \mathbf{w}_{\neg \mathbf{d}}, \mathbf{y}, \beta^w) \cdot p(\mathbf{h_d}|\mathbf{z}, \mathbf{w_d}, \mathbf{y}, \mathbf{x}, \beta^h). \quad (6)$$

We can also represent $p(z_d|\mathbf{z}_{\neg \mathbf{d}}, \alpha)$ with CRP as described in the previous section. Since $z_1, z_2, ...$ is a sequence of i.i.d random variables, they are exchangeable. Let us consider the dth variable z_d is the last observation, we can get the following expression:

$$p(z_d|\mathbf{z}_{\neg \mathbf{d}}, \alpha) \sim \sum_k^K \frac{N^k_{\neg d}}{N^{(.)}_{\neg d} - 1 + \alpha} \delta(z_d, k) + \frac{\alpha}{N^{(.)}_{\neg d} - 1 + \alpha} \delta(z_d, \bar{k}), \quad (7)$$

where k is an exist topic and $\bar{k}$ is a new topic, $N^k_{\neg d}$ is the number of microblogs assigned with topic k, $N^{(.)}_{\neg d}$ is the total number of microblogs, α is concentration parameter. All counters are

calculated with the current microblog d excluded.

If z_d equals an exist topic $z_d = k$, then we can calculate $p(\mathbf{w_d}|\mathbf{z}, \mathbf{w}_{\neg\mathbf{d}}, \mathbf{y}, \beta^w)$ by:

$$p(\mathbf{w_d}|\mathbf{z}, \mathbf{w}_{\neg\mathbf{d}}, \mathbf{y}, \beta^w) = \frac{\int_{\phi_k} \widetilde{f}(\mathbf{w_d}|\phi_k) \prod_{z_j=k, j\neq d} \widetilde{f}(\mathbf{w_j}|\phi_k) h(\phi_k) d\phi_k}{\int_{\phi_k} \prod_{z_j=k, j\neq d} \widetilde{f}(\mathbf{w_j}|\phi_k) h(\phi_k) d\phi_k}, \tag{8}$$

where $\widetilde{f}(\mathbf{w_d}|\phi_k) = \prod_{1\leq n\leq N_d, y_{d_n}=1} f(w_{d_n}|\phi_k)$. N_d is the number of words in microblog d. $f(w_{d_n}|\phi_k)$ is the density of word w_{d_n} given topic k. $\mathbf{w_d}$ are the words in microblog d. $h(\phi_k)$ is the density of base measure H.

If z_d is a new topic $z_d = \bar{k}$, then we can calculate $p(\mathbf{w_d}|z_d = \bar{k}, \mathbf{w}_{\neg\mathbf{d}}, \mathbf{y}, \beta^w)$ by:

$$p(\mathbf{w_d}|z_d = \bar{k}, \mathbf{w}_{\neg\mathbf{d}}, \mathbf{y}, \beta^w) = p(\mathbf{w_d}|\beta^w) = \int_{\phi_{\bar{k}}} \widetilde{p}(\mathbf{w_d}|\phi_{\bar{k}}) h(\phi_{\bar{k}}) d\phi_{\bar{k}}, \tag{9}$$

where $\widetilde{p}(\mathbf{w_d}|\phi_{\bar{k}}) = \prod_{1\leq n\leq N_d, y_{d_n}=1} p(w_{d_n}|\phi_{\bar{k}})$.

We can calculate the probabilities of generating hashtags from two situations as follows:

$$p(\mathbf{h_d}|\mathbf{z}, \mathbf{w_d}, \mathbf{y}, \mathbf{x}, \beta^h) = \begin{cases} \prod_{m=1}^{M_d} \sum_{n\in\widetilde{N}_d} \frac{M^{k,\neg d}_{w_{d_n}, h_{d_m}} + \beta^h}{M^{k,\neg d}_{w_{d_n},(.)} + \beta^h V} & x_{d_m} = 1 \\ \prod_{m=1}^{M_d} \sum_{n\in\widetilde{N}_d, w_{d_n}=h_{d_m}} \frac{M^{k,\neg d}_{w_{d_n},2} + \beta^h}{M^{k,\neg d}_{w_{d_n},(.)} + 2\beta^h} & x_{d_m} = 2, \end{cases} \tag{10}$$

where $\widetilde{N}_d$ represent the index set of topic words($y = 1$) in the microblog d, $M^{k,\neg d}_{w_{d_n}, h_{d_m}}$ is the number of occurrences that word w_{d_n} is translated to hashtag h_{d_m} given topic k, $M^{k,\neg d}_{w_{d_n},(.)}$ is the total number of occurrences that word w_{d_n} is under topic k, $M^{k,\neg d}_{w_{d_n},2}$ is the number of word w_{d_n} recommended as the second type of hashtag given topic k. All counters with $\neg d$ are calculated with the current microblog w_d excluded.

We sample the index variable x_{d_m} for mth hashtag in the microblog d as follows:

$$p(x_{d_m}|\mathbf{z}, \mathbf{w_d}, \mathbf{y}, \mathbf{x}_{\neg\mathbf{d_m}}, \mathbf{h}_d, \beta^h) \propto \sum_{n=1}^{\widetilde{N}_d} \varphi^{x_{d_m}}_{h_{d_m}, z_d, w_{d_n}} \frac{N^{\neg d_m}_{x_{d_m}} + \eta}{N^{\neg d_m}_{(.)} + 2\eta}, \tag{11}$$

where $N^{\neg d_m}_{x_{d_m}}$ is the number of hashtags that is generated by the type x_{d_m}, $N^{\neg d_m}_{(.)}$ is total number of hashtags, the counters with $\neg d_m$ are calculated with the current hashtag excluded.

After enough sampling iterations to burn in the Markov chain, φ^1 and φ^2 are estimated as follows:

$$\varphi^1_{h,k,w} = \frac{M^k_{w,h} + \beta^h}{M^k_{w,(.)} + \beta^h V}, \varphi^2_{h,k,w} = \frac{M^k_{w,2} + \beta^h}{M^k_{w,(.)} + 2\beta^h}, \tag{12}$$

The potential size of the probability alignment φ^1 between hashtag and word is $W \cdot V \cdot K$. The data sparsity may pose a more serious problem in estimating φ^1 than the topic-free word alignment case. We use interpolation smoothing technique for φ^1. In this paper, we employ smoothing as follows:

$$\varphi^{1*}_{h,k,w} = \gamma\varphi^1_{h,k,w} + (1-\gamma)P(h|w), \tag{13}$$

where $\varphi^{1*}_{h,k,w}$ is the smoothed topical alignment probabilities, $\varphi^1_{h,k,w}$ is the original topical alignment probabilities, $P(h|w)$ is topic-free word alignment probability. In this work, we obtain $P(h|w)$ by exploring IBM model-1 (Brown et al., 1993). γ is trade-off of two probabilities ranging from 0 to 1. When $\gamma = 0$, $\varphi^{1*}_{h,k,w}$ reduces to topic-free word alignment probability, and when $\gamma = 1$, there will be no smoothing in $\varphi^{1*}_{h,k,w}$.

2.2.3 Hashtag Recommendation

Suppose given an unlabeled dataset, we firstly discover the topic and determine topic/background words for each microblog. The collapsed Gibbs sampling is also applied for inference. The process is almost same as previous section described the model learning. The different is that there are no hashtags in the unlabeled dataset. Hence, when sampling z_d for the microblog d, we use the following equation:

$$p(z_d|\mathbf{w}, \mathbf{z}_{\neg\mathbf{d}}, \mathbf{y}, \alpha, \beta^w) \propto p(z_d|\mathbf{z}_{\neg\mathbf{d}}, \alpha) \cdot p(\mathbf{w_d}|\mathbf{z}, \mathbf{w}_{\neg\mathbf{d}}, \mathbf{y}, \beta^w). \tag{14}$$

Since there are no differences between the word alignments with each hashtags for a new topic in the unlabeled dataset, after the hidden variables of topic/background words and the topic of each microblog become stable, we only need to estimate the distribution of topics exist in the training dataset. Then we can estimate the distribution of topics for the microblog d in the unlabeled data by:

$$\chi_{dk} = \frac{p(k)p(w_{d_1}|k)p(w_{d_2}|k)...p(w_{d_{N_d}}|k)}{Z}, \tag{15}$$

where $p(w_{d_n}|k) = \frac{N_k^{w_{d_n}}+\beta}{N_k^{(\cdot)}+W\beta}$ and $N_k^{w_{d_n}}$ is a count of words w_{d_n} that are assigned to topic k in the corpus. And $p(k) = \frac{N_k}{N_{(\cdot)}+\alpha}$ is regarded as a prior for topic distribution, where Z is the normalized factor. With topic distribution χ and topic-specific word alignment table φ^*, we can rank hashtags for the microblog d in the unlabeled data through the following equation:

$$p(h_{d_m}|w_d, \chi_d, \varphi^*) \propto \sum_{z_d=1}^{K}\sum_{n=1}^{N_d}\sum_{x=1}^{C} p(z_d|\chi_d) \cdot p(w_{d_n}|w_d) \cdot p(x_{d_m}) \cdot p(h_{d_m}|w_{d_n}, z_d, x_{d_m}, \varphi^{x_{d_m}*}), \quad (16)$$

where C is the number of hashtag types. $p(w_{d_n}|w_d)$ is the weight of the word w_{d_n} in the microblog content w_d, which can be estimated by the IDF score of the word, $p(x_{d_m})$ is the probability of hashtag belong to the type x_{d_m}, we can estimate it with Eq.(11). Based on the ranking scores, we can suggest the top-ranked hashtags for each microblog.

3 Experiments

3.1 Data Collection

We use a dataset collected from Sina Weibo[1], which provides the Twitter-like service and is one of the most popular one in China, to evaluate the proposed approach and alternative methods. The original data set contains 282.2 million microblogs posted by around 1.1 million users. These microblogs were obtained by starting from a set of seed users and their follower/followee relations. We extract the microblogs posted with hashtags between Jan. 2012 and July 2013. Finally, 1,118,792 microblogs posted are selected for this work. The unique number of hashtags in the corpus is 305,227. We randomly select 100K as training data, 10K as development data, and 10K as test set. The hashtags marked in the original microblogs are considered as the golden standards.

3.2 Experiment Configurations

We use precision (P), recall (R), and F1-score (F_1) to evaluate the performance. Precision is calculated based on the percentage of "hashtags truly assigned" among "hashtags assigned by system". Recall is calculated based on the "hashtags truly assigned" among "hashtags manually assigned". F_1 is the harmonic mean of precision and recall. We do 500 iterations of Gibbs sampling to train the model. For optimizing the hyperparmeters of the proposed method and alternative methods, we use development data set to do it. In this work, the scale parameter α is set to $Gamma(5, 0.5)$. The other settings of hyperparameters are as follows: $\beta^w = 0.1$, $\beta^h = 0.1$, $\eta = 0.01$, and $\sigma = 0.01$. The smoothing factor γ in Eq.(13) is set to 0.8. For estimating the translation probability without topical information, we use GIZA++ 1.07 (Och and Ney, 2003) to do it.

Since hashtag recommendation task can also be modeled as a classification problem, we compare the proposed model with the following alternative methods:

- **Naive Bayes (NB)**: We formulate hashtag recommendation as a binary classification task and apply NB to model the posterior probability of each hashtag given a microblog.
- **Support Vector Machine (SVM)**: Similar to Naive Bayes, each hashtag can be regarded as one label and we use SVM to classify these microblogs.
- **Translation model (IBM-1)**: IBM model 1 is directly applied to obtain the alignment probability between the word and the hashtag (Liu et al., 2011).
- **Topical translation model (TTM)**: Ding et al. (2013) proposed the TTM for hashtag extraction. We implemented and extended their method for evaluating on the corpus constructed in this work. The number of topics in TTM is set to 20, and α is set to $50/K$. The hyperparameters used in TTM are also selected based on the development data set.

3.3 Experimental Results

Table 1 shows the comparisons of the proposed method with the state-of-the-art methods on the constructed evaluation dataset. "*CNHR*" denotes the method proposed in this paper. "*NHR1*" is a degenerate variation of CNHR, in which we consider all the hashtags are generated from distribution φ^1. "*NHR2*" is a model in which we consider all the hashtags are generated from

[1] http://www.weibo.com

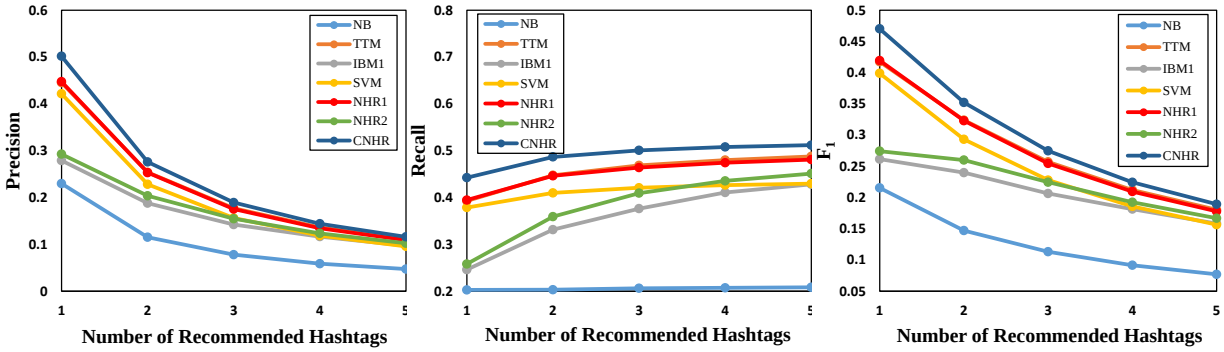

Figure 2: Precision, Recall and F_1 with recommended Hashtags range from 1 to 5

Table 1: Evaluation results of different methods on the evaluation collection.

Methods	Precision	Recall	F_1
NB	0.230	0.203	0.215
SVM	0.426	0.376	0.399
IBM1	0.279	0.246	0.261
TTM	0.445	0.393	0.417
NHR1	0.448	0.395	0.419
NHR2	0.293	0.258	0.274
CNHR	**0.502**	**0.442**	**0.470**

distribution φ^2. From the results, we can observe that discriminative methods achieve worse results than generative methods. We think that the large number of hashtags is one of the main reasons of the low performances.

From the results shown in Table 1, we also observe that the proposed method can achieve significantly better performance than existing methods. The relative improvement of proposed CNHR over TTM is around 12.7% in F_1. And we can see that the performances of TTM are similar as the results of NHR1. Since TTM and NHR1 are similar with each other except that TTM is based on LDA and NHR1 is adapted from DPMM. The results demonstrate the advantage of using DPMM over LDA. It does not need prior knowledge about number of topics. Comparing the results of the method CNHR with the methods NHR1 and NHR2 which do not take the types of hashtags into consideration, we can see that the proposed method benefits a lot from incorporating the types of hashtags.

Figure 2 shows the Precision, Recall, and F_1 curves of NB, IBM1, SVM, TTM, NHR1, NHR2 and CNHR on the test data. Each point of a curve represents the extraction of a different number of hashtags ranging from 1 to 5 respectively. In curves, the curve that is the highest of the graph indicates the best performance. Based on the results, we can observe that the performance of CNHR is the highest in all the curves. This indicates that the proposed method was significantly better than the other methods.

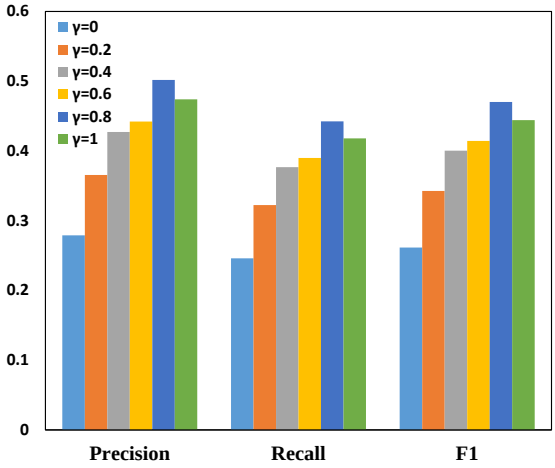
Table 2: The influence of the number of topics K of TTM.

K	Precision	Recall	F_1
10	0.441	0.389	0.413
20	**0.445**	**0.393**	**0.417**
30	0.432	0.381	0.405
40	0.413	0.364	0.387
50	0.391	0.345	0.367

In TTM, the number of topics K is also crucial factor. Table 2 shows the impact of the number of topics. From the table, we can observe that TTM obtains the best performance when K is set to 20. And performance decreases with more number of topics. We think that data sparsity may be one of the main reasons. With much more topic number, the data sparsity problem will be more serious when estimating topic-specific translation probability. We compare our method with the best performance of TTM.

From the description of the proposed model, we can know that there is a smooth parameter γ in the proposed method CNHR. To evaluate the impact of it, Figure 3 shows the influence of the translation probability smoothing parameter γ. When γ is set to 0.0, it means that the topical information is omitted. Comparing the results of $\gamma = 0.0$ and other values, we can observe that the topical information can benefit this task.

Figure 3: The influence of the smoothing parameter γ of CNHR.



When γ is set to 1.0, it represents the method without smoothing. The results indicate that it is necessary to address the sparsity problem through smoothing.

4 Related Works

Due to the usefulness of tag recommendation, many methods have been proposed from different perspectives (Heymann et al., 2008; Krestel et al., 2009; Rendle et al., 2009; Liu et al., 2012; Ding et al., 2013). Heymann et al. (Heymann et al., 2008) investigated the tag recommendation problem using the data collected from social bookmarking system. They introduced an entropy-based metric to capture the generality of a particular tag. In (Song et al., 2008), a Poisson Mixture Model based method is introduced to achieve the tag recommendation task. Krestel et al. (Krestel et al., 2009) introduced a Latent Dirichlet Allocation to elicit a shared topical structure from the collaborative tagging effort of multiple users for recommending tags. Ding et al. (2013) proposed to use translation process to model this task.

Based on the the observation that similar web pages tend to have the same tags, Lu et al. (2009) proposed a method taking both tag information and page content into account to achieve the task. They extended the translation based method and introduced a topic-specific translation model to process the various meanings of words in different topics. In (Tariq et al., 2013), discriminative-term-weights were used to establish topic-term relationships, of which users' perception were learned to suggest suitable hashtags for users. To handle the vocabulary problem in keyphrase extraction task, Liu et al. proposed a topical word trigger model, which treated the keyphrase extraction problem as a translation process with latent topics (Liu et al., 2012).

Most of the works mentioned above are based on textual information. Besides these methods, personalized methods for different recommendation tasks have also been paid lots of attentions (Liang et al., 2007; Shepitsen et al., 2008; Garg and Weber, 2008; Li et al., 2010; Liang et al., 2010; Rendle and Schmidt-Thieme, 2010; Huang et al., 2012). Shepitsen et al. (2008) proposed to use hierarchical agglomerative clustering to take into account personalized navigation context in cluster selection. In (Garg and Weber, 2008), the problem of personalized, interactive tag recommendation was also studied based on the statistics of the tags co-occurrence. Liang et al. (2010) proposed to the multiple relationships among users, items and tags to find the semantic meaning of each tag for each user individually and used this information for personalized item recommendation.

From the brief descriptions given above, we can observe that most of the previous works on hashtag suggestion did not take the types of hashtags into consideration. In this work, we propose to incorporate it into the generative methods.

5 Conclusions

In this paper, we study the problem of hashtag recommendation for microblogs. Since existing translation model based methods for this task regard all the hashtags generated from the same distribution, we propose a novel method which incorporates different type of hashtags have different distribution into the topical translation model for hashtag recommendation task. To evaluate the proposed method, we also construct a dataset from real world microblogging services. The results of experiments on the constructed dataset demonstrate that the proposed method outperforms state-of-the-art methods that do not consider these aspects.

Abstract

This paper proposes a graph-based readability assessment method using word coupling. Compared to the state-of-the-art methods such as the readability formulae, the word-based and feature-based methods, our method develops a coupled bag-of-words model which combines the merits of word frequencies and text features. Unlike the general bag-of-words model which assumes words are independent, our model correlates the words based on their similarities on readability. By applying TF-IDF (Term Frequency and Inverse Document Frequency), the coupled TF-IDF matrix is built, and used in the graph-based classification framework, which involves graph building, merging and label propagation. Experiments are conducted on both English and Chinese datasets. The results demonstrate both effectiveness and potential of the method.

1 Introduction

Readability assessment is a task that aims to evaluate the reading difficulty or comprehending easiness of text documents. It is helpful for educationists to select texts appropriate to the reading/grade levels of the students, and for web designers to organize texts on web pages for the users doing personalized searches for information retrieval.

Research on readability assessment starts from the early 20th century (Dale and Chall, 1948). Many useful readability formulae have been developed since then (Dale and Chall, 1948; McLaughlin, 1969; Kincaid et al., 1975). Currently, due to the development of natural language processing, the methods on readability assessment have made a great progress (Zakaluk and Samuels, 1988; Benjamin, 2012; Gonzalez-Dios et al., 2014). The word-based methods compute word frequencies in documents to estimate their readability (Collins-Thompson and Callan, 2004; Kidwell et al., 2009). The feature-based methods extract text features from documents and train classification models to classify the readability (Schwarm and Ostendorf, 2005; Feng et al., 2010; François and Fairon, 2012; Hancke et al., 2012).

In this paper, we propose a graph-based method using word coupling, which combines the merits of both word frequencies and text features for readability assessment. We design a coupled bag-of-words model, which correlates words based on their similarities on sentence-level readability computed using text features. The model is used in a graph-based classification framework, which involves graph building, graph merging/combination, and label propagation. We perform experiments on datasets of both English and Chinese. The results demonstrate both effectiveness and potential of our method.

The rest of this paper is organized as follows: Section 2 introduces backgrounds of our work. Section 3 presents the details of the method. Section 4 designs the experiments and explains the results. Finally, Section 5 concludes the paper with planned future work.

2 Background

In this section, we introduce briefly three research topics relevant to our work: readability assessment, the bag-of-words model and the graph-based label propagation method.

2.1 Readability Assessment

Research on readability assessment has developed three types of methods: the readability formula, the word-based methods and the feature-based methods (Kincaid et al., 1975; Collins-Thompson and Callan, 2004; Schwarm and Os-

*Corresponding author.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 411–420,
Lisbon, Portugal, 17-21 September 2015.

tendorf, 2005). During the early time, many well-known readability formulae have been developed to assess the readability of text documents (Dale and Chall, 1948; McLaughlin, 1969; Kincaid et al., 1975). Surface text features are defined in these formulae to measure both lexical and grammatical complexities of a document. The word-based methods focus on words and their frequencies in a document to assess its readability, which mainly include the unigram/bigram/n-gram models (Collins-Thompson and Callan, 2004; Schwarm and Ostendorf, 2005) and the word acquisition model (Kidwell et al., 2009). The feature-based methods focus on extracting text features from a document and training a classification model to classify its readability (Feng et al., 2010; François and Fairon, 2012; Hancke et al., 2012). Suitable text features are usually essential to the success of these methods. The Support vector machine and logistic regression model are two classification models commonly used in these methods.

2.2 The Bag-of-Words Model

The bag-of-words model is mostly used for document classification. It constructs a feature space that contains all the distinct words in a language (or the document set). A document is represented by a vector, whose components reflect the weight of every distinct word contained in the document. Normally, it assumes the words are independent. Now the capturing of the relationship among words has attracted considerable attention (Wong et al., 1985; Cheng et al., 2013). Inspired by these works, this paper adopts the bag-of-words model in readability assessment, and refines the model by computing similarity among words on reading difficulty.

2.3 The Graph-based Label Propagation Method

Graph-based label propagation is applied on a graph to propagate class labels from labeled nodes to unlabeled ones (Kim et al., 2013). It has been successfully applied in various applications, such as dictionary construction (Kim et al., 2013), word segmentation and tagging (Zeng et al., 2013), and sentiment classification (Ponomareva and Thelwall, 2012). Typically, a graph-based label propagation method consists of two main steps: graph construction and label propagation (Zeng et al., 2013). During the first step, a similarity function is required to build edges and compute weights between pairs of the nodes (Daitch et al., 2009). Some form of edge pruning is required to refine the graph (Jebara et al., 2009). After that, effective algorithms have been developed to propagate the label distributions to all the nodes (Subramanya et al., 2010; Kim et al., 2013).

3 The Proposed Method

In this section, we present GRAW (Graph-based Readability Assessment method using Word coupling), which constructs a coupled bag-of-words model by exploiting the correlation of readability among the words. Unlike the general bag-of-words model which models document relationship on topic, the coupled bag-of-words model extends it to model the relationship among documents on readability. In the following sections, we describe in detail how to build the coupled bag-of-words model. The model is then used in the graph-based classification framework for readability assessment.

3.1 The General Bag-of-Words Model

TF-IDF (Term Frequency and Inverse Document Frequency) is the most popular scheme of the bag-of-words model. Given the set of documents $\mathcal{D}$, the TF-IDF matrix M can be calculated based on the logarithmically scaled term (i.e. word) frequency (Salton and Buckley, 1988) as follows.

$$\begin{aligned} M_{t,d} &= tf_{t,d} \cdot idf_{t,d} \\ &= (1 + \log f(t,d)) \cdot \log \frac{|\mathcal{D}|}{|\{d|t \in d\}|} \end{aligned} \quad (1)$$

where $f(t,d)$ is the number of times that a term (word) t occurs in a document $d \in \mathcal{D}$.

3.2 The Coupled Bag-of-Words Model

As shown in Figure 1, three main stages are required to construct the coupled bag-of-words model: per-sentence readability estimation, word coupling matrix construction and coupled TF-IDF matrix calculation. The following sections describe the details of these stages.

3.2.1 Per-Sentence Readability Estimation

Two steps are required for the per-sentence readability estimation. The first is to compute a reading score of a sentence by heuristic functions. The second is to determine the difficulty level of the sentence by discretizing the score.

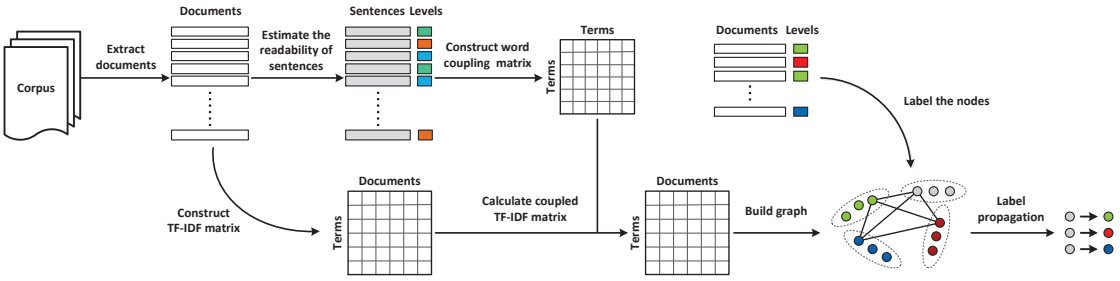

Figure 1: The Framework of GRAW

Step 1. Given a sentence s, its reading difficulty can be quantified as a reading score which is a continuous variable denoted by $r(s)$. The more difficult s is, the greater $r(s)$ will be. Based on text features of s, $r(s)$ can be computed by one of the eight heuristic functions listed in Table 1 which are grouped into three aspects.

Aspect	Function	Description
Surface	$len(s)$	the length of the sentence s.
	$ans(s)$	the average number of syllables (or strokes for Chinese) per word (or character for Chinese) in s.
	$anc(s)$	the average number of characters per word in s.
Lexical	$lv(s)$	the number of distinct types of POS, i.e. part of speech, in s.
	$atr(s)$	the ratio of adjectives in s.
	$ntr(s)$	the ratio of nouns in s.
Syntatic	$pth(s)$	the height of the syntax parser tree of s.
	$anp(s)$	the average number of (noun, verb, and preposition) phrases in s.

Table 1: Three aspects of estimating reading difficulty of sentences using heuristic functions

Step 2. Let η denote the pre-determined number of difficulty levels, r_{max} and r_{min} denote the maximum and minimum reading score respectively of all the sentences in $\mathcal{D}$. To determine the difficulty level $l^*(s)$ ($l^*(s) \in [1, \eta]$) of a sentence s, the range $[r_{min}, r_{max}]$ is divided into η intervals, so that each interval contains the reading scores of $\frac{1}{\eta}$ of all the sentences. The assumption is that all the sentences are equally distributed among the difficulty levels. $l^*(s)$ will be i, if the reading score $r(s)$ resides in the i-th interval.

For each of the three aspects, we compute one $l^*(s)$ for a sentence s by combining the heuristic functions using the following equations. The assumption is that the reading difficulty of a sentence may be determined by the maximum measure on the text features.

$$\begin{aligned} l^{sur}(s) &= \max\left[l^{len}(s), l^{ans}(s), l^{anc}(s)\right] \\ l^{lex}(s) &= \max\left[l^{lv}(s), l^{atr}(s), l^{ntr}(s)\right] \\ l^{syn}(s) &= \max\left[l^{pth}(s), l^{anp}(s)\right] \end{aligned} \tag{2}$$

3.2.2 Word Coupling Matrix Construction

Let $\mathcal{V}$ denote the set of all the words, a word coupling matrix is defined as $C^* \in \mathbb{R}^{|\mathcal{V}|\times|\mathcal{V}|}$, the element of which reflects the correlation between two words (i.e. terms). Two steps are required to construct this matrix. The first is to count the difficulty distributions of words, and the second is to compute the correlation between each pair of words according to the similarity of their difficulty distributions.

Step 1. Let $\mathcal{S}$ denote the set of all the sentences, p_t denote the difficulty distribution of a word (term) t. p_t is a vector containing η (i.e. the number of difficulty levels) values, the i-th part of which can be calculated by the following formula.

$$p_t(i) = \frac{1}{n_t} \cdot \sum_{s \in \mathcal{S}} \delta(t \in s) \cdot \delta(l^*(s) = i) \tag{3}$$

where n_t refers to the number of sentences in which t appears. The indicator function $\delta(x)$ returns 1 if x is true and 0 otherwise. $l^*(s)$ refers to one of the functions $l^{sur}(s)$, $l^{lex}(s)$ or $l^{syn}(s)$.

Step 2. Given two words (terms) t_1 and t_2, whose level distributions are p_{t_1} and p_{t_2} respectively, we measure the distribution difference $c_{KL}(t_1, t_2)$ using the Kullback-Leibler divergence (Kullback and Leibler, 1951), computed by the following formula.

$$c_{KL}(t_1, t_2) = \frac{1}{2}\left(KL(p_{t_1}||p_{t_2}) + KL(p_{t_2}||p_{t_1})\right) \tag{4}$$

where $KL(p||q) = \sum_i p(i) \log \frac{p(i)}{q(i)}$. After that, the logistic function is applied on the computed difference to get the normalized distribution similarity, i.e.

$$sim(t_1, t_2) = \frac{2}{1 + e^{c_{KL}(t_1, t_2)}} \tag{5}$$

Given a word t_i, only λ other words with highest correlation (similarity) are selected to build the

neighbor set of t_i, denoted as $\mathcal{N}(t_i)$. If a word t_j is not selected (i.e. $t_j \notin \mathcal{N}(t_i)$), the corresponding $sim(t_i, t_j)$ will be assigned 0. After that, the word coupling matrix (i.e. C^*) with $sim(t_i, t_j)$ as elements is normalized along the rows so that the sum of each row is 1. Based on three different $l^*(s)$, we construct three word coupling matrices C^{sur}, C^{lex} and C^{syn}.

3.2.3 Coupled TF-IDF Matrix Calculation

In the general bag-of-words model, the words are treated as independent of each other. However, for readability assessment, words may be correlated according to the similarity of their difficulty distributions. To improve the TF-IDF matrix M described in Section 3.1, we multiply it by the word coupling matrix C^*, so that the term frequencies are shared among the highly correlated (coupled) words. We denote the coupled TF-IDF matrix as M^*, obtained by the following formula.

$$M^* = C^* \cdot M \tag{6}$$

Specifically, three homogenous coupled TF-IDF matrices M^{sur}, M^{lex} and M^{syn} can be built according to the three word coupling matrices C^*.

3.3 Graph-based Readability Assessment

We employ the coupled bag-of-words model for readability assessment under the graph-based classification framework as described in the previous work (Zhu and Ghahramani, 2002). Firstly, we construct a graph representing the readability relationship among documents by using the coupled bag-of-words model to compute the relations among these documents. Secondly, we estimate reading levels of documents by applying label propagation on the graph.

3.3.1 Graph Construction

We build a directed graph G^* to represent the readability relation among documents, where nodes represent documents, and edges are weighted by the similarities between pairs of documents. Given a similarity function, we link documents d_i to d_j with an edge of weight G^*_{ij}, defined as:

$$G^*_{i,j} = \begin{cases} sim(d_i, d_j) & \text{if } d_j \in \mathcal{N}(d_i) \\ 0 & \text{otherwise} \end{cases} \tag{7}$$

where $\mathcal{N}(d_i)$ is the set of k-nearest neighbors of d_i determined by the similarity function.

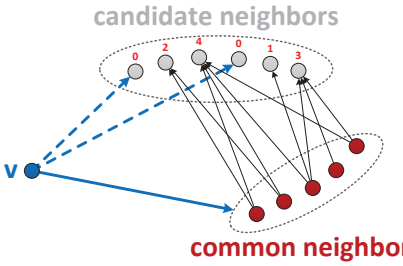

Figure 2: Illustration of the graph merging strategy

Given the coupled matrix $M^* \in \mathbb{R}^{m \times |\mathcal{D}|}$ which maps each document into a m-dimension feature space, the similarity function $sim(d_i, d_j)$ can be defined by the Euclidean distance as follows.

$$sim(d_i, d_j) = \frac{1}{\sqrt{\sum_{k=1}^{m} (M_{k,i} - M_{k,j})^2 + \epsilon}} \tag{8}$$

where ϵ is a small constant to avoid zero denominators.

Merge the three graphs Refer to Section 3.2, the three coupled TF-IDF matrices will lead to three different document graphs, denoted as G^{sur}, G^{lex} and G^{syn} respectively. To take advantage of the three aspects at one time, we need to merge the three graphs into one, denoted as G^c.

In G^c, each node also keeps k neighbors, and some edges shall be filtered out from the three graphs. The basic idea is to remove edges containing redundant information, as shown in Figure 2. For each node v, we firstly select the neighbors which are common in all the three graphs (i.e. $\mathcal{N}^{sur}(v) \cap \mathcal{N}^{lex}(v) \cap \mathcal{N}^{syn}(v)$). Secondly, for the rest candidate nodes, which are the neighbors of v in at least one graph, we select one by one the node which possesses the least number of common neighbors (from all the three graphs) with the nodes that are already selected in $\mathcal{N}^c(v)$. The objective is to keep the number of triangles in G^c to a minimum. The edge weights of G^c are averaged on the corresponding edges appeared in the three graphs.

Combine with the feature-based graph Previous studies usually extract text features from documents to assess the readability using classification models. Here, we also take into consideration the feature-based graph, where similarities among documents are computed on text features. We use the features defined in (Jiang et al., 2014), where the model based features are eliminated since the

computation depends on pre-assigned class labels, and represent a document as a vector of the feature values. We compute the similarity between any pair of documents using the Euclidean distance, and built the feature-based graph (denoted as G^f) in the same way as above.

Additionally, to take advantage of both graphs, we combine them into one (denoted as G^{cf}) using the following formula.

$$G^{cf}_{i,j} = \max\left[G^{c}_{i,j}, G^{f}_{i,j}\right] \quad (9)$$

3.3.2 Graph Propagation

Given a graph G^* constructed in previous sections, its nodes are divided into two sets: the labeled set V_l and the unlabeled set V_u. The goal of label propagation is to propagate class labels from the labeled nodes (i.e. documents) to the entire graph. Here, we use a simplified version of the label propagation method presented in (Subramanya et al., 2010), which has been proved effective (Kim et al., 2013). The method iteratively updates the label distribution on a document node using the following equation.

$$p_d^{(i)}(l) = \frac{1}{\kappa_d}\left(p_d^0(l)\delta(d \in V_l) + \sum_{v \in \mathcal{N}(d)} G_{d,v} p_v^{(i-1)}(l)\right) \quad (10)$$

At the left side of Eq.10, $p_d^{(i)}(l)$ is the afterward probability of l (i.e. the class label) on a node d at the i-th iteration. At the right side, κ_d is the normalizing constant to make sure the sum of all the probabilities is 1, and $p_d^0(l)$ is the initial probability of l on d if d is initially labeled (i.e. belonging to the labeled set V_l). $\delta(x)$ is the indicator function. $\mathcal{N}(d)$ denotes the set of neighbors of d. The iteration stops when the changes in $p_d^{(i)}(l)$ for all the nodes and label values are small enough (e.g. less than e^{-3}), or i exceeds a predefined number (e.g. greater than 30).

4 Empirical Studies

In this section, we conduct experiments on datasets of both English and Chinese, to investigate the following three research questions:

RQ1: Whether the proposed method (i.e. GRAW) outperforms the state-of-the-art methods for readability assessment?

RQ2: What are the effects of adding the word coupling matrix to the general bag-of-words model?

RQ3: Whether the graph merging strategy is effective, and whether the performance can be further improved by combining the feature-based graph.

4.1 Corpus and Metrics

To evaluate our proposed method, we collected two datasets. The first is CPT (*Chinese primary textbook*) (Jiang et al., 2014), which contains Chinese documents of six reading levels. The second is ENCT (*English New Concept textbook*) which contains English documents of four reading levels. Both datasets are built from well-known textbooks where documents are labeled as grade levels by credible educationists. The details of the datasets are listed in Table 2.

Dataset	Language	#Grade	#Doc	#Sent	#Word
CPT	Chinese	6	637	16145	234372
ENCT	English	4	279	4671	62921

Table 2: Statistics of the datasets on both English and Chinese

We conduct experiments on both datasets using the cross-validation which randomly divides a dataset into labeled (training) and unlabeled (test) sets. The labeling proportion is varied to investigate the performance of GRAW under different circumstances. To reduce variability, given certain labeling proportion, 100 rounds of cross-validation are performed, and the validation results are averaged over all the rounds. We choose the precision (P), recall (R) and F1-measure (F1) as the performance metrics.

4.2 Comparison to the State-of-the-Art Methods

To address RQ1, we implement the following readability assessment methods and compare GRAW to them: (1) SMOG (McLaughlin, 1969) and FK (Kincaid et al., 1975) are two widely used readability formulae. We reserve their core measures (i.e. text features, and number of strokes for Chinese instead of number of syllables), and refine the coefficients on both datasets to befit the reading (grade) levels. (2) SUM (Collins-Thompson and Callan, 2004) is a word-based method, which trains one unigram model for each grade level, and applies model smoothing both inter and intra the grade levels. (3) LR and SVM refer to two feature-based methods which incorporate text features defined in (Jiang et al., 2014) to represent documents as instances. The logistic regression model and

Table 3: The average Precision, Recall and F1-measure (%) per reading level of the seven methods for readability assessment on both datasets when the labeling proportion is 0.7

support vector machine are used as the classifiers respectively.

For GRAW, we implement label propagation on both the merged graph G^c and the final graph G^{cf} (Section 3.3), denoted as GRAW$_c$ and GRAW$_{cf}$ respectively. Table 3 gives the average performance measure per reading level resulted by the implemented methods on both datasets. Unless otherwise specified, we fixed η to 3, and λ to 2800 for CPT and 2000 for ENCT. The proportion of the labeled (training) set is set to 0.7.

In Table 3, the precision, recall and F1-measure of all the seven methods are calculated per reading (grade) level on both English and Chinese datasets. The values marked in bold in each row refer to the maximum (best) measure gained by the methods.

From Table 3, the readability formulae (SMOG and FK) perform poorly on either the precision or recall measure, and their F1-measure values are generally the poorest. Both SMOG and FK are designed for English, and have acceptable performance on the English dataset ENCT. The unigram model (SUM) performs a little better than the readability formulae. On ENCT, It has relatively good performance on grade levels 1 and 4, while on the Chinese dataset CPT, the performance is not satisfactory. The feature-based methods (LR and SVM) perform well on both ENCT and CPT, which means both the text features developed and the classifiers trained are useful. In general, GRAW$_c$ performs better than both LR and SVM, which demonstrates the effectiveness of our method. In addition, by combining the feature-based graph (GRAW$_{cf}$), GRAW can be improved, and performs the best on all the three metrics over the majority of reading levels on both datasets. The only exception is on level 5 in CPT, which suggests the requirement of further improvements.

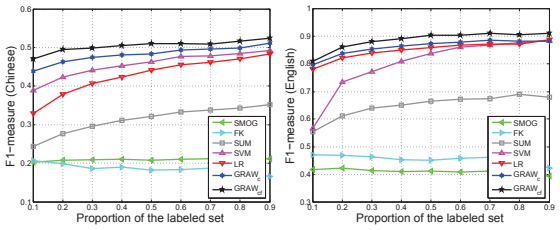

Figure 3: The average F1-measure of the seven methods on both datasets with the labeling proportion varied from 0.1 to 0.9

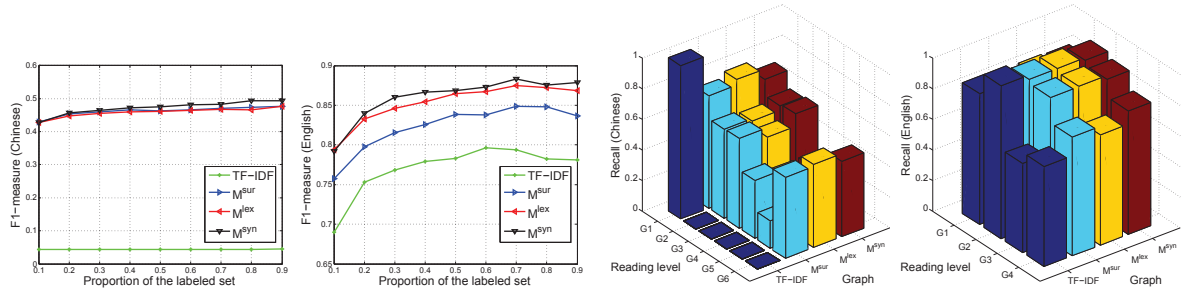
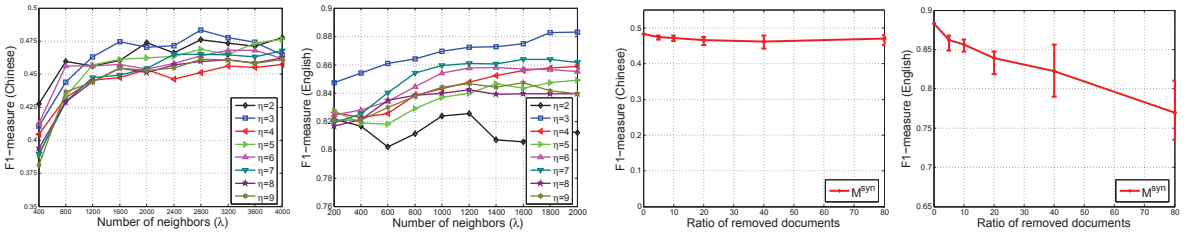
We study the effect of labeling proportion on the performance of these methods on both datasets. The F1-measure averaged over the reading levels is used, since it is a good representative of the three metrics according to Table 3. Figure 3 depicts the performance trends of all the methods.

From Figure 3, neither SMOG nor FK benefits



(a) Comparison of the average F1-measure between the coupling and general TF-IDF matrices

(b) Comparison of the Recall rate per reading level between the coupling and general TF-IDF matrices



(c) The effects of η and λ on the performance of the word coupling matrix

(d) The effect of corpus size on the performance of the word coupling matrix

Figure 4: Four perspectives on the effectiveness of the word coupling matrices

from the increasing size of the labeled set. This suggests that the performance of the readability formulae can hardly be improved by accumulating training data. The other 5 methods achieve better performance on larger labeled set, and outperform the two formulae even if the labeling proportion is small. Both LR and SVM perform better than SUM, but the performance is not good when the labeling proportion is less than 0.3, especially on the Chinese dataset. On the Chinese dataset, SVM performs better than LR, while on the English dataset, the situation is reversed. Both versions of GRAW outperform the other methods over the labeling ranges on both datasets. In addition, GRAW performs well when the labeling proportion is still small. Again, by combining the feature-based graph, the performance of GRAW is consistently improved.

In summary, GRAW can outperform the state-of-the-art methods for readability assessment on both English and Chinese datasets. By combining the feature-based graph, the performance of GRAW can be further improved.

4.3 Effects of the Word Coupling Matrix

For RQ2, we firstly compare the coupled bag-of-words model to the general model in the process of graph construction. Four graphs are built by using each of the three word coupling matrices (i.e. M^{sur}, M^{lex} and M^{syn}) and the TF-IDF matrix respectively. Label propagation is applied on each graph to predict reading levels of unlabeled documents. The labeling proportion is varied from 0.1 to 0.9 on both the English and Chinese datasets. Figure 4(a) depicts the average F1-measure resulted from the four graphs.

From Figure 4(a), the three word coupling matrices greatly outperform the TF-IDF matrix, especially on the Chinese dataset. This demonstrates that the word coupling matrices are very effective in improving the performance of the general bag-of-words model for readability assessment.

Secondly, we investigate the performance of the four matrices per reading level. Figure 4(b) depicts the recall rate per reading level of the four corresponding graphs in bar charts. The labeling proportion is set to 0.7. The recall rate is used because it makes the reason evident that the TF-IDF matrix performs poorly. From Figure 4(b), on the Chinese dataset, nearly all the unlabeled documents are classified as level 1 by the TF-IDF matrix, in which the word frequencies are too few to make meaningful discrimination among the reading levels. On the English dataset, the TF-IDF matrix performs better, but still prefers to classify documents into lower levels.

As described in Section 3.2.2, η (the number of difficulty levels of sentences) and λ (the number of neighbors pertained for each document node) are two parameters in building the word coupling

matrices. To investigate their effects on the performance of the built matrices, we vary the values of both η and λ, and compute the average F1-measure on the two datasets. Figure 4(c) depicts the results in line charts, where η varies from 2 to 9 step by 1, while λ varies from 400 to 4000 step by 400 on Chinese and from 200 to 2000 step by 200 on English (the difference is due to the dissimilar number of documents between the two datasets). The three word coupling matrices exhibit similar behavior during experiments, hence, only M^{syn} is depicted.

From Figure 4(c), a small η (e.g. 2 or 3) is good on the Chinese dataset. However, on the English dataset, $\eta = 2$ leads to the poorest performance. It seems the increasing of η causes vibrated performance, and the trend is further complicated when involving λ. Above all, $\eta = 3$ gives a preferable option on both datasets. For λ, most of the lines exhibit a similar trend that rises first and then keeps stable on both datasets, although some may drop when λ is too large. This suggests that making a relatively large number of the other words as the neighbors of one (i.e. $\lambda = 2800$ on the Chinese dataset and $\lambda = 2000$ on the English dataset) will make an effective word coupling matrix.

The word coupling matrix constructed in GRAW uses the whole corpus on either English or Chinese. To investigate if the corpus size takes effects on the performance of GRAW, we vary the proportion of the corpus used by randomly removing documents from each reading level. Figure 4(d) depicts the average F1-measure resulted by M^{syn}. The removing ratio is selected from $\{0, 0.05, 0.1, 0.2, 0.4, 0.8\}$. Both the mean values and deviations are shown on the line chart.

From Figure 4(d), on the Chinese dataset, the performance of GRAW suffers little from removing documents, even if only 20% documents are left for building the word coupling matrix. However, on the English dataset, the mean performance drops sharply and the deviation increases evidently. This suggests that cumulating sufficient corpus is required for building a suitable word coupling matrix in GRAW, and factors other than number of documents may influence the corpus quality, which deserves further study.

In summary, the word coupling matrix plays an essential role in GRAW. For building a suitable word coupling matrix, the number of difficulty levels of sentences (η) can be set to 3, and a relatively large number of the other words should be selected as the neighbors of a word. A sufficient corpus is required for refining the matrix.

4.4 Effectiveness of Graph Combination

For RQ3, we compare graphs built on each singular word coupling matrix (i.e. M^{sur}, M^{lex} and M^{syn}) to the merged graph (i.e. GRAW$_c$) and the combined graph (i.e. GRAW$_{cf}$). Figure 5 depicts the average F1-measure resulted after applying label propagation on these graphs with labeling proportion varied from 0.1 to 0.9. The feature-based graph (i.e. G^f) is also depicted for comparison.

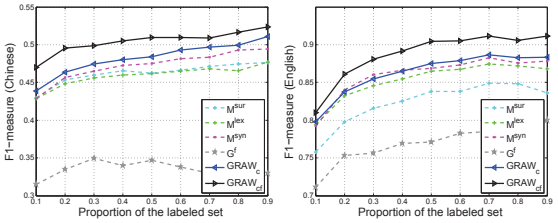


Figure 5: The average F1-measure of different types of graphs on the English and Chinese datasets

From Figure 5, the merged graph GRAW$_c$ outperforms the three basic graphs on both datasets in most cases. Within the three, M^{syn} performs best, especially on the English dataset, where it can outperform GRAW$_c$ slightly when the labeling proportion is small $(0.2 - 0.4)$. By combining the feature-based graph, GRAW$_{cf}$ performs even better on both datasets, although G^f performs poorest among all the graphs. In summary, the graph merging strategy is effective, and by combining the feature-based graph, the performance of GRAW can be improved. This demonstrates the potential of GRAW.

5 Conclusion

In this paper, we propose a graph-based readability assessment method using word coupling. The coupled bag-of-words model is designed, which exploits the correlation of readability among the words, and by applying TF-IDF, models the relationship among documents on reading levels. The model is employed in the graph-based classification framework for readability assessment, which involves graph building, merging, and label propagation. Experiments are conducted on both Chinese and English datasets. The results show that our method can outperform the commonly used

methods for readability assessment. In addition, the evaluation demonstrates the potential of the coupled bag-of-words model and the graph combination/merging strategies.

In our future work, we plan to verify the soundness of the results by applying our method on large volume corpus of both English and Chinese. In addition, we will investigate other ways of computing the word coupling matrices, such as incorporating word coherency or semantics, and develop efficient merging strategies which can be used for training classification models, as well as for building graphs.

Abstract

Social media represents a rich source of up-to-date information about events such as incidents. The sheer amount of available information makes machine learning approaches a necessity for further processing. This learning problem is often concerned with regionally restricted datasets such as data from only one city. Because social media data such as tweets varies considerably across different cities, the training of efficient models requires labeling data from each city of interest, which is costly and time consuming.

In this study, we investigate which features are most suitable for training generalizable models, i.e., models that show good performance across different datasets. We reimplemented the most popular features from the state of the art in addition to other novel approaches, and evaluated them on data from ten different cities. We show that many sophisticated features are not necessarily valuable for training a generalized model and are outperformed by classic features such as plain word-n-grams and character-n-grams.

1 Introduction

Incident information contained in social media has proven to frequently include information not captured by standard emergency channels (e.g. 911 calls, bystander reports). Therefore, stakeholders like emergency management and city administration can highly benefit from social media. Due to its unstructured and unfocused nature, automatic filtering of social media content is a necessity for further analysis. A standard approach for this filtering is automatic classification using a trained machine learning model (Agarwal et al., 2012; Schulz et al., 2013; Schulz et al., 2015b).

A problem for the classification approach is that language, style and named entities used in social media highly vary across different regions. Consider the following two tweets as examples: "RT: @People 0noe friday afternoon in heavy traffic, car crash on I-90, right lane closed" and "Road blocked due to traffic collision on I-495". Both tweets comprise entities that might refer to the same thing with different wording, either on a semantically low ("accident" and "car collision") or more abstract level ("I90" and "I-495"). With simple syntactical text similarity approaches using standard bag of words features, it is not easily possible to make use of this semantic similarity, even though it is highly valuable for classification.

These limitations impose constraints on the dataset, because tokens are likely to be related to the location where the text was created or contain location- or incident-sensitive topics. Models trained using spatially and temporally restricted data from one region are bound by the specific aspects of language and style expressed in the training data, thus, model reuse is not easily possible.

In this paper, we focus on the creation of generalized models. Such models avoid the use of features that — overfitting like — are only useful for a specific region. Generalized models are intended to work in different regions, even if training data originates only from one ore few regions. This can ensure high classification rates even in areas where only few training samples are available. Finally, in

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 421–430,
Lisbon, Portugal, 17-21 September 2015.

times of increasing growth of cities and the merging with surrounding towns to large metropolitan areas, they allow to cope with the latent transitions in token use.

To create generalized models for incident type classification (and social media classification in general) the most important step is an appropriate feature generation. Therefore, in this paper we investigate the suitability of standard and novel features and different machine learning algorithms for the creation of generalized classification models for incident type classification. We conduct intensive feature engineering and evaluation. For this purpose, we have collected and labeled 10 datasets with high regional variation. To the best of our knowledge, this is the first investigation of the challenges of heterogeneous datasets in this domain, and of the suitability of state of the art classification and feature extraction techniques.

In summary, our contributions are: 1) Investigation of features and feature groups for generalized social media/incident type classification models. 2) Identification of the best feature combinations and classifiers for a generalized model. For an evaluation (qualitative and inferential statistics) of ten tweet datasets with high regional variation we get an overall F-measure of $> 83\%$. 3) The evaluation shows that features extending a plain n-gram-based approach are not necessarily valuable for training a generalized model as these provide little improvement.

Following this introduction, we give an overview of related work in Section 2. In Section 3, we provide a description of our datasets followed by a comprehensive evaluation in Section 4. We close with our conclusion and future work in Section 5.

2 Related Work

A review of existing work on the classification of social media content shows which features, feature groups and algorithms are generally used (see table 1). Furthermore, the number of classes and the dominating approaches unfold. We report the ratios of labeled tweets for the individual approaches; however, we omit performance measures as these are directly related to the respective datasets used for evaluation.

Classifiers based on Support Vector Machines (SVM) or Naive Bayes (NB) clearly dominate in terms of performance for incident type classification. (Sakaki and Okazaki, 2010; Carvalho et al., 2010; Agarwal et al., 2012; Robert Power, 2013; Schulz and Janssen, 2014) trained an SVM, whereas (Agarwal et al., 2012; Imran et al., 2013; Schulz and Janssen, 2014) also evaluated an NB classifier. In contrast to these works, (Wanichayapong et al., 2011) followed a dictionary-based approach using traffic-related keywords. (Li et al., 2012) do not provide any information about the classifier used.

Feature groups are mostly based on word-n-grams, such as unigrams (Carvalho et al., 2010), bigrams (Imran et al., 2013), or the combination of unigrams and bigrams (Robert Power, 2013; Karimi et al., 2013; Agarwal et al., 2012). (Schulz and Janssen, 2014) combined unigrams, bigrams, and trigrams. Also, based on the words present in the text named entities such as locations, organizations, or persons were used by (Agarwal et al., 2012; Li et al., 2012; Schulz and Janssen, 2014).

Twitter-specific features were also used, including the number of hashtags, @-mentions or web-text features such as the presence of numbers or URLs (Li et al., 2012; Agarwal et al., 2012; Robert Power, 2013; Karimi et al., 2013; Imran et al., 2013; Schulz and Janssen, 2014).

Keywords also play a crucial role in feature design. (Sakaki and Okazaki, 2010) used earthquake-specific keywords, statistical features (the number of words in a tweet and the position of keywords), and word context features (the words before and after the earthquake-related keyword). (Wanichayapong et al., 2011) used traffic-related keywords in combination with location-related keywords. Furthermore, Li et al. (2012) iteratively refined a keyword-based search for retrieving a higher number of incident-related tweets.

Two approaches rely on more specific feature groups. The approach of (Schulz and Janssen, 2014) is the only one that uses TF-IDF scores. (Imran et al., 2013) use Kipper et al.'s (2006) extension of the Verbnet ontology for verbs.

The related approaches mostly use word-n-grams and a variety of Twitter-specific features. Datasets are spatially and temporally restricted and limited to a small number, complicating generalizability.

3 Data Collection and Processing

We are interested in generalizable models for different regions, user-generated content has been

Table 1: Overview of related approaches for incident type classification. (NEs = Named Entities)

Approach	Classifier	#Classes	#Tweets	N-Grams	#NEs	#URLs	TF-IDF	Twitter	Other
(Sakaki and Okazaki, 2010)	SVM	2	597	x					Context
(Carvalho et al., 2010)	SVM	2	3,300	x					
(Wanichayapong et al., 2011)	Keyw.	2	1,249						
(Agarwal et al., 2012)	NB, SVM	2	1,400	x	x	x			
(Li et al., 2012)	Undefined	2	Undef.		x			x	
(Robert Power, 2013)	Keyw., SVM	2	794	x				x	
(Karimi et al., 2013)	SVM	6	5,747	x				x	
(Imran et al., 2013)	NB	3	1,233	x		x		x	Verbnet
(Schulz and Janssen, 2014)	SVM, NB	4	2,000	x	x	x	x	x	

created in. For this purpose, we created 10 datasets with more than 20k labeled tweets to train and test models with respect to their generalization. In the following, we describe how this data was collected, preprocessed, and which features were generated.

3.1 Data Collection

We focus on tweets as suitable example for unstructured textual information shared in social media. The classification of incident-related tweets represents a challenge that is relevant for many cities. We use a complex four-class classification problem, where new tweets can be assigned to the classes "crash", "fire", "shooting", and a neutral class "not incident related". This goes beyond related work with a focus on two-class classification. Our classes were identified as the most common incident types in Seattle using the Fire Calls data set (http://seattle.data.gov), an official incident information source.

As ground truth data, we collected several city-specific datasets using the Twitter Search API. These datasets were collected in a 15 km radius around the city centres of Boston (USA), Brisbane (AUS), Chicago (USA), Dublin (IRE), London (UK), Memphis (USA), New York City (USA), San Francisco (USA), Seattle (USA), Sydney (AUS).

We selected these cities because of their huge regional distance, which allows us to evaluate our approaches with respect not only to geographical, but also to cultural variations. Also, for all cities, sufficiently many English tweets can be retrieved. We chose 15 km as radius to collect a representative data sample even from cities with large metropolitan areas. Despite the limitations of the Twitter Search API with respect to the number of geotagged tweets, we assume that our sample is, although by definition incomplete, highly relevant to our experiments.

We collected all available Tweets during limited time periods, resulting in three initial sets of tweets: 7.5M tweets collected from November, 2012 to February, 2013 for Memphis and Seattle (**SET_CITY_1**); 2.5M tweets collected from January, 2014 to March, 2014 for New York City, Chicago, and San Francisco (**SET_CITY_2**); 5M tweets collected from July, 2014 to August, 2014 for Boston, Brisbane, Dublin, London, and Sydney (**SET_CITY_3**).

For the manual labeling process, we had to select a subset of our original tweet set which included our classes of interest for model training and testing. Generating subsets is required because manual labeling of social media data is very expensive, especially if multiple annotators are involved. To generate subsets we used the approach of (Schulz et al., 2013) of extracting microposts using incident-related keywords. As a result, more than 200 keywords were identified for each class. Based on these incident-related keywords, we were able to accurately and efficiently filter the datasets. After applying keyword-filtering, we randomly selected 5.000 microposts for each city. Though one might assume that this pre-filtering leads to a biased dataset, (Schulz and Janssen, 2014) showed that keyword sampling does not influence the classification process as the performance of a keyword-based classifier is notably worse compared to supervised classifiers.

In the next step, we removed all redundant tweets as well as those with no textual content from the resulting sets as a couple of tweets contain keywords that are part of hashtags or @-mentions, but have no useful textual content. The tweets were then labeled manually by five annotators using the CrowdFlower (http://www.crowdflower.com/) platform. We retrieved the manual labels and selected those for

Table 2: Class distributions for all datasets.

Dataset	Classes			
	Crash	Fire	Shooting	No
Boston	347	188	28	2257
Sydney	587	189	39	2208
Brisbane	497	164	12	1915
Chicago	129	81	4	1270
Dublin	131	33	21	2630
London	283	95	29	2475
Memphis	23	30	27	721
NYC	129	239	45	1446
SF	161	82	61	1176
Seattle	204	153	139	390

which all coders agreed to at least 75%. In the case of disagreement, the tweets were removed. This resulted in ten datasets with regional diversity to be used for evaluation.

Table 2 lists the class distributions for each dataset. The distributions vary considerably, allowing us to evaluate with typical city-specific samples. Also, the "crash" class seems to be the most prominent incident type, whereas "shootings" are less frequent. One reason for this is that "shootings" do not occur as frequent as other incidents, whereas another less obvious reason might be that people tend to report more about specific incident types and that there is not necessarily a correlation between the real-world incidents and those mentioned in tweets. Although the data sets have been filtered based on keywords, the "no incident" class remains the largest class.

One of the key questions that motivates our work is to which extent the used words vary in each dataset as an effect of the spatial and cultural context. We thus analysed how similar all datasets are by calculating the intersection of tokens. We found that after preprocessing, between 14% and 23% tokens are shared between the datasets. We do not assume that every unique token is a city-specific token, but the large number of tweets in our evaluations gives a first indication that there is a diversity in the samples that either requires the training of several individual- or one generalizing model which is the focus of this paper.

3.2 Preprocessing and Feature Generation

To use our datasets for feature generation, i.e., for deriving different *feature groups* that are used for training a classification model, we had to convert the texts into a structured representation by means of preprocessing. Following this, we extracted several features for training classification models. To evaluate the best feature groups for incident type classification, we re-implemented commonly used feature extraction approaches from the state of the art. We further extended these feature groups by additional ones that seemed promising in this problem domain:

Preprocessing As a first step, the text was converted to Unicode to preserve non-Unicode characters. Specific URLs would not be useful for the classification process, therefore we replaced them with a common token "URL". We then removed stopwords and conducted tokenization. Every token was then analysed and non-alphanumeric characters were removed or replaced. Finally, we applied lemmatization to normalize all tokens. All preprocessing steps were performed by DKPro TC (de Castilho and Gurevych, 2014), a popular framework for text classification. After preprocessing, we generated several features (see Table 3). In the following, we give a description of the different feature groups.

Baseline Feature Sets As the most simple approach and as used in all related works, we represented tweets as a set of words and also as a set of characters with varying lengths. As features, we used a vector with the frequency of each n-gram. Most importantly, we evaluated the powerset of all different combinations of n-grams. For instance, if a length of $n = 2$ was chosen, we evaluated the three combinations $(n = 1), (n = 1, 2), (n = 2)$. Furthermore, as not all tokens are necessarily important for the classification process, we evaluated several top-k selection strategies, i.e., taking only the k most frequent n-grams into account. For this, we tested $k = 100, 1000, 5000$ as well as the approach using all n-grams. We treat these features as the baseline approach, and extend it by additional features, e.g. similarity, sentiment scores, Twitter-specific features.

Sentiment Features Emoticons are widely used to express emotions in textual content. Various text classification approaches make use of these, e.g. for sentiment analysis (Agarwal et al., 2011; Go et al., 2009). For incident type classification, they could also be useful as people link emotions with ongoing incidents, thus, we re-implemented three approaches for extracting sentiment features.

Table 3: Overview of all feature groups implemented for comparison

Feature Group	Description
Word-n-grams	Each tweet is represented as a powerset of word-n-grams of length $n = 1$ to $n = 3$.
Char-n-grams	Each tweet is represented as a powerset of char-n-grams of length $n = 1$ to $n = 5$.
POS_EMO	The Tweet NLP part-of-speech tagger (Owoputi et al., 2013) was used to identify emoticons. The ratio of emoticons to all tokens is calculated.
DICT_EMO	An emoticon library that is based on the suggestions from Agarwal et al. (Agarwal et al., 2011) was used comprising a set of 63 emoticons from Wikipedia. The number of positive and the number of negative emoticons in a tweet is calculated.
AGG_EMO	One single sentiment score based on the second approach by aggregating the number of positive and negative emoticons.
NER	We used the Stanford Named Entity Recognizer (Finkel et al., 2005) and applied the three class model to count the number of location, organization, and person mentions.
NR_CHAR	The number of characters in a tweet.
NR_SENT	The number of sentences in a tweet.
NR_TOKEN	The number of tokens in a tweet.
QUEST_RT	The proportion of question marks and sentences in a tweet.
EXCLA_RT	The proportion of exclamation marks and sentences in a tweet.
NR_AT_MN	The number of @-mentions in a tweet.
NR_HASHTAG	The number of hashtags in a tweet.
NR_URL	The number of URLs present in a tweet.
NR_SLANG	The number of colloquial words (i.e., *lol* or *ugh*). Feature extraction is based on the Tweet NLP POS-tags (Owoputi et al., 2013).
IS_RT	A boolean to indicate whether a tweet is a retweet.
NR_CARD	In conjunction with the named entities present in tweets, people tend to refer to street names (e.g.,*I-95*) or the number of injured people (e.g.,*2-people*). Thus, we create a feature for the number of cardinal numbers present in a tweet.
GREEDY_ST	Similarity scores following Greedy String Tiling (Wise, 1996) as a method to deal with shared sub-strings that do not appear in the same order.
LEVENST	The Levenshtein distance (Levenshtein, 1966) as an edit-distance metrics, i.e., the minimum number of edit operations that transform one tweet into another.
TF_IDF	As the baseline relies on plain frequency-based weighting, we calculate the traditional TF-IDF scores (Manning et al., 2009) for every tweet.

Named Entities: As shown in the state of the art, named entities, i.e. entities that have been assigned a name such as *Seattle*, are commonly used in tweets. Named entities might be valuable, as these are used frequently in incident-related tweets. Thus, we also incorporated Named Entity Recognition (NER) for feature extraction.

Stylistic Features: The style of a tweet could be an additional indicator for incident relatedness. For instance, a repetition of punctuations could point at a person that is expressing emotions resulting from an ongoing incident. Structured representation might indicate high quality.

Twitter-specific features As shown in related work, several Twitter-specific features seem to be valuable for incident type classification such as the number of @-mentions and hashtags.

Similarity Features The similarity of individual tweets might be helpful to identify common topics. We therefore implemented several similarity scores[1]. The rationale behind this is to embrace additional features that do not only take the raw frequencies of words into account, but also which words appear in which document.

To sum up, we re-implemented two approaches that will serve as a baseline, and 18 additional feature groups to extend them. In the following section, we will evaluate the usefulness of these approaches for training a generalizing model.

4 Evaluation

The goal of our evaluation is to determine which features were most useful for creating a generalizing model. We first describe our method, including the feature sets, the classification algorithms used, and our sampling procedure. This is followed by a results section in which we report differences in performance by means of qualitative and inferential statistics.

4.1 Method

The indicators for well-performing features in related work allows us to perform a condensed evaluation, compared to similar studies such as (Hasanain et al., 2014).

Our approach comprises three steps: First, we evaluated the baseline approaches, i.e., word- and char-n-grams. Second, we combined each of the remaining features with the best performing baseline feature. Third, we again selected the best performing combinations and evaluated their power set. To evaluate the suitability of different features for training generalizing models, we picked one dataset from the 10 presented in Section 3.1 for training, and tested on the remaining 9 datasets. We did not evaluate different models on datasets from only one city, as we were interested in generalizing models.

Selecting each city as training set resulted in 90 performance samples per model. The models were formed by combining the feature sets described in the previous section 3.2 or respectively, their combinations, with an SVM and NB classifier. We decided for these classification algorithms since they were the most successful in related work. Another reason for the choice of NB is its good performance in text classification tasks, as demonstrated by Rennie et al. (2003). We relied on the LibLinear implementation of an SVM because it has been shown that for a large number of features and a small number of instances, a linear kernel is comparable to a non-linear one (Hsu et al., 2003). As for SVMs parameter tuning is inevitable, we evaluated the best settings for the slack variable c whenever an SVM was used. For training and testing, we used the reference implementations in WEKA (Hall et al., 2009).

We calculated the F1-Measure for assessing performance, because it is well established in text classification, cannot be manipulated by the classification threshold parameter and allows to measure the overall performance of the approaches with an emphasis on the individual classes (Jakowicz and Shah, 2011). In Section 3.1, we demonstrated that the proportion of data representing individual classes varies strongly. We therefore weighted the F1-measure by this ratio and report the micro-averaged results over all datasets $\overline{F1}$. Given our focus on training a generalizable model, we deliberately did not focus on the performance variation in the individual datasets.

4.2 Results

In order to check whether our findings persist at least across the two learning algorithms, we did not aggregate the model performance samples but analyzed them for each algorithm separately. We therefore only have one independent variable, our feature groups, that affects the model performance. In order to keep p-value inflation low, we only compared the ten best performing models for each algorithm with respect to the F1-Measure. Note that even if the difference in performance between these models appears small, there are thus many worse models that were not explicitly listed.

Our samples generally do not fulfill the assumptions of normality and sphericity required by parametric tests for comparing more than two groups. Under the violation of these assumptions, non-parametric tests have more power and are less prone to outliers (Demsar, 2006). We therefore relied exclusively on the non-parametric tests suggested in literature: Friedman's test was used as non-parametric alternative to a repeated-measures one-way ANOVA, and Nemenyi's test[2] was used post-hoc as a replacement for Tukey's test.

In contrast to its parametric counterpart, Friedman's test is based on a ranking of the models induced by the performance measure, and therefore only relies implicitly on the latter. Each model is ranked from best to worst, with mean ranks being

[1]The respective similarity scores have been calculated on the whole document corpus after preprocessing.

[2]We chose Nemenyi's test because it is widely accepted in the machine learning community. A discussion of alternatives can be found in Herrera et al. (Herrera, 2008).

Table 4: Average F1-Measure $\overline{F1}$ for the ten best performing baseline feature groups

used in case of ties. The *Friedman statistic* is calculated by dividing the sum of squares of the mean ranks by the sum of squares error. For sufficiently many samples, the statistic follows a χ^2 distribution with $k-1$ degrees of freedom. The *q statistic* used in Nemenyi's test is similar to the one used by Tukey, but uses rank differences. It utilises the previous ranking from the Frieman test to calculate and relate the average ranks of two models, for each available pair. Two models are considered significantly different, if their difference in mean ranks exceeds a critical value, which varies for different significance levels. For a detailed description and examples of these tests, see (Jakowicz and Shah, 2011).

We illustrated the ranks and significant differences between the feature groups by means of the critical difference (CD) diagram. Introduced by Demsar (2006), this diagram lists the feature groups ordered by their rank, where lower rank numbers indicate higher performance. Feature groups are connected with bars if they are not significantly different, given $\alpha = 0.05$.

In the following, we will use shortcuts like *words(1000,1,2)* to denote the 1000 most frequent uni- and bigrams. The same applies for char-n-grams. Abbreviations can be found in Table 3.

4.2.1 Evaluation using LibLinear Classifier

We first evaluated which of our 20 baseline feature sets, as described in Section 3, lead to the best classification performance over different datasets. Notably, the ten best-performing approaches were all combinations of word-n-grams. Table 4 contains the average F-Measures for these approaches. The Friedman test indicated strong significant differences between the performances of these groups ($\chi^2_r(9) = 112.467, p < 0.001, \alpha = 0.01$). The subsequent Nemenyi test indicated strong significant pairwise differences between the performances of the models ($\alpha = 0.01$), with p-values listed in Table 2 in the supplementary.

Figure 1 illustrates the differences by means of a CD diagram: the approaches of using simple unigrams of the most frequent 5000 and all words provide the best results, i.e. they have the lowest rank. They are not significantly different from the 1000 most frequent word-uni and bigrams. Nevertheless, they are significantly better than all other baseline approaches.

This also applies to the char-n-gram approaches, that were not considered in this statistical comparison due to their inferior performance. It is important to note that the differences between the worst word-n-gram approaches and the best char-n-gram approaches could still be statistically non-significant.

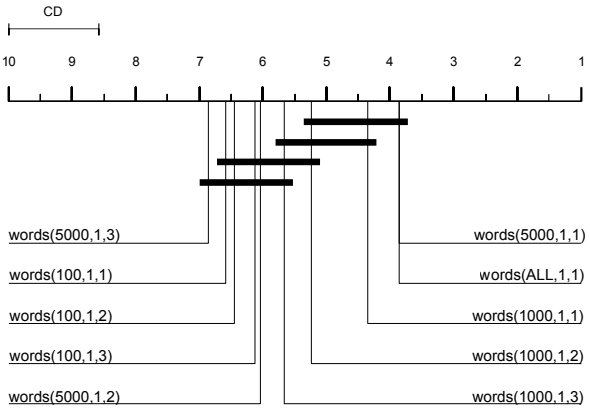

Figure 1: CD diagram with the ranks of the ten best performing baseline feature groups for LibLinear. Feature groups are connected if they are not significantly different ($\alpha = 0.05$).

The best performing baseline approach for LibLinear is using unigrams of the top 5000 words, i.e. *words(5000,1,1)*, with $\overline{F1} = 82.87$. We therefore picked this baseline feature group for the second part of our evaluation. We added each non-baseline feature individually to the selected baseline approach and compared the performances of these combinations and the non-extended baseline group. Table 6 lists the averaged F-Measure. When comparing the ten best-performing groups, the Friedman test showed strong significant differences between the performances of the models ($\chi^2_r(9) = 87.274, p < 0.001, \alpha = 0.01$). The Nemenyi test partly showed strong significant differences between the performances of the models (for the corresponding p-values see Table 3 in the supplementary). They are illustrated in the CD diagram in Figure 2. The tests indicate that adding *NER* and *NR_AT_MT* to the baseline approach provides the best performances with $\overline{F1} = 83.32$ and $\overline{F1} = 83.03$ respectively.

Finally, we evaluated the power set of these feature groups, i.e. we compared the individual groups and their combination. Table 5 contains the corresponding averaged F-Measures. For the resulting performance samples, the Friedman test showed strong significant differences between the models ($\chi^2_r(3) = 72.014, p < 0.001, \alpha = 0.01$). The Nemenyi test partly showed strong significant

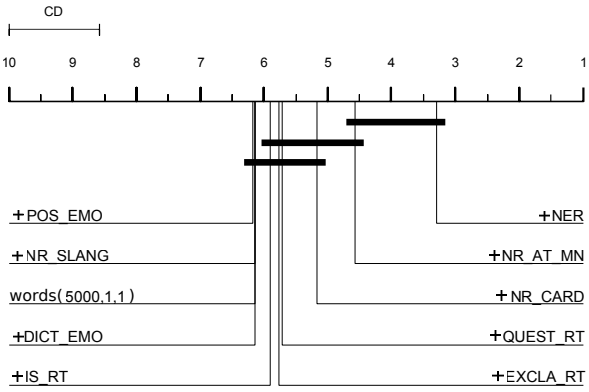

Figure 2: CD diagram with the ranks of the ten best performing feature groups for LibLinear, comprising the baseline and the baseline with an additional feature. Feature groups are connected if they are not significantly different ($\alpha = 0.05$).

Feature Group	words(5000,1,1)	+NER	+NER+NR_AT_MN	+NR_AT_MN
$\overline{F1}$	82.87	83.32	83.48	83.03

Table 5: Average F1-Measure $\overline{F1}$ for the power set of best performing feature groups and LibLinear.

differences ($\alpha = 0.001$), with p-values listed in Table 4 in the supplementary and illustrated in Figure 3. The diagram shows that the combination of *NER* and *NR_AT_MN* with the *words(5000,1,1)* baseline outperforms all other models with respect to F1 ($\overline{F1} = 83.48$), but does not differ significantly from the plain *NER* approach ($\overline{F1} = 83.32$). This combination gives us the final and best feature set for training a generalizing model over our datasets. As can be seen, the plain n-gram approach ($F1 = 82.87$) can be improved further by 0.5%.

4.2.2 Evaluation using Naive Bayes Classifier

In this section, we repeat the previous steps for the NB classifier. As baseline feature sets, we first evaluated the word-n-gram and char-n-gram approaches. The averaged F-Measures can be found in Table 4. The Friedman test showed strong significant differences between the performances of the models ($\chi^2_r(9) = 110.293, p < 0.001, \alpha = 0.01$). The Nemenyi test partly showed strong significant differences between the performances of the models (for the corresponding p-values see Table 1 in the supplementary). In contrast to the LibLinear classifier, using the 5000 most frequent combinations of two to five subsequent characters, i.e. *chars(5000,2,5)* provide the best F1 score ($\overline{F1} = 80.48$). Thus, char-n-grams outperform the word-n-gram approaches with respect to F1.

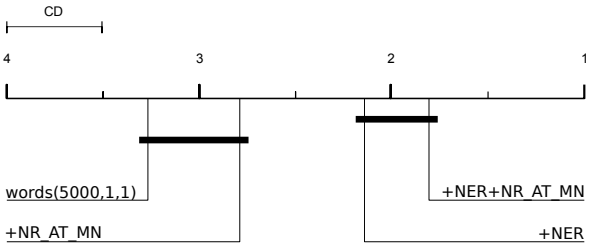

Figure 3: CD diagram with the ranks of the best baseline feature groups, complemented with a combination of the best performing feature sets, for LibLinear. Feature groups are connected if they are not significantly different ($\alpha = 0.05$).

The CD diagram in Figure 5 shows that using either the 5000 most frequent char-n-grams with a length of two to five and two to four respectively, the 1000 most frequent word-n-grams with a length of one and one to two respectively, and the 1000 most frequent char-n-grams with a length of two to four do not differ significantly. However, using either the 5000 most frequent char-n-grams with a length of two to five and two to four respectively significantly outperform all other baseline approaches. As a subsequent step, we added each single feature to *chars(5000,2,5)* as the best baseline approach to find if these provide better performance for the NB classifier. Table 6 contains the corresponding averaged F-Measures. Though the Friedman test indicated strong significant differences between the performances of the models ($\chi^2_r(9) = 22.209, p = 0.008, \alpha = 0.01$), the subsequent Nemenyi test did not indicate significant pairwise differences. We can therefore not repeat the third step of our evaluation, but infer that for a NB classifier, the plain char-n-gram-based approach is sufficient for training a generalizing model for our dataset.

The results indicate that LibLinear provides a better avg. performance ($\overline{F1} = 83.32$) when training a generalizing model, compared to the NB classifier ($\overline{F1} = 80.48$).

5 Conclusion and Future Work

In this paper, we compared the performance of different popular feature groups and classification algorithms for the task of training a generalizing model for incident type classification. We carefully selected the most popular feature groups from related work, and separately evaluated them

Feature Group	words(5000,1,1)	+DICT_EMO	+NER	+NR_CARD	+NR_AT_MN	+POS_EMO	+NR_SLANG	+EXCLA_RT	+QUEST_RT	+IS_RT
$\overline{F1}$	82.87	82.87	83.32	83.06	83.03	82.87	82.87	82.88	82.88	82.88

(a) LibLinear

Feature Group	chars(5000,2,5)	+DICT_EMO	+QUEST_RT	+NER	+NR_AT_MN	+NR_HASHTAG	+POS_EMO	+NR_SLANG	+NR_SENT	+EXCLA_RT
$\overline{F1}$	80.48	80.48	80.49	80.55	80.51	80.48	80.48	80.48	80.48	80.50

(b) NaiveBayes

Table 6: Average F1-Measure $\overline{F1}$ for the ten best performing combinations of the best baseline and an additional feature

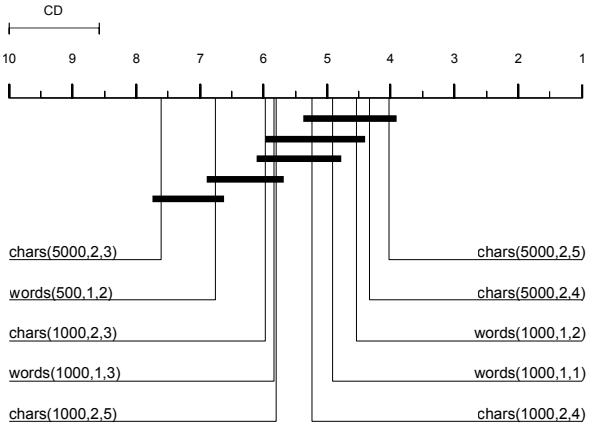

Figure 4: CD diagram with the ranks of the ten best performing baseline feature groups for Naive Bayes. Feature groups are connected if they are not significantly different ($\alpha = 0.05$).

Figure 5: Ranks of NB baseline feature groups.

for the LibLinear and NB classification algorithms on ten spatially and temporally diverse datasets. The resulting F1-measure samples indicate that training a generalizing model, i.e., a model that is applicable on previously unseen incident-related data, is still a challenging task. We found that LibLinear provides a better averaged performance compared to the NB classifier. More surprisingly, additional feature groups that are commonly used in related work do not necessarily outperform a plain n-gram-based approach. This highlights the need for other novel approaches for training generalizing classification models. Especially in the domain of incident detection and emergency management, our findings are important because less time consuming techniques showed nearly the same performance as sophisticated ones.

There are two main topics for our future work. First, we will investigate the performance of models generated with biased datasets on unfiltered datasets. This is relevant, if a technique like filtering is used to include more relevant class examples in a dataset than provided with an original sample – a necessary step to realize a labeled dataset for model learning of a rare-class task. Second, we will work on using novel features for the creation of generalized models. One example is the utilization of the Semantic Web to generate abstract features, utilizing a technique called Semantic Abstraction (Schulz et al., 2015a). Semantic Abstraction has shown to improve the generalization of tweet classification by deriving features from Linked Open Data and using location and temporal mentions.

Flexible Domain Adaptation for Automated Essay Scoring Using Correlated Linear Regression

Abstract

Most of the current automated essay scoring (AES) systems are trained using manually graded essays from a specific prompt. These systems experience a drop in accuracy when used to grade an essay from a different prompt. Obtaining a large number of manually graded essays each time a new prompt is introduced is costly and not viable. We propose domain adaptation as a solution to adapt an AES system from an initial prompt to a new prompt. We also propose a novel domain adaptation technique that uses Bayesian linear ridge regression. We evaluate our domain adaptation technique on the publicly available Automated Student Assessment Prize (ASAP) dataset and show that our proposed technique is a competitive default domain adaptation algorithm for the AES task.

1 Introduction

Essay writing is a common task evaluated in schools and universities. In this task, students are typically given a prompt or essay topic to write about. Essay writing is included in high-stakes assessments, such as Test of English as a Foreign Language (TOEFL) and Graduate Record Examination (GRE). Manually grading all essays takes a lot of time and effort for the graders. This is what Automated Essay Scoring (AES) systems are trying to alleviate.

Automated Essay Scoring uses computer software to automatically evaluate an essay written in an educational setting by giving it a score. Work related to essay scoring can be traced back to 1966 when Ellis Page created a computer grading software called Project Essay Grade (PEG). Research on AES has continued through the years. The recent Automated Student Assessment Prize (ASAP) Competition[1] sponsored by the Hewlett Foundation in 2012 has renewed interest on this topic. The agreement between the scores assigned by state-of-the-art AES systems and the scores assigned by human raters has been shown to be relatively high. See Shermis and Burstein (2013) for a recent overview of AES.

AES is usually treated as a supervised machine learning problem, either as a classification, regression, or rank preference task. Using this approach, a training set in the form of human graded essays is needed. However, human graded essays are not readily available. This is perhaps why research in this area was mostly done by commercial organizations. After the ASAP competition, research interest in this area has been rekindled because of the released dataset.

Most of the recent AES related work is prompt-specific. That is, an AES system is trained using essays from a specific prompt and tested against essays from the same prompt. These AES systems will not work as well when tested against a different prompt. Furthermore, generating the training data each time a new prompt is introduced will be costly and time consuming.

In this paper, we propose domain adaptation as a solution to this problem. Instead of hiring people to grade new essays each time a new prompt is introduced, domain adaptation can be used to adapt the old prompt-specific system to suit the new prompt. This way, a smaller number of training essays from the new prompt is needed. In this paper, we propose a *novel* domain adaptation technique based on Bayesian linear ridge regression.

The rest of this paper is organized as follows. In Section 2, we give an overview of related work on AES and domain adaptation. Section 3 describes the AES task and the features used. Section 4 presents our novel domain adaptation algorithm.

Section 5 describes our data, experimental setup, and evaluation metric. Section 6 presents and discusses the results. We conclude in Section 7.

2 Related Work

We first introduce related work on automated essay scoring, followed by domain adaptation in the context of natural language processing.

2.1 Automated Essay Scoring

Since the first AES system, Project Essay Grade, was created in 1966, a number of commercial systems have been deployed. One such system, e-rater (Attali and Burstein, 2004), is even used as a replacement for the second human grader in the Test of English as a Foreign Language (TOEFL) and Graduate Record Examination (GRE). Other AES commercial systems also exist, such as IntelliMetric[2] and Intelligent Essay Assessor (Foltz et al., 1999).

AES is generally considered as a machine learning problem. Some work, such as PEG (Page, 1994) and e-rater, considers it as a regression problem. PEG uses a large number of features with regression to predict the human score. e-rater uses natural language processing (NLP) techniques to extract a smaller number of complex features, such as grammatical error and lexical complexity, and uses them with stepwise linear regression (Attali and Burstein, 2004). Others like (Larkey, 1998) take the classification approach. (Rudner and Liang, 2002) uses Bayesian models for classification and treats AES as a text classification problem. Intelligent Essay Assessor uses Latent Semantic Analysis (LSA) (Landauer et al., 1998) as a measure of semantic similarity between essays. Other recent work uses the preference ranking based approach (Yannakoudakis et al., 2011; Chen and He, 2013).

In this paper, we also treat AES as a regression problem, following PEG and e-rater. We use regression because the range of scores of the essays could be very large and a classification approach does not work well in this case. It also allows us to model essay scores as continuous values and scale them easily in the case of different score ranges between the source essay prompt and the target essay prompt.

The features used differ among the systems, ranging from simple features (e.g., word length, essay length, etc) to more complex features (e.g., grammatical errors). Some of these features are generic in the sense that they could apply to all kinds of prompts. Such features include the number of spelling errors, grammatical errors, lexical complexity, etc. Others are prompt-specific features such as bag of words features.

[2]http://www.vantagelearning.com/products/intellimetric/

2.2 Domain Adaptation

The knowledge learned from a single domain might not be directly applicable to another domain. For example, a named entity recognition system trained on labeled news data might not perform as well on biomedical texts (Jiang and Zhai, 2007). We can solve this problem either by getting labeled data from the other domain, which might not be available, or by performing domain adaptation.

Domain adaptation is the task of adapting knowledge learned in a source domain to a target domain. Various approaches to this task have been proposed and used in the context of NLP. Some commonly used approaches include EasyAdapt (Daumé III, 2007), instance weighting (IW) (Jiang and Zhai, 2007), and structural correspondence learning (SCL) (Blitzer et al., 2006).

We can divide the approaches of domain adaptation into two categories based on the availability of labeled target data. The case where a small number of labeled target data is available is usually referred to as *supervised* domain adaptation (such as EasyAdapt and IW). The case where no labeled target domain data is available is usually referred to as *unsupervised* domain adaptation (such as SCL). In our work, we focus on *supervised* domain adaptation.

Daumé III (2007) described a domain adaptation scheme called EasyAdapt which makes use of feature augmentation. Suppose we have a feature vector $\boldsymbol{x}$ in the original feature space. This scheme will map this instance using the mapping functions $\Phi^{\mathrm{s}}(\boldsymbol{x})$ and $\Phi^{\mathrm{t}}(\boldsymbol{x})$ for the source and target domain respectively, where

$$\Phi^{\mathrm{s}}(x) = \langle \boldsymbol{x}, \boldsymbol{x}, \mathbf{0} \rangle$$
$$\Phi^{\mathrm{t}}(x) = \langle \boldsymbol{x}, \mathbf{0}, \boldsymbol{x} \rangle,$$

and $\mathbf{0}$ is a zero vector of length $|\boldsymbol{x}|$. This adaptation scheme is attractive because of its simplicity and ease of use as a pre-processing step, and also because it performs quite well despite its simplicity. It has been used in various NLP tasks such

as word segmentation (Monroe et al., 2014), machine translation (Green et al., 2014), word sense disambiguation (Zhong et al., 2008), and short answer scoring (Heilman and Madnani, 2013). Our work is an extension of this scheme in the sense that our work is a generalization of EasyAdapt.

3 Automated Essay Scoring

This section describes the Automated Essay Scoring (AES) task and the features we use for the task.

3.1 Task Description

In AES, the input to the system is a student essay, and the output is the score assigned to the essay. The score assigned by the AES system will be compared against the human assigned score to measure their agreement. Common agreement measures used include Pearson's correlation, Spearman's correlation, and quadratic weighted Kappa (QWK). We use QWK in this paper, which is also the evaluation metric in the ASAP competition.

3.2 Features and Learning Algorithm

We model the AES task as a regression problem and use Bayesian linear ridge regression (BLRR) as our learning algorithm. We choose BLRR as our learning algorithm so as to use the correlated BLRR approach which will be explained in Section 4. We use an open source essay scoring system, EASE (Enhanced AI Scoring Engine)[3], to extract the features. EASE is created by one of the winners of the ASAP competition so the features they use have been proven to be robust. Table 1 gives the features used by EASE.

Useful n-grams are defined as n-grams that separate good scoring essays and bad scoring essays, determined using the Fisher test (Fisher, 1922). Good scoring essays are essays with a score greater than or equal to the average score, and the remainder are considered as bad scoring essays. The top 201 n-grams with the highest Fisher values are then chosen as the bag features. We perform the calculation of useful n-grams separately for source and target domain essays, and join them together using set union during the domain adaptation experiment. This is done to prevent the system from choosing only n-grams from the source domain as the useful n-grams, since the number of source domain essays is much larger than the target domain essays.

EASE uses NLTK (Bird et al., 2009) for POS tagging and stemming, aspell for spellchecking, and WordNet (Fellbaum, 1998) to get the synonyms. Correct POS tags are generated using a grammatically correct text (provided by EASE). The POS tag sequences not included in the correct POS tags are considered as bad POS. EASE uses scikit-learn (Pedregosa et al., 2011) for extracting unigram and bigram features. For linear regression, a constant feature of value one is appended for the bias.

4 Correlated Bayesian Linear Ridge Regression

First, consider the single-task setting. Let $\boldsymbol{x} \in \mathbb{R}^p$ be the feature vector of an essay. p represents the number of features in $\boldsymbol{x}$. The generative model for an observed real-valued score y is

$$\begin{aligned} &\alpha \sim \Gamma(\alpha_1, \alpha_2), && \lambda \sim \Gamma(\lambda_1, \lambda_2), \\ &\boldsymbol{w} \sim \mathcal{N}(\mathbf{0}, \lambda^{-1} I), && f(\boldsymbol{x}) \stackrel{\text{def}}{=} \boldsymbol{x}^{\mathrm{T}} \boldsymbol{w}, \\ &y \sim \mathcal{N}(f(\boldsymbol{x}_i), \alpha^{-1}). \end{aligned}$$

Here, α and λ are Gamma distributed hyper-parameters of the model; $\boldsymbol{w} \in \mathbb{R}^p$ is the Normal distributed weight vector of the model; f is the latent function that returns the "true" score of an essay represented by $\boldsymbol{x}$ by linear combination; and y is the noisy observed score of $\boldsymbol{x}$.

Now, consider the two-task setting, where we indicate the source task and the target task by superscripts s and t. Given an essay with feature vector $\boldsymbol{x}$, we consider its observed scores y^{s} and y^{t} when evaluated in task s and task t separately. We have scale hyper-parameters α and λ sampled as before. In addition, we have the correlation ρ between the two tasks. The generative model relating the two tasks is

$$\begin{aligned} \rho &\sim p_\rho, \\ \boldsymbol{w}^{\mathrm{t}}, \boldsymbol{w}^{\mathrm{s}} &\sim \mathcal{N}(\mathbf{0}, \lambda^{-1} I), \\ f^{\mathrm{t}}(\boldsymbol{x}) &\stackrel{\text{def}}{=} \boldsymbol{x}^{\mathrm{T}} \boldsymbol{w}^{\mathrm{t}}, \\ f^{\mathrm{s}}(\boldsymbol{x}) &\stackrel{\text{def}}{=} \rho \boldsymbol{x}^{\mathrm{T}} \boldsymbol{w}^{\mathrm{t}} + (1-\rho^2)^{1/2} \boldsymbol{x}^{\mathrm{T}} \boldsymbol{w}^{\mathrm{s}}, \\ y^{\mathrm{t}} &\sim \mathcal{N}(f^{\mathrm{t}}(\boldsymbol{x}), \alpha^{-1}), \\ y^{\mathrm{s}} &\sim \mathcal{N}(f^{\mathrm{s}}(\boldsymbol{x}), \alpha^{-1}), \end{aligned}$$

where p_ρ is a chosen distribution over the correlation; and $\boldsymbol{w}^{\mathrm{t}}$ and $\boldsymbol{w}^{\mathrm{s}}$ are the weight vectors of the

[3] https://github.com/edx/ease

Feature Type	Feature Description
Length	Number of characters Number of words Number of commas Number of apostrophes Number of sentence ending punctuation symbols (".", "?", or "!") Average word length
Part of speech (POS)	Number of bad POS n-grams Number of bad POS n-grams divided by the total number of words in the essay
Prompt	Number of words in the essay that appears in the prompt Number of words in the essay that appears in the prompt divided by the total number of words in the essay Number of words in the essay which is a word or a synonym of a word that appears in the prompt Number of words in the essay which is a word or a synonym of a word that appears in the prompt divided by the total number of words in the essay
Bag of words	Count of useful unigrams and bigrams (unstemmed) Count of stemmed and spell corrected useful unigrams and bigrams

Table 1: Description of the features used by EASE.

target and the source tasks respectively, and they are identically distributed but independent. In this setting, it can be shown that the correlation between latent scoring functions for the target and the source tasks is ρ. That is,

$$\mathbb{E}(f^{\mathrm{t}}(\boldsymbol{x})f^{\mathrm{s}}(\boldsymbol{x}')) = \lambda^{-1}\rho\boldsymbol{x}^{\mathrm{T}}\boldsymbol{x}'. \qquad (1)$$

This, in fact, is a generalization of the EasyAdapt scheme, for which the correlation ρ is fixed at 0.5 [(Daumé III, 2007), see eq. 3]. Two other common values for ρ are 1 and 0; the former corresponds to a straightforward concatenation of the source and target data, while the latter is the shared-hyperparameter setting which shares α and λ between the source and target domain. Through adjusting ρ, the model traverses smoothly between these three regimes of domain adaptation.

EasyAdapt is attractive because of its (frustratingly) ease of use via encoding the correlation within an expanded feature representation scheme. In the same way, the current setup can be achieved readily by the expanded feature representation

$$\begin{aligned}\Phi^{\mathrm{t}}(\boldsymbol{x}) &= \langle \boldsymbol{x}, \mathbf{0}_p \rangle\,, \\ \Phi^{\mathrm{s}}(\boldsymbol{x}) &= \left\langle \rho\boldsymbol{x}, (1-\rho^2)^{1/2}\boldsymbol{x} \right\rangle\end{aligned} \qquad (2)$$

in $\mathbb{R}^{2p}$ for the target and the source tasks. Associated with this expanded feature representation is the weight vector $\boldsymbol{w} \stackrel{\text{def}}{=} (\boldsymbol{w}^{\mathrm{t}}, \boldsymbol{w}^{\mathrm{s}})$ also in $\mathbb{R}^{2p}$. As we shall see in Section 4.1, such a representation eases the estimation of the parameters.

The above model is related to the multi-task Gaussian Process model that has been used for joint emotion analysis (Beck et al., 2014). There, the *intrinsic coregionalisation model* (ICM) has been used with *squared-exponential covariance function*. Here, we use the simpler *linear covariance function* (Rasmussen and Williams, 2006), and this leads to Bayesian linear ridge regression. There are two reasons for this choice. The first is that linear combination of carefully chosen features, especially lexical ones, usually gives good performance in NLP tasks. The second is in the preceding paragraph: an intuitive feature expansion representation of the domain adaptation process that allows ease of parameter estimation.

The above model is derived from the Cholesky decomposition

$$\begin{pmatrix} 1 & \rho \\ \rho & 1 \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ \rho & (1-\rho^2)^{1/2} \end{pmatrix} \begin{pmatrix} 1 & \rho \\ 0 & (1-\rho^2)^{1/2} \end{pmatrix}$$

of the desired correlation matrix that will eventually lead to equation (1). Other choices are possible, as long as equation (1) is satisfied. However, the current choice has the desired property that the $\boldsymbol{w}^{\mathrm{t}}$ portion of the combined weight vector is di-

rectly interpretable as the weights for the features in the target domain.

4.1 Maximum Likelihood Estimation

We estimate the parameters (α, λ, ρ) of the model using penalized maximum likelihood. For α and λ, the gamma distributions are used. For ρ, we impose a distribution with density $p_\rho(\rho) = 1 + a - 2a\rho$, $a \in [-1, 1]$. This distribution is supported only in $[0, 1]$; negative ρs are not supported because we think that negative transfer of information from source to target domain prompts in this essay scoring task is improbable. In our application, we slightly bias the correlations towards zero with $a = 1/10$ in order to ameliorate spurious correlations.

For the training data, let there be n^{t} examples in the target domain and n^{s} in the source domain. Let X^{t} (resp. X^{s}) be the n^{t}-by-p (resp. n^{s}-by-p) design matrix for the training data in the target (resp. source) domain. Let $\boldsymbol{y}^{\mathrm{t}}$ and $\boldsymbol{y}^{\mathrm{s}}$ be the corresponding observed essay scores. The expanded feature matrix due to equation (2) is

$$X \stackrel{\text{def}}{=} \begin{pmatrix} X^{\mathrm{t}} & 0 \\ \rho X^{\mathrm{s}} & (1-\rho^2)^{1/2} X^{\mathrm{s}} \end{pmatrix}.$$

Similarly, let $\boldsymbol{y}$ be the stacking of $\boldsymbol{y}^{\mathrm{t}}$ and $\boldsymbol{y}^{\mathrm{s}}$. Let $K \stackrel{\text{def}}{=} \lambda^{-1} X X^{\mathrm{T}} + \alpha^{-1} I$, which is also known as the Gramian for the observations. The log marginal likelihood of the training data is (Rasmussen and Williams, 2006)

$$L = -\frac{1}{2}\boldsymbol{y}^{\mathrm{T}} K^{-1} \boldsymbol{y} - \frac{1}{2}\log|K| - \frac{n^{\mathrm{t}} + n^{\mathrm{s}}}{2}\log 2\pi.$$

This is penalized to give L_p by adding

$$\begin{gathered}(\alpha_1 - 1)\log(\alpha) - \alpha_2\alpha + \alpha_1 \log \alpha_2 - \log\Gamma(\alpha_1) \\ +(\lambda_1 - 1)\log(\lambda) - \lambda_2\lambda + \lambda_1 \log \lambda_2 - \log\Gamma(\lambda_1) \\ + \log(1 + a - 2a\rho).\end{gathered}$$

The estimation of these parameters is then done by optimising L_p. In our implementation, we use scikit-learn for estimating α and λ in an inner loop, and we use gradient descent for estimating ρ in the outer loop using

$$\frac{\partial L_p}{\partial \rho} = \frac{1}{2}\operatorname{tr}\left(\left(\gamma\gamma^T - K^{-1}\right)\frac{\partial K}{\partial \rho}\right) - \frac{2a}{1 + a - 2a\rho},$$

where $\gamma \stackrel{\text{def}}{=} K^{-1} y$ and

$$\frac{\partial K}{\partial \rho} = \lambda^{-1}\begin{pmatrix} 0 & X^{\mathrm{t}}(X^{\mathrm{s}})^{\mathrm{T}} \\ X^{\mathrm{s}}(X^{\mathrm{t}})^{\mathrm{T}} & 0 \end{pmatrix}.$$

4.2 Prediction

We report the mean prediction as the score of an essay. This uses the mean weight vector $\bar{\boldsymbol{w}} = \lambda^{-1} X^{\mathrm{T}} K^{-1} \boldsymbol{y} \in \mathbb{R}^{2p}$, which may be partitioned into two vectors $\bar{\boldsymbol{w}}^{\mathrm{t}}$ and $\bar{\boldsymbol{w}}^{\mathrm{s}}$, each in $\mathbb{R}^p$. The prediction of a new essay represented by $\boldsymbol{x}_*$ in the target domain is then given by $\boldsymbol{x}_*^{\mathrm{T}} \bar{\boldsymbol{w}}^{\mathrm{t}}$.

5 Experiments

In this section, we will give a brief description of the dataset we use, describe our experimental setup, and explain the evaluation metric we use.

5.1 Data

We use the ASAP dataset[4] for our domain adaptation experiments. This dataset contains 8 prompts of different genres. The average length of the essays differs for each prompt, ranging from 150 to 650 words. The essays were written by students ranging in grade 7 to grade 10. All the essays were graded by at least 2 human graders. The genres include narrative, argumentative, or response. The prompts also have different score ranges, as shown in Table 2.

We pick four pairs of essay prompts to perform our experiments. In each experiment, one of the essay prompts from the pair will be the source domain and the other essay prompt will be the target domain. The essay set pairs we choose are $1 \rightarrow 2$, $3 \rightarrow 4$, $5 \rightarrow 6$, and $7 \rightarrow 8$, where the pair $1 \rightarrow 2$ denotes using prompt 1 as the source domain and prompt 2 as the target domain, for example. These pairs are chosen based on the similarities in their genres, score ranges, and median scores. The aim is to have similar source and target domains for effective domain adaptation.

5.2 Experimental Setup

We use 5-fold cross validation on the ASAP training data for evaluation. This is because the official test data of the competition is not released to the public. We divide the target domain data randomly into 5 folds. One fold is used as the test data, while the remaining four folds are collected together and then sub-sampled to obtain the target-domain training data. The sizes of the sub-sampled target-domain training data are 10, 25, 50 and 100, with the larger sets containing the smaller sets. All essays from the source domain are used.

[4] https://www.kaggle.com/c/asap-aes/data

Set	# Essays	Genre	Avg len	Score	
				Range	Median
1	1,783	ARG	350	2–12	8
2	1,800	ARG	350	1–6	3
3	1,726	RES	150	0–3	1
4	1,772	RES	150	0–3	1
5	1,805	RES	150	0–4	2
6	1,800	RES	150	0–4	2
7	1,569	NAR	250	0–30	16
8	723	NAR	650	0–60	36

Table 2: Selected details of the ASAP data. For the genre column, ARG denotes *argumentative* essays, RES denotes *response* essays, and NAR denotes *narrative* essays.

Our evaluation considers the following four ways in which we train the AES model:

SourceOnly Using essays from the source domain only;

TargetOnly Using 10, 25, 50, and 100 sampled essays from the target domain only;

SharedHyper Using correlated Bayesian linear ridge regression (BLRR) with ρ fixed to 0 on source domain essays and sampled essays from the target domain.

EasyAdapt As SharedHyper, but with $\rho = 0.5$;

Concat As SharedHyper, but with ρ fixed to 1.0;

ML-ρ Using correlated BLRR with ρ maximizing the likelihood of the data.

Since the source and target domain may have different score ranges, we scale the scores linearly to range from -1 to 1. When predicting on the test essays, the predicted scores of our system will be linearly scaled back to the target domain score range and rounded to the nearest integer.

We build upon scikit-learn's implementation of BLRR for our learning algorithm. To ameliorate the effects of different scales of features, we normalize the features: length, POS, and prompt features are linearly scaled to range from 0 to 1 according to the training data; and the feature values for bag-of-words features are $\log(1 + \text{count})$ instead of the actual counts.

We use scikit-learn version 0.15.2, NLTK version 2.0b7, and aspell version 0.60.6.1 in this experiment. The BLRR code (`bayes.py`) in scikit-learn is modified to obtain valid likelihoods for use in the outer loop for estimating ρ. We use scikit-learn's default value for the parameters α_1, α_2, λ_1, and λ_2 which is 10^{-6}.

Set #	QWK scores		
	BLRR	SVM	Human
1	0.761	0.781	0.721
2	0.606	0.621	0.814
3	0.621	0.630	0.769
4	0.742	0.749	0.851
5	0.784	0.782	0.753
6	0.775	0.771	0.776
7	0.730	0.727	0.721
8	0.617	0.534	0.629

Table 3: In-domain experimental results.

5.3 Evaluation Metric

Quadratic weighted Kappa (QWK) is used to measure the agreement between the human rater and the system. We choose to use this evaluation metric since it is the official evaluation metric of the ASAP competition. Other work such as (Chen and He, 2013) that uses the ASAP dataset also uses this evaluation metric. QWK is calculated using

$$\kappa = 1 - \frac{\sum_{i,j} w_{i,j} O_{i,j}}{\sum_{i,j} w_{i,j} E_{i,j}},$$

where matrices O, $(w_{i,j})$, and E are the matrices of observed scores, weights, and expected scores respectively. Matrix $O_{i,j}$ corresponds to the number of essays that receive a score i by the first rater and a score j by the second rater. The weight entries are $w_{i,j} = (i-j)^2/(N-1)^2$, where N is the number of possible ratings. Matrix E is calculated by taking the outer product between the score vectors of the two raters, which are then normalized to have the same sum as O.

6 Results and Discussion

In-domain results for comparison First, we determine indicative upper bounds on the QWK scores using Bayesian linear ridge regression (BLRR). To this end, we perform 5-fold cross validation by training and testing within each domain. This is also done with linear support vector machine (SVM) regression to confirm that BLRR is a competitive method for this task. In addition, since the ASAP data has at least 2 human annotators for each essay, we also calculate the human agreement score. The results are shown in Table 3. We see that the BLRR scores are close to the the human agreement scores for prompt 1 and

Method	QWK Scores n^{t} =10	25	50	100
1 → 2				
SourceOnly	0.434			
TargetOnly	0.069	0.169	0.279	0.395

Table 4: QWK scores of the six methods on four domain adaptation experiments, ranging from using 10 target-domain essays (second column) to 100 target-domain essays (fifth column). The scores are the averages over 5 folds. Setting $a \rightarrow b$ means the AES system is trained on essay set a and tested on essay set b. For each set of six results comparing the methods, the best score is boldfaced and the second-best score is underlined.

prompts 5 to 8, but fall short by 10% to 20% for prompts 2 to 4. We also see that BLRR is comparable to linear SVM regression, giving almost the same performance for prompts 4 to 7; slightly poorer performance for prompts 1 to 3; and much better performance for prompt 8. The subsequent discussion in this section will refer to the BLRR scores in Table 3 for in-domain scores.

Importance of domain adaptation The results of the domain adaptation experiments are tabulated in Table 4, where the best scores are boldfaced and the second-best scores are underlined. As expected, for pairs $1 \rightarrow 2$, $3 \rightarrow 4$, and $5 \rightarrow 6$, all the scores are below their corresponding upper bounds from the in-domain setting in Table 3. However, for pair $7 \rightarrow 8$, the QWK score for domain adaptation with 100 target essays outperforms that of the in-domain, albeit only by 0.4%. This can be explained by the small number of essays in prompt 8 that can be used in both the in-domain and domain adaptation settings, and that domain adaptation additionally involves prompt 7 which has more than twice the number of essays; see column two in Table 2. Hence, domain adaptation is effective in the context of small number of target essays with large number of source essays. This can also be seen in Table 4 where we have simulated small number of target essays with sizes 10, 25, 50, and 100. When we compare the scores of TargetOnly against the best scores and second-best scores, we find that domain adaptation is effective and important in improving the QWK scores.

By the above argument alone, one might have thought that an overwhelming large number of source domain essays was sufficient for the target domain. However, this is not true. When we compare the scores of SourceOnly against the best scores and second-best scores, we find that domain adaptation again improves the QWK scores. In fact, with just 10 additional target domain essays, effective domain adaptation can improve over SourceOnly for all target domains 2, 4, 6, and 8 respectively.

This is the first time where the effects of domain adaptation are shown in the AES task. In addition, the large improvement with a small number of additional target domain essays in $5 \rightarrow 6$ and $7 \rightarrow 8$ suggests the high domain-dependence nature of the task: *learning on one essay prompt and testing on another should be strongly discouraged.*

Contributions by target-domain essays It is instructive to understand why domain adaptation is important for AES. To this end, we estimate the contribution of bag-of-words features to the overall prediction by computing the ratio

$$\frac{\sum_{i \text{ over bag-of-words features}} w_i^2}{\sum_{i \text{ over all features}} w_i^2}$$

using weights learned in the in-domain setting; see Table 1 for the complete list of features. For domains 2, 4, 6, and 8, which are the target domains in the domain adaptation experiments, these ratios are 0.37, 0.73, 0.69, and 0.93. The ratios for the other four domains are similarly high. This shows that bag-of-words features play a significant role in the prediction of the essay scores. We examine the number of bag-of-words features that 100 additional target domain essays would add to SourceOnly; that is, we compare the bag-of-words features for SourceOnly with those of SharedHyper, EasyAdapt, Concat, and ML-ρ for $n^{\mathrm{t}} = 100$. The numbers of these additional features, averaged over the five folds, are 269, 351, 377, and 291 for target domains 2, 4, 6, and 8 respectively. In terms of percentages, these are 67%, 87%, 94%, and 72% more features over SourceOnly. Such a large number of additional bag-of-words features contributed by target-domain essays, together with the fact that these features are given high weights, means that target-domain essays are important.

Comparing domain adaptation methods We now compare the four domain adaptation methods: SharedHyper, EasyAdapt, Concat, and ML-ρ. We recall that the first three are constrained cases of the last by fixing ρ to 0, 0.5, and 1 respectively. First, we see that SharedHyper is a rather poor domain adaptation method for AES, because it gives the lowest QWK score, except for the case of using 25, 50, and 100 target essays in adapting from prompt 7 to prompt 8, where it is better than Concat. In fact, its scores are generally close to the TargetOnly scores. This is unsurprising, since in SharedHyper the weights are effectively not shared between the target and source training examples: only the hyper-parameters α and λ are shared. This is a weak form of information sharing between the target and source domains. Hence, we expect this to perform suboptimally when the target and source domains bear more than spurious relationship, which is indeed the case here because we have chosen the source and target domain pairs based on their similarities, as described in Section 5.1.

We now focus on EasyAdapt, Concat, and ML-ρ, which are the better domain adaptation methods from our results. We see that ML-ρ either gives the best or second-best scores, except for the one case of $5 \rightarrow 6$ with 10 target essays. In comparison, although Concat performs consistently well for $1 \rightarrow 2$, $3 \rightarrow 4$, and $5 \rightarrow 6$, its QWK scores for $7 \rightarrow 8$ are quite poor and even lower than those of TargetOnly for 25 or more target essays. In contrast to Concat, EasyAdapt performs well for $7 \rightarrow 8$ but not so well for the other three domain pairs.

Let us examine the reason for contrasting results between EasyAdapt and Concat to appreciate the flexibility afforded by ML-ρ. The ρ estimated by ML-ρ for the pairs $1 \rightarrow 2$, $3 \rightarrow 4$, $5 \rightarrow 6$, and $7 \rightarrow 8$ with 100 target essays are 0.81, 0.97, 0.76, and 0.63 averaged over five folds. The lower estimated correlation ρ for $7 \rightarrow 8$ means that prompt 7 and prompt 8 are not as similar as the other pairs are. In such a case as this, Concat, which in effect considers the target domain to be exactly the same as the source domain, can perform very poorly. For the other three pairs which are more similar, the correlation of 0.5 assumed by EasyAdapt is not strong enough to fully exploit the similarities between the domains. Unlike Concat and EasyAdapt, ML-ρ has the flexibility to allow it to traverse effectively between the different degrees of domain similarity or relatedness based on the source domain and target domain training data. In view of this, we consider *ML-ρ to be a competitive default domain adaptation algorithm for the AES task*.

In retrospect of our present results, it can be obvious why prompts 7 and 8 are not as similar as we would have hoped for more effective domain adaptation. Both prompts ask for narrative essays, and these by nature are very prompt-specific and require words and phrases relating directly to the prompts. In fact, referring to a previous discussion on the *contributions by target-domain essays*, we see that weights for the bag-of-words features for prompt 8 contribute a high of 93% of the total. When we examine the bag-of-words features, we see that prompt 7 (which is to write about patience) contributes only 19% to the bag-of-words features of prompt 8 (which is to write about laughter) in the in-domain experiment. This means that 81% of the bag-of-words features, which are important to narrative essays, must be contributed by the target-domain essays relating to prompt 8. Future work on domain adaptation for AES can explore chosing the prior p_ρ on ρ to better reflect the nature of the essays involved.

7 Conclusion

In this work, we investigate the effectiveness of using domain adaptation when we only have a small number of target domain essays. We have shown that domain adaptation can achieve better results compared to using just the small number of target domain data or just using a large amount of data from a different domain. As such, our research will help reduce the amount of annotation work needed to be done by human graders to introduce a new prompt.

Abstract

Engaging in a debate with oneself or others to take decisions is an integral part of our day-to-day life. A debate on a topic (say, *use of performance enhancing drugs*) typically proceeds by one party making an assertion/claim (say, *PEDs are bad for health*) and then providing an evidence to support the claim (say, *a 2006 study shows that PEDs have psychiatric side effects*). In this work, we propose the task of automatically detecting such evidences from unstructured text that support a given claim. This task has many practical applications in decision support and persuasion enhancement in a wide range of domains. We first introduce an extensive benchmark data set tailored for this task, which allows training statistical models and assessing their performance. Then, we suggest a system architecture based on supervised learning to address the evidence detection task. Finally, promising experimental results are reported.

1 Introduction

In recent years there has been a growing interest in the area of argumentation mining (Green et al., 2014; Cardie et al., 2015; Wells, 2014). Part of this awakening is the The Debater™ project[1] whose goal is to develop technologies that will assist humans to debate and reason, e.g., by automatically suggesting arguments relevant to an examined topic. The minimal definition of such an argument (Walton, 2009) is a set of statements, made up of three parts – a claim (aka conclusion, proposition), a set of evidence (aka premises), and an inference from the evidence to the claim. Needless to say, evidence plays a critical role in a persuasive argument.

In most debate related skills, such as natural language understanding and generation, humans currently have an inherent advantage over a machine. However, in the ability to provide high quality and diverse evidence, machines have a very promising potential, being able to swiftly process large quantities of information. Nonetheless, since most of the relevant information is represented by unstructured text, successfully exploiting these resources requires the ability to identify evidence in free text. This is exactly the focus of our work. Specifically, we formally define the task of evidence detection, introduce an architecture for attacking this problem, and demonstrate its performance over dedicated manually labeled data.

Before defining the task formally, we introduce three concepts which will be used throughout this paper. These concepts were earlier defined in (Aharoni et al., 2014) and we use the same definitions here. **Topic**: a short phrase that frames the discussion. **Claim**: a general, concise statement that directly supports or contests the topic. **Context Dependent Evidence (CDE)**: a text segment that directly supports a claim in the context of the topic. The first three rows of Table 1 show examples of a topic, a claim and CDE.

For the purpose of this work, we assume that we are given a concrete topic, a relevant claim, and potentially relevant documents, provided either manually or by automatic methods (Cartright et al., 2011; Levy et al., 2014). Our task, which we term Context Dependent Evidence Detection (CDED), is to automatically pinpoint CDE within these documents. We further require that a detected CDE is reasonably well phrased, and easily understandable in the given context, so that it can be instantly and naturally used to support the claim in a discussion. Table 1 gives examples of valid CDE (V) and non-valid CDE (X) according to the definition mentioned above.

It is well recognized that one can support a claim using different types of evidence (Rieke and Sillars, 2001; Seech, 2008). Furthermore, for different use cases, different evidence types could be more suitable. Correspondingly, we develop a classification approach that is able to identify and distinguish between three common evidence types (Rieke and Sillars, 1984; Seech, 2008):

- **Study** Results of a quantitative analysis of data, given as numbers, or as conclusions. (Table 1 S1);

[2]Note ibuprofen is considered a PED

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 440–450,
Lisbon, Portugal, 17-21 September 2015.

Topic: Use of performance enhancing drugs (PEDs) in professional sports	
Claim A: PEDs can be harmful to athletes health	
S1: A 2006 study examined 320 athletes for psychiatric side effects induced by anabolic steroid use. The study found a higher incidence of mood disorders in these athletes compared to a control group.	V
S2: The International Agency for Research on Cancer classifies androgenic steroids as "Probably carcinogenic to humans."	V
S3: Rica Reinisch, a triple Olympic champion and world record-setter at the Moscow Games in 1980, has suffered numerous miscarriages and recurring ovarian cysts following drug abuse.	V
S4: The UN estimates that there are more than 50 million regular users of heroin, cocaine and synthetic drugs.	X
S5: FDA does not approve ibuprofen[2] for babies younger than six months due to risk of liver damage.	X
S6: Doping can ultimately damage your health.	X
Claim B: Use of PED is inline with the spirit of sport	
S7: Professor Savulescu, a philosopher and bioethicist, believes that biological manipulation embodies the sports spirit: the capacity to improve ourselves on the basis of reason and judgment.	V

Table 1: Examples for defined concepts. The V/X indicates if the candidate is a CDE to the claim above it, according to our definition.

- **Expert** Testimony by a person / group / committee / organization with some known expertise / authority on the topic. (Table 1 S2, S7);
- **Anecdotal** A description of an episode(s), centered on individual(s) or clearly located in place and/or in time. (Table 1 S3);

Examining the valid and non-valid CDEs in Table 1 it should be clear that the distinction between them is often quite subtle. For example, it is possible that a piece of text has the characteristics of a certain evidence type, but does not support the claim (see S4 in Table 1). It is also possible that a piece of text supports the claim, but is irrelevant in the context of the topic (see S5 in Table 1). It could also be the case that a piece of text entails the claim, but adds no new information to support it (see S6 in Table 1).

We present here a pipeline architecture, relying on supervised learning, to handle the different aspects of CDED which shows promising results over a variety of topics. We demonstrate that the proposed solution and features can generalize well, namely that models learned over different topics can perform reasonably well on an entirely new topic. On average, for a significant fraction of claims the proposed system succeeds to propose relevant CDE amongst its top 4 predictions, and properly determines the evidence type. Furthermore we show that we are able to automatically pinpoint claims for which the performance of the system are of even greater quality, enabling the user to obtain higher precision for these claims.

We believe that the ability to automatically provide evidence for given claims will have many practical uses, helping layman and professionals in different domains, to reach decisions and prepare for discussions, from a lawyer presenting a case in court, to a politician considering a new policy.

2 Related work

CDED is related to several other information retrieval and NLP tasks. Probably the closest of which is the relatively unexplored task of Evidence Retrieval (ER) (Cartright et al., 2011; Bellot et al., 2013). However, while ER focus is on identifying whole documents, in CDED the goal is to pinpoint a typically much shorter text segment which can be used directly to support a claim. Furthermore, ER is typically performed for factual assertions, while in CDED one may want to consider a wider range of claim types (Rieke and Sillars, 2001), cf. claim B in Table 1.

Another important line of related work is the Textual Entailment (TE) framework (Dagan et al., 2009; Glickman et al., 2005). A text fragment, T, is said to entail a textual hypothesis H if the truth of H can be most likely inferred from T. While TE can be an important component in a CDED approach, and perhaps vice versa, the tasks are quite different. Namely, the goal of TE is detecting semantic inference while the goal of CDED is to provide evidence which can enhance the persuasion of a claim. For example, common instances of TE are rephrases or summarizations of a sentence, however they cannot serve to support a claim within a discussion, as they merely repeat it (Table 1, S6). On the other hand, an anecdotal story may have strong emotional impact that will effectively support a claim during a discussion, although the truth of the claim cannot be inferred from such evidence. Furthermore, similar to ER, TE focuses only on factual assertions, while we focus on a wider range of claims (Rieke and Sillars, 2001), cf. claim B in Table 1.

Question answering (QA) (Dang et al., 2007) also has some similar aspects to the proposed task, although aiming at a very different goal, which is to provide an explicit – typically unique and concise – answer, to a question.

The proposed CDED task should be seen as another contribution in the emerging field of argumentation mining, with several important distinct characteristics. Previous works suggested extracting full ar-

	Topics	Claims	Articles with CDE	CDE	avg. % of claims with CDE	avg. # CDE per claim
Study	30	1587	136	1018	31 (22)	2.2 (0.9)
Expert	37	1702	214	1896	46 (22)	1.9 (0.8)
Anecdotal	22	1137	70	382	17 (11)	2.0 (1.6)
Total	39	1734	274	3057	60 (17)	2.9 (3.7)

Table 2: 'Topics' indicate the number of topics included for each CDE type. This determines the number of claims considered for each type. The next columns indicate the number of articles in which at least one CDE was found; the total number of CDE detected for each type; the average percent of claims for which at least one CDE was found; and for these claims, the average number of CDE found. Note that the total number of CDE is not a simple sum of the CDE per type, as CDE can be assigned with more than one type. Standard deviations of distribution across topics are given in parenthesis where relevant.

guments (Mochales Palau and Moens, 2009), analyzing argument structure (Peldszus, 2014), and identifying relations between arguments (Cabrio and Villata, 2012; Ghosh et al., 2014). Other works focused on specific domains such as evidence-based legal documents (Mochales Palau and Moens, 2011; Ashley and Walker, 2013), online debates (Cabrio and Villata, 2012; Boltužić and Šnajder, 2014), and product reviews (Villalba and Saint-Dizier, 2012; Yessenalina et al., 2010). In addition, some works based on machine-learning techniques, used the same topic in training and testing (Rosenfeld and Kraus, 2015; Boltužić and Šnajder, 2014), relying on features from the topic itself in identifying arguments. In contrast, here, we focus on detecting an essential constituent of an argument – the evidence – rather then detecting whole arguments, or detecting other argument parts like claims (Levy et al., 2014; Lippi and Torroni, 2015). In addition, we do not limit ourselves to a particular domain, nor assume that the topic of the discussion is known in advance. Finally, we aim to pinpoint evidence in a clearly defined context, given by the pre–specified claim. Thus, the developed system should not only find pieces of text that have general evidence characteristics but further identify which of these candidates can be used to support a specific claim. Hence, as we demonstrate in our results, an essential part of a CDED system should be dedicated to model and assess the semantic relation of a candidate evidence to the given claim and topic.

3 Data

Since CDED is a new and rather complicated task, it is beneficial to examine and understand the nature of the data before moving on to developing a working solution. We therefore start by explaining the manual data annotation process, and several important observations over the resulting data.

To train and assess the classifiers in our system we rely on data collected by the procedure described in (Aharoni et al., 2014). Briefly, given a topic and a corresponding relevant claim, extracted from a Wikipedia article by human annotators, the annotators were asked to mark corresponding evidence – text segments supporting the claim. To limit the amount of time annotators spend on these tasks, labeling was restricted to the article in which the claim was found. The task was split into two stages. First, in the detection stage, five annotators read the article, and mark all CDE candidates they locate. Next, in the confirmation stage all the candidates suggested by the annotators are presented to another set of five annotators, which confirm or reject each candidate, and determine the type(s) of accepted candidates. Candidates which were confirmed by the majority of the annotators are considered CDE, and are assigned the type(s) suggested by at least three annotators.

A total of 547 Wikipedia articles associated with 58 different topics were annotated through this procedure. The topics were selected at random from *Debatabase*[3] covering a wide variety of domains, from atheism to the role of wind power in future energy supply. Out of these topics, 39 were selected at random for training and testing the classifiers included in the system. We refer to these data as the *train and test data*. The remaining 19 topics were used for tuning various feature parameters, and developing auxiliary classifiers, as described in Section 5. We refer to these data as the *held-out* data.

In the 39 topics comprising the train and test data, a total of $3,057$ distinct CDE were found in 274 articles (See Table 2). The data is highly unbalanced towards non CDE sentences. For example, for type Study, only 31% of the claims had at least one CDE. Of these 31% claims, on average, a claim was associated with 2.17 CDEs. Further, on average these 2.17 CDEs together span 1.5 sentences, whereas an average article in our data consists of 150 sentences. In other words, even for claims with at least one CDE of type Study, on average only 2% of the sentences in the claim's article are part of such Study CDE.

In general, CDE in the examined data varied in length from less than a sentence to more than a paragraph. However, 90% of these CDE were composed of segments of up to three sentences within the same paragraph. Furthermore, in 95% of the cases, CDEs were

[3] http://idebate.org/debatabase

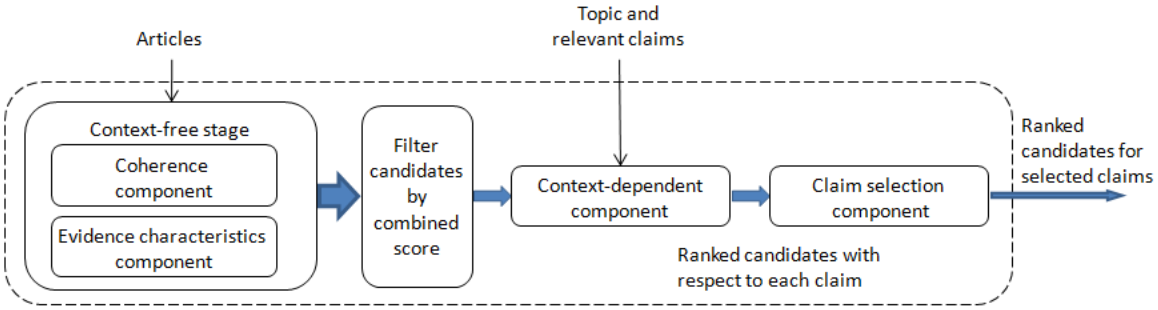

Figure 1: Schematic description of the CDED system proposed in this work.

comprised of full sentences. Examining CDEs that start or end mid-sentence, reveals that in most cases the CDE is more concise in these boundaries, but is still a valid CDE when extending the boundaries to include the full sentence. We therefore decided not to address this issue here, and we extend all CDE boundaries to full sentences.

Apparently CDE of type Study and type Expert are far more common in Wikipedia compared to Anecdotal CDE. We expect this distribution to change in other less scientifically inclined corpora.

Finally, the variance between different topics was substantial, as depicted in Table 2 (refer to the standard deviations mentioned in parenthesis). For example, the percentage of claims with Expert CDE varies from 10% in the topic *banning gambling* to 95% in the topic *US responsibility for the Mexican drug wars*. This observed variability obviously adds to the difficulty and complexity of the task.

In the experiments reported in this paper, out of the 39 topics in the train and test data, we exclude from the evaluation of each type, topics that had less than three CDE of that type. This leaves a total of 30, 37, and 22 topics for types Expert, Study, and Anecdotal, respectively.

The current work is the first to report results over these CDE data, which are more than 4 times larger compared to the data released in (Aharoni et al., 2014). These data are now freely available for research purposes [4].

4 System Architecture

The input to our system is a topic, a set of related articles and a set of relevant claims detected within these articles. Given this input, our system provides the user with a ranked list of candidate CDEs, originating from the text in the claim's article, for an automatically selected subset of the input claims.

In general, we observe that a text segment should satisfy three criteria to be considered CDE of a specific type. It must be coherent; it must have characteristics of the relevant Evidence type; and finally, of course, it should support the claim.

In addition to these observations, we note that a priori, we do not expect all claims to be supported by all CDE types (Park and Cardie, 2014). For example, opinion claims like claim B in Table 1 are expected to be less supported by Study evidence compared to factual claims, like claim A in Table 1. Moreover, as evident from Table 2, many claims do not have any associated CDE in the same article. Thus, the system performance may naturally improve if it will propose candidate CDE of a particular type, only to an automatically identified subset of the input claims.

Based on these observations, we are led to suggest an architecture which approaches CDED via a pipeline of modular components. Each of these components relies upon the results of its precedents, and is specifically designed to address a single aspect of those mentioned above. The resulting architecture is depicted in Figure 1. Briefly, in the proposed architecture, the first two components are *context-free*, i.e., focused on the general characteristics of a candidate, still not taking into account the context of the claim, nor the topic. The third component is *context-dependent*, considering the relation of the candidate to the claim and topic. Finally, the fourth component aims to identify a subset of the claims for which CDE will be proposed.

We consider all text segments composed of one, two or three consecutive sentences, included within the same paragraph as candidates (see Section 5 for more details). Given a set of such *candidate CDEs* – or simply, *candidates* – the first component, termed the *coherence component*, estimates the coherence of each candidate. For example, consider CDE S1 in Table 1. A candidate which includes only the second sentence is incoherent, as it includes critical unresolved anaphora, that cannot be understood without the previous sentence. In parallel, the second component, termed the *evidence characteristics component*, estimates the extent to which the candidate's statistical signature matches that of the examined evidence type. For example, if no quantitative analysis of data is reported, the candidate typically cannot be considered Study evidence, regardless of the claim and topic. Next, we only

[4] https://www.research.ibm.com/haifa/dept/vst/mlta_data.shtml

retain candidates for which the average score of the first two components was relatively high, aiming to further focus our attention on the most promising candidates.

The retained candidates are then considered by the *context-dependent* component which aims to determine if the examined candidate indeed supports the provided claim in the context of the topic. Thus, this component ranks all retained candidates with respect to each claim. Finally, the *claim selection* component aims to rank all input claims, according to the probability that CDEs are indeed found amongst top-ranking candidate for the claim.

Dividing the overall task into sub-tasks has several benefits. First, it allows training each component over its most suitable data, in which the signal of the relevant features is easier to capture. For example, many of the features for the *context-dependent* component aim to determine the semantic relatedness between the claim and a candidate. If one would have tried to tackle the entire CDED task simultaneously, the training data for this component would have been masked by many candidates that are highly related to the claim, although are not CDE – e.g., definitions of some aspects of the claim. These candidates would have blurred the signal that should be captured by the semantic relatedness features, as they represent candidates with negative labels that are nonetheless semantically related to the claim. By separating the tasks, we allow the *context-dependent* component to avoid this inherent difficulty, and train over much cleaner data.

Second, our pipeline allows efficient handling of the CDED task in terms of run time. Semantic relatedness features are often relatively complex and demanding in terms of run time. The significant filtering done after the *context-free* stage, reduces the number of candidates for which we have to calculate these features.

Finally, we note that some of the modular components we develop as part of the pipeline might be of interest by themselves. For example, context-free evidence detection might be useful in cases in which the claim and topic are not defined (Lippi and Torroni, 2015).

Naturally, we expect that different evidence types will have different characteristics. For example, numbers are expected to be more common in CDE of type Study compared to CDE of type Expert. Anecdotal CDE is perhaps expected to be less semantically related to the corresponding claim, as it may have a more associative relation to the claim, compared to CDE of types Study or type Expert. Correspondingly, all components are developed, trained, and assessed, independently for each CDE type.

In summary, the full flow of our system upon receiving a new topic with associated articles and claims, is as follows:

1. All articles are split into sentences, and all consecutive segments up to three sentences within a paragraph are generated as candidates.
2. Each candidate is assigned a score by the two components in the *context-free* stage and their scores are averaged. [5]
3. A dynamic programming algorithm selects a complete coverage of the article by non-overlapping candidates with the maximal average *context-free* score. The rest of the candidates are discarded.
4. The remaining candidates across all articles are sorted and only the top 15% of these candidates are retained. [6]
5. For each claim, the *context-dependent* component ranks all retained candidates within the claim's article with respect to the claim.
6. The claim selection component considers all claims and the candidates ranked with respect to each claim and assigns a score per claim. If the claim–score is below a pre–computed threshold, no candidate CDE will be presented for that claim.

All components are based on a Logistic Regression (LR) classifier, and the class probability is used as the candidate score.

5 Technical approach

In this section, we provide more technical details for each of the components in our architecture.

5.1 Coherence component

This component aims to score a candidate according to its coherence. For example, a candidate with an unresolved anaphora, or one that breaks a quotation in the middle, is expected to receive a relatively low score. As mentioned, this component considers all text segments composed of 1–3 consecutive sentences included within the same paragraph. This decision is based on the observation that such segments cover 90% of CDE in the labeled data. Reaching a full coverage requires examining segments up to 25 sentences, which would vastly increase run time, for a relatively small gain. Thus, for example, for a single paragraph with five sentences, our system will examine a total of $5 + 4 + 3 = 12$ candidates. For an article including 30 such paragraphs, a total of 360 candidates will be considered. During training, segments that conform to a labeled CDE were considered positive examples, while segments that overlap a labeled CDE, but either include additional sentence(s), or exclude part of the CDE sentences were considered negative examples.

Dominant features for this classifier included: presence of incomplete quotes; presence of contrast related conjunctive adverbs – e.g., `however`,

[5] With additional training data, we might be able to learn a more sophisticated function to combine both scores.

[6] This percentage was determined according to performance on the held-out data set. We have also experimented with methods where the threshold is score–based rather than percentage–based, which gave similar results.

nevertheless; segment length; and presence of unresolved co-references.

5.2 Evidence characteristics component

This component aims to estimate to what extent a candidate represents evidence of a certain type. The train and test data for this component consisted of all text segments composed of 1-3 consecutive sentences, included within the same paragraph. Positive examples are all labeled CDE of the corresponding evidence type. Negative examples are all candidates that do not overlap labeled CDE of the relevant type, including CDE of other types.

The dominant features for the classifier used in this component relied on the following mechanisms:

- **Lexicons** – including external lexicons (the Harvard IV-4 dictionary) and manually and automatically compiled in-house lexicons. Specifically, for each evidence type, we manually compiled a lexicon of words characterizing this type by looking at examples from the held-out data. This resulted with high–precision / low–recall lexicons. For example, for type Expert we used a lexicon of words describing persons and organizations that may have some relevant expertise, such as: economist, philosopher, court. In addition, we used the held-out data to automatically learn wider lexicons of words that are significantly associated with each type. All the in-house lexicons are described in detail in the supplementary material.

- **Named Entity Recognition (NER)**. We used the Stanford NER (Finkel et al., 2005) to extract named entities such as person and organization, and an in-house NER (Lally et al., 2012) to extract more fine grained categories such as "educational organization" and "leader".

- **Patterns**. We used regular expressions to represent features like: does that candidate contain a quote; does it contain a citation; does it contain numeric quantitative results. In addition, we generated complex regular expressions which combine the above lexicons with NER results to capture patterns indicative of different types. For example, the pattern [Person/organization, 0 to 10 wildcard words, an opinion verb - such as believe, conclude, etc.] was highly indicative of Expert evidence (cf. Table 1 S7).

- **Subjectivity classifier**. We manually labeled $1,750$ sentences, selected at random from articles in the held-out data, as either subjective or objective. Next, each sentence was represented by a concatenation of two feature vectors – (i) a bag-of-words representation, limited to a handcrafted subjectivity lexicon containing 100 words; (ii) a bag-of-patterns representation based on patterns observed as frequent in the subjective sentences, detected by a modification of the SPM algorithm (Srikant and Agrawal, 1996). An LR classifier was then trained over the labeled sentences.

5.3 Context-dependent component

The goal of this component is to estimate whether a candidate can be used to support a claim while discussing the given topic. The training data for this component are [topic / claim / CDE] triplets. Triplets in which the CDE and claim were linked in the labeled data – namely, the CDE was identified as evidence for the claim – were considered as positive examples. Negative examples were generated by combining claims and CDEs detected in the same topic and article, but that were not linked in our labeled data.

The features for the classifier used in this component can be conceptually divided into four types: (i) Semantic relatedness between the candidate and the claim (ii) Semantic relatedness between text related to the candidate and the claim (iii) Relative location of the candidate with respect to the claim and (iv) sentiment–agreement between the candidate and the claim.

In general, we rely on two methods to assess the semantic relatedness between two texts. The first is based on the cosine similarity between TF-IDF vectors representing each text. Before constructing the TF-IDF vectors each text is augmented with acronym expansions, and lexical relations (including antonym, derivationally related and pertainym) from WordNet (Miller, 1995). The second, relies on the average cosine similarity between the Word2Vec (Mikolov et al., 2013) representation of all pairs of words in the two texts, where in each pair one word is taken from the first text and the other word from the second.

For each of these two methods, we consider the semantic relatedness between the claim and: Specified slots in the candidate as detected by an in-house slot grammar parser (McCord, 1990; McCord et al., 2012); The entire candidate text; The header/sub-header of the section/subsection containing the candidate; Titles of citations referred to from the candidate.

5.4 Claim selection component

The goal of this component is to rank all claims according to the probability that the claim's article includes CDE of the relevant type, associated with the claim. The training data consisted of all claims, where positive examples included claims for which at least one CDE of the relevant type existed in the labeled data and negative examples included all remaining claims.

A thresholding mechanism on the component score is used to determine the claims for which candidates will be presented. This threshold was selected by optimizing the F1 score over the set of held-out topics.

The features used by this component exploited three types of information:

- **Claim properties**: We used the held-out data to

generate two types of lexicons. The first lexicon is generated separately per evidence type. It includes claim words that were found to be significantly associated with positive examples, namely with claims for which CDE were found. For example, for type Study, this lexicon included words such as `lead`, `result`, `development` and `significant`. The second lexicon aimed to characterize words that are significantly associated with factual claims vs. non–factual claims, with the expectation that certain evidence types might be more/less common for each of these two claim categories. For this, 550 randomly selected claims were annotated as factual/non–factual. Words identified as characterizing factual claims included `increase`, `important`, and `relate`, while words like `natural`, `freedom`, and `right` were found dominant for non-factual claims.

- **Claim's relevance to topic and article**: We expect that when an article's main topic is highly related to the claim, it will more likely include CDE for that claim. Similarly we expect that for claims at the heart of the topic, CDE is more likely to be provided. These properties are assessed by measuring the semantic relatedness between (i) the claim and the content of the claim's article and (ii) the claim and topic.

- **Properties of claim's article** : Specifically, we mainly consider the scores provided by the context-dependent component to all candidates examined in the claim's article. If the observed scores are relatively high/low, we expect the article to be more/less likely to include evidence of the considered type. Various statistics of these scores, such as the maximum score and the standard deviation are used as features aiming to capture this intuition.

6 Experimental Results

6.1 Evaluation

We evaluated our approach using the Leave-One-Out schema: for every topic, we trained the classifiers using the claims and associated CDE in all other topics and then applied the resulting models to the left out topic.

In general, we consider a candidate as true-positive if it includes all sentences included in the CDE and no additional sentences. However, for our analysis it is also interesting to separate between (i) errors in selecting the segment boundaries and (ii) errors of down the line components that are affected by these errors. Thus, we also include the *overlap* measure where we consider a candidate as true-positive if at least one sentence within it overlaps a sentence in a labeled CDE.

Our final assessment measure is the mean reciprocal rank (MRR), that is the inverse of the rank of the first CDE detected for a particular claim, averaged over all claims selected by the *claim selection component.* This is motivated by the observation that in most practical use cases, it is usually more important to be able to support many claims, than to provide all the CDE available for a single claim. We define the MRR of a claim with no CDE (errors of the claim selection component) to be 0.

Finally, we report the macro-averaged results over the different topics, that is all topics have the same weight regardless the amount of labeled claims and labeled CDE detected for them. The rational behind this is that we wish to ensure that our system does reasonably well across all topics examined. We note that micro-averaging gave overall similar results.

6.2 Comparison to Baselines

To assess the necessity and contribution of the different components we compare our full pipeline to partial pipelines, where some of the component are disabled or replaced by simple baselines. These baselines are described below.

First, we consider the **No Context-Free Stage (NCFS)** baseline which aims to assess the contribution of the *context-free* stage by skipping this stage, and passing all candidates directly to the *context-dependent* component.

Next, we consider the **Basic Claim Selection (BCS)** baseline which replaces the claim selection component. It ranks claims according to the top score of the candidate CDE for the claim. A threshold was selected on top of the training data, such that the average percentage of claims passing the threshold is equal to the average percentage of claims with CDEs in the labeled data.

Since, to the best of our knowledge, this is the first work to address CDED, there is no prior-art to compare our results to. However, to ensure that this task is indeed empirically different from related tasks, and demands a specialized pipeline to handle, we compare with two baselines that are often used in related tasks.

The **BM25** basline handles CDED as an IR task, where the claim represents the query, and all CDE candidates represent the documents in a standard IR setting. After pre-processing, which includes tokenization, stop word removal, and stemming (Porter, 1997) we use BM25 (Robertson et al., 1996) to rank all relevant candidates according to their similarity to the query, namely to the input claim.

The **W2V** baseline handles CDED as a purely semantic relatedness task using state of the art semantic relatedness measure of Word2Vec (Mikolov et al., 2013). Thus, we use the average cosine similarity between the Word2Vec representations of all words in a given candidate to all words in the claim, to rank all relevant candidates with respect to each claim.

Type	MRR				MRR overlap			
	Pipeline	NCFS	W2V	BM25	Pipeline	NCFS	W2V	BM25
Study	0.37	0.19	0.09	0.14	0.51	0.39	0.24	0.23
Expert	0.41	0.29	0.28	0.15	0.58	0.52	0.50	0.24
Anecdotal	0.18	0.04	0.04	0.04	0.31	0.11	0.11	0.11

Table 3: Macro-averaged MRR for each CDE type. Only claims with CDE in the labeled data were considered in these results.

6.3 Results

We start by assessing the proposed pipeline prior to the claim selection component. Table 3 reports the MRR following the context-dependent component when filtering out claims for which no CDE were found in the labeled data.

Impact of context free stage: Comparing the pipeline performance to the baseline using only the context dependent component (NCFS baseline), the results indicate the necessity of the context-free stage in our pipeline. That is, assessing the coherence of candidates, as well as their evidence characteristics, seems to be essential to properly address CDED. In particular, the fact that the gain is observed both in the MRR measure and in the MRR-overlap measure suggests that both the context-free components are valuable.

Impact of context dependent stage: Comparing the NCFS basline to W2V and BM25 baselines shows that for type Study, the context-dependent component alone still has an advantage over a single semantic relatedness feature. Observing feature weights learned by the LR classifier, we estimate that much of this advantage is due to also taking into consideration semantic relatedness of the claim to texts related to the candidate, namely the header of the section containing the candidate and titles of citations referred to from the candidate.

For types Expert and Anecdotal the performance of the context-dependent component are similar to those of the W2V baseline. For type Expert, this suggests that most of the signal in the context-dependent component comes from semantic relatedness between the claim and candidate CDE. Results for type Anecdotal are significantly lower. This was somewhat expected, given the smaller size of Anecdotal data available to train our classifiers (Table 2). The declined performance of the W2V and BM25 baselines for this type, further suggests that the semantic relatedness of CDE and claims for this type are less direct.

Impact of detecting segment boundaries: Comparing the *overlap* MRR measure to the exact MRR highlights that identifying the correct segment boundaries is still a challenge, and once we improve this aspect, we can expect a significant improvement in the results.

Impact of claim selection component: We next turn to assess the contribution of the claim selection component. Table 4 compares the final MRR results – at the end of the pipeline – for claims selected by the claim selection component, vs. claims selected by the BCS baseline. Additionally, to demonstrate the value of claim selection in general, we add results when considering all claims. For types Expert and Study the claim selection component shows a clear advantage over the baselines. Furthermore, the improved performance is achieved when passing a higher percentage of claims than the BCS baseline (34% vs 31% for Study and 52% vs 46% for Expert, Figure 2). Admittedly, for Anecdotal CDE the performance of claim selection are poor. For this component the small sample size for Anecdotal CDE was even more acute – there were only 151 claims with CDE of type Anecdotal – thus few positive examples to train this component.

Type	Pipeline	BCS	All claims
Study	0.25	0.16	0.12
Expert	0.34	0.23	0.20
Anecdotal	0.04	0.05	0.03

Table 4: Macro-averaged MRR over: 1) claims selected by the claim selection component, 2) claims selected by basic claim selection, and 3) all claims.

Recall that the claim selection component's threshold was tuned over the held-out data to optimize the F1 measure with respect to claims with/without CDE. However, for some applications one may favor higher precision at the expense of providing candidate CDEs for less claims. Figure 2 shows that indeed, for type Study, considering more strict thresholds of the claim selection component monotonically improves the system's overall precision, as reflected by the improved MRR. Similar results were obtained for type Expert.

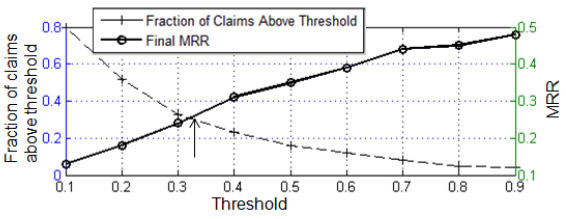

Figure 2: MRR and average fraction of passed claims as function of the claim selection threshold for type Study. Arrow indicates threshold used to obtain the results in Table 4.

6.4 Examples of System Performance

To provide some intuition for the results of our system, Table 5 shows the 4 top ranking candidate CDE

According to econometric studies, negative side effects of aid can include an unbalanced appreciation of the recipient's currency, increasing corruption, and adverse political effects such as postponements of necessary economic and democratic reforms.	X
Many econometric studies in recent years have supported the view that development aid has no effect on the speed with which countries develop.	V
An inquiry into aid effectiveness by the UK All Party Parliamentary Group (APPG) for Debt, Aid and Trade featured evidence from Rosalind Eyben, a Fellow at the Institute of Development Studies.	X
A very large part of the spend money on development aid is simply wasted uselessly. According to Gerbert van der Aa, for the Netherlands, only 33% of the development aid is successful, another 33% fails and of the remaining 33% the effect is unclear. This means that for example for the Netherlands, 1.33 to 2.66 billion is lost as it spends 4 billion in total of development aid.	V

Table 5: Top ranking candidates for the claim *aid is ineffective* in the context of the topic *trade vs. aid*

of type Study for the claim *aid is ineffective* in the context of the topic *trade vs. aid*. Among these, 2 were indeed labeled as CDE. The other two exemplify common errors of our system. Candidate 1 can be used to support a highly related claim such as *aid has negative side effects*, but does not directly support the claim under consideration. Candidate 3 mentions a relevant study, but does not present its results, hence cannot be used to support the claim.

7 Conclusions and Future Work

We have provided the definitions for the CDED task, and described a system architecture that addresses the issues at the heart of the task. We assessed the performance of the proposed approach over a novel benchmark dataset, demonstrating the validity of our architecture, and the necessity of all its components.

There are still many open issues to address and directions in which to expand the task and labeled data which we hope to address in future work.

In this paper we define CDE only in the context of *supporting* a claim. However, in many scenarios providing *counter* evidence can also be very useful. As evidence supporting and contesting a claim share many semantic and syntactic features, we believe that detecting both cases simultaneously might be easier to accomplish, although to enhance the practical use of such a solution, one may need to develop an additional component, determining the polarity of the detected CDE.

Another natural direction to pursue is expanding the documents which are considered for CDED beyond the article containing the claim. These can include additional Wikipedia articles and other resources such as newspaper archives, scientific literature, blogs, etc. This poses additional challenges in gathering labeled data, as it will require a mechanism to decide which documents to label per claim and will probably increase the number of documents to be labeled. Expanding to additional corpora will probably require development of additional features, to capture signals unique to each corpus. For example, in newspaper archives, the identity of the author might prove an important feature.

Finally, in this work we used manually identified claims and articles. Combining a CDED solution with recent works in the field of argumentation mining (Cartright et al., 2011; Levy et al., 2014; Lippi and Torroni, 2015), may give rise to a new generation of methods, that will be able to automatically construct relevant arguments on demand, for a variety of topics.

Abstract

We use character-based statistical machine translation in order to correct user search queries in the e-commerce domain. The training data is automatically extracted from event logs where users re-issue their search queries with potentially corrected spelling within the same session. We show results on a test set which was annotated by humans and compare against online autocorrection capabilities of three additional web sites. Overall, the methods presented in this paper outperform fully productized spellchecking and autocorrection services in terms of accuracy and F1 score. We also propose novel evaluation steps based on retrieved search results of the corrected queries in terms of quantity and relevance.

1 Introduction

Spelling correction is an important feature for any interactive service that takes input generated by users, e.g. an e-commerce web site that allows searching for goods and products. Misspellings are very common with user-generated input and the reason why many web sites offer spelling correction in the form of "Did you mean?" suggestions or automatic corrections. Autocorrection increases user satisfaction by correcting obvious errors, whereas suggestions make it convenient for users to accept a proposed correction without retyping or correcting the query manually. Spelling correction is not a trivial task, as search queries are often short and lack context. Misspelled queries might be considered correct by a statistical spelling correction system as there is evidence in the data through frequent occurrences.

While common successful methods (cf. Section 1.1) rely on either human-annotated data or the entire web, we wanted to use easily accessible in-domain data and on top of that technology that is already available. In this work, we use user event logs from an e-commerce web site to fetch similar search query pairs within an active session. The main idea is that users issue a search query but alter it into something similar within a given time window which might be the correction of a potential typo. To the best of our knowledge, the idea of collecting query corrections using user session and time information is novel. Previous work suggested collecting queries using information that a user clicked on a proposed correction. Our proposed method for collecting training data has several advantages. First, we do not rely on a previous spelling correction system, but on user formulations. Second, for many search queries, especially from the tail where search recall is generally low, these misspellings yield few results, and thus, users looking for certain products are inclined to correct the query themselves in order to find what they are looking for. We use Damerau-Levenshtein distance (Damerau, 1964) on character level as similarity criterion, i.e. queries within a specific edit distance are considered to be related.

The steps proposed in this work are:

1. Extraction of similar user queries from search logs for bootstrapping training data (Section 2),
2. classification and filtering of data to remove noisy entries (Section 3), and

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 451–460, Lisbon, Portugal, 17-21 September 2015.

3. spelling correction cast into a statistical machine translation framework based on character bigram sequences (Section 4).

We also evaluate the work thoroughly in Section 5 where we compare our method to three other online sites, two of them from the e-commerce domain, and present a novel approach that determines quality based on retrieved search results. We show examples indicating that our method can handle both corrections of misspelled queries and queries with segmentation issues (i.e. missing whitespace delimiters). A summary can be found in Section 6.

To our knowledge, this is the first work that uses character-based machine translation technology on user-generated data for spelling correction. Moreover, it is the first to evaluate the performance in an e-commerce setting with there relevant measures.

1.1 Related Work

One of the more prominent papers on autocorrection of misspelled input is (Whitelaw et al., 2009). The three-step approach incorporates a classification step that determines whether a word is misspelled, computes the most likely correction candidate and then, again, classifies whether this candidate is likely to be correct. An error model based after (Brill and Moore, 2000) is trained on similar word pairs extracted from large amounts of web sites, and a language model is used to disambiguate correction candidates based on left and right context around the current position. Our method differs in several ways. First, we consider full query pairs as training data, and do not use single words as primary mode of operation. Second, we do not train explicit error models $P(w|s)$ for words w and observed corrections s, but use standard phrase-based machine translation modeling to derive phrase and lexical translation models. Although our level of context is shorter, especially for long words, the system automatically uses cross-word level context.

The idea of using consecutive user queries from a stream of events to improve ranking of web search results was described in (Radlinski and Joachims, 2005). The authors introduce the notion of *query chains* that take advantage of users reformulating their queries as a means to learn better ranking functions. The classification of query chains is performed by support vector machines, and its training data is generated in a supervised fashion by manual inspection and annotation. In contrast, we do not manually annotate any of our training data. Since our initial sets are quite noisy, we apply a couple of heuristics that try to produce a cleaner subset of the data that contains mostly misspelled queries and their potential correction candidates.

Another focus of researchers was specifically to tackle misspelled web search queries and use search engine logs for training and evaluation data (Gao et al., 2010), which differs from our work by collecting data using "click-through" enforcement. The user is presented with a spelling correction, and if she clicks on it, they learn that the correction is valid. Our method does not need a previous spelling correction to work. In addition, our proposed method has the potential to learn corrections of new and rare terms that will not be produced by an automatic spelling correction.

In (Zhang et al., 2006), the authors use a conventional spellchecker to correct web queries through additional reranking of its output by a ranking SVM. The training data is in part automatically extracted, but also contains manually annotated pairs and, thus, is a semi-supervised approach. In this paper, we use an unsupervised approach to generate training data. Query spelling correction that is based on click-through data and uses a phrase-based error model is reported in (Sun et al., 2010). Our models operate on character sequences instead of words, and we do not observe issues with identity transformations (i.e. non-corrections for correctly spelled input).

In (Cucerzan and Brill, 2004), the authors investigate a transformation method that corrects unlikely queries into more likely variants based on web query logs. The iterative approach transforms a search query based on word uni- and bigram decompositions, and the authors evaluate on both a large set that contains around 17% misspelled queries and a smaller set that is based on successive user-reformulated similar queries, a similar setup that we use to extract our training data. They stress the importance of a good language model, as performance drops drastically going from a bigram to a unigram LM.

The use of character-based models in combination with statistical machine translation is not novel and was proposed for spelling correction, e.g., in (Formiga and Fonollosa, 2012), (Liu et al.,

2013) or (Chiu et al., 2013). The authors compare a distance-based approach including a language model, a confusion network-based approach, a translation approach through a heuristically defined phrase table coding all character transformations, and a character-based machine translation approach using standard procedures (automatic word alignment and phrase extraction). The training data is manually created in contrast to our work where we automatically bootstrap training data from query logs. Research has also been done for translation of closely related languages (e.g. (Vilar et al., 2007) and (Nakov and Tiedemann, 2012)) and transliteration (e.g. (Deselaers et al., 2009)). An early summary paper with various spelling-related problems (non-word error detection, isolated-word error correction, and context-dependent word correction) can be found in (Kukich, 1992).

2 Extraction of training data

We use event logs that track user interactions on an e-commerce web site. Each action of a user visiting the site is stored in a data warehouse and HDFS (Hadoop Distributed File System). We store several billion of these user records on a daily basis. The setup allows us to efficiently process large amounts of data points using a Map-Reduce framework via Hadoop[1]. As part of user event tracking, all interactions on the site are stored in the database, e.g. which search terms were entered, which links were clicked, and what actions resulted in this (i.e. buying an item, adding it to a like or watch list, or simply advancing to the next page of search results, and so on). We focus on search terms that users enter within a given period of time.

Our hypothesis is that users that enter consecutive search terms are not satisfied with the results and try to modify the query until the results are acceptable. We then analyze the sequence of search queries as part of each user session. We only extract consecutive search queries that are similar in terms of character-level Damerau-Levenshtein edit distance which is the minimum number of character insertions, deletions, substitutions and transpositions (i.e. the swapping of two characters). Note that spelling correction in this kind of environment also needs to address segmentation of queries in case of missing whitespace. It is quite common to find query terms being concatenated without the use of a space character, e.g. *calvinklein*, *ipadair* or *xboxone*. Also, search queries are short in nature and often lack context, and particularly for the e-commerce domain largely consist of brand and product names and associated attributes (e.g. size of clothing).

Our method extracts similar search query pairs that will be used in our statistical machine translation setup as training data. Table 1 shows examples that we extract from the event logs. We use edit distance thresholds of 3 and 5 characters, where the latter is generally noisier. Noise in this context is everything that is not related to misspelled queries. After a closer look, we observe that many queries are simply rewrites, i.e., users either make refinements to their original query by adding more words to narrow down results, e.g., *leather wallet* → *leather wallet men*, deleting words to decrease specificity, e.g., *gucci belt* → *gucci*, or simply going through various related products or attributes, e.g., *iphone 5* → *iphone 5s* → *iphone 6* where they progress through different products or *nike air 9* → *nike air 9.5* → *nike air 10* where they iterate through different sizes.

The logs on HDFS are organized as sessions where each session contains a stream of user events up to a specific time of inactivity. We use event timestamps to determine how long the users need between consecutive queries, and discard similar query pairs if they are above a threshold of 20 seconds. We use Hadoop-based mapper and reducer steps for the data extraction procedure. In the mappers, pairs of similar user search queries get emitted as per above edit distance criterion on character level, whereas the reducer simply accumulates all counts for identical search query pairs. Due to the size of the data, we run the Hadoop extraction jobs on 24-hour log portions, thus obtaining separate data sets for each day. Overall, we can extract several hundred thousand to several million similar query pairs on a daily basis for edit distance thresholds of 3 and 5, respectively.

We pull several months of data from the Hadoop logs and accumulate each daily pull with unique entries for training our spelling correction system. As mentioned above, search queries that are similar but where the original query is not misspelled make up a big portion of the extracted data. The following section focuses on how to filter the data to result in containing mostly query pairs that fit

Table 1: Extracted query pairs found in user event logs. Labels in column 4 indicate whether user-initiated spelling correction (Yes) has taken place vs. a search reformulation that entails the source query not being misspelled (No).

our use case, i.e. mappings from misspelled to corrected ones.

3 Filtering non-misspelled input

We tested a heuristic approach to filtering search query pairs: a combination of regular expressions and thresholded feature scores that detect search progressions and refinements which should be removed from the training data as they do not represent valid user corrections.

The manual filtering heuristic calculates a sequence of features for each search query pair, and as soon as a feature fires, the entry is removed. In the following, we will use the notation (x, y) for a search query pair that is extracted from the logs explained by our method in the previous section. Query x is a user search query, and query y is a similar query issued by the user in the same session within a specific time window. Example query pairs are (*babydoll*, *baby dolls*), (*bike wherl*, *bike wheel*) or (*size 12 yellow dress*, *size 14 yellow dress*). We use the following features as part of this process:

Regular expressions. We remove search query pairs (x, y) if y is a rewrite of x using search-related operators, e.g. $y =$"x" which adds quotation marks around the query (and, thus, has an edit distance of 2). Example: (*bluetooth speakers*, *"bluetooth speakers"*).

LM ratio. We use an English language model trained on publicly available corpora (e.g. Europarl), frequent queries and web content from the e-commerce domain to calculate log-likelihoods for each query and filter entries if the ratio is above zero, i.e. $\log p(x/y) = \log p(x) - \log p(y) > 0$. This step essentially removes query pairs (x, y) if the log-likelihood of query y is smaller than x which usually indicates that the correction is more perplexing than the original query. Example: (*bluetooth ear phones*, *bluetooth ear hpones*) with a log-likelihood ratio of -7.31 + 16.43 > 0 is removed as a typo actually appears on the "corrected" side.

Edit operations. We use a simple heuristic that detects search refinements in terms of word insertions and deletions: a word-level edit distance criterion is used to remove entries where edit operations indicate insertions or deletions of full words. We also detect substitutions on number tokens which are also excluded from training data. Examples: (*polo shirt*, *polo shirt xl*), (*nikon d700*, *nikon d7100*).

Frequent terms. We look at queries (x, y) and use a vocabulary with relative frequencies based on the query data y to determine whether substitutions on word level change a frequent token into another frequent token. Examples: (*snake bat wooden*, *snake bat wood*), (*hd dvds*, *hd dvd*) where *wood*/*wooden* and *dvds*/*dvd* are both frequent tokens and, thus, most likely rewrites and not corrections.

Language ID. The primary search language on US sites is English, but there is also a non-negligible mix of other languages, Spanish in particular. We do not remove all queries that are not identified as English because language identification on (often short) search queries is a non-trivial

Method	#queries	#tokens	MT Acc
all data	80.5M	235.6M	62.0%
heuristic filter	12.6M	40.1M	65.5%

Table 2: Filtering training data with a heuristic set of features. Accuracies are given on DEV for MT baselines with differences only in the data setup.

task with a high error rate and filtering for only English would remove a lot of valid entries. We simply remove query pairs where x is identified as either Spanish or Unknown based on Google's Compact Language Detector[2]. Example: (*accesorios cuarto*, *accesorios de cuarto*).

These heuristics help us to reduce the training data size from 80 million noisy search query pairs with around 235 million tokens to 12.5 million query pairs with roughly 40 million tokens that are of higher quality and most likely spelling corrections.

Table 2 shows results of this filtering step in terms of data sizes and the accuracy on the dev set (cf. Section 4). We observe that the filtering scheme reduces overall training size by almost 85% and increases accuracy on the development set by 3.5% absolute. The removal of query pairs is very aggressive at this point, and overall quality of the spelling correction framework might benefit from a more careful selection. We will look into improved variants of filtering through a maximum entropy classifier trained on actual search results in the future.

4 Autocorrection framework

We cast the autocorrection task into character-based statistical machine translation. For this, we prepare the data by splitting words into sequences of lowercased characters and use a special character to mark whitespace that indicates word boundaries. Once these sequences of characters are corrected, i.e. translated, they are merged back to the full word forms. Table 3 shows an example search query being preprocessed, translated and postprocessed. We use bigram characters instead of single characters, as suggested in (Tiedemann, 2012), in order to improve the statistical alignment models and make them more expressive.

For training the autocorrection system we use basic methods and open-source tools for statistical machine translation. The character alignment is obtained by using GIZA++ (Och and Ney, 2003) for 4, 3 and 2 iterations of IBM Model 1, HMM, and IBM Model 3, respectively. As opposed to the standard machine translation task, we did not observe improvements from IBM Model 4 and do not use it as part of the alignment process.

We use Moses (Koehn et al., 2007) for standard phrase extraction, building KenLM language models (Heafield, 2011) and tuning. The standard set of features is used, including a phrase model, word lexicon model, length penalty, jump penalty and a language model. The model weights are optimized using MERT (Och, 2003). The Moses framework allows us to easily conduct experiments with several settings and find the optimal one for our task at hand. We experiment with varying context sizes for phrase table and language model, additional features and different scoring methods, e.g. BLEU (Papineni et al., 2002) in comparison to directly maximizing accuracy on the dev set. A more detailed description of those experiments including results will follow in Section 5.

Evaluation data. In order to evaluate our proposed framework, we extracted 10,000 query pairs from a one week period not part of the training data. The initial size of 3.5M query pairs was reduced to 10k by exponential reservoir sampling (Osborne et al., 2014) after sorting by frequency. The result is a set of representative query pairs that focuses more on frequent misspellings, but also contains rare queries from the tail of the distribution.

We asked humans to create a gold reference annotation that we can use for tuning and evaluation purposes. The guidelines were to check whether for a search query pair (x, y), the left query x is misspelled, and if so, whether the similar candidate y is a correct correction or else provide the most likely correction. If x was not misspelled, the guidelines instructed to propagate query x to the gold reference y, i.e. for those cases, we have identity or a true negative. If query x is not English, the annotators had to mark those entries and we removed them from the set. This step affected 798 queries (i.e. around 8%, mostly Spanish), and the final set contains 9202 query pairs. We split those into half to produce 4,600 queries for dev and 4,602 for test. The true negatives in those sets (i.e. entries that do not need to be corrected) are ~15%. We are aware that this approach focuses on

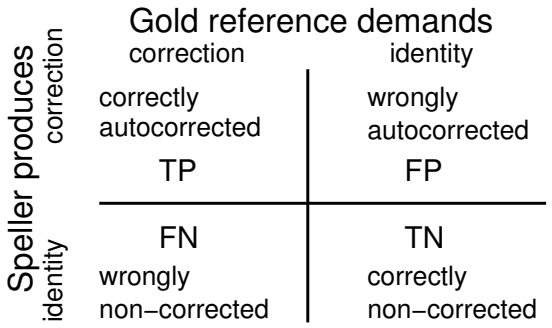

Figure 1: Scoring schema.

recall over precision, as the majority of queries is usually not misspelled. Nevertheless, exponential reservoir sampling helps us to focus on the head of that distribution, and our main goal is to evaluate the capabilities of the spelling correction framework, not the overall system integration. A final investigation in combination with query expansion that will be evaluated in the context of the live site is left for future work. Detailed statistics on the two sets can be found in Table 4.

Additional training data. In addition to the parallel data pull from the query logs as described in Section 2, we also take the top queries from those logs where we are sure they are most likely correct and can be used as gold reference (e.g. search queries like *handbags* or *wedding dress* appear thousands of times), and generate artificially noisified variants based on an English keyboard layout and statistics derived from our development set. On the dev set, we calculated a character error rate of roughly 6%, and this rate is used as a mutation rate for the artificially introduced noise. We also determine the following edit operation rates based on the dev set: 6% character transpositions, 18% for deletions, 33% for insertions, and 43% for substitutions. The target character for substitutions and insertions is based on a random Gaussian distribution with a distance mean 1 and standard deviation of 1 around the selected character, i.e. we target neighboring keys on the keyboard. For the query *wedding dress*, e.g., this method introduces misspelled variants such as *weddig dress*, *weedimg dress*, or *weddinb dreess*. We run this method 10 times on a set of 688k queries and remove all duplicates, resulting in additional 4.6M search query pairs with around 13M tokens for the training data.

As a final step, we add frequent queries from user event logs but also product titles of the live inventory to the language model. In total, the monolingual portion of the data contains roughly 31M entries with 319M tokens which are added to the target side of the bilingual training portion.

5 Experiments

In this section, we report on a series of hillclimbing experiments used to optimize performance. In the following, we use standard information retrieval criteria for evaluation, namely accuracy, precision, recall, and F1 score. Figure 1 depicts a natural way of how the scoring is performed. TP denotes true positives, FN false negatives, FP false positives, and TN true negatives, respectively. Note that for the case where the gold reference demands a correction, and the speller produces a wrong correction different from the source query, we have to increase both false positives FP and false negatives FN. With this, we can do stan-

TEST [%]	Acc	Prec	Rec	F1
online A	68.8	**84.0**	64.2	72.8
online B	63.0	77.4	60.2	67.7
online C	56.3	58.6	60.7	59.7
MT (this work)	**70.6**	74.0	**72.3**	**73.1**
MT (alt. setup)	70.2	77.1	69.3	73.0

Table 5: Comparison of accuracy, precision, recall and F1 score against other online sites on the test set.

dard calculation of accuracy as $(TP + TN)/(P + N)$ with $P = TP + FN$ and $N = TN + FP$, precision as $TP/(TP + FP)$, recall as TP/P, and F1 score as $2TP/(2TP + FP + FN)$.

5.1 Hillclimbing and performance

We compare the performance of our autocorrection system with that of three other online search engines, both from the e-commerce as well as web search domain. For this, we automated entering our search terms on the corresponding sites and extracted candidates from "Did you mean..." suggestions or "Showing results for..." autocorrections. Table 5 shows that our method outperforms all other systems in accuracy, recall and F1 score. We argue that recall in our setup is more important than precision because the goal is to correct as much as possible as autocorrection is usually invoked by the search backend as a result of low or *null* recall size.

Gradual improvements were made to the system setup and we track those on the development set. Table 6 gives a couple of major waypoints in the hillclimbing process. The baseline incorporates all extracted training data and uses phrases up to length 3 (i.e. up to three character bigrams for both source and target side). The baseline language model uses 6-grams. This setup is trained on very noisy data that contains a lot of search refinements that are not actual misspellings. The filtered data improves results. In general, we observe a 3-4% relative improvement across all scores when using bigrams instead of single characters. We experiment with additional phrase features as part of the phrase table and add 5 features based on phrase pair-specific edit operations, i.e. the number of insertions, deletions, substitutions, transpositions and final overall edit distance, which helps to increase precision. The artificially noisified data gives additional small gains, as well as direct optimization of accuracy instead of BLEU or WER. We did not observe significant differences when tuning on BLEU versus WER. Most of the improvement though comes from increasing context size, i.e., 10-gram language models and lengths up to 5 bigram character spans for both source and target phrases. We also observe that iterative correction, i.e. running the speller a second time over already corrected data, further improves performance slightly which is in-line with findings in (Cucerzan and Brill, 2004) and (Gubanov et al., 2014).

Increasing precision. We also investigated a system setup that focuses on precision over recall in order to be more in sync with the online systems that have been most likely optimized to a more cautious correction mode. Our previous experiments prefer recall which is due to the 85:15 split of misspelled vs. correct queries in the dev set. For a more conservative mode that focuses on precision, we updated the dev set by automatically adding "mostly-correct" queries with identity as correction candidate. For this, we extracted the most frequent queries with a high number of search results which can be deemed to be "almost" correct. The dev size increased to roughly 22k queries with an approximate split of 85:15 for "correct" vs. misspelled. This is a more realistic setting if the correction is applied to *all* incoming queries, irrespective of the number of corresponding search results (note also that this mode is different from our initial one where we apply corrections only to queries with low or *null* results). We also found that tuning on Matthews Correlation Coefficient (Matthews, 1975) balances better precision versus recall, especially for unbalanced classes which is the case here (i.e. 85:15 split).

In the last line of Table 6 we added more data extracted over several additional months. The additional data amounts to 60M queries, therefore increasing the total training size to 72M queries. This final setup, as described, improves precision but hurts recall slightly. Overall, the F1 and accuracy measures are still improved which is most likely due to the additional training data.

Finally, we ran a large-scale experiment and extracted the 100k most frequent unique queries (which account for 7.8M queries based on their actual frequencies). Since they represent the most common queries, some of them typed thousands of times by the users, they are deemed to be

DEV [%]	Acc	Prec	Rec	F1
baseline	62.0	66.2	61.0	63.5
+filtered data	65.5	68.8	67.6	68.2
+phrase length 5	67.2	70.0	69.6	69.8
+phrase features	67.3	71.2	68.3	69.8
+artificial noise	67.8	71.4	68.3	69.8
+10-gram LM	68.7	71.9	70.5	71.2
+tune on Acc	68.9	72.1	70.3	71.2
+iterative 2nd run	69.0	72.2	70.5	71.4
+alt. setup (Prec)	69.5	75.4	68.5	71.8

Table 6: Hillclimbing on the dev set.

Query	Category distribution
moto x	50% cell phones, 30% automotive, 5% clothing, ...
tory burch fitbit	75% jewelry, 20% sports, ...
madden 15	65% games, 18% toys, 7% collectibles, ...

Table 7: Item category distributions for queries.

"mostly" correct. We autocorrect the set through our best system which results in changed queries in <0.5% of the cases after manual filtering of non-errors (e.g. segmentation differences that are handled separately by our query expansion system, e.g. *rayban* → *ray ban* which are equivalent in the search backend) and when compared against the original input set. This means that most of the queries are left unchanged and that the decoding process of the SMT system does a good job in classifying whether a correction is needed or not. Manual inspection of the most frequent differences shows that changes actually happen on frequently misspelled words which are part of those top 100k queries, e.g. *micheal* → *michael*, *infared* → *infrared*, or *accesories* → *accessories*.

5.2 Search evaluation

An interesting way to evaluate the performance of the autocorrection system is to look at it from a search perspective. If the goal is to improve user experience in search and retrieve more relevant results, we need to compare the search result sets in terms of quantity and quality. For quantity we are mainly interested in how many queries lead to 0 search results before and after autocorrection. Table 8 shows these numbers for our test set. We improve the rate of *null* results by 51.8% absolute. In a deeper analysis we see that out of the 81.6% in the source set we improve the query behavior for 63.8% queries after autocorrection while we only decrease from non-*null* to *null* for 1.6%. A manual inspection of the 1.6% shows that those queries already led to very low search results (<10) even for the source.

TEST [%]	*null* results	KL div. < 1
misspelled	81.6	40.9
gold corrections	27.1	100.0
online A	36.5	84.4
online B	36.0	82.1
online C	33.0	76.4
MT (this work)	**29.8**	**86.0**

Table 8: Search results evaluation on the test set. For *null* results, lower rates are better. For KL div. evaluation, higher rates are better, as they indicate a closer match with the category distribution from the gold corrections.

For quality, we compare the search result sets for the autocorrected queries with those of the reference and get an estimate of how similar each autocorrected query behaves to the expected behavior given by its gold correction. In particular, we extract the categories from all items which are returned as part of the search API calls (see Table 7). We use Kullback-Leibler divergence (Kullback and Leibler, 1951) to compute the difference between the category distributions. The KL divergence defines the information lost when using one distribution to approximate another:

$$D(P||Q) = \sum_i P(i) \cdot \ln\left(\frac{P(i)}{Q(i)}\right)$$

In our case, we use the category distribution of the results of the reference query as the observed data P which we want to model with the category distribution Q from the results of the autocorrected query. This gives us a more realistic evaluation of the method, as it is more relevant to the retrieval problem that autocorrection is trying to address. The queries *perfumes for women* and *perfume for women*, e.g., retrieve similar amounts and types of items although their strings are different (note the plural *s* in the first one) which is penalized when computing accuracy on string level.

In order to deal with zero-probability events, we smooth both distributions such that they contain exactly the same categories. For this we add categories that are present in one distribution but not

Misspelled query	Correction
adidda whatch blooto	adidas watch bluetooth
awrppstale buttin shirt	aeropostale button shirt
bangen olafsn headset	bang olufsen headset
camra exesers	camera accessory
crystal and righston cuf ring	crystal and rhinestone cuff ring
fauxfurmidcalfwesternboots	faux fur mid calf western boots
fotbool chus	football shoes
otherbooxiphon5	otterbox iphone 5
womens realhairsaltandpeper	womens real hair salt and pepper

Table 9: Examples of misspelled user search queries that the presented system is able to correct.

the other with a very small probability which we subtract from the highest probability in the distribution so that all probabilities still sum up to 1. In the case of getting 0 search results for either the autocorrected or reference query we cannot compute the KL divergence and we simply mark those cases with a high number. If both queries return 0 search results we return a distance of 0. Note that with this we do not penalize queries that are misspelled and should have been corrected even if they still retrieve 0 items in search after correction. However, in this test we are only interested in the search results we get and not in the correction itself.

Table 8 shows that the presented method is closest in terms of KL divergence to category distributions of search results based on the gold references. Even though this is a nice and easy way to indicate quality of search results, we do not claim this method to be an in-depth analysis of relevance of search results and leave this for future work.

5.3 Examples

The examples in Table 9 demonstrate the abilities of the presented spelling correction framework. We are able to handle extremely misspelled queries, e.g. due to phonetic spelling by possibly non-native speakers (*camra* → *camera*, *chus* → *shoes*), words being glued together due to missing whitespace (*fauxfurmid...* → *faux fur mid...*), or brand name confusions (*righston* → *rhinestone*).

6 Conclusion

In this paper, we presented a powerful spelling correction system for the e-commerce domain using statistical phrase-based machine translation based on character bigram sequences. We extracted training data from event logs where users issue similar search queries within a certain period of time. Filtering through various heuristics is used to clean the initially noisy data set and remove entries not related to spelling errors. We evaluated our system against established online search sites, both in the general and e-commerce domain, and showed favorable results in terms of recall and retrieval rates.

We plan to further invest in improving precision. For this, we feel that adding full word-level models will help to overcome the somewhat limited context present in our character sequence-based models. We also plan to investigate the prototype directly in query expansion as part of the search backend.

Acknowledgments

The authors would like to thank the Localization team at eBay for creating gold corrections for the evaluation sets, and members of the HLT and Search teams for fruitful discussions as well as reading early drafts of this work and giving valuable feedback.

Abstract

The paper presents the results of the first large-scale human evaluation of automatic grammatical error correction (GEC) systems. Twelve participating systems and the unchanged input of the CoNLL-2014 shared task have been reassessed in a WMT-inspired human evaluation procedure. Methods introduced for the Workshop of Machine Translation evaluation campaigns have been adapted to GEC and extended where necessary. The produced rankings are used to evaluate standard metrics for grammatical error correction in terms of correlation with human judgment.

1 Introduction

The field of automatic grammatical error correction (GEC) has seen a number of shared tasks of different scope and for different languages. The most impactful were the CoNLL-2013 and CoNLL-2014 (Ng et al., 2013; Ng et al., 2014) shared tasks on Grammatical Error Correction for ESL (English as a second language) learners. They were preceded by the HOO shared tasks (Dale and Kilgarriff, 2011; Dale et al., 2012). Shared tasks for other languages took place as well, including the QALB workshops for Arabic (Mohit et al., 2014) and NLP-TEA competitions for Chinese. These tasks use automatic metrics to determine the quality of the participating systems.

However, these efforts pale in comparison to competitions organized in other fields, e.g. during the annual Workshops for Machine Translation (WMT). It is a central idea of the WMTs that automatic measures of machine translation quality are an imperfect substitute for human assessments. Therefore, manual evaluation of the system outputs are conducted and their results are reported as the final rankings of the workshops. These human evaluation campaigns are an important driving factor for the advancement of MT and produce insightful "by-products", such as a huge number of human assessments of machine translation outputs that have been used to evaluate automatic metrics.

We believe that the unavailability of this kind of quality assessment may stall the development of GEC, as all the shared tasks and the entire field have to cope with an inherent uncertainty of their methods and metrics. We hope to make a step towards alleviating this lack of confidence by presenting the results of the first[1] large-scale human evaluation of automatic grammatical error correction systems submitted to the CoNLL-2014 shared task. Most of our inspiration is drawn from the recent WMT edition (Bojar et al., 2014) and its metrics task (Macháček and Bojar, 2014).

We also provide an analysis of correlation between the standard metrics in GEC and human judgment and show that the commonly used parameters for standard metrics in the shared task may not be optimal. The uncertainty about metrics quality leads to proposals of new metrics, with Felice and Briscoe (2015) being a recent example. Based on human judgments we can show that this proposed metric maybe less useful than hoped.

2 Evaluation of GEC systems

Madnani et al. (2011) addresses two problems of GEC evaluation: 1) a lack of informative metrics and 2) an inability to directly compare the performance of systems developed by different researchers. Two evaluation methodologies are presented, both based on crowdsourcing which are used to grade types of errors rather than system performance as presented in this work. Chodorow et al. (2012) draw attention to the many evalua-

[1]During the camera-ready preparation phase, we learned about similar research by Napoles et al. (2015). After contacting the authors, it was agreed to treat both works as fully concurrent. Future work will compare the results.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 461–470,
Lisbon, Portugal, 17-21 September 2015.

tion issues in error detection which make it hard to compare different approaches. The lack of consensus is due to the nature of the error detection task. The authors argue that the choice of the metric should take into account factors such as the skew of the data and the application that the system is used for.

The most recent addition is Felice and Briscoe (2015) who present a novel evaluation method for grammatical error correction that scores systems in terms of improvement on the original text.

3 The CoNLL-2014 shared task

The goal of the CoNLL-2014 shared task (Ng et al., 2014) was to evaluate algorithms and systems for automatically correcting grammatical errors in English essays written by second language learners of English. Training and test data was annotated with 28 error types. Participating teams were given training data with manually annotated corrections of grammatical errors and were allowed to use publicly available resources for training.

Twenty-five student non-native speakers of English were recruited to write essays to be used as test data. Each student wrote two essays. The 50 test essays were error-annotated by two English native speakers. The essays and error annotations were made available after the task. The MaxMatch (M^2) scorer (Dahlmeier and Ng, 2012) has been used as the official shared task evaluation metric.

4 Data collection

4.1 Sampling sentences for evaluation

The system outputs of the CoNLL-2014 shared task serve as evaluation data. The test set consists of 1312 sentences, there are twelve system outputs available. The thirteenth participant NARA is missing from this set. However, in GEC evaluation there is also the input to consider. Often system outputs are equal to the unmodified input, as it is most desirable if there are in fact no errors. We include INPUT as the thirteenth system.

Due to the small number of modifications that GEC systems apply to the input, there is not only a large overlap with the input, but also among all systems (Figure 1). If we sample systems uniformly, we lose easily obtainable pairwise judgments for systems with the same output, and if we collapse before sampling we introduce a strong bias towards ties. To counter that bias, we abandon uniform sampling of test set sentences and use

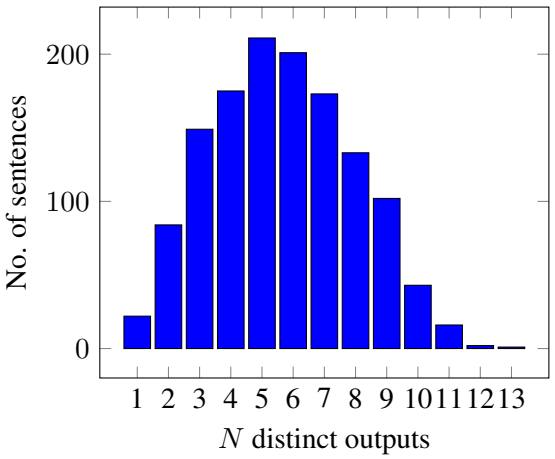

Figure 1: Frequencies of distinct corrected sentences produced by 13 systems per input sentence.

instead a parametrized distribution that favors diverse sets of outputs.

The probability p_i for a set of outputs O_i is calculated as follows: N is the number of systems to be evaluated, M is the maximum number of sentences presented to the evaluator in a single ranking (we use $M = 5$). The set of system outputs to be evaluated $E = \{O_1, \ldots, O_n\} \quad \forall_{1 \leq i \leq n} |O_i| = N$, consists of n $(= 1312)$ sets O_i of N output sentences each. Every sentence in O_i can overlap with other sentences multiple times, so for each set O_i we define the corresponding multiset of multiplicities U_i, such that $\sum_{u \in U_i} u = N$.

We define $c_i(j)$ as the number of possible ways to choose at most M different sentences that cover j systems for the i-th set of outputs:

$$c_i(j) = \left| \left\{ S \subseteq U_i : |S| \leq M \wedge \sum_{u \in S} u = j \right\} \right|.$$

Then the expected number C_i of systems covered by choosing at most M sentences is
