$$w_{i,j} = \frac{\phi_1 \overline{\text{ro}}_{i,j} + \phi_2 \overline{\text{fu}}_{i,j} + \phi_3 \overline{\text{cc}}_{i,j} + \phi_4 \overline{\text{at}}_{i,j}}{\sum \phi_n} \tag{5}$$

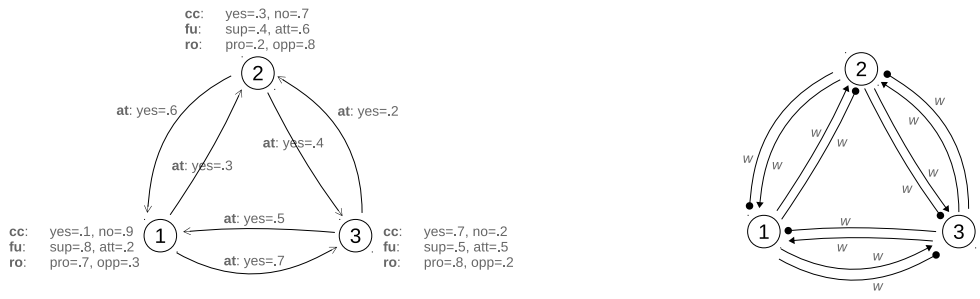

Figure 2: An example evidence graph before (left) and after (right) the predicted probabilities of the different levels have been combined in a single edge score.

In our implementation, the combined evidence graphs can be constructed without a weighting, and then be instantiated with a specific weighting to yield the combined edge scores $w_{i,j}$.

Procedure: As before, we first tune the hyperparameters in the inner CV, train the model on the whole training data and predict probabilities on all items of the test set. Also, we predict all items in the training data "as unseen" in a second inner CV using the best hyperparameters. This procedure is executed for every level. Using the predictions of all four levels, we then build the evidence graphs for training and test set.

Finding the right weighting: We evaluate two versions of the evidence graph model. The first version (**EG equal**) gives equal weight to each level-specific edge score. The second version (**EG best**) optimizes the weighting of the base classifiers with a simple evolutionary search on all evidence graphs of the training set, i.e. it searches for a weighting that maximizes the average level evaluation score of the decoded argumentation structures in the training set. Finally, all evidence graphs of the test set are instantiated with the selected weighting (the equal one or the optimized one) and evaluated.

5.6 Comparison: MST parser

Finally, we compare our models to the well-known mstparser[4], which was also used in the discourse parsing experiments of Baldridge et al. (2007). The mstparser applies 1-best MIRA structured learning, a learning regime that we expect to be superior over the simple training in the previous models. In all experiments in this paper, we use 10 iterations for training, the non-projective 1-best MST decoding, and no second order features. The base mstparser model (**MP**) evaluated here uses the same features as above, as well as its own features extracted from the dependency structure. Second, we evaluate a pre-classification scenario (**MP+p**), where the predictions of the base classifiers trained in the above models for central claim, role and function are added as additional features. We expect this to improve the central claim identification as well as the edge labeling.

For the full task involving all levels, we combine the mstparser with an external edge labeler, as the internal edge labeler is reported to be weak. In this setting (**MP+r**), we replace the edge labels predicted by the mstparser with the predictions of the base classifier for argumentative function. Furthermore, the combination of pre-classification, mstparser and external relation labeler (**MP+p+r**) is evaluated. Finally, we evaluate a scenario (**MPϵ+p+r**) where the mstparser has access only to its own features and to those of the pre-classification, but not to the features described in Section 5.3, and the external relation labeller is used. In this scenario, the mstparser exclusively serves as a meta-model on the base classifier's predictions.

6 Results

All results are reported as average and standard deviation over the 50 folds resulting from 10 iterations of (the outer) 5-fold cross validation. We use the following metrics: macro averaged F1, F1 for positive attachment, and Cohen's Kappa κ. For significance testing, we apply the Wilcoxon signed-rank test on the macro averaged F1 scores and assume a significance level of α=0.01.

6.1 Attachment task

Table 1 shows the results in the attachment task. The rule-based baseline scores are equal for both

Table 2: Number and percentage of valid trees for the "simple" attachment model

languages, since they rely only on the annotated structure of the parallel corpus. Here, attach-to-first is the lower bound, attach-to-preceding is a more competitive baseline, as we had hypothesized in section 5.2.

The learned classifier (simple) beats both baselines in both languages, although the improvement is much smaller for English than for German. In general, the classifier lacks precision compared to recall: It predicts too many edges. As a result, the graph constructed from the predicted edges for one text very often does not form a tree. In Table 2, we give a summary of how often tree constraints are fulfilled, showing that without decoding, valid trees can only be predicted for 15.4% of the texts in German and for 10.7% of the texts in English. The most frequently violated constraint is "out degree", stating that every node in the graph should have at most one outgoing edge. Note that all other models, the baselines as well as the MST decoding models, are guaranteed to predict tree structures.

The simple+MST model yields slightly lower F1-scores for positive attachment than without decoding, trading off a loss of 10 points in recall of the over-optimistic base classifier against a gain of 5 in precision. However, the output graphs are constrained to be trees now, which is rewarded by a slight increase in the summarizing metrics macro F1 and κ.

The evidence graph models (EG equal & EG best) clearly outperform the simple and simple+MST model, indicating that the attachment classification can benefit from jointly predicting the four different levels. Note, that the EG model with equal weighting scores slightly better than the one with optimized weighting for German but not for English. However, this difference is not significant ($p>0.5$) for both languages, which indicates that the search for an optimal weighting is not necessary for the attachment task.

The overall best result is achieved by the mstparser model. We attribute this to the superior structured learning regime. The improvement of MP over EP equal and best is significant in both languages ($p<0.008$). Using pre-classification further improves the results, although difference is neither significant for German ($p=0.4$) nor for English ($p=0.016$).

6.2 Full task

Until now, we only focused on the attachment task. In this subsection we will present results on the impact of joint prediction for all levels.

The results in Table 3 show significant improvements of the EG models over the base-classifiers on the central claim, the function and the attachment levels ($p<0.0001$). This demonstrates the positive impact of jointly predicting all levels. The EG models achieve the best scores in central claim identification and function classification, and the second best result in role identification. The differences between EG equal and EG best are not significant on any level, which again indicates that

Table 3: Results for the full task: for German (above) and English (below), best values highlighted.

we can dispense with the extra step of optimizing the weighting and use the simple equal weighting. These result are consistent across both languages.

The pure labeled mstparser model (MP) performs worse than the base classifiers on all levels except for the attachment task. Adding pre-classification yields significant improvements on all levels but role identification. Using the external relation labeler drastically improves function classification and indirectly also role identification. The combined model (MP+p+r) yields best results for all mstparser models, but is still significantly outperformed by EG equal in all tasks except attachment classification. There, the mstparser models achieve best results, the improvement of MP+p+r over EG equal is significant for English ($p<0.0001$) and for German ($p=0.001$). Interestingly, the meta-model (MPϵ+p+r) which has access to its own features and to those of the pre-classification, but not to the features described in Section 5.3, performs nearly as good as or equal to the combined model (MP+p+r).

The only level not benefiting from any MST model in comparison with the base classifier is the role classification: In the final MST, the role of each segment is only implicitly represented, and can be determined by following the series of the role-switches of each argumentative function from the segment to the root. The loss of accuracy for predicting the argumentative role is much smaller for German than for English, probably due to the better attachment classification in the first place.

Finally, note that the EG best model gives the highest total score when summed over all levels, followed by EG equal and then MP+p+r.

Projecting further improvements: We have shown that joint prediction of all levels in the evidence graph models helps to improve the classification on single levels. To measure exactly how much a level contributes to the predictions of other levels, we simulate better base classifiers and study their impact. To achieve this, we artificially improved the classification of one target level by overwriting a percentage of its predictions with ground truth. The overwritten predictions where drawn randomly, corresponding to the label distribution of the target level. E.g. for a 20% improvement on the argumentative function level, the predictions of 20% of the true "attack"-items were set to attack and the predictions of 20% of the true "support"-items were set to support, irrespective of whether the classifier already chose the correct label.

The results of the simulations are presented in Figure 3 for English only, due to space constraints. The results for German exhibit the same trends. The figure plots the κ-score on the y-axis against the percentage of improvement on the x-axis. Artificially improved levels are drawn as a dashed line. As the first plot shows, function classifica-

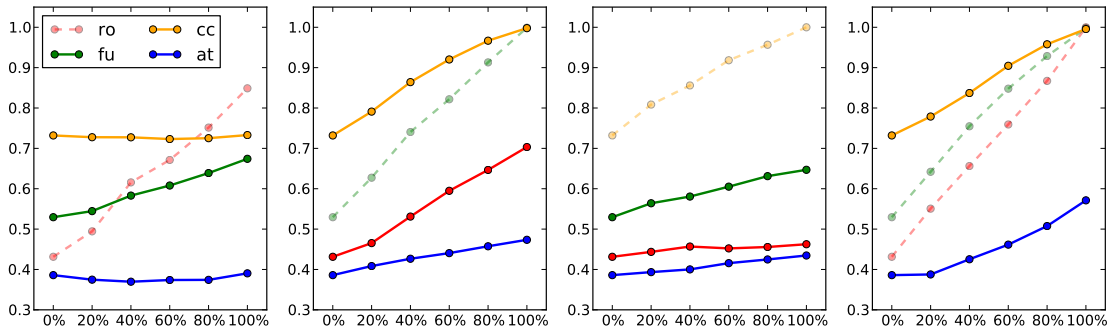

Figure 3: Simulations of the effect of better base classifiers in the EG equal model for English: dashed levels artificially improved, x = number of predictions overwritten with ground truth; y = average κ score in 10 iterations of 5fold CV.

tion is greatly improved by a better role classification (due to the logical connection between them), whereas the other levels are unaffected. In contrast, all levels would benefit from a better function classification, most importantly even the attachment classification. Potential improvements in the central claim identification mostly affect function classification (as these classification tasks partly overlap: central claims will not be assigned a function they cannot have). Finally, a combined improvement on the logically coupled task of role and function identification, would even more help the attachment classification. It might thus be useful to work on a better joint role and function classifier in near future.

Evidence combination: As pointed out by one reviewer, combining the evidence in an edge score as a weighted sum, see (5), instead of a product of probabilities might be inadequate and could result in a model that optimizes the highest scored but not the most probable structure. We compared the EG equal against an EG model with a product of probability. The model scores are nearly identical and do not show a significant difference.

7 Summary and Outlook

We introduced a new approach to argumentation mining that we applied to a parallel German/English corpus of 112 short texts. For the purposes of automatic mining, the original more fine-grained annotation in the corpus was reduced to a slightly simplified scheme consisting of support and attack relations among argumentative discourse units. We did not address the segmentation step here but focused on structure prediction, which we broke into a number of subtasks. Our new *evidence graph* model jointly predicts different aspects of the structure by combining the different subtask predictions in the edge weights of an evidence graph; we then apply a standard MST decoding algorithm. This model not only outperforms two reasonable baselines and two simple models for the difficult subtask of attachment/relation identification, but also improves the results for central claim identification and relation classification, and it compares favorably to a 3-pass mstparser pipeline.

To the best of our knowledge, this is the first data-driven model of argumentation structure that optimizes argumentation structure globally for the complete sequence of input segments. Furthermore, it is the first model jointly tackling segment type classification, relation identification and relation type classification.

Although a direct comparison with results from related work on other corpora is not possible, we can draw indirect comparisons. The first learned model without decoding (simple) is similar to the one presented by Stab and Gurevych (2014). Since it is outperformed by our joint MST decoding model on our data, we assume similar gains could be accomplished on their student essay dataset.

Our next step is to apply the method to other corpora and to more complex text, where the identification of non-participating segments (which are irrelevant for the argumentation) needs to be accounted for. Furthermore, we plan to investigate structured models that not only jointly predict but jointly learn the different aspects of the argumentation graph.

Acknowledgments

We are grateful to the anonymous reviewers for their thoughtful comments. We want to thank Željko Agić, Stergos Afantenos and Christoph Teichmann for fruitful discussions and Wladimir Sidorenko for feedback on an earlier version of the paper. Abstract

Monolingual alignment is the task of pairing semantically similar units from two pieces of text. We report a top-performing supervised aligner that operates on short text snippets. We employ a large feature set to (1) encode similarities among semantic units (words and named entities) in context, and (2) address cooperation and competition for alignment among units in the same snippet. These features are deployed in a two-stage logistic regression framework for alignment. On two benchmark data sets, our aligner achieves F_1 scores of 92.1% and 88.5%, with statistically significant error reductions of 4.8% and 7.3% over the previous best aligner. It produces top results in extrinsic evaluation as well.

1 Introduction

Computer applications frequently require semantic comparison between short snippets of natural language text. Such comparisons are key to paraphrase detection (Das and Smith, 2009; Madnani et al., 2012), textual similarity identification (Agirre et al., 2015; Sultan et al., 2015) and recognition of textual entailment (Dagan and Glickman, 2004; Padó et al., 2015). And they underpin applications such as short answer grading (Mohler et al., 2011), question answering (Hixon et al., 2015), machine translation evaluation (Padó et al., 2009), and machine reading (de Marneffe et al., 2007).

A central problem underlying all text comparison tasks is that of *alignment*: pairing related semantic units (i.e. words and phrases) across the two snippets (MacCartney et al., 2008; Thadani and McKeown, 2011; Thadani et al., 2012; Yao et al., 2013a; Yao et al., 2013b; Sultan et al., 2014a). Studies have shown that such tasks can benefit from an explicit alignment component (Hickl and Bensley, 2007; Sultan et al., 2014b; Sultan et al., 2015). However, alignment is still an open research problem. We present a supervised monolingual aligner that produces top results in several intrinsic and extrinsic evaluation experiments. We pinpoint a set of key challenges for alignment and design a model with components targeted at each.

Lexical and phrasal alignments can both be represented as pairs of words – in the form of many-to-many mappings among the two phrases' component words in the latter case. Thus without loss of generality, we formulate alignment as a binary classification task where given all word pairs across two sentences, the goal is to assign each a class label in {*aligned*, *not aligned*}. However, this is not a straightforward classification scenario where each word pair can be treated independently – words in the same snippet can play both mutually cooperating and competing roles in complex ways. For example, semantically similar words in a snippet can be in competition for alignment with a word in the other snippet, whereas words that constitute a phrase can provide supporting evidence for one another (e.g. in named entity alignments such as `Watson` ↔ `John Hamish Watson`). To handle such interdependencies, we employ a two-stage logistic regression model – stage 1 computes an alignment probability for each word pair based solely on its own feature values, and stage 2 assigns the eventual alignment labels to all pairs following a comparative assessment of stage 1 probabilities of cooperating and competing pairs.

On two alignment data sets reported in (Brockett, 2007) and (Thadani et al., 2012), our aligner demonstrates respective F_1 scores of 92.1% and 88.5%, with statistically significant error reductions of 4.8% and 7.3% over the previous best aligner (Sultan et al., 2014a). We also present extrinsic evaluation of the aligner within two text comparison tasks, namely sentence similarity identification and paraphrase detection, where it demonstrates state-of-the-art results.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 949–959,
Lisbon, Portugal, 17-21 September 2015.

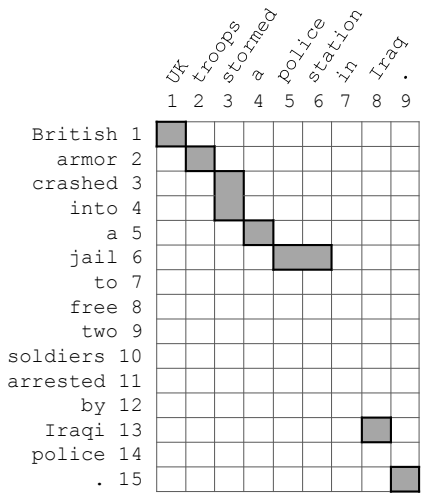

Figure 1: A human-aligned sentence pair from the MSR alignment corpus. The shaded cells depict the alignment, which can also be represented as the set of word index pairs $\{(1,1),(2,2),(3,3),(4,3),(5,4),\ldots,(15,9)\}$.

2 Alignment: Key Pieces of the Puzzle

We illustrate with examples key pieces of the alignment puzzle and discuss techniques used by existing aligners to solve them. We use the term 'unit' to refer to both words and phrases in a snippet.

Figure 1 shows a shortened version of sentence pair 712 in the MSR alignment corpus *dev* set (Brockett, 2007) with related units aligned by human annotators. Evident from these alignments is the fact that aligned units are typically semantically similar or related. Existing aligners utilize a variety of resources and techniques for computing similarity between units: WordNet (MacCartney et al., 2008; Thadani and McKeown, 2011), PPDB (Yao et al., 2013b; Sultan et al., 2014a), distributional similarity measures (MacCartney et al., 2008; Yao et al., 2013b) and string similarity measures (MacCartney et al., 2008; Yao et al., 2013a). Recent work on neural word embeddings (Mikolov et al., 2013; Baroni et al., 2014) have advanced the state of distributional similarity, but remain largely unexplored in the context of alignment.

Lexical or phrasal similarity does not entail alignment, however. Consider function words: the alignment $(5,4)$ in Figure 1 exists not just because both units are the word `a`, but also because they modify semantically equivalent units: `jail` and `police station`. The influence of context on content word alignment becomes salient particularly in the presence of competing words. In Figure 1, `(soldiers(10), troops(2))` are not aligned despite the two words' semantic equivalence *in isolation*, due to the presence of a competing pair, `(armor(2), troops(2))`, which is a better fit *in context*.

The above examples reveal a second aligner requirement: the ability to incorporate context into similarity calculations. Existing supervised aligners use various contextual features within a learning algorithm for this purpose. Such features include both shallow surface measures (e.g., the relative positions of the tokens being aligned in the respective sentences, similarities in the immediate left or right words) (MacCartney et al., 2008; Thadani and McKeown, 2011; Yao et al., 2013a) and syntactic measures like typed dependencies (Thadani and McKeown, 2011; Thadani et al., 2012). Sultan et al. (2014a) design an unsupervised model that more directly encodes context, via surface and dependency-based neighbors which allow contextual similarity to be represented as a weighted sum of lexical similarity. But their model lacks a key structural advantage of supervised models: to be able to use an arbitrarily large feature set to robustly encode lexical and/or contextual similarity.

The third and final key component of an aligner is a mechanism to combine lexical/phrasal and contextual similarities to produce alignments. This task is non-trivial due to the presence of cooperating and competing units. We first discuss competing units: semantically similar units in one snippet, each of which is a potential candidate for alignment with one or more units in the other snippet. At least three different possible scenarios of varying difficulty exist concerning such units:

- Scenario 1: No competing units. In Figure 1, the aligned pair `(British(1), UK(1))` represents this scenario.
- Scenario 2: Many-to-one competition: when multiple units in one snippet are similar to a single unit in the other snippet. In Figure 1, pairs `(armors(2), troops(2))` and `(soldiers(10), troops(2))` are in such competition.
- Scenario 3: Many-to-many competition: when similar units in one snippet have multiple potential alignments in the other snippet.

Groups of mutually cooperating units can also exist where one unit provides supporting evidence

for the alignment of other units in the group. Examples (besides named entities) include individual words in one snippet that are grouped together in the other snippet (e.g., `state of the art` ↔ `state-of-the-art` or `headquarters in Paris` ↔ `Paris-based`).

We briefly discuss the working principles of existing aligners to show how they respsond to these challenges. MacCartney et al. (2008), Thadani and McKeown (2011) and Thadani et al. (2012) frame alignment as a set of phrase edit (insertion, deletion and substitution) operations that transform one snippet into the other. Each edit operation is scored as a weighted sum of feature values (including lexical and contextual similarity features), and an optimal set of edits is computed. Yao et al. (2013a; 2013b) take a sequence labeling approach: input snippets are considered sequences of units and for each unit in one snippet, units in the other snippet are considered potential labels. A first order conditional random field is used for prediction. Sultan et al. (2014a) treat alignment as a bipartite matching problem and use a greedy algorithm to perform one-to-one word alignment. A weighted sum of two words' lexical and contextual similarities serves as the pair's edge weight.

Noticeable in the designs of the supervised aligners is a lack of attention to the scenarios competing units can pose – alignment of a unit depends only on its own feature values. While the unsupervised aligner by Sultan et al. (2014a) employs techniques to deal with such scenarios, it allows only one-to-one alignment, which fundamentally limits the set of reachable alignments.

3 Approach

We primarily focus on word alignment, which Yao et al. (2013b) report to cover more than 95% of all alignments in multiple human-annotated corpora. Named entities are the only phrasal units we consider for alignment; in a later section we discuss how our techniques can be extended to general phrasal alignment.

Figure 2 shows our two-stage logistic regression model. We address the first two challenges, namely identifying lexical and contextual similarities, in stage 1 of the model. Given input text snippets $\boldsymbol{T}^{(1)} = (T_1^{(1)}, ..., T_n^{(1)})$ and $\boldsymbol{T}^{(2)} = (T_1^{(2)}, ..., T_m^{(2)})$ where $T_k^{(t)}$ is the k-th word of snippet $\boldsymbol{T}^{(t)}$, the goal of this stage is to assign each word pair of the form $(T_i^{(1)}, T_j^{(2)})$ an alignment

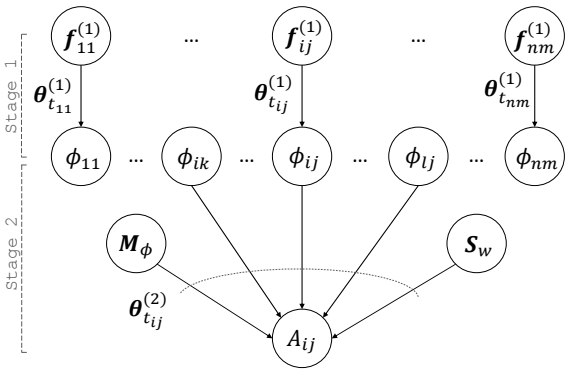

Figure 2: Two-stage logistic regression for alignment. Stage 1 computes an alignment probability ϕ_{ij} for each word pair based on local features $\boldsymbol{f}_{ij}^{(1)}$ and learned weights $\boldsymbol{\theta}_{t_{ij}}^{(1)}$ (see Section 4.1). Stage 2 assigns each pair a label $A_{ij} \in \{$*aligned*, *not aligned*$\}$ based on its own ϕ, the ϕ of its cooperating and competing pairs, a max-weighted bipartite matching $\boldsymbol{M}_\phi$ with all ϕ values as edge weights, the semantic similarities $\boldsymbol{S}_w$ of the pair's words and words in all cooperating pairs, and learned weights $\boldsymbol{\theta}_{t_{ij}}^{(2)}$ for these global features.

probability ϕ_{ij}, based on the pair's lexical and contextual similarity features. We discuss our stage 1 features in Section 4.1.

We categorize each word along two different dimensions: (1) whether or not it is part of a named entity, and (2) which of the following groups it belongs to: content words, function words, and punctuation marks. This distinction is important because, (1) certain features apply only to certain types of words (e.g., acronymy applies only to named entities; punctuation marks do not participate in dependency relationships), and (2) certain features can be more important for certain types of words (e.g., the role of a function word depends heavily on its surrounding words and therefore contextual features can be more important for function words). Combined, the two above dimensions form a domain of six possible values which can be represented as the Cartesian product $\{$*non-named entity*, *named entity*$\} \times \{$*content word*, *function word*, *punctuation mark*$\}$. Each member of this set is a *word type* in our model; for instance, *named entity function word* is a word type.

This notion of types is then extended to word pairs in $\boldsymbol{T}^{(1)} \times \boldsymbol{T}^{(2)}$: the type of pair $(T_i^{(1)}, T_j^{(2)})$ is the union of the types of $T_i^{(1)}$ and $T_j^{(2)}$. Given

the pair's stage 1 feature vector $\boldsymbol{f}_{ij}^{(1)}$ and the stage 1 weight vector $\boldsymbol{\theta}_{t_{ij}}^{(1)}$ for its type t_{ij}, we compute its stage 1 alignment probability ϕ_{ij} as:

$$\phi_{ij} = \frac{1}{1 + e^{-\boldsymbol{\theta}_{t_{ij}}^{(1)} \cdot \boldsymbol{f}_{ij}^{(1)}}}$$

The weight vector $\boldsymbol{\theta}_t^{(1)}$ for word pair type t is derived by minimizing the L1-regularized loss:

$$J(\boldsymbol{\theta}_t^{(1)}) = -\frac{1}{N_t} \sum_{p=1}^{N_t} \Big[y_t^{(p)} \log(\phi_t^{(p)}) + (1 - y_t^{(p)}) \log(1 - \phi_t^{(p)}) \Big] + \lambda \|\boldsymbol{\theta}_t^{(1)}\|_1$$

where N_t is the number of word pairs of type t over all sentence pairs in the training data, $y_t^{(p)}$ is the gold label for pair p of type t ($1 =$ *aligned*, $0 =$ *not aligned*), and $\phi_t^{(p)}$ is its stage 1 alignment probability.

Stage 2 of the model assigns the final alignment label $A_{ij} \in \{0, 1\}$ to $(T_i^{(1)}, T_j^{(2)})$. Like stage 1, it uses L1-regularized logistic regression to compute an alignment probability for each word pair, but additionally assigns a final $0/1$ label using a 0.5 threshold. Stage 2 factors in the stage 1 probabilities of cooperating and competing pairs as well as a maximum-weighted matching $\boldsymbol{M}_\phi$ between $\boldsymbol{T}^{(1)}$ and $\boldsymbol{T}^{(2)}$, where word pairs in $\boldsymbol{T}^{(1)} \times \boldsymbol{T}^{(2)}$ are weighted by their stage 1 ϕ values. Such global knowledge is useful in addressing cooperation and competition among words. We describe our stage 2 features in Section 4.2.

The two stages are trained separately, each as *n* standard logistic regression models where *n* is the number of word pair types for which at least one instance per class is observed in the training data. The stage 1 models are first trained and used to make predictions for each training sentence pair (for each training pair, all other training pairs are used to train the model). Given all the stage 1 alignment probabilities and the other stage 2 features, the stage 2 models are then trained. At test time, the two sets of trained models (i.e. stage 1 and 2 models) are successively applied to each input sentence pair.

4 Features

As mentioned above, we train a separate model for each individual word pair type. Our feature set is largely the same across word pair types, with some differences. In the two following sections, we discuss these features and indicate the associated word pair types. We assume alignment of the two words $T_i^{(1)} \in \boldsymbol{T}^{(1)}$ and $T_j^{(2)} \in \boldsymbol{T}^{(2)}$.

4.1 Stage 1: Assessing Pairs Individually

4.1.1 Word Similarity Features

Our first feature combines neural word embeddings, used previously for word similarity prediction (Mikolov et al., 2013; Baroni et al., 2014), with a paraphrase database (Ganitkevitch et al., 2013). Our feature is the output of a ridge regression model trained on human annotations of word similarity (Radinsky et al., 2011; Halawi et al., 2012; Bruni et al., 2014) with two features: the cosine similarity between the neural embedding vectors of the two words (using a publicly available set of 400-dimensional word vectors (Baroni et al., 2014)), and the presence/absence of the word pair in the PPDB XXXL database. This regression model produces similarities (sim henceforth) in $[0, 1]$, though we only consider similarities above 0.5 as lower scores are often noisy. To deal with single-letter spelling errors, we consider $T_i^{(1)}$ and $T_j^{(2)}$ to be an exact match if exactly one of the two is correctly spelled and their Levenshtein distance is 1 (words of length ≥ 3 only).

We also use the following semantic and string similarity features: a boolean feature that is 1 iff one of $T_i^{(1)}$ and $T_j^{(2)}$ is hyphenated and the other is identical to a hyphen-delimited part of the first, the same feature for highly similar ($sim \geq 0.9$) words, two features that show what proportion of the characters of one word is covered by the other if the latter is a prefix or a suffix of the former and zero otherwise (length < 3 words are discarded).

For named entities, we (1) consider acronymy as exact match, (2) use membership in two lists of alternative country names and country-nationality pairs (from Wikipedia) as features, and (3) include a feature that encodes whether $T_i^{(1)}$ and $T_j^{(2)}$ belong to the same named entity (determined by one mention containing all words of the other, e.g., `Einstein` and `Albert Einstein`).

4.1.2 Contextual Features

Effective identification of contextual similarity calls for a robust representation of word context in a sentence. Our contextual features are based on two different sentence representations. The word-

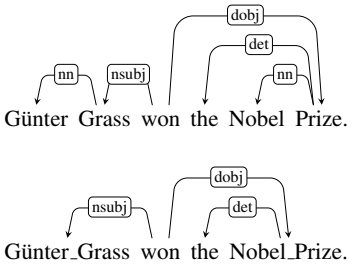

Figure 3: Word and entity-based representations of a sentence. Words in the same named entity are grouped together in the latter representation.

based representation treats each individual word as a semantic unit whereas the entity-based representation (1) groups together words in a multi-word named entity, and (2) treats non-name words as individual entities. Figure 3 shows an example. The two representations are complementary – the entity-based representation can capture equivalences between mentions of different lengths of a named entity, while the word-based representation allows the use of similarity resources for named entity words. Non-name words are treated identically. For simplicity we only discuss our word-based features below, but each feature also has an entity-based variant.

Dependency-based context. These features apply only if neither of $T_i^{(1)}$ and $T_j^{(2)}$ is a punctuation mark. We compute the proportion of identical and highly similar ($sim \geq 0.9$) parents and children of $T_i^{(1)}$ and $T_j^{(2)}$ in the dependency trees of $\boldsymbol{T}^{(1)}$ and $\boldsymbol{T}^{(2)}$ (Stanford collapsed dependencies (de Marneffe et al., 2006)). Equivalent dependency types (Sultan et al., 2014a) are included in the above computation, which encode semantic equivalences between typed dependencies (e.g., *nsubjpass* and *dobj*). We employ separate features for identicality and similarity. Similar features are also computed for a dependency neighborhood of size 2 (parents, grandparents, children and grandchildren), where we consider only content word neighbors.

Dependency neighbors of $T_i^{(1)}$ and $T_j^{(2)}$ that are less similar ($0.9 > sim \geq 0.5$; e.g., (`gas, energy`) or (`award, winner`)) can also contain useful semantic information for an aligner. To accommodate this relatively large range of word similarities, rather than counting such pairs, we find a maximum-weighted bipartite matching of $T_i^{(1)}$ and $T_j^{(2)}$ neighbors in a neighborhood of size 2 using the primal-dual algorithm (content words only), where word similarities across the two neighborhoods serve as edge weights. We use as a feature the sum of similarities between the matched neighbors, normalized by the total number of content words in the two neighborhoods.

Surface-form context. We draw several contextual features from nearby words of $T_i^{(1)}$ and $T_j^{(2)}$ in the surface forms of $\boldsymbol{T}^{(1)}$ and $\boldsymbol{T}^{(2)}$: (1) whether the left and/or the right word/lemma is identical , (2) whether the two are highly similar ($sim \geq 0.9$), (3) the longest common word/lemma sequence containing $T_i^{(1)}$ and $T_j^{(2)}$ such that at least one word in the sequence is a content word, (4) proportion of identical and highly similar ($sim \geq 0.9$) words in a neighborhood of 3 content words to the left and 3 content words to the right; we use two versions of this feature, one compares neighbors only in the same direction (i.e. left with left, right with right) and the other compares neighbors across the two directions, (5) similarly to dependency-based context, similarity in a max-weighted matching of all neighbors with $sim \in [0.5, 0.9)$ in the above $[-3, 3]$ window. For punctuation mark pairs, we use an additional feature indicating whether or not they both mark the end of their respective sentences.

4.2 Stage 2: Cooperation and Competition

We consider two groups of mutually cooperating words in a sentence: (1) words that belong to the same named entity, and (2) words in a sentence that are joined together to form a larger word in the other sentence (e.g., `state-of-the-art`). Speaking in terms of $T_i^{(1)}$, the goal is to be able to use any evidence present for a $(T_k^{(1)}, T_j^{(2)})$ alignment also as evidence for a $(T_i^{(1)}, T_j^{(2)})$ alignment if $T_i^{(1)}$ and $T_k^{(1)}$ both belong to such a group. We call $T_i^{(1)}$ and $T_k^{(1)}$ mutually cooperating words with respect to $T_j^{(2)}$ in such cases. Any word $T_l^{(1)} \in \boldsymbol{T}^{(1)}$ which is not a cooperating word for $T_i^{(1)}$ is a competing word: a word that can potentially make $(T_i^{(1)}, T_j^{(2)})$ a less viable alignment by having a larger stage 1 alignment probability in $(T_l^{(1)}, T_j^{(2)})$. We call a pair $(T_k^{(1)}, T_j^{(2)})$ a cooperating (competing) pair for $(T_i^{(1)}, T_j^{(2)})$ if $T_k^{(1)}$ is a cooperating (competing) word for $T_i^{(1)}$ with respect to $T_j^{(2)}$. With a reversal of word order and appropriate substitution of indexes, the above discussion

equally holds for $T_j^{(2)}$.

Given sets of stage 1 probabilities $\mathbf{\Phi}_{ij}^{cop}$ and $\mathbf{\Phi}_{ij}^{cmp}$ of cooperating and competing pairs for the pair $(T_i^{(1)}, T_j^{(2)})$, we employ three features to deal with scenario 2 of Section 2: (1) $\max(\phi_{ij}, \max(\mathbf{\Phi}_{ij}^{cop}))$: the greater of the pair's own stage 1 alignment probability and the highest among all cooperating pair probabilities, (2) $\max(\mathbf{\Phi}_{ij}^{cmp})$: the highest of all competing pair probabilities, and (3) a binary feature indicating which of the two above is larger.

To address scenario 3, we construct a weighted bipartite graph: nodes represent words in $\boldsymbol{T}^{(1)}$ and $\boldsymbol{T}^{(2)}$ and the weight of each edge represents the stage 1 alignment probability of a word pair in $\boldsymbol{T}^{(1)} \times \boldsymbol{T}^{(2)}$. We find a max-weighted bipartite matching $\boldsymbol{M}_\phi$ of word pairs in this graph. For each word pair, we employ a feature indicating whether or not it is in $\boldsymbol{M}_\phi$. The presence of $(T_i^{(1)}, T_j^{(2)})$ and $(T_k^{(1)}, T_l^{(2)})$ in $\boldsymbol{M}_\phi$, where all four words are similar, is a potential indicator that $(T_i^{(1)}, T_l^{(2)})$ and $(T_k^{(1)}, T_j^{(2)})$ are no longer viable alignments.

Low recall has traditionally been the primary weakness of supervised aligners (as we later show in Table 1). Our observation of the aligner's behavior on the *dev* set of the MSR alignment corpus (Brockett, 2007) suggests that this happens primarily due to highly similar word pairs being left unaligned even in the absence of competing pairs because of relatively low contextual evidence. Consequently, aligner performance suffers in sentences with few common or similar words. To promote high recall, we employ the higher of a word pair's own lexical similarity and the lexical similarity of the cooperating pair with the highest stage 1 probability as a stage 2 feature.

The stage 2 feature set is identical across word pair types, but as in stage 1, we train individual models for different pair types.

5 Experiments

5.1 System Evaluation

We report evaluation on two alignment data sets and extrinsic evaluation on two tasks: sentence similarity identification and paraphrase detection.

5.1.1 Alignment

We adopt the evaluation procedure for aligners reported in prior work (MacCartney et al., 2008; Thadani and McKeown, 2011; Yao et al., 2013a).

	Aligner	P %	R %	F_1 %	E %
MSR	MacCartney et al. (2008)	85.4	85.3	85.3	21.3
	Thadani & McKeown (2011)	89.5	86.2	87.8	33.0
	Yao et al. (2013a)	93.7	84.0	88.6	35.3
	Yao et al. (2013b)	92.1	82.8	86.8	29.1
	Sultan et al. (2014a)	93.7	**89.8**	91.7	43.8
	Our Aligner	**95.4**	89.0	**92.1**	**47.3**
EDB++	Thadani et al. (2012)	76.6	83.8	79.2	12.2
	Yao et al. (2013a)	91.3	82.0	86.4	15.0
	Yao et al. (2013b)	90.4	81.9	85.9	13.7
	Sultan et al. (2014a)	**93.5**	82.5	87.6	**18.3**
	Our Aligner	92.1	**85.2**	**88.5**	**18.3**

Table 1: Performance on two alignment data sets. Improvements in F_1 are statistically significant.

Data. The MSR alignment corpus (Brockett, 2007) contains 800 *dev* and 800 *test* sentence pairs from the PASCAL RTE 2006 challenge. Each pair is aligned by three human annotators; Fleiss Kappa agreement of about 0.73 ("substantial agreement") is reported on both sets. Following prior work, we only consider the *sure* alignments, take the majority opinion on each word pair, and leave out three-way disagreements.

The Edinburgh++ corpus (Thadani et al., 2012) contains 714 training and 306 test sentence pairs. Each test pair is aligned by two annotators and the final gold alignments consist of a random but even selection of the two sets of annotations.

Evaluation metrics. Our primary evaluation metrics are macro-averaged precision (*P*), recall (*R*) and F_1 score. A fourth metric E measures the proportion of sentence pairs for which the system alignments are identical to the gold alignments.

Model setup. For each corpus, we train our model using the dev set and evaluate on the test set. We use the logistic regression implementation of Scikit-learn (Pedregosa et al., 2011) and use leave-one-out cross-validation on the dev pairs to set the regularization parameter C.

Results. Table 1 shows the performance of different aligners on the two test sets. Our aligner demonstrates the best overall performance in terms of both F_1 and E. Wilcoxon signed-rank tests (with Pratt's treatment for zero-difference pairs) show that the improvements in F_1 over the previous best aligner (Sultan et al., 2014a) are statistically significant at $p < 0.01$ for both test sets.

5.1.2 Identification of Sentence Similarity

Given two input sentences, the goal in this task, known also as Semantic Textual Similarity (STS), is to output a real-valued semantic similarity score.

System	Pearson's r	Rank
Han et al. (2013)	**73.7**	1
Yao et al. (2013a)	46.2	66
Sultan et al. (2014a)	67.2	7
Our Aligner	67.8	4

Table 2: STS results. Performances of past systems are reported by Sultan et al. (2014a).

Data. To be able to directly compare with past aligners, we select three data sets (*headlines*: pairs of news headlines; *OnWN*, *FNWN*: gloss pairs) from the 2013 *SEM STS corpus (Agirre et al., 2013), containing 1500 sentence pairs in total. Sultan et al. (2014a) reports the performance of two state-of-the-art aligners on these pairs.

Evaluation metric. At SemEval, STS systems output a similarity score in $[0, 5]$. For each individual test set, the Pearson product-moment correlation coefficient (Pearson's r) is computed between system scores and human annotations. The final evaluation metric is a weighted sum of r's over all test sets, where the weight assigned to a set is proportional to its number of pairs.

Method. Being a logistic regression model, stage 2 of our aligner assigns each word pair an alignment probability. For STS, we compute a length-normalized sum of alignment probabilities of content word pairs across the two sentences. We include all pairs with probability > 0.5; the remaining pairs are included in decreasing order of their probabilities and already included words are ignored. Following (Sultan et al., 2014a), we normalize by dividing with the harmonic mean of the numbers of content words in the two sentences.

Results. Table 2 shows the performance of different aligners on the three STS 2013 test sets. We also show the performance of the contest-winning system (Han et al., 2013). Our STS system demonstrates a weighted correlation of 67.8%, which is better than similar STS systems based on the two previous best aligners. The difference with the next best aligner is statistically significant at $p < 0.05$ (two-sample one-tailed z-test). Overall, our system outperforms 86 of the 89 participating systems.

5.1.3 Paraphrase Detection

Given two input sentences, the goal in this task is to determine if their meanings are the same.

Data. The MSR paraphrase corpus (Dolan et al., 2004) contains 4076 *dev* and 1725 *test* sentence pairs; a paraphrase label (*true*/*false*) for each pair is provided by human annotators.

System	A %	P %	R %	F_1 %
Madnani et al. (2012)	**77.4**	**79.0**	89.9	**84.1**
Yao et al. (2013a)	70.0	72.6	88.1	79.6
Yao et al. (2013b)	68.1	68.6	**95.8**	79.9
Sultan et al. (2014a)	73.4	76.6	86.4	81.2
Our Aligner	73.2	75.3	88.8	81.5

Table 3: Paraphrase results. Performances of past systems are taken from (Sultan et al., 2014a).

Evaluation Metrics. We report performance in terms of: (1) accuracy in classifying the sentences into *true* and *false* classes (A), and (2) true class precision (P), recall (R) and F_1 score.

Method. Following prior aligners (MacCartney et al., 2008; Yao et al., 2013b; Sultan et al., 2014a), we output a *true* decision for a test sentence pair iff the length-normalized alignment score for the pair exceeds a threshold derived from the dev set.

Results. The top row of Table 3 shows the best result by any system on the MSR test set. Among all aligners (all other rows), ours achieves the best F_1 score and the second best accuracy.

We report paraphrase detection results primarily to allow comparison with past aligners. However, this simplistic application to a complex task only gives a ballpark estimate of an aligner's quality.

	Model	P %	R %	F_1 %	E %
MSR	Two-Stage Model	**95.4**	**89.0**	**92.1**	**47.3**
	Stage 1 Only	92.9	85.6	89.1	28.0
EDB++	Two-Stage Model	92.1	**85.2**	**88.5**	**18.3**
	Stage 1 Only	**93.0**	79.0	85.4	13.7

Table 4: Performance with and without stage 2.

5.2 Ablation

We perform ablation tests to find out how important (1) the two-stage framework, and (2) the different features are for our aligner.

5.2.1 Results without Stage 2

Stage 1 of our aligner can operate as an aligner by itself by mapping each alignment probability to a 0/1 alignment decision based on a threshold of 0.5. From a design perspective, this is an aligner that does not address scenarios 2 and 3 of Section 2.

The performance of the aligner with and without stage 2 is shown in Table 4. On each test set, the F_1 and E scores increase with the addition of stage 2. On the MSR test set, performance improves along all dimensions. On the Edinburgh++ test set, the

Table 6: Results without different stage 2 features.

precision drops a little, but this effect is offset by a larger improvement in recall. These results show that stage 2 is central to the aligner's success.

5.2.2 Without Different Stage 1 Features

We exclude different stage 1 features (which fall into one of two groups: lexical and contextual) and examine the resulting model's performance. Table 5 shows the results. The subtraction sign represents the exclusion of the corresponding feature.

Without any lexical feature (i.e., if the model relies only on contextual features), both precision and recall decrease, resulting in a considerable overall performance drop. Exclusion of word similarity resources (i.e. embeddings and PPDB) improves precision, but again harms overall performance.

Without any contextual features, the model suffers badly in both precision and recall. The extreme overall performance degradation indicates that contextual features are more important for the aligner than lexical features. Leaving out surface-form neighbors results in a larger performance drop than when dependency-based neighbors are excluded, pointing to a more robust role of the former group in representing context. Finally, our entity-based representation of context neither helps nor harms system performance, but relying only on entity-based neighbors has detrimental effects. Factoring in semantic similarities of named entities should improve the utility of these features.

5.2.3 Without Different Stage 2 Features

Table 6 shows the aligner's performance after the exclusion of different stage 2 features. Leaving out the stage 1 alignment probabilities harms overall performance the most by causing a large drop in precision. Exclusion of the maximum-weighted bipartite matching feature results in worse recall and overall performance. The lexical similarity feature improves overall results only on the MSR test set but increases recall on both test sets.

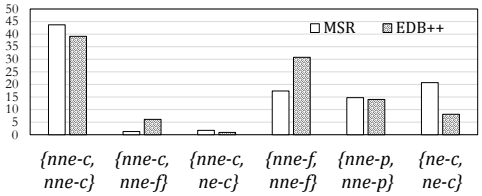

Figure 4: % distribution of aligned word pair types; *nne*: non-named entity, *ne*: named entity, *c*: content word, *f*: function word, *p*: punctuation mark.

	MSR			EDB++		
Pair Type	P %	R %	F_1 %	P %	R %	F_1 %
{*nne-c*, *nne-c*}	95.7	84.3	89.7	92.2	89.2	90.7
{*nne-c*, *nne-f*}	100.0	2.7	5.3	61.4	7.7	13.6
{*nne-c*, *ne-c*}	89.2	66.7	76.3	71.9	43.4	54.1
{*nne-f*, *nne-f*}	90.7	86.0	88.3	93.4	86.5	89.8
{*nne-p*, *nne-p*}	99.4	99.2	99.3	93.0	91.5	92.2
{*ne-c*, *ne-c*}	96.2	97.8	97.0	90.9	94.2	92.6

Table 7: Performance on different word pair types.

5.3 Error Analysis

We examine the aligner's performance on different word pair types. Figure 4 shows the % distribution of word pair types with at least 20 aligned instances in at least one test set. These six types account for more than 99% of all alignments in both test sets.

Table 7 shows the results. We ignore punctuation mark pairs in the following discussion. Performance is worst on the two rarest types: {*nne-c*, *nne-f*} and {*nne-c*, *ne-c*}, due primarily to very low recall. A relatively low availability of positive examples in the training sets (in the hundreds, in contrast to thousands of examples for each of the other three types) is a primary factor affecting classifier performance on these two pair types. The {*nne-c*, *nne-f*} pairs, nonetheless, are intrinsically the most difficult type for a word aligner because they occur frequently as part of phrasal alignments. On {*nne-c*, *ne-c*} pairs, errors also occur due to failure in recognition of certain named entity types (e.g., acronyms and multiword named entities) and the aligner's lack of world knowledge (e.g., in `daughter` ↔ `Chelsea`).

Low recall remains the primary issue, albeit to a much lesser extent, for {*nne-c*, *nne-c*} and {*nne-f*, *nne-f*} pairs. For the former, two major sources of error are: (1) inability to utilize contextual evidence outside the local neighborhood examined by the aligner, and (2) failure to address one-to-many alignments. Low recall for the latter follows naturally, as function word alignment is heavily dependent on related content word alignment. On {*ne-c*, *ne-c*} pairs the aligner performs the best, but still suffers from the two above issues.

6 Related Work

We mentioned major standalone monolingual aligners and briefly discussed their working principles in Section 2. There are, however, at least two additional groups of related work which can inform future research on monolingual alignment. First, alignment is often performed in the context of extrinsic tasks, e.g., textual entailment recognition (Wang and Manning, 2010), question answering (Heilman and Smith, 2010), discourse generation (Roth and Frank, 2012) and redundancy detection (Thadani and McKeown, 2008). Such systems may contain useful design elements yet to be utilized by standalone aligners. Second, a large body of work exists in the bilingual alignment literature (Och and Ney, 2003; Blunsom and Cohn, 2006; Chang et al., 2014), elements of which (such as the machine learning models) can be useful for monolingual aligners (see (Yao et al., 2013a) for an example).

7 Conclusions and Future Work

We present a two-stage classification framework for monolingual alignment that demonstrates top results in intrinsic and extrinsic evaluation experiments. While our work focuses primarily on word alignment, given a mechanism to compute phrasal similarity, the notion of cooperating words can be exploited to extend our model for phrasal alignment. Another important future direction is the construction of a robust representation of context, as our model currently utilizes contextual information only within a local neighborhood of a predefined size and therefore fails to utilize long-distance semantic relationships between words. Incorporating a single background model which is trained on all word pair types might also improve performance, especially on types that are rare in the training data. Finally, studying the explicit requirements of different extrinsic tasks can shed light on the design of a robust aligner.

Abstract

We present a new method for semantic role labeling in which arguments and semantic roles are jointly embedded in a shared vector space for a given predicate. These embeddings belong to a neural network, whose output represents the potential functions of a graphical model designed for the SRL task. We consider both local and structured learning methods and obtain strong results on standard PropBank and FrameNet corpora with a straightforward product-of-experts model. We further show how the model can learn jointly from PropBank and FrameNet annotations to obtain additional improvements on the smaller FrameNet dataset.

1 Introduction

Semantic role labeling (SRL) is the task of identifying the semantic arguments of a predicate and labeling them with their semantic roles. A key challenge in this task is sparsity of labeled data: a given predicate-role instance may only occur a handful of times in the training set. Most existing SRL systems model each semantic role as an atomic unit of meaning, ignoring finer-grained semantic similarity between roles that can be leveraged to share context between similar labels, both within and across annotation conventions.

Low-dimensional embedding representations have been shown to be successful in overcoming sparsity and representing label similarity across a wide range of tasks (Weston et al., 2011; Srikumar and Manning, 2014; Hermann et al., 2014; Lei et al., 2015). In this paper, we present a new model for SRL that embeds candidate arguments and semantic roles (in context of a predicate frame) in a shared vector space. A feed-forward neural network is learned to capture correlations of the respective embedding dimensions to create argument and role representations. The similarity of these two representations, as measured by their dot product, is used to score possible roles for candidate arguments within a graphical model. This graphical model jointly models the assignment of semantic roles to all arguments of a predicate, subject to structural linguistic constraints.

Our model has several advantages. Compared to linear multiclass classifiers used in prior work, vector embeddings of the predictions overcome the assumption of modeling each semantic role as a discrete label, thus capturing fine-grained label similarity. Moreover, since predictions and inputs are embedded in the same vector space, and features extracted from inputs and outputs are decoupled, our approach is amenable to joint learning of multiple annotation conventions, such as PropBank and FrameNet, in a single model. Finally, as with other neural network approaches, our model obviates the need to manually engineer feature conjunctions.

Our underlying inference algorithm for SRL follows Täckström et al. (2015), who presented a dynamic program for structured SRL; it is targeted towards the prediction of full argument spans. Hence, we present empirical results on three span-based SRL datasets: CoNLL 2005 and 2012 data annotated with PropBank conventions, as well as FrameNet 1.5 data. We also evaluate our system on the dependency-based CoNLL 2009 shared task by assuming single word argument spans, that represent semantic dependencies, and limit our experiments to English. On all datasets, our model performs on par with a strong linear model baseline that uses hand-engineered conjunctive features. Due to random parameter initialization and stochasticity in the online learning algorithm used to train our models, we observed considerable variance in performance across datasets. To resolve this variance, we adopt a product-of-experts model that

combines multiple randomly-initialized instances of our model to achieve state-of-the-art results on the CoNLL 2009 and FrameNet datasets, while coming close to the previous best published results on the other two. Finally, we present even stronger results for FrameNet data (which is scarce) by jointly training the model with PropBank-annotated data.

2 Background

In this section, we briefly describe the SRL task and discuss relevant prior work.

2.1 Semantic Role Labeling

SRL annotations rely on a frame lexicon containing *frames* that could be evoked by one or more *lexical units*. A lexical unit consists of a word lemma conjoined with its coarse-grained part-of-speech tag.[1] Each frame is further associated with a set of possible *core* and *non-core* semantic roles which are used to label its arguments. This description of a frame lexicon covers both PropBank and FrameNet conventions, but there are some differences outlined below. See Figure 1 for example annotations.

PropBank defines frames that are essentially sense distinctions of a given lexical unit. The set of PropBank roles consists of seven generic core roles (labeled A0-A5 and AA) that assume different semantics for different frames, each associating with a subset of the core roles. In addition, there are 21 non-core roles that encapsulate further arguments of a frame, such as temporal (AM-TMP) and locative (AM-LOC) adjuncts. The non-core roles are shared between all frames and assume similar meaning. In contrast, a FrameNet frame often associates with multiple lexical units and the frame lexicon contains several hundred core and non-core roles that are shared across frames. For example, the FrameNet frame Theft could be evoked by the verbs *steal*, *pickpocket*, or *lift*, while PropBank has distinct frames for each of them. The Theft frame also contains the core roles Goods and Perpetrator that additionally belong to the Commercial_transaction and Committing_crime frames respectively.

A typical SRL dataset consists of sentence-level annotations that identify (possibly multiple) target predicates in each sentence, a disambiguated frame for each predicate, and the associated argument spans (or single word argument heads) labeled with their respective semantic roles.

2.2 Related Work

SRL using PropBank conventions (Palmer et al., 2005) has been widely studied. There have been two shared tasks at CoNLL 2004-2005 to identify the phrasal arguments of verbal predicates (Carreras and Màrquez, 2004; Carreras and Màrquez, 2005). The CoNLL 2008-2009 shared tasks introduced a variant where semantic dependencies are annotated rather than phrasal arguments (Surdeanu et al., 2008; Hajič et al., 2009). Similar approaches (Das et al., 2014; Hermann et al., 2014) have been applied to frame-semantic parsing using FrameNet conventions (Baker et al., 1998). We treat PropBank and FrameNet annotations in a common framework, similar to Hermann et al. (2014).

Most prior work on SRL rely on syntactic parses provided as input and use locally estimated classifiers for each span-role pair that are only combined at prediction time.[2] This is done by picking the highest scoring role for each span, subject to a set of structural constraints, such as avoiding overlapping arguments and repeated core roles. Typically, these constraints have been enforced by integer linear programming (ILP), as in Punyakanok et al. (2008). Täckström et al. (2015) interpreted this as a graphical model with local factors for each span-role pair, and global factors that encode the structural constraints. They derived a dynamic program (DP) that enforces most of the constraints proposed by Punyakanok et al. and showed how the DP can be used to take these constraints into account during learning. Here, we use an identical graphical model, but extend the model of Täckström et al. by replacing its linear potential func-

[1] We borrow the term "lexical unit" from the frame semantics literature. The CoNLL 2005 dataset is restricted to verbal lexical units, while the CoNLL 2009 and 2012 datasets contains both verbal and nominal lexical units. FrameNet has lexical units of several coarse syntactic categories.

[2] Some recent work have successfully proposed joint models for syntactic parsing and SRL instead of a pipeline approach (Lewis et al., 2015).

tions with a multi-layer neural network. A similar use of non-linear potential functions in a structured model was proposed by Do and Artières (2010) for speech recognition, and by Durrett and Klein (2015) for syntactic phrase-structure parsing.

Feature-based approaches to SRL employ hand-engineered linguistically-motivated feature templates to represent the semantic structure. Some recent work has focused on low-dimensional representations that reduce the need for intensive feature engineering and lead to better generalization in the face of data sparsity. Lei et al. (2015) employ low-rank tensor factorization to induce a compact representation of the full cross-product of atomic features; akin to this work, they represent semantic roles as real-valued vectors, but use a different scoring formulation for modeling potential arguments. Moreover, they restrict their experiments to CoNLL 2009 semantic dependencies. Roth and Woodsend (2014) improve on the state-of-the-art feature-based system of Björkelund et al. (2010) by adding distributional word representations trained on large unlabeled corpora as features.

Collobert and Weston (2007) use a neural network and do not rely on syntactic parses as input. While they use non-standard evaluation, they report accuracy similar to the ASSERT system (Pradhan et al., 2005), to which we compare in Table 4. Very recently, Zhou and Xu (2015) proposed a deep bidirectional LSTM model for SRL that does not rely on syntax trees as input; their approach achieves the best results on CoNLL 2005 and 2012 corpora to date, but unlike this work, they do not report results on FrameNet and CoNLL 2009 dependencies and do not investigate joint learning approaches involving multiple annotation conventions.

For FrameNet-style SRL, Kshirsagar et al. (2015) recently proposed the use of PropBank-based features, but their system performance falls short of the state of the art. Roth and Lapata (2015) proposed another approach exploring linguistically motivated features tuned towards the FrameNet lexicon, but their performance metrics are significantly worse than our best results.

The inspiration behind our approach stems from recent work on bilinear models (Mnih and Hinton, 2007). There have been several recent studies representing input observations and output labels with distributed representations, for example, in the WSABIE model for image annotation (Weston et al., 2011), in models for embedding labels in structured graphical models (Srikumar and Manning, 2014), and in techniques to learn joint embeddings of predicate words and their semantic frames in a vector space (Hermann et al., 2014).

3 Model

Our model for SRL performs inference separately for each marked predicate in a sentence. It assumes that the predicate has been automatically disambiguated to a semantic frame drawn from a frame lexicon, and the semantic roles of the frame are used for labeling the candidate arguments in the sentence. Formally, we are given a sentence x in which a predicate t, with lexical unit ℓ, has been marked. Assuming that the semantic frame f of the predicate has already been identified (see §4.2 for this step), we seek to predict the set of spans that correspond to its overt semantic arguments and to label each argument with its semantic role. Specifically, we model the problem as that of assigning each span $s \in \mathcal{S}$, from an over-generated set of candidate argument spans $\mathcal{S}$, to a semantic role $r \in \mathcal{R}$. The set of semantic roles $\mathcal{R}$ includes the special null role $\varnothing$, which is used to represent non-overt arguments. Thus, our algorithm performs the SRL task in one step for a single predicate frame. For the span-based SRL task, in a sentence of n words, there could be $O(n^2)$ potential arguments. For statistical and computational reasons we prune the set of spans $\mathcal{S}$ using a set of syntactically-informed heuristics from prior work (see §4.2).

3.1 Graphical Model

We make use of a graphical model that represents global assignment of arguments to their semantic roles, subject to linguistic constraints (Punyakanok et al., 2008; Täckström et al., 2015). Under this graphical model, we assume a parameterized potential function that assigns a real-valued compatibility score $g(s, r; \boldsymbol{\theta})$ to each span-role pair $(s, r) \in \mathcal{S} \times \mathcal{R}$, where $\boldsymbol{\theta}$ denotes the model parameters. Below, we consider two types of potential functions. As a baseline, similar to most prior work, one could use a simple linear function of discrete input features $g_{\text{L}}(s, r; \boldsymbol{\theta}) = \boldsymbol{\theta}^\top \cdot \boldsymbol{\phi}(r, s, x, t, \ell, f)$, where $\boldsymbol{\phi}(\cdot)$ denotes a feature function. In this work, we instead propose a multi-layer feed-forward neural network potential function, specified in §3.2. Given these local factors, we employ the dynamic program of Täckström et al. to enforce global constraints on the inferred output.

Table 1: Span features $\boldsymbol{\phi}(s, x, t, \ell)$ in Figure 2.

Let $\mathcal{R}^{|\mathcal{S}|}$ denote the set of all possible assignments of semantic roles to argument spans (s_i, r_i) for $s_i \in \mathcal{S}$ that satisfy the constraints. Given a potential function $g(s, r) \triangleq g(s, r; \boldsymbol{\theta})$, the probability of a joint assignment $\boldsymbol{r} \in \mathcal{R}^{|\mathcal{S}|}$, subject to the constraints, is given by

$$p(\boldsymbol{r} \mid x, t, \ell, f) = \exp\left(\sum_{s_i \in \mathcal{S}} g(s_i, r_i) - A(\mathcal{S})\right), \quad (1)$$

where the log-partition function $A(\mathcal{S})$ sums over all satisfying joint role assignments:

$$A(\mathcal{S}) = \log \sum_{\boldsymbol{r}' \in \mathcal{R}^{|\mathcal{S}|}} \exp\left(\sum_{s_i \in \mathcal{S}} g(s_i, r_i')\right). \quad (2)$$

3.2 Neural Network Potentials

Our approach replaces the standard linear potential function $g_{\text{L}}(s, r; \boldsymbol{\theta})$ with the real-valued output of a feed forward neural network with non-linear hidden units. The network structure is outlined in Figure 2. The frame f and role r are initially encoded using a one-hot encoding as $\boldsymbol{i}_f$ and $\boldsymbol{i}_r$. In other words, $\boldsymbol{i}_f$ and $\boldsymbol{i}_r$ have all zeros except for one position at f and r respectively. These are passed through fully connected linear layers to give $\boldsymbol{e}_f$ and $\boldsymbol{e}_r$. We call these linear layers the *embedding* layers since $\boldsymbol{i}_f$ selects the embedding of the frame f and $\boldsymbol{i}_r$ for r. Next, $\boldsymbol{e}_f$ and $\boldsymbol{e}_r$ are passed through a fully connected rectified linear layer (Nair and Hinton, 2010), to obtain the final frame-role representation $\boldsymbol{v}_{(f,r)}$. For the candidate span, the process is similar. Atomic features $\boldsymbol{\phi}(s, x, t, \ell)$ for the argument span s are extracted first. (These features are the non-conjoined features used in the linear model of Täckström et al.; see Table 1 for the list). These are next passed through a fully-connected linear embedding layer to get the span embedding $\boldsymbol{e}_s$, which is subsequently passed through a fully connected rectified linear layer to obtain $\boldsymbol{v}_s$, the final span representation. The final output is the dot product of $\boldsymbol{v}_s$ and $\boldsymbol{v}_{(f,r)}$:

$$g_{\text{NN}}(s, r; \boldsymbol{\theta}) = \boldsymbol{v}_s^\top \cdot \boldsymbol{v}_{(f,r)}. \quad (3)$$

The weights of all the layers constitute the parameters $\boldsymbol{\theta}$ of the neural network. We initialize $\boldsymbol{\theta}$ randomly, with the exception of embedding parameters corresponding to words, which are initialized from pre-trained word embeddings (see §4.4 for details). We train the network as described in §3.3.[3]

Note that unlike typical linear models, the atomic span features are not explicitly conjoined with each other, the frame or the role. Instead the hidden layers learn to emulate span feature conjunctions and frame and role feature conjunctions in parallel.[4] Moreover, note that span $\boldsymbol{v}_s$ and frame-role $\boldsymbol{v}_{(f,r)}$ representations are decoupled in this model. This decoupling is important as it allows us to train a single model in a multitask setting. We demonstrate this by successfully combining PropBank and FrameNet training data, as described in §5.

3.3 Parameter Estimation

We consider two methods for parameter estimation.

[3] Various other network structures are worth investigating, such as concatenating the span, frame and role representations and passing them through fully connected layers. This treatment, for example, has been used by Chen and Manning (2014) for syntactic parsing. We leave these explorations to future work.

[4] We found that adding feature conjunctions to the network's input layer did not improve performance in practice.

Local Estimation In local estimation, we treat each span-role assignment pair $(s, r) \in \mathcal{S} \times \mathcal{R}$ as an individual binary decision problem and maximize the corresponding log-likelihood of the training set.[5] Denote by $z_{s,r} \in \{0, 1\}$ the decision variable, such that $z_{s,r} = 1$ iff span s is assigned role r. By passing the potential $g_{\text{NN}}(s, r; \boldsymbol{\theta})$ through the logistic function, we obtain the log-likelihood $l(z_{s,r}; \boldsymbol{\theta}) \triangleq \log p(z_{s,r} \mid x, t, \ell, f)$ of an individual training example. Here,

$$p(z_{s,r} \mid x, t, \ell, f) = \begin{cases} \frac{1}{1+e^{-g_{\text{NN}}(s,r;\boldsymbol{\theta})}} & \text{if } z_{s,r} = 1 \\ \frac{e^{-g_{\text{NN}}(s,r;\boldsymbol{\theta})}}{1+e^{-g_{\text{NN}}(s,r;\boldsymbol{\theta})}} & \text{if } z_{s,r} = 0 \end{cases}$$

Thus, the gold role for a given span according to the training data serves as the positive example, while all the other potential roles serve as negatives. To maximize the log-likelihood, we use Adagrad (Duchi et al., 2011). This requires the gradient of the log-likelihood with respect to the parameters $\boldsymbol{\theta}$, which can be derived using the chain rule.

Structured Estimation In structured estimation, we instead learn a globally normalized probabilistic model that takes the structural constraints into account during training. This method is closely related to the linear approach of Täckström et al. (2015), as well as to the fine-tuning of a neural CRF described by Do and Artières (2010).

We train the model by maximizing the log-likelihood of the training data, again using Adagrad. From Equation (1), we have that the log-likelihood $l(\boldsymbol{r}; \boldsymbol{\theta}) \triangleq \log p(\boldsymbol{r} \mid x, t, \ell, f)$ of a single (structured) training example $(\boldsymbol{r}, \mathcal{S}, x)$ is given by

$$l(\boldsymbol{r}; \boldsymbol{\theta}) = \sum_{s_i \in \mathcal{S}} g(s_i, r_i) - A(\mathcal{S}) \,. \tag{4}$$

By application of the chain rule, the gradient of the log-likelihood factorizes as

$$\frac{\partial l(\boldsymbol{r}; \boldsymbol{\theta})}{\partial \boldsymbol{\theta}} = \frac{\partial l(\boldsymbol{r}; \boldsymbol{\theta})}{\partial g_{\text{NN}}} \frac{\partial g_{\text{NN}}}{\partial \boldsymbol{\theta}} \,, \tag{5}$$

where we have used the shorthand g_{NN} for brevity. It is easy to show that the first term $\partial l(\boldsymbol{r}; \boldsymbol{\theta}) / \partial g_{\text{NN}}$ factors into the marginals over edges in the DP lattice, which can be computed with the forward-backward algorithm (recall that the potentials are in simple correspondence with the edge scores in the DP lattice, see Täckström et al. (2015, §4) for details). Again, the chain rule can be used to compute the gradient $\partial g_{\text{NN}} / \partial \boldsymbol{\theta}$ with respect to the parameters of each layer in the network.

[5] An alternate way to locally train the neural network would be to treat the scores as potentials in a multiclass logistic regression model and optimize log-likelihood, as is done with the locally-trained linear model from Täckström et al. (2015), but we did not investigate this alternative in this work.

3.4 Product of Experts

As we will observe in Tables 2 to 5, random initialization of the neural network parameters $\boldsymbol{\theta}$ causes variance in the performance over different runs. We found that using a straightforward product-of-experts (PoE) model (Hinton, 2002) at inference time reduces this variance and results in significantly higher performance. This PoE model is a very simple ensemble, being the factor-wise sum of the potential functions from K independently trained neural networks:

$$g_{\text{PoE}}(s, r; \boldsymbol{\theta}) = \sum_{j=1}^{K} g_{\text{NN}}^{(j)}(s, r, \boldsymbol{\theta}) \,. \tag{6}$$

where $g_{\text{NN}}^{(j)}(s, r, \boldsymbol{\theta})$ is the score from model j.

4 Experimental Setup

In this section we describe the datasets used, the required preprocessing steps, the baselines compared to and the details of our experimental setup.

4.1 Datasets and Significance Testing

We evaluate our approach on four standard datasets. For span-based SRL using PropBank conventions (Palmer et al., 2005), we evaluate on both the CoNLL 2005 shared task dataset (Carreras and Màrquez, 2005), and the larger CoNLL 2012 dataset derived from the OntoNotes 5.0 corpus (Weischedel et al., 2011). We also evaluate our model on the CoNLL 2009 shared task dataset (Hajič et al., 2009), that annotates roles for semantic dependencies, rather than full argument spans. For the CoNLL datasets, we use the standard training, development and test sets. For frame-semantic parsing using FrameNet conventions (Baker et al., 1998), we follow Das et al. (2014) and Hermann et al. (2014) in using the full-text annotations of the FrameNet 1.5 release and follow their data splits.

We use the standard evaluation scripts for each task and use a paired bootstrap test (Efron and Tibshirani, 1994) to assess the statistical significance of the results. For brevity, we only give the p-values for the observed differences between our best and second best models on each of the test sets.

4.2 Preprocessing and Frame Identification

All datasets are preprocessed with a part-of-speech tagger and a syntactic dependency parser, both trained on the CoNLL 2012 training split, after converting the constituency trees to Stanford-style dependencies (De Marneffe and Manning, 2013). The tagger is based on a second-order conditional random field (Lafferty et al., 2001) with standard emission and transition features; for parsing, we use a graph-based parser with structural diversity and cube-pruning (Zhang and McDonald, 2014).

On the WSJ development set (section 22), the labeled attachment score of the parser is 90.9% while the part-of-speech tagger achieves an accuracy of 97.2%. On the CoNLL 2012 development set, the corresponding scores are 90.2% and 97.3%. Both the tagger and the parser, as well as the SRL models use word cluster features (see Table 1). Specifically, we use the clusters with 1000 classes from Turian et al. (2010), which are induced with the Brown algorithm (Brown et al., 1992). To generate the candidate arguments $\mathcal{S}$ (see §3.2) for the CoNLL 2005 and 2012 span-based datasets, we follow Täckström et al. (2015) and adapt the algorithm of Xue and Palmer (2004) to use dependency syntax. For the dependency-based CoNLL 2009 experiments, we modify our approach to assume single length spans and treat every word of the sentence as a candidate argument. For FrameNet, we follow the heuristic of Hermann et al. (2014).

As mentioned in §3, we automatically disambiguate the predicate frames. For FrameNet, we use an embedding-based model described by Hermann et al. (2014). For PropBank, we use a multiclass log-linear model, since Hermann et al. did not observe better results with the embedding model.

To ensure a fair comparison with the closest linear model baseline, we ensured that the preprocessing steps, the argument candidate generation algorithm for the span-based datasets and the frame identification methods are identical to Täckström et al. (2015, §3.2, §6.2-§6.3).

4.3 Baseline Systems

In addition to comparing to Täckström et al. (2015), whose setup is closest to ours, we also compare to prior state-of-the-art systems from the literature.

For CoNLL 2005, we compare to the best non-ensemble and ensemble systems of Surdeanu et al. (2007), Punyakanok et al. (2008) and Toutanova et al. (2008). The ensemble variants of these systems use multiple parses and multiple SRL systems to leverage diversity. In contrast to these ensemble systems, our product-of-experts model uses only a single architecture and one syntactic parse; the constituent models differ only in random initialization. We also compare with the recent deep bidirectional LSTM model of Zhou and Xu (2015).

For CoNLL 2012, we compare to Pradhan et al. (2013), who report results with the (non-ensemble) ASSERT system (Pradhan et al., 2005), and to the model of Zhou and Xu (2015).

For CoNLL 2009, we compare to the top system from the shared task (Zhao et al., 2009), two state-of-the-art systems that employ a reranker (Björkelund et al., 2010; Roth and Woodsend, 2014), and the recent tensor-based model of Lei et al. (2015). We also trained the linear model of Täckström et al. on this dataset (their work omitted this experiment), as a baseline.

Finally, for the FrameNet experiments, we compare to the state-of-the-art system of Hermann et al. (2014), which combines a frame-identification model based on WSABIE (Weston et al., 2011) with a log-linear role labeling model.

4.4 Hyperparameters and Initialization

There are several hyperparameters in our model (§3.2). First, the span embedding dimension of $\boldsymbol{e}_s$ was fixed to 300 to match the dimension of the pre-trained GloVe word embeddings from Pennington et al. (2014) that we use to initialize the embeddings of the word-based features in $\boldsymbol{\phi}(s, x, t, \ell)$. Preliminary experiments showed random initialization of the word-based embeddings to be inferior to pre-trained embeddings. The remaining model parameters were randomly initialized. The frame embedding dimension was chosen from $\{100, 200, 300, 500\}$, while the hidden layer dimension was chosen from $\{300, 500\}$. For PropBank, we fixed the role embedding dimension to 27, which is the number of semantic roles in PropBank datasets (ignoring the AA role, that appears with negligible frequency). For FrameNet, the role embedding dimension was chosen from $\{100, 200, 300, 500\}$. In the Adagrad algorithm, the mini-batch size was fixed to 100 for local estimation (§3.3). For structured estimation (§3.3), a batch size of one was used, since each structured instance contains multiple local factors. The learning rate was chosen from $\{0.1, 0.2, 0.5, 1.0\}$ for local learning and from $\{0.01, 0.02, 0.05, 0.1\}$ for struc-

tured learning.[6] All hyperparameters were tuned on the respective development sets for each dataset with a straightforward grid-search procedure. In the product-of-experts setup, we train $K = 10$ models, each with a different random seed, and combine them at inference time (see Equation (6)).

5 Empirical Results

Table 2 shows results on the CoNLL 2005 development set and the WSJ and Brown test sets. Our individual neural network models are on par with the best linear single-system baselines that use carefully chosen feature combinations, but has variance across reruns. On the WSJ test set, the product-of-experts model featuring neural networks trained with structured learning achieves higher F_1-score than all non-ensemble baselines, except the LSTM model of Zhou and Xu. It is on par and at times better than ensemble baselines that use diverse syntactic parses. The PoE model outperforms all baselines on the Brown test set, exhibiting its generalization power on out-of-domain text. Overall, using structured learning improves recall at a slight expense of precision when compared to local learning, leading to an increase in the complete argument structure accuracy (*Comp.* in the tables).

Table 3 shows results on the CoNLL 2009 task. Following Lei et al. (2015), we present results using the official evaluation script, along with additional metrics that do not count frame predictions. Note that the linear baseline of Täckström et al.

[6] We observed a strong interaction between learning rate and mini-batch size. Since the number of factors per frame structure is much larger than 100, lower learning rates are better suited for structured estimation.

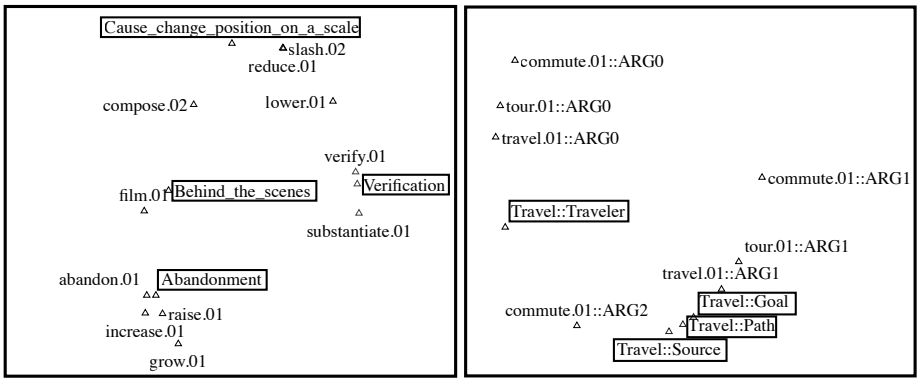
outperforms most prior work, including ones that employs rerankers, except on the Brown test set. Our neural network model performs even better, achieving state-of-the-art results on all metrics.

Table 4 shows the results on the span-based CoNLL 2012 data. The trends observed on the CoNLL 2005 data hold here as well, with structured training yielding an increase in precision at the cost of a small drop in recall. This leads to improvements in both F_1 score and complete structure accuracy. The product-of-experts model trained with structured learning here yields results better than the ASSERT system (Pradhan et al., 2013), but akin to CoNLL 2005, our system falls short in comparison to Zhou and Xu's F_1-score. In contrast to the smaller CoNLL 2005 data, even our single (non-PoE) model outperforms the linear model of Täckström et al. (2015) on the CoNLL 2012 data. We hypothesize that the relative abundance of the latter counteracts the risk for overfitting of the larger number of parameters in our model.

Finally, Table 5 shows the results on FrameNet data, which is very small in size. Here, structured learning does not help and in fact leads to a small drop in performance. Our locally-trained neural network model performs comparably to the linear model of Täckström et al. (2015). However we achieve significant improvements in both F_1-score and full structure accuracy by training our model with a dataset composed of both FrameNet and CoNLL 2005 data.[7] The ability to train in this multitask setting is a unique capability of our approach, and yields state-of-the-art results for FrameNet.

Figure 4 shows the effect of adding increasing amount of CoNLL 2005 data to supplement the FrameNet training corpus in this multitask setting. The Y-axis plots F_1-score on the development data averaged across runs for the local non-PoE model. With increasing amount of PropBank data, performance increases in small steps, and peaks when all the data is added. This shows that with more PropBank data we could further improve performance on the FrameNet task; we leave further exploration of multitask learning of predicate argument structures, including multilingual settings, to future work.

[7] The joint model does not improve results for PropBank. This is likely due to the much larger CoNLL 2005 training set, compared to the FrameNet data (39,832 training sentences in the former as opposed to 3,256 sentences in the latter).



(a) (b)

Figure 3: Two-dimensional t-SNE projections (Van der Maaten and Hinton, 2008) of joint PropBank and FrameNet (boxed) embeddings of frames (a) and frame-role pairs (b).

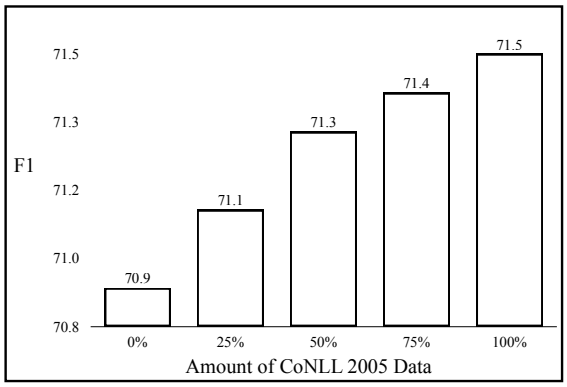


Figure 4: F_1 score on the FrameNet development data averaged over runs versus the percentage of CoNLL 2005 data used to append the FrameNet training corpus. For this plot, we used the locally trained non-PoE model.

5.1 Qualitative Analysis of Embeddings

Figure 3 shows example embeddings from the model trained jointly on FrameNet and PropBank annotations. Figure 3a shows the proximity of the learned embeddings $\boldsymbol{e}_f$ of frames from both FrameNet and PropBank. Figure 3b shows the embeddings for frame-role pairs $\boldsymbol{v}_{(f,r)}$ (the output of the hidden rectified linear layer). Here, we fix the FrameNet frame Travel and the similar PropBank frames commute.01, tour.01 and travel.01 are visualized along with their semantic roles. We observe that the model learns very similar embeddings for the semantically related roles across both datasets. Note that there is a clear separation of the agentive roles from the others for both conventions and how the FrameNet and PropBank counterparts of each type of role are proximate in vector space.

6 Conclusion

We presented a neural network model for semantic role labeling that learns to embed both inputs and outputs in the same vector space. We considered both local and structured training methods for the network parameters from supervised SRL data. Empirically, our approach achieves state-of-the-art results on two standard datasets with a product of experts model, while approaching the performance of a recent deep recurrent neural network model on two other datasets. By training the model jointly on both FrameNet and PropBank data, we achieve the best result to date on the FrameNet test set. Finally, qualitative analysis indicates that the model represents semantically similar annotations with proximate vector-space embeddings.

Acknowledgments

We thank Tom Kwiatkowski, Slav Petrov and Fernando Pereira for comments on early drafts. We are also thankful to Mike Lewis, Mark Yatskar and Luke Zettlemoyer for valuable feedback. Finally, we thank the three anonymous reviewers for suggestions that enriched the final version of the paper.

Abstract

Relational phrases (e.g., "got married to") and their hypernyms (e.g., "is a relative of") are central for many tasks including question answering, open information extraction, paraphrasing, and entailment detection. This has motivated the development of several linguistic resources (e.g. DIRT, PATTY, and WiseNet) which systematically collect and organize relational phrases. These resources have demonstrable practical benefits, but are each limited due to noise, sparsity, or size. We present a new general-purpose method, RELLY, for constructing a large hypernymy graph of relational phrases with high-quality subsumptions using collective probabilistic programming techniques. Our graph induction approach integrates small high-precision knowledge bases together with large automatically curated resources, and reasons collectively to combine these resources into a consistent graph. Using RELLY, we construct a high-coverage, high-precision hypernymy graph consisting of 20K relational phrases and 35K hypernymy links. Our evaluation indicates a hypernymy link precision of 78%, and demonstrates the value of this resource for a document-relevance ranking task.

1 Introduction

One of the many challenges in natural language understanding is interpreting the multi-word phrases that denote relationships between entities. Semantically organizing the complex relationships between diverse phrases is crucial to applications including question answering, open information extraction, paraphrasing, and entailment detection (Yahya et al., 2012; Fader et al., 2011; Madnani et al., 2012; Dagan et al., 2005). For example, a corpus containing the phrase "George Burns was married to Gracie Allen" allows us to answer the query "Who was the spouse of George Burns?" However, "Jay Z is in a relationship with Beyoncé" provides insufficient information to determine whether the couple is married. To capture the knowledge found in text, relational phrases need to be systematically organized with lexical links like synonymy ("married to" and "spouse of") and hypernymy ("in a relationship" generalizing "married to").

Many projects address the challenge of understanding relational phrases, but existing linguistic resources are often limited to synonymy, suffer from low precision, or have low coverage. Systems such as DIRT (Lin and Pantel, 2001), RESOLVER (Yates and Etzioni, 2009), and WiseNet (Moro and Navigli, 2012) have used sophisticated clustering techniques to determine synonymous phrases, but do not provide subsumption information. The PATTY (Nakashole et al., 2012) project goes beyond clustering and introduces a subsumption hierarchy, but suffers from sparsity and contains few hypernymy links. The HARPY (Grycner and Weikum, 2014) project extended PATTY, generating 600K hypernymy links, but with low precision. Berant et al. (2011) introduced entailment graphs that provided a high-quality subsumption hierarchy. This method required partitioning the graph and the largest component consisted of 120 relations. A number of manually-curated relational taxonomies such as WordNet (Fellbaum, 1998), VerbNet (Kipper et al., 2008), and FrameNet (Baker et al., 1998) also offer high-precision hierarchies with limited coverage.

In this paper, we introduce RELLY, a method for producing a hypernymy graph that has both high coverage and precision. We build on previous work, integrating the high-precision knowledge in resources such as YAGO (Suchanek et al.,

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 971–981,
Lisbon, Portugal, 17-21 September 2015.

2007) and WordNet with noisy statistical information from OpenIE projects PATTY and HARPY. RELLY maintains a consistent graph by including collective global constraints such as transitivity, asymmetry, and acyclicity. Scalability is often a concern when employing collective reasoning over large corpora, but our system can produce graphs with over 100K edges on conventional hardware. As a result, we produce a large, complete, and high-precision hypernym graph that includes alignments and type information.

RELLY leverages probabilistic soft logic (PSL) (Bach et al., 2015), a popular probabilistic modeling framework, to collectively infer hypernymy links at scale. PSL uses continuously-valued variables and evidence, allowing easy integration of uncertain statistical information while encoding dependencies between variables using a first-order logic syntax. We define a PSL model with rules that combine statistical features, semantic information, and structural constraints. Statistical features, such as argument overlap and alignments to WordNet verbs senses, allow RELLY to learn from large text collections. Semantic information, such as type information for relation arguments, improves precision of the resulting inferences. Structural constraints, such as transitivity and acyclicity, enforce a complete and consistent set of edges. Using this PSL model, we learn rule weights with a small amount of training data and then perform joint inference over all hypernymy links in the graph.

We highlight three major contributions of our work. First, we introduce RELLY, a scalable method for integrating statistical and semantic signals to produce a hypernymy graph. RELLY is extensible and can easily incorporate additional information sources and features. Second, we generate a complete and precise hypernymy graph over 20K relational phrases and 35K hypernymy links. We have publicly released this hypernymy graph as a resource for the NLP community. Third, we present a thorough empirical evaluation to measure the precision of the hypernymy graph as well as demonstrate its usefulness in a real-world document ranking task. Our results show a high precision (0.78) and superior performance in document ranking compared to state-of-the-art models such as word2vec (Mikolov et al., 2013).

2 Background

Before describing the details of RELLY, we begin with necessary background information on the task of semantically organizing relational phrases, as well as the probabilistic soft logic modeling language which we use to develop our hypernymy graph construction method.

2.1 Relational Phrases

Relational phrases are textual representations of relations which occur between named entities (e.g., "Terry Pratchett") or noun phrases (e.g., "the great writer"). Nakashole et al. (2012) identify relational phrases with the *semantic type signature* of the relation, i.e. the fine-grained lexical types of left- and right-hand side arguments. For example, "Terry Pratchett published his new novel The Colour of Magic" is an instance of the relational phrase "<*person*> published his * ADJ novel <*book*>." In this case, the left-hand argument (the domain of the relation) has the type <*person*> and the right-hand argument (the range of the relation) has the type <*book*>.

Several projects from the Open Information Extraction community have addressed the task of finding synonyms of relational phrases using clustering algorithms. The biggest collection of relational phrases and their synonyms is currently the PATTY project (Nakashole et al., 2012), with around 350,000 semantically typed relational phrases. Prominent alternatives are WiseNet (Moro and Navigli, 2012), which offers 40,000 synsets of relational phrases, PPDB (Ganitkevitch et al., 2013), which contains over 220 million paraphrase pairs, as well as DIRT and VerbOcean (Lin and Pantel, 2001; Chklovski and Pantel, 2004) which inspired the approach and results pursued here.

Relational phrases can be further organized into a hierarchical structure according to their hypernymy (subsumption) relationships. For example, "<*person*> moves to <*country*>" is a hypernym of the relational phrase "<*musician*> emigrates to <*country*>." Of the aforementioned collections, only PATTY attempts to automatically create a subsumption hierarchy for the extracted relational phrases. The authors of the HARPY system argue that the sparseness of PATTY's graph comes from the lack of general phrases in the source corpus. As a solution, they propose using the WordNet verb hierarchy (which contains general

verb senses) to construct a similar hierarchy with PATTY's relational phrases. The graph obtained by HARPY consists of around 600,000 hypernymy links for around 20,000 relational phrases. However, the final graph was not evaluated for precision; rather, the evaluation was instead concentrated on the alignment between verb senses and relations.

In this paper we will make use of several concepts that are closely related to hypernymy, which we define below. Note that although the following definitions concern verbs, we also apply them to relational phrases:

- *hypernym*: the verb Y is a hypernym of the verb X if Y is more general than X. *To perceive* is a hypernym of *to listen* (Bai et al., 2010).
- *troponym*: the verb Y is a troponym of the verb X if doing Y is doing X, in some manner. *To lisp* is a troponym of *to talk* (Bai et al., 2010). Troponym is a verb counterpart for *hyponym*, which applies to nouns. In this work we use these two terms interchangeably.
- *entailment*: the verb Y is entailed by X if, by doing X, you must be doing Y. *To sleep* is entailed by *to snore* (Bai et al., 2010).

2.2 Probabilistic Soft Logic

Our approach is based on probabilistic soft logic (PSL), a popular statistical relational learning system which we briefly describe here. PSL is a templating language for a class of graphical models known as hinge-loss Markov random fields. PSL models are specified using rules in first-order logic syntax, expressing dependencies between interrelated variables. For example, the PSL rule

$$w : \textsc{Hypernym}(P_1, P_2) \wedge \textsc{Hypernym}(P_2, P_3) \Rightarrow \textsc{Hypernym}(P_1, P_3)$$

expresses the transitivity of hypernyms: if phrase P_1 is a hypernym of phrase P_2 and P_2 is a hypernym of P_3, then P_1 is a hypernym of P_3. Rules are weighted (w) to indicate their importance in the model, and weight learning in PSL allows these weights to be learned from training data.

Each rule is ground by substituting the variables in the rule with constants, e.g. "married to" and "relative of" for P_1 and P_2. However, unlike previous approaches such as Markov logic networks, the atoms in each logical rule take values in the [0,1] continuous domain. In addition to providing a natural way of incorporating uncertainty and similarity into models, continuous-valued variables allow the inference objective to be formulated as convex optimization making MAP inference extremely efficient, with empirical performance that scales linearly with the number of ground rules.

3 Hypernymy Graph Construction

In this section we detail RELLY, our system for constructing a hypernymy graph. RELLY incorporates semantic and statistical information from sources such as YAGO, WordNet, PATTY, and HARPY, and uses PSL to combine and reason over these sources. For each source, we introduce a PSL predicate (Table 1). The predicates are divided into three categories: *statistical* (continuous-valued features arising from statistical methods), *semantic* (binary predicates acquired from knowledge bases) and *output* (the target variables). We relate these predicates with a series of rules which combine alignment links, argument similarity, and hierarchical information. The collection of rules defines the PSL model, which we describe in Section 3.1 and Table 2.

In the resulting hypernymy graph, an edge from a relational phrase $R1$ to a relational phrase $R2$ denotes that $R1$ is more specific than $R2$, i.e. $R2$ is a hypernym of $R1$. For example, there is an edge from $R1$ ="<*musician*> emigrates to <*country*>" to $R2$ = "<*person*> moves to <*country*>." In the PSL model the strength of this edge is represented by the confidence score of the predicate $hyponym(R1, R2)$.

3.1 PSL Rules

The PSL rules that define the model are shown in Table 2. Each of the rules is additionally supplied with a weight which describes its importance in the model. The weights are learned from a small hand-crafted hierarchy of relational phrases. The full PSL model combines multiple statistical and semantic signals into the hypernymy graph.

Our model includes rules to encode signals that provide evidence for hypernymy, as well as rules to encode consistency in the graph. One statistical signal for phrase subsumption is *argument overlap*. If the arguments to a relational phrase $R1$ are also found as arguments to another relational phrase $R2$, $R1$ and $R2$ may be synonymous or

Table 1: PSL predicates;
$R1, R2$ are relational phrases, $Vb1, Vb2$ WordNet verb senses and $TL1, TR1, T1, T2$ YAGO types

PSL predicate	Type	Description
$weedsInclusion(R1, R2)$	statistical	degree of inclusion of sets of argument pairs of relations defined as $\frac{\lvert ArgsR1\rvert}{\lvert ArgsR1 \cap ArgsR2\rvert}$ (Weeds and Weir, 2003)
$pattySubsumption(R1, R2)$	statistical	PATTY subsumption (Nakashole et al., 2012)
$harpy(R1, Vb1)$	statistical	alignment links between relational phrases and WordNet verb senses (Grycner and Weikum, 2014)
$wordnetHyponym(Vb1, Vb2)$	semantic	hyponymy link between WordNet verb senses
$lType(R1, TL1)$	semantic	left (domain) type of arguments of a relational phrase
$rType(R1, TR1)$	semantic	right (range) type of arguments of a relational phrase
$yagoHyponym(T1, T2)$	semantic	$T1$ is a subtype of $T2$ in YAGO hierarchy
$candidateHyponym(R1, R2)$	output	relational phrase $R1$ is more specific than $R2$ (without enforcing consistent argument types)
$hyponym(R1, R2)$	output	relational phrase $R1$ is more specific than $R2$

$R2$ may be a hypernym of $R1$. We use two measures of argument overlap, $weedsInclusion$ and $pattySubsumption$, in rules 1 and 2, respectively, to capture the relationship between argument overlap and subsumption. Another signal, used in rule 3, is the *alignment* between relational phrases and WordNet verb senses. If relational phrases $R1$ and $R2$ are aligned to WordNet verb senses $Vb1$ and $Vb2$ which are in a hyponymy relationship, then this is evidence that $R1$ is more specific than $R2$. An example of using HARPY alignment links and WordNet hierarchy is shown in Figure 1.

We encode local consistency requirements using Rules 4–6. Rule 4 (*types compatibility*) is a constraint to restrict hypernymy links to be between relations whose types are compatible, i.e they are identical or the types of the more specific relation are subtypes of the types of the more general relation. Rules 5 and 6 create a *transitive closure* of both WordNet and YAGO hierarchies. As a result of these rules, we can use indirect hyponyms (in rule 3) or indirect subtypes (in rule 4).

Finally, rules 7, 8 and 9 shape the structure of the output graph with collective global constraints. Rule 7 (*asymmetry*) removes bidirectional links, rule 8 (*transitivity*) creates a transitive closure of the graph and rule 9 (*acyclicity*) prevents the creation of small cycles in the graph.

3.2 RELLY Overview

RELLY has four stages: data pre-processing, rule weight learning, inference, and thresholding.

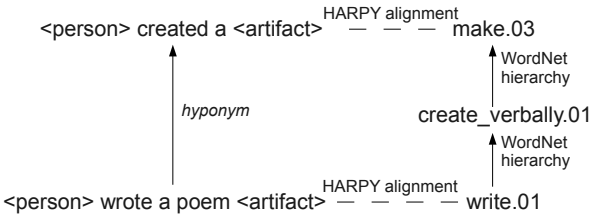

Figure 1: HARPY alignment usage

First, in the data pre-processing stage, we assign confidence scores of 0 or 1 for the binary-valued semantic predicates in the PSL model. For example, the $wordnetHyponym(Vb1, Vb2)$ confidence score is set to 1 if there is a hyponymy link between verb senses $Vb1$ and $Vb2$ and 0 otherwise. In other cases, the confidence is set to a similarity score of a feature which is represented by a predicate. For example, the $weedsInclusion(R1, R2)$ confidence is equal to the Weeds inclusion score between relations $R1$ and $R2$.

In the next stage the weights of the PSL rules described in Table 2 are learned from a small handcrafted graph of relational phrases. The weight learning is performed using an EM algorithm. Later, the most-probable explanation (MPE) state of the output predicates is inferred.

Finally, we export the inferred confidence scores of the predicate $hyponym$ and perform additional cleaning. Whenever two links contradict each other (e.g. we have both $hyponym(R1, R2)$ and $hyponym(R2, R1)$) we remove the link with

Table 2: PSL rules

Id	Feature	PSL rule
1	Weeds inclusion	$weedsInclusion(R1, R2) \Rightarrow candidateHyponym(R1, R2)$
2	Patty subsumption	$pattySubsumption(R1, R2) \Rightarrow candidateHyponym(R1, R2)$
3	Harpy alignment	$wordnetHyponym(Vb1, Vb2) \wedge harpy(R1, Vb1) \wedge harpy(R2, Vb2)$ $\Rightarrow candidateHyponym(R1, R2)$
4	Types compatibility	$candidateHyponym(R1, R2) \wedge lType(R1, TL1) \wedge rType(R1, TR1)$ $\wedge lType(R2, TL2) \wedge rType(R2, TR2) \wedge yagoHyponym(TL1, TL2)$ $\wedge yagoHyponym(TR1, TR2) \Rightarrow hyponym(R1, R2)$
5	WordNet hierarchy	$wordnetHyponym(Vb1, Vb2) \wedge wordnetHyponym(Vb2, Vb3)$ $\Rightarrow wordnetHyponym(Vb1, Vb3)$
6	Yago hierarchy	$yagoHyponym(T1, T2) \wedge yagoHyponym(T2, T3)$ $\Rightarrow yagoHyponym(T1, T3)$
7	Asymmetry	$hyponym(R1, R2) \Rightarrow \neg hyponym(R2, R1)$
8	Transitivity	$hyponym(R1, R2) \wedge hyponym(R2, R3) \Rightarrow hyponym(R1, R3)$
9	Acyclicity	$hyponym(R1, R2) \wedge hyponym(R2, R3) \Rightarrow \neg hyponym(R3, R1)$

the lower confidence score. If both predicates have the same confidence score we exclude them both from the final graph. Additionally, we only consider links with a confidence score above an empirically chosen threshold of 0.2.

4 Evaluation

In our experiments, we use a large corpus of relational phrases to construct a hypernymy graph using RELLY. We evaluate RELLY using both intrinsic and extrinsic evaluation. In the intrinsic evaluation, we asked human annotators to judge the relationship between two relational phrases and compared results from several hypernymy graphs. In the extrinsic evaluation, we used the hypernymy graph for a real-world document ranking task and measured the mean reciprocal rank (MRR) for a number of methods. In both evaluations, the hypernymy graph constructed by RELLY demonstrates significantly better performance than competing algorithms.

4.1 Dataset

We use RELLY to build a hypernymy graph with data from the PATTY and HARPY projects. The input to our system consists of 20,812 relational phrases and the associated argument types extracted from the English-language Wikipedia website using the PATTY system. For simplicity, we only include relational phrases that contain exactly one verb (e.g. "took the throne"), excluding noun phrases (e.g. "member of") and phrases containing multiple verbs (e.g. "hit and run"). The verb "to be" and modal verbs were not considered in the dataset. We also include HARPY alignments to the corresponding verb senses in WordNet for each phrase in the corpus. Additionally, we use a subset of the type-subsumption hierarchy from YAGO consisting of 144 types and 323 subsumption relationships.

During graph inference, RELLY evaluated 7.9M possible hypernymy links using 9.7M ground logical rules and constraints. Ultimately, RELLY produced 35,613 hypernymy links between relational phrases with confidence scores above 0.2. The hypernymy graph consisted of 3,730 roots. Running RELLY on a multi-core 2.27GHz server with 64GB of RAM required approximately 20 hours. For comparison, PATTY produced 8,162 subsumption links out of 350,569 phrases with approximately 2,300 roots.

4.2 Intrinsic Evaluation

In our intrinsic evaluation, we assess the precision of hypernymy links inferred by RELLY and compare with the precision of hypernymy graphs of PATTY and HARPY. In this evaluation, we measure precision for both the most confident hypernymy links in the system (precision@100) and the precision of a random sample of 100 hypernymy links. Each set of hypernymy links were presented to several human annotators for labeling.

To measure precision@100, we choose the top 100 hypernymy links using the confidence scores reported by PSL. We similarly choose the top 100 links from PATTY using the PATTY subsumption

score. Since HARPY does not provide confidence scores, we were unable to compute precision@100 for HARPY.

For each of the three systems, we used the full set of hypernymy links they produce, which consisted of 8K links from PATTY, 600K links from HARPY and 35K links from RELLY. We randomly sampled 100 hypernymy links from each of these systems.

We presented the selected hypernymy links to several human annotators. The labeling task required the annotator to judge the relationship between two relational phrases in a hypernymy link. For each relational phrase, we provided annotators with type information about the phrase arguments (domain and range) and examples of sentences that use the relational phrase. Based on this information, annotators could make one of four judgments: (1) the phrases are unrelated; (2) the phrases are synonymous; (3) the first phrase is more specific than the second phrase; (4) the second phrase is more specific than the first phrase. This evaluation task had good inter-annotator agreement, with a Cohen's Kappa of 0.624. Separately, the precision@100 dataset had Cohen's Kappa of 0.708 and the randomly sampled dataset had Cohen's Kappa of 0.521.

We show the results of the intrinsic evaluation in Table 3 with 0.9-confidence Wilson score interval (Brown et al., 2001). In comparison to HARPY and PATTY, RELLY has higher precision for both precision@100 and random evaluations. Precision in RELLY is comparable to PATTY, but RELLY has more than four times as many hypernym links. HARPY has far more hypernymy links, but with a precision of 0.43, we find that many of these links are incorrect.

Table 4 includes example hypernymy links from RELLY. There are examples where PATTY's subsumption is a dominant signal ("<*person*> publicly accused <*person*>" ⇒ "<*person*> accused <*person*>"). We also observe YAGO type hierarchy influence ("<*athlete*> played for <*team*>" ⇒ "<*person*> played for <*organization*>"), as well as the influence of combined WordNet hierarchy with HARPY alignments ("<*person*> marry daughter <*person*>" ⇒ "<*person*> joins <*person*>"). The advantage of RELLY is that it computes the final graph jointly and incorporates transitivity, asymmetry and acyclicity rules. It leads to less semantic drift in longer hypernymy chains

Table 3: Intrinsic evaluation

	Prec.	**Range**	**Cvg.**
precision@100			
RELLY	0.87	0.81 - 0.92	35K
PATTY	0.83	0.76 - 0.90	8K
random sample			
RELLY	0.78	0.71 - 0.84	35K
PATTY	0.75	0.68 - 0.82	8K
HARPY	0.43	0.35 - 0.52	600K

(e.g. Figure 2) compared with PATTY where "<*organization*> merged <*organization*>" can lead to "<*team*> beat <*team*>".

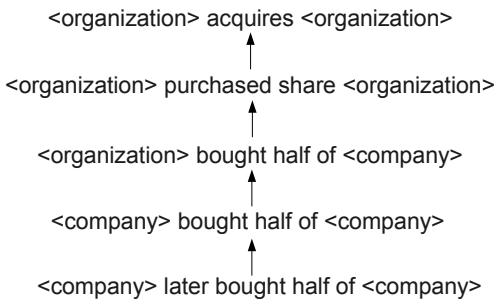

Figure 2: Chain of hypernymy

4.3 Ablation Study

Two advantages of RELLY that we have highlighted are easily incorporating new information sources and collectively enforcing global constraints. To analyze the influence of these system components, we performed an ablation study where we omitted PSL rules corresponding to specific model features. Using this approach, we quantify the importance of these features to RELLY's performance.

First, we demonstrate the value of type information in determining hypernymy. The YAGO type hierarchy allows RELLY to detect hypernymy links between relational phrases where types do not match exactly, but are compatible through type subsumption. When the YAGO type hierarchy rules are omitted from the model, coverage is reduced dramatically; the resulting hypernymy graph contains only 12,000 hypernymy links in contrast to the 35,000 links in the original model. Additionally, removing YAGO type information harms precision, with a precision of 0.75 ± 0.09

Table 4: Example RELLY hypernymy links

Hyponym relational phrase			Hypernym relational phrase		
Domain	Text pattern	Range	Domain	Text pattern	Range
head of state	abdicated in favor of	sovereign	person	resigns as	person
person	publicly accused	person	person	accused	person
person	marry daughter	person	person	joins	person
person	had paid	person	person	interacted with	person
athlete	played for	team	person	played for	organization

Table 5: Results for Entailment graphs induction

	Prec.	Rec.	F1
Berant et al. (2011)	0.422	0.434	0.428
PSL	**0.461**	**0.435**	**0.447**

with 0.9-confidence Wilson score interval for a random sample of 100 examples.

Next, we show how global constraints on the hypernymy graph such as anti-symmetry and acyclicity improve the quality of the hypernymy graph. Since the relational phrases generated by PATTY are clustered to find synonymous relations, these global constraints prevent RELLY from merging clusters. When the anti-symmetry and acyclicity rules were removed from the model, the resulting hypernymy graph included approximately 500 additional hypernymy links, while 10 existing links were removed. We manually evaluated the newly introduced links, and found that the majority of links were false positives.

4.4 Entailment Graph Induction

We compared the performance of PSL against the Integer Linear Programming (ILP) formulation by (Berant et al., 2011). The comparison was performed on the task of creating entailment graphs as described in (Berant et al., 2011). This task is strongly related to finding hypernyms of relational phrases. The experiments were executed on the dataset of 10 manually annotated graphs. In total this dataset contains 3,427 positive and 35,585 negative examples. Our model uses the transitivity rule ($entails(A,B) \wedge entails(B,C) \Rightarrow entails(A,C)$). We also include the local entailment scores ($score(A,B) \Rightarrow entails(A,B)$) which were released by (Berant et al., 2011). Table 5 presents micro-averaged precision, recall and F1 scores for this comparison.

PSL was much faster than the other exact methods used for this problem. To compare efficiency we measured the run-time of our method. Without any graph decomposition it took on average 232 seconds. The experiments were performed on a multi-core 2.67GHz server with 32GB of RAM. The methods reported in (Berant et al., 2012), which did not utilize graph decomposition method, had run-time above 5000 seconds.

4.5 Extrinsic Evaluation

The ultimate goal of producing a high-quality hypernymy graph is to deepen our understanding of natural language and improve performance on the many NLP applications. One such application is document retrieval, where billions of queries are performed each day through search engines. In our extrinsic evaluation, we demonstrate how a hypernymy graph can improve performance on a document ranking and retrieval task.

We consider a task where an input query document is compared to a corpus of documents with the aim of finding the most relevant related documents. To isolate the evaluation to relational phrases, we *anonymize* the documents, by replacing all named entities and noun phrases with placeholders. For example, the sentence "`The villain has already fled to the Republica de Isthmus`" is anonymized to "`⋆ has already fled to ⋆`." Anonymized retrieval has potential applications in security and for sensitive documents.

We collected a dataset consisting of movie plot summaries from two different websites, Wikipedia and the Internet Movie Database (IMDB). We chose plot synopses from 25 James Bond movies and 23 movies based on the Marvel Comics characters. For each plot synopsis, we have two plot descriptions: one from Wikipedia and another from IMDB. Given a query in the form of an anonymized plot description from one website, the task is to rank the anonymized plot descriptions

from the other dataset using relational phrase similarity. For example, given a query plot description of "Iron Man" from Wikipedia, rank plot descriptions from IMDB with the goal of maximizing the ranking of the corresponding "Iron Man" plot summary. We evaluate the quality of these rankings using the mean reciprocal rank (*MRR*) score, $\text{MRR} = \frac{1}{|Q|}\sum_{i=1}^{|Q|}\frac{1}{\text{rank}_i}$. Here, Q is the number of documents in the collection (i.e. 2*48 = 96) and rank_i is the position of the counterpart document in the ranking of document i.

As baseline algorithms, we use a unigram word2vec model and a bigram model. In the unigram word2vec model documents are represented by the average of the 300-dimensional word vectors trained on part of Google News dataset (about 100 billion words) (Mikolov et al., 2013). We could not use the bigram word2vec model because of the frequent occurrence of the placeholder symbol. In the bigram model, documents are represented by vectors in the bag-of-bigrams model with bigram frequency weights. The similarity measure in both cases is the cosine similarity measure.

As the first of our approaches we proposed a solution purely based on relational phrases. In the *relational phrases* model we extract relational phrases from a text and we map them to their synsets from PATTY (clusters of synonyms). A phrase is mapped to a synset if the Jaccard similarity between tokens of extracted relation and tokens of one of the phrases in the synset is above a threshold. Next we represent the document as a vector of the relational phrase synsets weighted by the frequency of the synset in the document (bag-of-relational_phrases). The similarity score between two documents is the cosine similarity between two vectors representing two documents. The ranking is created based on the similarity scores. In the *relational phrases + hypernyms* model we add hypernyms of the extracted relational phrases to the document vector (based on the hypernymy graph). Hypernyms are additionally weighted by the confidence score produced by the algorithm described in the Section 3. In the second approach we combine relational phrases models with the best of the baselines. The similarity score is then equal to $\lambda sim_1 + (1-\lambda) sim_2$. The λ parameter is trained on a different dataset (2*8 plot descriptions of Harry Potter movies). Training was performed by maximization of the MRR score using grid search. We consider the combination of the *bigram* model with *relational phrases*, as well as the combination of the *bigram* model with *relational phrases + hypernyms*.

Table 6: Extrinsic evaluation (Bond & Marvel)

	MRR score
word2vec	0.26
bigram	0.55
relational phrases	0.28
+ hypernyms	0.25
+ bigrams	0.58
+ hypernyms + bigrams	**0.60**

The results of the experiment are presented in Table 6. The best MRR score was obtained by *relational phrases + hypernyms + bigrams* model. The number of samples, 96, was large enough for statistical significance. We performed a paired t-test for MRR between each of these methods. The obtained p-values were below 0.05.

5 Related Work

The biggest sources of hypernyms, subsumptions, and hierarchical structure can be found in existing knowledge bases. Examples of these are Freebase (Bollacker et al., 2008), YAGO, DBPedia (Lehmann et al., 2014), and Google Knowledge Vault (Dong et al., 2014). However, these knowledge bases are mainly concentrated on named entities and noun phrases, and the variety of relations between entities is much smaller. Relations and information about them are underrepresented.

Open Information Extraction systems try to solve this problem by extracting new relations from natural text. These new relations do not necessarily follow the standard schema of knowledge bases. Additionally, these systems often organize the newly extracted relations by clustering or hierarchy construction. A first attempt to extract and cluster similar relations was presented in DIRT. This work was followed by projects such as ReVerb, PATTY, WiseNet, NELL (Carlson et al., 2010), and RESOLVER (Yates and Etzioni, 2009). PATTY and WiseNet also introduced semantic types to their concept of relational phrases. All of these systems rely on the co-occurrence of arguments of clustered relations. A different approach was presented in PPDB, where the authors

cluster phrases based on the similarity of translations to other languages.

Of these systems, only PATTY attempted to create a hierarchy of relations and the result was very sparse. HARPY aimed to overcome this problem by disambiguating and aligning relational phrases with WordNet, and performing a simple reconstruction of the WordNet hierarchy on top of relational phrases from PATTY. A very similar problem was addressed in the entailment graph project (Levy et al., 2014). The authors automatically created graphs of entailments between propositions, using Integer Linear Programing as one of the main components. Propositions can be encoded as triples of form *(subject, relation, object)*. Edges in the entailment graph occur between these triples, whereas edges connect typed relations in PATTY and HARPY. Moreover, the relations in the propositions were mainly limited to single verbs, whereas in our case we also consider longer relational phrases. Relations with semantic types were also used in typed entailment graphs (Berant et al., 2011). However, the type hierarchy was not considered there, which prevented from creating links between two relations with different semantic types. The input dataset was also smaller – the biggest graph consisted of 118 relations.

Although there is a scarcity of automatically created taxonomies of relations, there exist several manually curated taxonomies. Manually crafted verb or relation hierarchies are available in WordNet, VerbNet and FrameNet. WordNet has 13,767 verb synsets, which are organized into a hierarchy with 13,239 hypernymy links.

Automatic construction of taxonomies of named entities or noun phrases has received much more attention than organization of verbs or relations. In (Snow et al., 2006), the WordNet taxonomy was extended by 10,000 novel noun synsets with hypernym-hyponym links. In (Bansal et al., 2014), the authors reconstructed WordNet's noun hypernymy/hyponymy hierarchy from scratch using a probabilistic graphical model formulation. Another method of organizing noun phrases was proposed in (Mehdad et al., 2013), where an entailment graph of noun phrases was constructed.

Building a hypernymy graph for relational phrases is strongly related with the textual entailment task (Dagan et al., 2010). This concept was introduced in the Recognizing Textual Entailment (RTE) shared task (Dagan et al., 2005). Instead of short typed relational phrases, the input data are two texts – the entailing text T and the hypothesis text H. According to (Dagan et al., 2005)'s definition, "T entails H if, typically, a human reading T would infer that H is most probably true."

In RELLY, we use probabilistic soft logic (PSL) as the main ingredient of our approach. PSL was successfully used for numerous other applications including knowledge graph construction (Pujara et al., 2013), trust in social networks (Huang et al., 2012b), ontology alignment (Broecheler and Getoor, 2009), and social group modeling (Huang et al., 2012a).

6 Conclusion

This paper presents RELLY, a scalable method for integrating statistical and semantic signals to produce a hypernymy graph of relational phrases. We used RELLY to create a hypernymy graph that has both high coverage and precision, as shown in our evaluation. RELLY is extensible and can easily incorporate additional information sources and features. The hypernymy graph of relational phrases could potentially be useful for many problems of natural language processing and information retrieval. For example, we applied the hypernymy graph to a document-relevance task, which we used to evaluate RELLY extrinsically. As a future work, RELLY can incorporate more information sources and statistical signals and be expanded to infer multi-verb or noun relational phrases. The RELLY resource is publicly available at `www.mpi-inf.mpg.de/yago-naga/patty/`.

Abstract

We present an unsupervised hard EM approach to automatically mapping instructional recipes to action graphs, which define what actions should be performed on which objects and in what order. Recovering such structures can be challenging, due to unique properties of procedural language where, for example, verbal arguments are commonly elided when they can be inferred from context and disambiguation often requires world knowledge. Our probabilistic model incorporates aspects of procedural semantics and world knowledge, such as likely locations and selectional preferences for different actions. Experiments with cooking recipes demonstrate the ability to recover high quality action graphs, outperforming a strong sequential baseline by 8 points in F1, while also discovering general-purpose knowledge about cooking.

1 Introduction

Instructional language describes how to achieve a wide variety of goals, from traveling successfully to a desired location to cooking a particular dish for dinner. Despite the fact that such language is important to our everyday lives, there has been relatively little effort to design algorithms that can automatically convert it into an actionable form. Existing methods typically assume labeled training data (Lau et al., 2009; Maeta et al., 2015) or access to a physical simulator that can be used to test understanding of the instructions (Branavan et al., 2009; Chen and Mooney, 2011; Bollini et al., 2013). In this paper, we present the first approach for unsupervised learning to interpret instructional recipes using text alone, with application to cooking recipes.

Given a recipe, our task is to segment it into text spans that describe individual actions and construct an *action graph* whose nodes represent actions and edges represent the flow of arguments across actions, for example as seen in Fig. 1. This task poses unique challenges for semantic analysis. First, null arguments and ellipses are extremely common (Zwicky, 1988). For example, sentences such as "Bake for 50 minutes" do not explicitly mention what to bake or where. Second, we must reason about how properties of the physical objects are changed by the described actions, for example to correctly resolve what the phrase "the wet mixture" refers to in a baking recipe. Although linguistic context is important to resolving both of these challenges, more crucial is common sense knowledge about how the world works, including what types of things are typically baked or what ingredients could be referred to as "wet."[1]

These challenges seemingly present a chicken and egg problem — if we had a high quality semantic analyzer for instructions we could learn common sense knowledge simply by reading large bodies of text. However, correctly understanding instructions requires reasoning with exactly this desired knowledge. We show that this conflict can be resolved with an unsupervised learning approach, where we design models to learn various aspects of procedural knowledge and then fit them to unannotated instructional text. Cooking recipes are an ideal domain to study these two challenges simultaneously, as vast amounts of recipes are available online today, with significant redundancy in their coverage that can help bootstrap the overall learning process. For example, there are over 400 variations on "macaroni and cheese" recipes on allrecipes.com, from "chipotle

[1]The goal of representing common sense world knowledge about actions and objects also drives theories of frame semantics (Fillmore, 1982) and script knowledge (Schank and Abelson, 1977). However, our focus is on inducing this style of knowledge automatically from procedural texts.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 982–992,
Lisbon, Portugal, 17-21 September 2015.

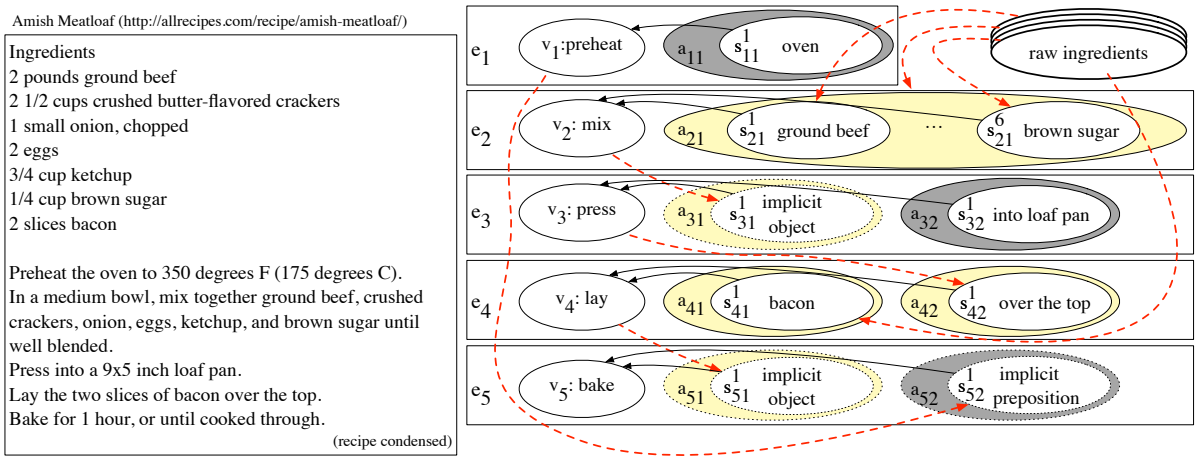

Figure 1: An input recipe (left) and a partial corresponding output action graph (right). Each rectangle (e_i) represents an action. The leftmost oval (v_i) in each action is the action's verb and the following ovals (a_{ij}) represents the verb's arguments. The yellow ovals represent foods; the grey ovals represent locations. Argument ovals with dotted boundaries are implicit, i.e., not present in text. The inner white ovals (s_{ij}^k) are string spans. The red dashed lines represent connections to string spans from their originating verb or raw ingredient. The string spans also connect to their associated verb in the action diagram to model the flow of ingredients. For example, there is a directed path from each raw ingredient to the implicit object of bake, representing that the object being baked is composed of all of the raw ingredients.

macaroni and cheese," to "cheesy salsa mac."

We present two models that are learned with hard EM algorithms: (1) a segmentation model to extract the actions from the recipe text, and (2) a graph model that defines a distribution over the connections between the extracted actions. The common sense knowledge is encoded in the second model which can, for example, prefer graphs that model implicit verb arguments when they better match the learned selectional preferences. The final action graph is constructed with a local search algorithm, that allows for global reasoning about ingredients as they flow through the recipe.

Experiments demonstrate the ability to recover high quality action graphs, gaining up to 8 points in F1 over a strong baseline where the ingredients flow sequentially through the verbs. The learned models are also highly interpretable, specifying for example that "dough" likely contains "flour" and that "add" generally requires two food arguments, even if only one is mentioned in the sentence.

2 Task Definition

Procedural text such as a recipe defines a set of actions, i.e. *predicates*, applied to a set of objects, i.e. *arguments*. A unique challenge in procedural text understanding is to recover how different arguments flow through a chain of actions; the results of intermediate actions (e.g., "Boil the pasta until al dente.") provide the inputs for future actions (e.g., "Drain."). We represent these correspondences with an *action graph*. In this section, we first describe our structured representation of recipe text, then we define how components of the recipe connect. Finally, we will show how given a recipe and a set of connections we can construct an action graph that models the flow of ingredients through the recipe. Fig. 1 provides a detailed running example for the section.

2.1 Recipe R

A recipe R is a piece of text that describes a list of instructions and a (possibly-empty) set of raw ingredients that are required to perform the instructions. The first step is to segment the text into a list of verb-argument tuples, called *actions*, $E_R = \{e_1 = (v_1, \mathbf{a}_1), \ldots, e_n = (v_n, \mathbf{a}_n)\}$. Sec. 6 will describe an unsupervised approach for learning to segment recipes. Each action e_i pairs a verb v_i with a list of arguments $\mathbf{a}_i$, where a_{ij} is the j^{th} argument of verb v_i. In Fig. 1, each row contains an action with a verb in the white oval and its arguments in the yellow and gray ovals.

Each argument is a tuple $a_{ij} = (t_{ij}^{syn}, t_{ij}^{sem}, S_{ij})$ with a syntactic type $t^{syn}(a) \in T^{syn} = \{DOBJ, PP\}$, a semantic type $t^{sem}(a) \in$

$T^{sem} = \{food, location, other\}$, and a list of text string spans $S_{ij} = \{s_{ij}^1, \ldots, s_{ij}^{|S_{ij}|}\}$, where s_{ij}^k is the k^{th} span in the j^{th} argument of verb v_i. In Fig. 1, the spans of each argument are represented by the white ovals inside of the argument ovals. For example, a_{21} contains a span for each raw ingredient being mixed in the second action (e.g., s_{21}^1 ="ground beef," s_{21}^6 ="brown sugar"). The syntactic type determines whether the argument is the direct object or a prepositional phrase argument of the verb in the recipe text. All other syntactic constructs are ignored and left for future work. The semantic types include food, location, and other. In Fig. 1, yellow ovals represent foods and gray ovals represent locations. Arguments of other semantic types are marked as $other$ (e.g., "Mash **using a fork**").

We also augment the set of arguments for each verb to include *implicit* arguments with empty string spans. This allows making connections to arguments that the author does not mention explicitly (e.g., the elided direct object of "bake" in e_5). Every verb is assigned one implicit PP argument, and, if a verb has no argument with syntactic type $DOBJ$, an implicit direct object. These arguments have indeterminate semantic types, which are to be determined based on how they connect to other actions. For example, in Fig. 1, when the implicit object of "bake" is connected to the output of the "lay" action, it is inferred to be of type $food$ since that is what is created by the "lay" action. However, when the implicit PP argument of "bake" is connected to the output of the "preheat" action, it is inferred to be a location since "preheat" does not generate a food.

2.2 Connections C

Given a segmented recipe, we can build graph connections. A *connection* identifies the origin of a given string span as either the output of a previous action or as a new ingredient or entity being introduced into the recipe. A connection is a six-tuple $(o, i, j, k, t^{syn}, t^{sem})$ indicating that there is a connection from the output of v_o to the argument span s_{ij}^k with syntactic type $t^{syn} \in T^{syn}$ and semantic type $t^{sem} \in T^{sem}$. We call o the *origin index* and i the *destination index*. For example, in Fig. 1, the connection from the output of the "press" verb (e_3) to "over the top" (s_{42}^1) would be $(3, 4, 2, 1, PP, food)$. If a span introduces raw ingredient or new location into the recipe, then $o = 0$; in Fig. 1, this occurs for each of the spans that represent raw ingredients as well as "oven" and "into loaf pan."

Given a recipe R, a set of connections C is valid for R if there is a one-to-one correspondence between spans in R and connections in C, and if the origin indexes of connections in C are 0 or valid verb indexes in R, $\forall(o, i, j, k, t^{syn}, t^{sem}) \in C,\ o \in \{\mathbb{Z} \mid 0 \leq o \leq |E_R|\}$.

2.3 Action graph G

A recipe R and a set of connections C define an *action graph*, which is a directed graph $G = (V, E)$. Each raw ingredient, verb, and argument span is represented by a vertex in V. Each argument span vertex is connected to its associated verb vertex, and each connection $c = (o, i, j, k, t^{syn}, t^{sem})$ adds a corresponding edge to E. Edges from connections with semantic type $food$ propagate ingredients through the recipe; edges from connections with semantic type $location$ propagate a location. Fig. 1 shows an action graph. By following the edges, we can tell that the implicit food entity that is being baked in the final action has been formed from the set of ingredients in the mixing action and the bacon from e_4 and that the baking action occurs inside the oven preheated in e_1.

3 Probabilistic connection model

Our goal is, given a segmented recipe R, to determine the most likely set of connections, and thus the most likely action graph. We model (1) a prior probability over C, $P(C)$ (Sec. 3.1), and (2) the probability of seeing a segmented recipe R given a set of connections C, $P(R|C)$ (Sec. 3.2). The most likely set of connections will maximize the joint probability: $P(R|C)P(C)$. A summary of this model is presented in Fig. 2, and the details are described in the this section.

3.1 Connections prior model

The probability of a set of connections C depends on features of the incoming set of connections for each action. Let a *destination subset* $\mathbf{d}_i \subseteq C$ be the subset of C that contains all connections that have i as the destination index. In Fig. 1, $\mathbf{d}_3$ contains the connection from v_2 to the implicit object as well as a connection to "into loaf pan" with an origin index of 0. Using the chain rule, the probability of C is equal to the product of the probability

- **Input:** A set of connections C and a recipe R segmented (**Sec. 6**) into its actions $\{e_1 = (v_1, \mathbf{a}_1), \ldots, e_n = (v_n, \mathbf{a}_n)\}$
- The joint probability of C and R is $P(C, R) = P(C)P(R|C)$, each defined below:

1. **Connections Prior (Sec. 3.1)**: $P(C) = \prod_i P(\mathbf{d}_i|\mathbf{d}_1, \ldots, \mathbf{d}_{i-1})$
   Define $\mathbf{d}_i$ as the list of connections with destination index i. Let $c_p = (o, i, j, k, t^{syn}, t^{sem}) \in \mathbf{d}_i$. Then,
   - $P(\mathbf{d}_i|\mathbf{d}_1, \ldots, \mathbf{d}_{i-1}) = P(vs(\mathbf{d_i})) \prod_{c_p \in \mathbf{d_i}} P(\mathbb{1}(o \rightarrow s^k_{ij})|vs(\mathbf{d_i}), \mathbf{d}_1, \ldots, \mathbf{d}_{i-1}, c_1, \ldots, c_{p-1})$
     (a) $P(vs(\mathbf{d_i}))$: multinomial verb signature model (**Sec. 3.1.1**)
     (b) $P(\mathbb{1}(o \rightarrow s^k_{ij})|vs(\mathbf{d_i}), \mathbf{d}_1, \ldots, \mathbf{d}_{i-1}, c_1, \ldots, c_{p-1})$: multinomial connection origin model, conditioned on the verb signature of $\mathbf{d}_i$ and all previous connections (**Sec. 3.1.2**)
2. **Recipe Model (Sec. 3.2)**: $P(R|C) = \prod_i P(e_i|C, e_1, \ldots, e_{i-1})$
   For brevity, define $\mathbf{h}_i = (e_1, \ldots, e_{i-1})$.
   - $P(e_i|C, \mathbf{h}_i) = P(v_i|C, \mathbf{h}_i) \prod_j P(a_{ij}|C, \mathbf{h}_i)$ (**Sec. 3.2**)

Figure 2: Summary of the joint probabilistic model $P(C, R)$ over connection set C and recipe R.

of each of the destination subsets:

$$P(C) = \prod_i P(\mathbf{d}_i|\mathbf{d}_1, \ldots, \mathbf{d}_{i-1}).$$

The probability of each destination subset decomposes into two distributions, a verb signature model and a connection origin model:

$$P(\mathbf{d}_i|\mathbf{d}_1, \ldots, \mathbf{d}_{i-1}) = P(vs(\mathbf{d_i})) \times \prod_{c_p \in \mathbf{d_i}} P(\mathbb{1}(o \rightarrow s^k_{ij})|vs(\mathbf{d_i}), \mathbf{d}_1^{i-1}, c_1^{p-1}).$$

We define each of these distributions below.

3.1.1 Verb signature model

A destination subset $\mathbf{d}_i$ deterministically defines a *verb signature* g_i for verb v_i based on the syntactic and semantic types of the connections in $\mathbf{d}_i$ as well as whether or not each connection has a non-zero origin index. If the origin index is 0 for all connections in $\mathbf{d}_i$, we call v_i a *leaf*. (In Fig, 1, v_1 (preheat) and v_2 (mix) are leafs.) The formal definition of a verb signature is as follows:

Definition 1 The *verb signature* g_i for a verb v_i given a destination set $\mathbf{d}_i$ consists of two parts:

1. **type:** $\{t^{syn} \mid \exists (o, i, j, k, t^{syn}, food) \in \mathbf{d}_i\}$
2. **leaf:** true iff $(o, i, j, k, t^{syn}, t^{sem}) \in \mathbf{d}_i \Rightarrow o = 0$

For example, in Fig. 1, the signature for the "mix" action is $g_2 = (\{DOBJ\}, true)$ and the signature for the "lay" action is $g_4 = (\{DOBJ, PP\}, false)$. Given that there are two syntactic types (i.e., $DOBJ$ and PP) and each verb signature can either be labeled as a leaf or not, there are eight possible verb signatures.

We define a deterministic function that returns the verb signature of a destination subset: $vs(\mathbf{d}_i) = g_i$. $P(vs(\mathbf{d}_i))$ is a multinomial distribution over the possible verb signatures.

3.1.2 Connection origin model

We define $\mathbb{1}(o \rightarrow s^k_{ij})$ as an indicator function that is 1 if there is a connection from the action with index o to the span s^k_{ij}. The probability that a string span has a particular origin depends on (1) the verb signature of the span's corresponding verb, and (2) the previous connections. If, for example, g_i has **leaf**$= true$, then the origin of s^k_{ij} must be 0. If an origin has been used in a previous connection, it is much less likely to be used again.[2]

We assume that a destination subset is a list of connections: if $c_p \in \mathbf{d}_i$, we define c_1^{p-1} as the connections that are prior to c_p in the list. Similarly, $\mathbf{d}_1^{i-1}$ is the set of destination sets $(\mathbf{d}_1, \ldots, \mathbf{d}_{i-1})$. The connection origin model is a multinomial distribution that defines the probability of an origin for a span conditioned on the verb signature and all previous connections:

$$P(\mathbb{1}(o \rightarrow s^k_{ij})|vs(\mathbf{d_i}), \mathbf{d}_1^{i-1}, c_1^{p-1}),$$

[2] A counterexample in the cooking domain is separating egg yolks from egg whites to be used in separate components, only to be incorporated again in a later action.

where $c_p = (o, i, j, k, t^{syn}, t^{sem})$.

3.2 Recipe model

Given a set of connections C for a recipe R, we can determine how the actions of the recipe interact and we can calculate the probability of generating a set of recipe actions $E_R = \{e_1 = (v_1, \mathbf{a}_1), \ldots, e_n = (v_n, \mathbf{a}_n)\}$. Intuitively, R is more likely given C if the destinations of the connections are good text representations of the origins. For example, a string span "oven" is much more likely to refer to the output of the action "Preheat the oven" than "Mix flour and sugar."

We define the history $\mathbf{h}_i$ of an action to be the set of all previous actions: $\mathbf{h}_i = (e_1, \ldots, e_{i-1})$. The probability of a recipe R given a set of connections C can be factored by the chain rule:

$$P(R|C) = \prod_i P(e_i|C, \mathbf{h}_i).$$

Given C and a history $\mathbf{h}_i$, we assume the verb and arguments of an action are independent:

$$P(e_i|C, \mathbf{h}_i) = P(v_i|C, \mathbf{h}_i) \prod_j P(a_{ij}|C, \mathbf{h}_i).$$

Since the set of connections deterministically defines a verb signature g_i for a verb v_i, we can simplify $P(v_i|C, \mathbf{h}_i)$ to the multinomial distribution $P(v_i|g_i)$. For example, if g_i defines the verb to have an ingredient direct object, then the probability of "preheat" given that signature will be lower than the probability of "mix."

The probability of an argument $a_{ij} = (t^{syn}_{ij}, t^{sem}_{ij}, S_{ij})$ given the connections and history decomposes as follows:

$$\begin{aligned} P(a_{ij}|C, \mathbf{h}_i) &= P(t^{syn}_{ij}, t^{sem}_{ij}|C, \mathbf{h}_i) \\ &\times P(S_{ij}|t^{syn}_{ij}, t^{sem}_{ij}, C, \mathbf{h}_i). \end{aligned}$$

3.2.1 Argument types model

The first distribution, $P(t^{syn}_{ij}, t^{sem}_{ij}|C, \mathbf{h}_i)$, ensures that the syntactic and semantic types of the argument match the syntactic and semantic type of the incoming connections to spans of that argument. The probability is 1 if all the types match, 0 otherwise. For example, in Fig. 1, this distribution would prevent a connection from the "preheat" action to the food argument a_{42}, i.e., "over the top," since the semantic types would not match.

3.2.2 String span models

The second distribution, $P(S_{ij}|t^{syn}_{ij}, t^{sem}_{ij}, C, \mathbf{h}_i)$, models how likely it is to generate a particular string span given the types of its encompassing argument, the connections, and history. We assume the probability of each span is independent:

$$P(S_{ij}|t^{syn}_{ij}, t^{sem}_{ij}, C, \mathbf{h}_i) = \prod_{s^k_{ij} \in S_{ij}} P(s^k_{ij}|t^{syn}_{ij}, t^{sem}_{ij}, C, \mathbf{h}_i).$$

We break this distribution into three cases. To help describe the separate cases we define the function $origin(s, C)$ to determine the origin index of the connection in C to the span s. That is, $origin(s^k_{ij}, C) = o \Leftrightarrow \exists (o, i, j, k, t^{syn}, t^{sem}) \in C$.

Part-composite model When the encompassing argument is a food and the origin is a previous verb (i.e., $P(s^k_{ij}|t^{syn}_{ij}, t^{sem}_{ij} = food, origin(s^k_{ij}) \neq 0, C, \mathbf{h}_i)$), then the probability of the span depends on the ingredients that the span represents given the connections in C. For example, "dressing" is more likely given ingredients "oil" and "vinegar" than given "chicken" and "noodles". We use IBM Model 1 (Brown et al., 1993) to model the probability of a composite destination phrase given a set of origin food tokens. Let $food(s^k_{ij}, C)$ be the set of spans in food arguments such that there is a directed path from those arguments to s^k_{ij}. IBM Model 1 defines the probability of a span given the propagated food spans, $P(s^k_{ij}|food(s^k_{ij}, C))$.[3]

Raw food model When the encompassing argument is a food but the origin index is 0 (i.e., $P(s^k_{ij}|t^{syn}_{ij}, t^{sem}_{ij} = food, origin(s^k_{ij}) = 0, C, \mathbf{h}_i)$), then there is no flow of ingredients into the span. A span that represents a newly introduced raw ingredient (e.g., "bacon" in e_4 of Fig. 1) should have a high probability. However, spans that denote the output of actions (e.g, 'batter," "banana mixture") should have low probability. We use a naïve Bayes model over the tokens in the span $P(s|\text{is raw}) = \prod_\ell P(w_\ell|\text{is raw})$ where w_ℓ is the ℓ^{th} token in s (e.g., "mixture" would have a very low probability but "flour" would be likely).

Location model When the encompassing argument is a location (i.e., $t^{sem}_{ij} = location$),

[3] IBM Model 1 cannot handle implicit arguments. In this case, we model the probability of having an implicit food argument given the length of the connection (i.e., implicit food arguments nearly deterministically connect to the previous action). The probability of non-empty string spans is scaled accordingly to ensure a valid probability distribution.

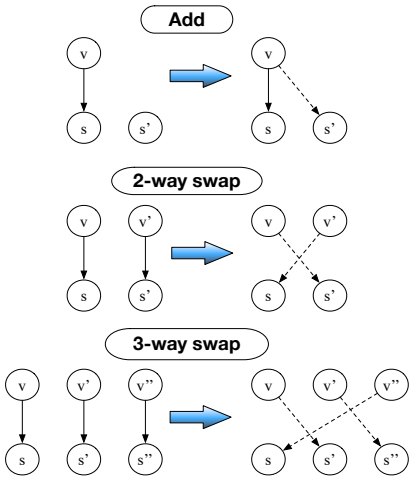

Figure 3: The three types of search operators. For swaps, one of the origins can be 0.

$P(S_{ij}|t_{ij}^{syn}, t_{ij}^{sem}, C, \mathbf{h})$ models the appropriateness of the origin action's location for the destination. If the string span is not implicit, the model deterministically relies on string match between the span and the location argument of the verb at the origin index. For example, the probability of "the preheated oven" conditioned on an origin with location "oven" is 1, but 0 for an origin with location "bowl." If the span s_{ij}^k is empty, we use a multinomial model $P(loc(origin(s_{ij}^k, C))|v_i)$ that determines how likely it is that an action v_i occurs in the location of the origin verb. For example, baking generally happens in an oven and grilling on a grill, but not vice versa. For example, in Fig. 1, the probability of the location span of "bake" is determined by P("oven" | "bake").

4 Local Search

Connections among actions and arguments identify which ingredients are being used by which action. For example, in Fig. 1, we know that we are baking something that contains all the ingredients introduced in e_2 and e_4 because there is a path of connections from the introduction of the raw ingredients to the implicit object of "bake". We cannot make decisions about the origins of arguments independently; the likelihood of each edge depends on the other edges. Identifying the most likely set of connections is, therefore, intractable.

We adopt a local search approach to infer the best set of connections.[4] We initialize the set of connections using a sequential algorithm that connects the output of each event to an argument of the following event, which is a strong baseline as shown in Sec. 8. We score potential local search operators that can be applied to the current set of connections C and make a greedy selection that improves $P(C, R)$ the most until no search operator can improve the probability. We constrain the search so all verbs have a direct object (i.e., implicit direct objects connect to a previous action).

We employ three types of search operators (see Fig. 3 for details). **OP_ADD** changes the origin index of a connection in C from 0 to the index of an event. **OP_2SWAP** swaps the origin indexes of two connections. This works even if one of the origin indexes is 0. **OP_3SWAP** rotates the origin indexes of three connections. This works even if one of the origin indexes is 0. For efficiency reasons, we only allow 3-way swaps with destination indexes within 4 events of each other.

Algorithm 1 Pseudocode for learning $P(C, R)$

Input: Initialized $P(C, R)$, recipe dataset $\mathcal{R}$
Repeat until convergence:
  E-step: Update $C \longleftarrow \arg\max_C P(C, R)$ for each $R \in \mathcal{R}$ using local search (Sec. 4)
  M-step: Update parameters of $P(C, R)$ using action graphs generated in E-step
Return $P(C, R)$

5 Learning

We use hard EM to learn the probabilistic models. Pseudocode is given in Alg. 1. At each iteration, we use our local search algorithm and the current probabilistic models to annotate each recipe in the data set with its most likely set of connections C (Sec. 4). Then, we re-estimate the parameters of the probabilistic models using the recipe-connections pairs as training data. A small (33 recipes) development set was used to determine when to stop the iterations. Experimental details and model initialization are described in Sec. 7.

6 Segmentation

Our inference and learning algorithms assume as input a recipe segmented into a set of events $E_R = \{(v_1, \mathbf{a}_1), \ldots, (v_n, \mathbf{a}_n)\}$. We designed a segmentation system that could be trained on our unannotated data set of mostly imperative sentences.

[4] Similar local search methods have been shown to work well for other NLP tasks, including recent work on dependency parsing (Zhang et al., 2014).

Our system achieves an F1 score of 95.6% on the task of identifying the correct verbs in the test set.[5]

Segmentation model We define a generative model for recipes as:

$$P(R) = P(n) \prod_{i}^{n} P(v_i) P(m \mid v_i) \prod_{j=1}^{m} P(a_{ij}).$$

We first select a number of verbs n in the recipe from a geometric distribution. Given the number of verbs, we select a set of verbs $\mathbf{V} = \{v_1, \ldots, v_n\}$ using a multinomial distribution. For each verb v_i, we select a number of arguments m from a separate multinomial distribution that has the probability of 0, 1, 2, or 3+ arguments given the verb, $P(m \mid v_i)$. For each argument, we generate a string using a bigram model, $P(a_{ij}) = \prod_{\ell} P(w_\ell | w_{\ell-1})$, where w_ℓ is the ℓ^{th} word of a_{ij}.

Inference Given tokenized sentence $T = (w_1, \ldots, w_k)$, we enumerate all possible segmentations and choose the one with the highest probability. To keep this efficient, we use a closed set of possible verbs and assume a closed set of words (e.g., prepositions, adverbs) can only follow the start token in the argument bigram model. Thus, annotating the verbs in a sentence determines a unique set of argument strings. Despite scoring the segmentations for all possible sets of verbs, we found the process to be very efficient in practice.

Learning For unsupervised learning, we again employ a hard EM approach. We initialize our models, segment all of the training data, re-estimate the parameters, and iterate these steps until performance on a development set converges.

We estimate the initial verb multinomial model using counts from the first word of each sentence in the dataset, which are normally verbs in imperative sentences, and filter out any words that have no verb synsets in WordNet (Miller, 1995). All other models are initialized to be uniform.

7 Experimental Setup

Data Set We collected 2456 recipes (with over 23,000 sentences) from allrecipes.com by searching for 20 dish names (e.g., including "banana muffins", and "deviled eggs"). We randomly sampled, removed, and hand labeled 33 recipes for a development set and 100 recipes for test. All models were trained on the unannotated recipes; the dev set was used to determine the stopping point for training. Each recipe in the test set has 13 actions on average.

Recipe pre-processing To pre-process each recipe, we first use the segmentation system described in Sec. 6. Then, we use a string classification model to determine the semantic type (e.g., $food$, $location$, or $other$) of an argument based on its spans. We identify spans as raw ingredients based on string match heuristics (e.g., in Fig. 1, the span "crushed crackers" represents the ingredients "crushed butter-flavored crackers"). We stem all words and ignore function words.

Sequential Baseline Because most connections are sequential – i.e., argument spans are most often connected to the output of the previous verb – sequential connections make a strong baseline; we connect the output of each predicate to the first available argument span of the following predicate. If no argument exists, an implicit argument is created. We run this baseline with and without first identifying raw ingredients in the recipe; if raw ingredient spans are identified, the baseline will not connect the previous event to those spans. Performance suffers significantly if the raw ingredients are not identified beforehand.

Evaluation metrics We report F-measure by comparing the predicted connections from actions to spans (i.e., where the origin index > 0) against gold standard annotations. We don't evaluate connections to raw ingredients as we create those connections during pre-processing (see Sec. 7).

Model initialization The verb signature model (Sec. 3.2) is initialized by first identifying $food$ arguments using string overlap with the ingredient list. All other arguments' types are considered unknown, and partial counts were awarded to all verb signatures consistent with the partial information. The first verb in each recipe was assumed to be the only leaf. The string classification model for the pre-processing step was initialized by using the initialized verb signature model to identify the types of $DOBJ$ arguments. The string classification model was estimated using the argument tokens given the types. We initialized the part-composite model (Sec. 3.2.2) so that exact string matches between ingredients and spans are given

[5] Early efforts using a state-of-the-art parser could only achieve an F1 score of 73.6% for identifying verbs, likely due to a lack of imperative sentences in the training data. This result motivated us to develop our segmentation system.

Algorithm	Prec	Rec	F1
Automatic segmentations			
Sequential baseline	55.7	52.7	54.1
Sequential baseline w/ ingredients	60.4	57.2	58.8
Our model before EM	65.8	62.7	64.2
Our model after EM	**68.7**	**65.0**	**66.8**
Oracle segmentations			
Sequential baseline	67.8	65.2	66.5
Sequential baseline w/ ingredients	73.5	70.7	72.0
Our model before EM	77.1	74.8	75.9
Our model after EM	**81.6**	**78.5**	**80.0**

Table 1: Performance of our algorithm against the sequential baselines.

Verb	Top location tokens	
bake	oven - 55.4%	min - 0.7%
mix	bowl - 32.6%	hand - 0.9%
press	pan - 24.7%	dish - 6.5%
stir	bowl - 5.5%	skillet - 2.0%
fry	heat - 11.9%	skillet - 10.2%
cool	rack - 10.5%	pan - 3.8%
boil	water - 15.5%	saucepan - 5.2%

Table 2: The top scoring location token for example verbs. The percentage is the percent of times the verb has that as a visible location token.

high probabilities and those without are given low probabilities. Given the initialized string classification model, the raw food model (Sec. 3.2.2) is initialized counting whether or not tokens in food arguments occur in the ingredient list. The probability of an implicit location (Sec. 3.2.2) is initialized to a hand-tuned value using the dev set.

8 Results

Quantitative Results We trained our model for four iterations of hard EM until performance converged on the development set. Table 1 presents our results on the test set. We compare our model to the sequential baselines using both the output of our segmentation system and oracle segmentations. We perform significantly better than the sequential baselines, with an increase in F1 of 8 points over the more competitive baseline using our segmentation system and an increase of 8 points using the oracle segmentations.

Qualitative Results We find that the learned models demonstrate interpretable cooking knowledge. Table 3 shows the top composite tokens for different ingredients as learned by the part-composite model (Sec. 3.2.2). The composite tokens show parts of the ingredient (e.g., after "eggs" can be split into "whites" or "yolks") or composites that are likely to contain an ingredient (e.g., "flour" is generally found in "batter" and "dough"). Unsurprisingly, the word "mixture" is one of the top words to describe a combination of ingredients, regardless of the ingredient. The model also learns modifiers that describe key properties of ingredients (e.g., flour is "dry" but bananas are "wet") which is important when evaluating connections for sentences such as "Fold the wet mixture into the dry ingredients."

Verb	Top verb signature	(%)
add	$\{DOBJ, PP\}$	58%
	$\{DOBJ\}$	27%
combine	$\{DOBJ\}$:leaf	68%
	$\{DOBJ\}$	17%
bake	$\{DOBJ\}$	95%
grease	{}:leaf	75%
pour	$\{DOBJ, PP\}$	68%
	$\{DOBJ\}$	27%
reduce	$\{PP\}$	90%
	$\{DOBJ\}$	8%

Table 4: The top verb signatures for example verbs. The syntactic types identify which arguments of the verb are foods and "leaf" means no arguments of the verb connect to previous actions.

Table 2 shows the location preferences of verbs learned by the location model (Sec. 3.2.2). Some verbs show strong preferences on locations (e.g., "bake" occurs in an oven, "mix" in a bowl). The top location for a "boil" action is in "water," but in other recipes "water" is an ingredient.

Finally, Table 4 shows learned verb signatures. For example, "add" tends to be a non-leaf action, and can take one or two food arguments (e.g., one food argument: "Heat the pan. Add onions." vs. two food arguments: "Add the wet mixture to the dry mixture.") We learn that the most likely verb signature for "add" has two food arguments; since over 74% of the occurrences of "add" in the dataset only have one visible argument, the segmentation alone is not enough to determine the signature.

Errors Finally, we performed an error analysis on the development set. 24% of the errors were due to missing or incorrect actions caused by segmentation errors. Among the actions that were segmented correctly, 82% of the outgoing connections were sequential. Of those, our system missed 17.6% of the sequential connections and 18.3% of the non-sequential connections.

Ingredient	Top composite tokens
eggs	egg, yolk, mixture, noodles, whites, cook, top, potato, cold, fill
beef	beef, mixture, grease, meat, excess, cook, top, loaf, sauce, ground
flour	flour, mixture, dough, batter, top, crust, ingredients, sauce, dry, pie
noodles	noodles, cook, mixture, egg, sauce, top, meat, drain, pasta, layer
chicken	chicken, mixture, salad, cook, dressing, pasta, soup, breast, vegetables, noodles
pumpkin	pumpkin, mixture, pie, filling, temperature, seeds, mash, oven, crust, dough
bananas	banana, mixture, batter, muffin, bread, egg, wet, cup, ingredients, slice

Table 3: Examples of ingredients with their top inferred composite words.

9 Related work

Our work relates to a substantial body of research that transforms natural language instructions into actionable plans (Artzi and Zettlemoyer, 2013, Chen and Mooney, 2011, Branavan et al., 2011, Branavan et al., 2009, McMahon et al., 2006). Most of these approaches do interactive learning in virtual environments or simulations, while we learn from the redundancy seen in the text of different instances of similar recipes.

There is also significant related work on supervised learning for instructions. A recent series of studies have explored parsing of cooking recipes (Mori et al., 2012; Mori et al., 2014; Maeta et al., 2015). However, they assume annotated data, study Japanese recipes, and make edge connections independently without taking into account the flow of ingredients. Tasse and Smith (2008) develops annotation for English recipes, but do not mark connections from implicit roles, and only studied segmentation models. Lau et al. (2009) develop models to interpret how-to instructions, but also assume supervision, and do not make connections between different actions.

Data-driven extraction of cooking knowledge has been explored in the context of building a cooking ontology (Gaillard et al., 2012; Nanba et al., 2014). In contrast, our work induces probabilistic cooking knowledge as part of unsupervised learning process for understanding recipes. Cooking knowledge is also closely related to script knowledge, but most prior work focus on newswire and children's books rather than procedural language (Fujiki et al., 2003; Chambers and Jurafsky, 2009; Pichotta and Mooney, 2014; Balasubramanian et al., 2013) or rely on crowdsourced descriptions to learn procedural knowledge (Regneri et al., 2010; Regneri et al., 2011; Frermann et al., 2014). There is work on related, but distinct, tasks that use recipes, including identifying actionable refinements from online recipe reviews (Druck and Pang, 2012) and extracting structured information from ingredient lists (Greene, 2015)

Cooking recipes have also been studied in the context of grounded language learning, e.g., to build robots that can cook (e.g., Bollini et al., 2013, Beetz et al., 2011), or to align cooking videos to natural language descriptions of actions (Regneri et al., 2013) or recipe texts (Malmaud et al., 2014; Malmaud et al., 2015). Our work complements these efforts by recovering fine-grained procedural semantics from text alone.

Finally, detection and resolution of implicit arguments is an instance of zero anaphora detection and resolution (Silberer and Anette, 2012, Tetreault 2002, Whittemore et al., 1991, Palmer et al., 1986). We present an empirical approach for understanding these phenomena in instructions.

10 Conclusion

We presented unsupervised methods for segmenting and identifying latent connections among actions in recipe text. Our model outperformed a strong linear baseline, while learning a variety of domain knowledge, such as verb signatures and probable ingredient components for different composites. Future work includes learning a more comprehensive model of locations (e.g., identifying nested locations such as an oven and a pan in the oven), enriching action graphs with greater semantic coverage (e.g., durations, tools, amounts), and training and evaluating on larger datasets. We also plan to use our techniques to support related tasks, such as instructional recipe generation.

Abstract

Comparison is one of the most important phenomena in language for expressing objective and subjective facts about various entities. Systems that can understand and reason over comparative structure can play a major role in the applications which require deeper understanding of language. In this paper we present a novel semantic framework for representing the meaning of comparative structures in natural language, which models comparisons as predicate-argument pairs interconnected with semantic roles. Our framework supports not only adjectival, but also adverbial, nominal, and verbal comparatives. With this paper, we provide a novel dataset of gold-standard comparison structures annotated according to our semantic framework.

1 Introduction

Representing the meaning of text has long been a focus in linguistics and deriving computational models of meaning has been pursued by various semantic tasks such as semantic parsing. Deep semantic parsing (as opposed to shallow semantic parsing, such as semantic role labeling) aims to map a sentence in natural language into its corresponding formal meaning representation (Zelle and Mooney, 1996; Berant and Liang, 2014). There has been a renewed interest in deeper semantic representations of natural language (Banarescu et al., 2013) in NLP community. Open-domain semantic representations enable inference and reasoning, which is required for many language understanding tasks such as reading comprehension tests and open-domain question answering. Comparison is a common way for expressing differences in sentiment and other properties towards some entity. Comparison can happen in very simple structures such as 'John is taller than Sam', or more complicated constructions such as 'The table is longer than the sofa is wide'. So far the computational semantics of comparatives and how they affect the meaning of text has not been studied effectively. That is, the difference between the existing semantic and syntactic representation of comparatives is not distinctive enough for enabling deeper understanding of a sentence. For instance, the general logical form representation of the sentence 'John is taller than Susan' using the Boxer system (Bos, 2008) is the following:

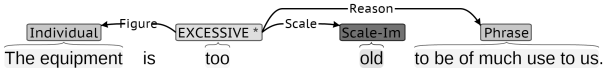
$$named(x0, john, per) \\ \& \; named(x1, susan, nam) \\ \& than(taller(x0), x1) \quad (1)$$

The above meaning representation does not fully capture the underlying semantics of the adjective 'tall' and what it means to be 'taller'. A human reader can easily infer that actually the height of John is greater than the height of Susan. Another example to consider is the sentence 'John is tall', which basically has the typical logical form $tall(john)$ –which is a very superficial representation for the meaning of the predicate 'tall'. Likewise, a human reader can infer that defining someone as 'tall' in some domain of discourse entails that this person is somehow 'taller' than some other population (say their average), however, the earlier typical logical form representation does not enable such inferences.

In this paper we introduce a novel framework for semantic representation and computational analysis of the structure of comparison in natural language. This framework enables deeper representation of semantics of comparatives, including all different types of comparison within *compara-*

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 993–1002,
Lisbon, Portugal, 17-21 September 2015.

tives, superlatives, equatives, excessives, and assetives, and the way they are related to their corresponding semantic roles. Together with this paper, we provide a dataset of gold-annotated comparative structures using our meaning representation, which enables training models on comparison constructions. We propose a new approach for automatic extraction of comparison structures from a given text. A semantic representation of the comparison expressed by the sentence 'The equipment is too old to be much of use to us.' augmented under our representation would be the following:



Throughout this paper we define a comparison to be any statement comparing two or more entities, expressing some kind of measurement on a scale, or indicating some degree of having a measurable property. The details of these variations will be discussed in Section 3.

2 Background

In this section we provide a linguistic background on comparison constructions in language, which provides the basis of our semantic framework (to be presented in Section 3).

2.1 Comparative Structures in Language

Measurement in natural language is mainly expressed in sentences having comparative morphemes such as *more, less, -er, as, too, enough, -est, etc*[1]. Comparatives can be either adjectival, adverbial, nominal, or verbal, i.e., the main component of the sentence carrying out the measurement can have either of these parts of speech.

Adjectival Comparatives: Canonical examples of comparative sentences contain adjectives, e.g., 'tall' or 'pretty'. Even within adjectival comparatives, there is a good deal of structural variety. Consider the following examples:

(1) a. Mary is *taller* than Susan.
b. Mary is 3 inches *taller* than Susan.
c. Mary is *taller* than 5 feet.

[1]These morphemes are counted as the main comparison operators. For easier representation, throughout this paper we specify the smallest constituent containing any of these morphemes as the comparison operator, which is *italicized* in the sentences.

The comparative form of the adjective 'tall' in sentence 1a is viewed as an expression denoting a *greater than ($\succ$)* relation between two individuals, 'Mary' and 'Susan', on the scale of 'tallness'. The degree-theoretic analysis of such adjectives brings up the notion of *Gradable Adjectives*: many adjectives describe qualities that can be measured according to *degrees* on *scales*, such as the scale of 'size', 'beauty', 'age', etc. These adjectives can be used with comparative morphemes, indicating less or more of a particular quality on a scale. Gradable adjectives can express specific relations between individuals on a scale, e.g., in sentence 1b Mary is taller than Susan by a measure of 3 inches.

Comparison on the scale does not always involve two individuals. For example consider sentence 1c which denotes a comparison being made between an individual and a specific point on the scale of 'tallness'. All the earlier examples are among the simplest types of comparative structures using adjectives. Consider the following example:

(2) Mary is *taller* than the bed is long.

In sentence 2 we have a case of *subcomparatives*, where we compare 'Mary' and 'bed' according to two different dimensions: height and length. Each dimension provides a degree, and the degrees are ultimately related by the *greater than ($\succ$)* relation. Scalability is known to be universal in language and a wide variety of linguistic phenomena can be explained in terms of degrees and scales (Solt, 2015).

The Semantics of Scales: A fairly common view (Kennedy, 2007) is that a scale S is a triple of the following form:

$$S = \langle D, \succ, DIM \rangle \quad (2)$$

where D is a set of degrees, $\succ$ is an ordering relation on D, and DIM is the dimension of measurement.[2]

Individuals are linked to degrees by measure functions. A measure function μ_S is the function that maps an individual x to the degree on the scale S that represents x's measure with respect to the dimension DIM. For example, the μ_{HEIGHT} measure function is a function that maps individuals to their respective heights. Under this model, we represent the comparative structure of the sentences 1a-1c as follows:

[2]To know more about the theory of scales and restrictions on dimensions and degrees refer to (Solt, 2015).

(3) a. $\mu_{HEIGHT}(Mary) \succ \mu_{HEIGHT}(Susan)$
b. $\mu_{HEIGHT}(Mary) \succeq \mu_{HEIGHT}(Susan) + 3$"
c. $\mu_{HEIGHT}(Mary) \succ 5\ feet$

A generic comparative interpretation of some degree of tallness under $HEIGHT$ scale is as follows:

$$[\![tall]\!] = \lambda d \lambda x.\mu_{HEIGHT}(x) \succeq d \quad (3)$$

where d is the degree argument which is supplied by some form of degree morpheme: a degree modifier (e.g., too, very), a measure phrase (e.g. 1.7 inches), or simply comparative or superlative morphology. Under this model, we can also represent the comparative structure of the sentence 'Mary is tall'[3], where there is no explicit degree argument. A common assumption is that the degree role is played by a phonologically null degree morpheme called pos, which denotes a context-dependent threshold or standard of comparison (Kennedy, 2007; Heim, 2007). For instance, in a specific context of adult men in north America being 'tall' could be interpreted as being over 6 feet.

Non-canonical Comparatives: Comparative structures can also be verbal, nominal, and adverbial. Consider the following verbal comparatives:

(4) a. The women ate *more* than men did.
b. The lake cooled *more* than 4 degrees.

It has been proposed (Wellwood et al., 2012) that measure functions (μ) can be applied both to individuals and to events, in the latter case measuring either the event or an entity related to the event. The comparative interpretation for the two sentences 4a and 4b is as follows:

(5) a. $\mu_{volume}(eat(women)) \succ \mu_{volume}(eat(men))$
b. $\lambda e.\mu_{coolness}(e)(lake) \succ 4\ degrees$

where cool is a function that takes an event e and an object x (here 'lake') and returns a degree representing the amount to which x changes in coolness as a result of participating in e. The underlying scale of verbal comparatives is sometimes ambiguous, e.g., in sentence 5a it is not clear whether the women ate more in volume or in quantity.

Comparative structures can also be nominal. Consider the following sentences:

(6) a. *More* juniors than seniors came to the ceremony.
b. We bought *more* milk than wine.

The meaning of sentences presented above must be stated with reference to degrees as well (Solt, 2015). Hence, the scale for the comparison sentence 6a is the numerical counting by integers and the scale for sentence 6b is something corresponding to a mass dimension, here perhaps liquid volume. Adverbial comparatives share many of their characteristics with the adjectival and verbal class, which we do not develop further for brevity. For example the sentence 'Mary ran *faster* than Sam' is an example of adverbial comparison, where the implicit 'speed' attribute of the 'running' event associated with Mary and Sam is being compared.

2.2 Categories of Comparison

There are various ways for making comparisons, each indicating different degrees of difference or similarity. Following are the major categories for degrees of comparison together with example sentences[4]:

(7) Comparative
a. Mary is *taller* than Susan.
b. Dogs are *more* intelligent than rabbits.

(8) Superlative
a. Mary is the *tallest* girl in her class.
b. Dogs are the *most* intelligent among pets.

(9) Equative
a. Mary is *as* tall as Bill.
b. Dogs are *as* intelligent as cats.

(10) Excessive
a. Mary is *too* short for basketball.
b. Dogs are *too* intelligent to be fooled.

(11) Assetive
a. Mary is tall *enough* to reach the shelf.
b. Dogs are intelligent *enough* to find their way home.

3 Semantic Framework of Comparison

As discussed earlier, having a deep meaning representation of comparison structures can help us

[3]Such cases are called *positive* usage of the adjective. The *negative* (also called antonym) usage would be 'Mary is short'.

[4]As shown in example sentences of Table 1, there can be non-adjectival comparisons in each of these categories as well.

build computational models of comparison in natural language and perform inferential tasks in various domains. Here we introduce a novel semantic framework of comparison. This framework is based on the linguistic interpretations presented in Section 2, but formalized and adapted to suit our semantic computational framework.

We model comparatives as inter-connected predicate-argument structures, where predicates are the main comparison operators (implicit and explicit comparison morphemes), and arguments are connected to the predicates via semantic roles (relations). Our framework includes not only explicit comparisons, but also implicit ones in the form of an evaluation or a measurement on a scale, which will be explained throughout this section. More detailed and complete list of the predicates, semantic roles, and arguments can be found in the supplementary material.

Predicates: Table 1 lists all the predicate operators under our framework. As the table shows, there are four main types of predicates: *comparatives, extremes, bases, and measurements*. Most of these types can be associated with operators from any of our parts of speech: Adjective (JJ), Adverb (RB), Noun (NN), and Verb (VB). The predicate operator in each of the examples is italicized. The *comparatives* type also includes the operators < and =<, which are the opposite of the operators > and >= presented in the table. It is important to note that the 'base positive' predicate is actually the implicit pos operator (as mentioned in Section 2.1; however, for easier representation we specify it by marking its corresponding adjective or adverb. The same thing happens for measurement predicates. Also, our framework captures the subtle difference between the meaning of 'Mary is $[tall]_{positive}$' and 'Mary is 5 feet $[tall]_{measurement-explicit}$'. The earlier means that Mary is tall according to some standard of tallness in a context, while the latter means that Mary's height equals the degree of 5 feet.

Semantic Roles: Each predicate is characterized by its arguments and each argument is connected to the predicates by a relation (semantic role) type. Table 2 shows the possible semantic role types for a predicate. *Figure* is the core role for a comparison structure, i.e., any comparison should have a role indicating the main entity which is being evaluated/measured/compared on a scale. The simplest form of comparative predicate, e.g., 'John is taller than Sam', involves two main roles: Figure (John) and Ground (Sam). The non-core roles are mainly associated with non-comparative comparisons

Arguments: Last but not least, each role points to an argument, which can have various types, as listed in Table 3. The most frequent argument type is individual, as in 'John is taller than Sam'. The other notable role is Phrase-value, which represents an interesting comparison phenomena. In the corresponding example in the table, the speed of John's driving is explicitly being compared with some point on the scale of speed to which 'he was allowed'. Such *ground* roles are classified as phrase-value, where a verb phrase signifies a point of comparison on scale, not an individual entity. Figure 1 shows an example of predicate-argument structure under the described semantic framework.

4 Predicting Comparison Structures

Given an input sentence, we want to predict the predicate operators, their semantic roles, and arguments. We decompose this problem into three sub-problems:

- Labeling predicate candidates using a multi-class classifier
- For each predicate, considering the set of all possible argument spans:
  - Use a classifier for predicting the role type label
  - Use a classifier for predicting the argument type label

Our overall approach, to be described in this section, is similar to the works on joint inference with global constraints for learning event relations and process structures (Do et al., 2012; Berant et al., 2014).

Predicting Predicates: The first step in comparison structure prediction is to identify and label the predicates. For this purpose we train a multi-class classifier that labels all one-word constituents in the sentence with any of predicate types in Table 1 or *None* (indicating that the constituent is not a predicate). The set of all possible predicate labels is named P.

We used various features for training the predicate classifier: we extract the lemma and POS tag of the word, POS tag of children, siblings, parent and root of the sentence in the dependency

Predicate Type	Subtype	Examples
Comparatives: Comparing against one or more entities.	>	• JJ: The car was *more* modern than I had imagined. • RB: John ran *faster* than Susan. • NN: *More* cookies than cakes were purchased. • VB: Coffee is *less* consumed than tea.
	>=	• JJ: Pizza is *as* expensive as pasta. • RB: The men ran *as* fast as the women did. • NN: That college hires *as* much professors as we do. • VB: Athletes drink as much as others.
	Superlative	• JJ: Mary is the *tallest* among her colleagues. • RB: Mike talked the *most* loudly of the group. • NN: The juniors found the *most* rock of all. • VB: The fire fighters ran the *most* among others.
Extreme: Indicating having enough or too much of a quality or quantity.	Excessive	• JJ: Mary is *too* tall to fit in the chair. • RB: Sam ran *too* fast to get caught. • NN: There are *too* many students at the party. • VB: The kid screamed *too* much.
	Assetive	• JJ: Mary is smart *enough* to accept the offer. • RB: The machine works steadily *enough*. • NN: There are *enough* professors at the party. • VB: Jack passed *enough* interviews to prove himself.
Polarity: Base form expression of +/- quality.	Positive	• JJ: Mary is *tall*. • RB:John talks *beautifully*.
	Negative	• JJ: Susan is *short*. • RB: Philip walks *slowly*.
Measurement: Indicating a measurement on a scale.	Explicit	• JJ: Mary is 5 feet *tall*. • RB: Philip is driving 60mph *fast*.
	Implicit	• JJ: Mary is *5 feet*. • RB: Philip is driving *60mph*.

Table 1: The predicate types defined under our framework.

Figure 1: A full annotation of a sample predicate-argument structure under the described semantic framework.

tree, POS tag and lemma of two adjacent words, similarity features from WordNet (Miller, 1995), word polarity features, and most importantly 'attribute concepts' for words which are adjectives (Bakhshandeh and Allen, 2015). The 'attribute concepts' are the different properties that an adjective can describe, for instance 'height' and 'thickness' are the attributes of the adjective 'gangling'. Last but not least, we include the conjunction of all these features.

Predicting Roles and Arguments: Given the predicates, one should label the predicate-argument role and predict the argument type. Here we take an approach used for semantic role labeling (Punyakanok et al., 2008): given a predicate, we collect all constituents in the sentence to build a set of plausible candidate arguments. As a result, each predicate has a set of candidate arguments which should be labeled with their argument types and be assigned with a semantic role edge. Here we jointly train two logistic regression classifiers for predicting semantic role type and argument type of a predicate-argument pair, using argument identification features from (Punyakanok et al., 2008) and using the structured averaged Perceptron algorithm (Collins, 2002). The role types can be any of the roles from table 2 or *None* (set R), and the argument types can be any

Relation Type	Description	Example
Figure	The main role being compared to something else.	- [Lara] is taller than the tree.
Ground	The main role against which the figure is compared.	- Lara is taller than the [tree].
$\text{Difference}_{\text{degree}}$	The 'plus' and 'times' roles, signifying an amount of difference on a degree.	- Sam is [twice] taller than Jim.
Domain	The explicit expression of the domain/population in which the comparison takes place	- Mary is the most intelligent among [her classmates].
Reason	The reason associated with the excessive and assetive predicates	- John is too lazy [to wake up].
$\text{Measurement}_{\text{degree}}$	The main indication of a measurement	- Henry is [5 feet] tall.
Scale	The scale on which the comparison takes place	- The [height] of the chair equals the [length] of the sofa.

Table 2: The role types under our framework.

Argument Type	Subtype	Example
Individual: An entity being compared against others.	-	- [John] is a better performer than Susie.
Reference: A referring entity, the actual antecedent of which would be resolved in discourse-level.	-	- John is 2" taller than [that].
Phrase: Introduces a degree on scale.	Value	- John was driving faster than [he was allowed].
Amount: The expression of the amount in a measurement.	Value	- Mary is [5 feet] tall. - Mary is [twice] taller than Bill.
	Very Low-Low	- Mary is [a little bit] taller than John.
	High-Very High	- Mary is [a lot] taller than Bill.
Bound: A bound/approximation being set on the amount that is expressed.	Exact	- Mary is [exactly] 5 feet tall.
	Approximate	- Sam was [about] three times faster than others.
	Lower	- John walks [at least] twice faster than you.
	Higher	- Mary is [at most] twice as smart as the others.
Scale: The scale on which the measurement is done.	Explicit	- The [height] of the bridge is too low for the van.
	Implicit	- Sam is more [available] than John is.

Table 3: The argument types under our framework.

of the ones from table 3 or *None* (set G). At the end of this stage we have two scores: $sc_{p,j,r} = log\ Pr_{p,j,r}$ where $p \in P$ is a predicate type, j is a candidate argument, $r \in R$ is a role type; and $sc_{p,j,g} = log\ Pr_{p,j,g}$ where $g \in G$.

Joint Inference: Given a sentence with its extracted predicates[5], for each predicate labeled as p, the goal is the following: find the best assignment for the indicators $y = \{y_{p,j,r} \mid p \in P, 1 < j \leq n, r \in R\}$ and $x = \{x_{p,j,g} \mid p \in P, 1 < j \leq n, g \in G\}$. Here n is the number of candidate arguments for the given predicate. We model the problem as an Integer Linear Programming (ILP). We formulate the problem as follows:

$$\arg\max_{y,x} \sum_{\substack{1<j\leq n \\ r\in R}} sc_{p,j,r}\ y_{p,j,r} + \sum_{\substack{1<j\leq n \\ g\in G}} sc_{p,j,g}\ x_{p,j,g} \quad (4a)$$

$$\mathbf{s.t.} \sum_{r\in R, r\neq None} y_{p,j,r} = 1 \quad (4b)$$

$$\sum_{g\in G} y_{p,j,g} = 1 \quad (4c)$$

$$\sum_{1<j\leq n} y_{p,j,r} = 1 \quad (4d)$$

$$y_{p,j,None} = x_{p,j,None} \quad (4e)$$

$$\sum_{1<j\leq n} y_{p,j,Figure} = 1. \quad (4f)$$

The hard constraints $4b - 4c$ each indicate a restriction on the structure of the predicate-argument relation and labels: each argument can have only

[5] A constituent is a predicate if it is labeled with any $p \in P$ and $p \neq None$.

one role and argument type ($4b - 4c$), each predicate can only have one of each role type ($4d$), a 'None' role type should be matched with a 'None' argument type ($4e$), and each predicate should have exactly one 'Figure' role ($4f$). There are also some other specific constraints such as the fact that a predicate labeled with 'comparative' cannot have a 'Domain' role type and vice verse.

5 Experimental Setup

5.1 Dataset Creation

In order to make our gold-annotated dataset we used OntoNotes (Pradhan et al., 2007) release 5.0 corpus. OntoNotes covers various genres such as conversations, news-wire, and Weblogs, which provides distinctive variations of comparison structures in natural language. Furtheremore, we think our annotations can potentially provide augmentations on OntoNotes, so using the original OntoNotes sentences can be beneficial.

One approach for pinpointing comparison sentences is to mine for some known patterns and train a classifier for distinguishing comparison and non-comparison sentences (Jindal and Liu, 2006b). However, as demonstrated earlier, the variety of comparison structures is so vast that being limited to some specific patterns or syntactic structures will not serve our purpose. In order to address this issue, we randomly selected 2000 sentences from OntoNotes which contained an adjective, an adverb, or any of the comparison morphemes. This set contained some non-comparison sentences, such as 'John admitted to the crime too'.

In order to make the final set of comparison sentences we performed the following task: we define a comparative sentence as a sentence that contains at least one predicate operator as defined in Section 3. Hence, we provided three human experts with a full predicate operator types table and asked each of them to annotate any predicate operator found in the given sentences. Then we retained any sentences with at least one predicate operator which was annotated by at least two of the three judges. We further refined the set to include equal number of predicate types. This resulted in 531 sentences.

After collecting the comparison sentences, we asked the annotators to provide gold-standard annotation of predicate-argument structure of the sentences. This involves the annotator to read the annotation guideline and basically understand the semantic framework for comparison structures that we introduced in Section 3. Initially, we ran a pilot study on a set of 50 sentences where each sentence was annotated by two of the experts. We used pilot results for iterating over the annotation schema and guideline and resolving issues regarding low agreement predicates and argument types[6], until getting to average agreement $\kappa = 0.80$. We split the dataset into 30% and 70% for testing and training respectively.

5.2 Evaluation

Here we evaluate the performance of our proposed predicate-argument structure prediction. We present the following two methods:

- **ILP Method**: Our full approach as described in Section 4. Here we used the Gurobi[7] optimization package for finding an exact solution for our ILP formalization.

- **Baseline**: A simple pattern-based method which uses lexical patterns for predicting predicate type and argument types. This method uses the generic comparative morphemes such as 'er', 'est', 'more' and 'less' for detecting any specific type of predicate. For identifying predicate arguments it relies on rules which use syntactic structure, e.g., for a 'greater' predicate identified by 'er' morpheme, the 'left' argument is always the main subject of the sentence. This method annotates anything not recognized by patterns as 'None'.

Here with compare their predictions on test set to the gold standard annotations and compute micro-averaged precision, recall and F1 score. For this analysis we remove the 'equative' predicate type, given its very low frequency in our training set. Moreover, here we do not include the positive and negative predicate types, as these take only one role argument which is 'figure', making the prediction task trivial.

Table 4 shows the results of predicate type prediction. The final reported average in this table excludes the type 'None'. The best performing category in both methods is 'superlative', which is because of its more typical structure which makes it

[6]The disagreements were mainly on fine-grained predicate types, which were resolved by collapsing some of the types together.

[7]www.gurobi.com

easier to be predicted. In general, the precision of predicate prediction is very high in ILP method, which is due to the fact that our predicates are the comparison operators indicated by the comparison morphemes. The baseline performs considerably weaker than ILP method for predicting *less* and *greater* predicates. This is because predicting these types requires a more complicated analysis where simple morphological and syntactic patterns can result in many false positives.

Table 5 depicts the results of the role type prediction. The weighted average in this table is based on frequency, excluding the type 'None'. The precision on role prediction varies across different types. Overall, the baseline performs weakly on predicting role types, which is dues to the complicated structure of roles.

The best prediction of ILP method is on scales, which has benefited from the attribute concept feature. The weaker performing types have been affected by the low-frequency occurrence in the training set. There are many cases of very long and complex sentences in our dataset. One major reason behind some of the false predictions is incorrect dependency parse for long sentences. One notable issue here is that for easier prediction and analysis, we had asked our annotators to mark only the head words for phrasal arguments. This had often caused lower agreement among annotators and hence worse predictions on the system trained on the dataset. In future, we are going to switch to span-based argument identification.

	ILP Method			Baseline		
Predicate Type	**P**	**R**	**F1**	**P**	**R**	**F1**
Assetive	100	46	63	100	26	41
Greater	90	82	86	54	68	60
Superlative	96	79	87	89	73	80
Excessive	100	43	60	100	24	38

6 Related Work

The syntax and semantics of comparison in language have been studied in linguistics for a long time (Bresnan, 1973; Cresswell, 1976; Von Stechow, 1984). However, so far, computational modeling of the semantics of comparison components of natural language has not been developed as elaborately as needed. The main efforts on computational aspects of comparatives have been in the context of sentiment analysis. Jindal and Liu (2006b) introduced the first approach for the identification of sentences containing comparisons. Their system trains a Naive Bayes classifier for labeling sentences as comparative or non-comparative.

	ILP Method			Baseline		
Role Type	**P**	**R**	**F1**	**P**	**R**	**F1**
Plus	67	31	42	11	17	13

Table 5: The evaluation result on role type prediction.

Later works progressed into identifying the components of the comparisons: comparative predicates and arguments. For example for the sentence "Canon's optics is better than those of Sony and Nikon.", the extracted relation should be: (better, {optics}, {Canon}, {Sony, Nikon}). Jindal and Liu (2006a) detect such arguments by labeling sequential rules. Xu et al. (2011) use Conditional Random Fields (Lafferty et al., 2001) to extract relations between two entities, an attribute and a predicate phrase. These works all provide a rudimentary basis for computational analysis of comparatives, however, they lack depth and breadth as they are limited to the limited comparison structure *(Entity1, Entity2, aspect)* expressed within some sequential patterns. It is evident that the framework of comparison proposed in this paper goes beyond simple triplet annotation of comparison structures and is more representative of the linguistics literature on comparatives and measurements.

The most recent related work on comparatives (Kessler, 2014) focuses on argument identification task: given a comparative predicate, they find the arguments corresponding to it. They train a classifier for this task emphasizing on syntax information. Most of the entities in their training data are products (cameras, cars, and phones). Another recent work (Kessler and Kuhn, 2014) concentrates on the annotation of what they call multi-word predicates (such as 'more powerful', where

the comparison is not one-word such as 'calmer'). They show that annotating the modifier of comparatives (i.e., the adjectives) gives better results in classification. Both these works share the major shortcoming of the earlier works, as they are very limited to their specific patterns and fail to enable deeper representation and analysis of various complex comparative structures.

7 Conclusion

Systems that can understand and reason over comparatives are crucial for various NLP applications ranging from open-domain question answering to product review analysis. Understanding comparatives requires a semantic framework which can represent their underlying meaning. In this paper we presented a novel semantic framework for representing the meaning of various comparison constructions in natural language. We mainly modeled comparisons as predicate-argument pairs which are connected via semantic roles. Our framework supports all possible parts of speech and variety of measurements and comparisons, hence providing a unique computational representation of the underlying semantics of comparison. Furthermore, we introduced an ILP-based method for predicting the predicate-argument structure of comparison sentences.

With this paper, we provide a novel dataset of gold-standard annotations based on our semantic framework. We are planning on expanding our gold-standard annotations under this framework for having more training data. Our semantic framework on comparison constructions enables us to do logical reasoning and inference over comparatives. In the future, we are planning to design a reading comprehension task where we use this framework for answering comparison questions from a paragraph containing various interrelated comparisons.

Last but not least, the works on broad-coverage semantic parsing (Allen et al., 2008; Bos, 2008) can all benefit from our semantic framework. We will be extending the TRIPS logical form (Allen et al., 2008) according to this framework and will modify the grammar to generate the deeper representations.

Abstract

Sarcasm is generally characterized as a figure of speech that involves the substitution of a literal by a figurative meaning, which is usually the *opposite* of the original literal meaning. We re-frame the sarcasm detection task as a type of word sense disambiguation problem, where the *sense* of a word is either *literal* or *sarcastic*. We call this the Literal/Sarcastic Sense Disambiguation (LSSD) task. We address two issues: 1) how to collect a set of target words that can have either literal or sarcastic meanings depending on context; and 2) given an utterance and a target word, how to automatically detect whether the target word is used in the literal or the sarcastic sense. For the latter, we investigate several distributional semantics methods and show that a Support Vector Machines (SVM) classifier with a modified kernel using word embeddings achieves a 7-10% F1 improvement over a strong lexical baseline.

1 Introduction

Recognizing sarcasm is important for understanding people's actual sentiments and beliefs. For example, failing to recognize the following message as being sarcastic "I love that I have to go back to the emergency room", will lead a sentiment and opinion analysis system to infer that the author's sentiment is positive towards the event of "going to the emergency room". Current approaches have framed the sarcasm detection task as predicting whether a full utterance is sarcastic or not (Davidov et al., 2010; González-Ibáñez et al., 2011; Riloff et al., 2013; Liebrecht et al., 2013; Maynard and Greenwood, 2014).

We propose a re-framing of sarcasm detection as a type of word sense disambiguation problem: given an utterance and a target word, identify whether the *sense* of the target word is *literal* or *sarcastic*. We call this the Literal/Sarcastic Sense Disambiguation (LSSD) task. In the above utterance, the word "love" is used in a sarcastic, non-literal sense (the author's intended meaning being most likely the opposite of the original literal meaning - a negative sentiment, such as "hate"). Two key challenges need to be addressed: 1) how to collect a set of target words that can have a literal or a sarcastic sense, depending on context; and 2) given an utterance containing a target word, how can we determine whether the target word is used in its literal sense (e.g., "I *love* to take a nice stroll in the park every morning"), or in a sarcastic sense (e.g., "I *love* going to the dentist.").

To address the first challenge, we need to identify a set of words from sarcastic utterances, which have a figurative/sarcastic sense (e.g., "love" in the utterance "I love going to the dentist"). We propose a crowdsourcing task where Turkers in Amazon Mechanical Turk (MTurk) platform are given sarcastic utterances (tweets labeled with #sarcasm or #sarcastic hashtags) and are asked to re-phrase those messages so that they convey the author's intended meaning ("I *love* going to the dentist" can be rephrased as "I *hate* going to the dentist" or "I *don't like* going to the dentist"). [1] Given this parallel dataset, we use unsupervised alignment techniques to identify semantically opposite words (e.g., "love" ↔ "hate", "brilliant" ↔ "stupid", "never" ↔ "always"). The words from these pairs that appear in the original sarcastic utterances are then considered as our collection of target words (e.g., "love", "brilliant", "never") that can have both a sarcastic and a literal sense depending on the context (Section 2).

To address the second challenge, we compare several distributional semantics methods generally used in word sense disambiguation tasks (Sec-

Lisbon, Portugal, 17-21 September 2015.

Target	Sense	Utterance
great	S	... starting off the new year great !!!!! sick in bed ...
	L	... you don't need a record label to have great music ...
	L_{sent}	... i'm in love with this song great job justin ...
proud	S	yay something to be proud of 3rd poorest in the NATION ...
	L	im filipino with dark brown eye and forever true and proud ...
	L_{sent}	but i'm proud of all the beliebers AROUND THE WORLD ...

Table 1: Examples of Targets and their Senses

tion 3). We show that using word embeddings in a modified SVM kernel achieves the best results (Section 4). To collect training and test datasets for each of the target words, we use Twitter messages that contain those words. For the *sarcastic sense* (S), we use tweets that contain the target word and are labeled with the #sarcasm or #sarcastic hashtags. For the *literal sense* (L), we collect tweets that contain the target word and are not labeled with the #sarcastic or #sarcasm hashtags. Table 1 shows examples of two targets words ("great" and "proud") and their sarcastic sense (S) and literal sense (L). In addition, for the *literal sense*, we also consider a special case, where the tweets are labeled with either positive or negative hashtags (e.g., #happy, #sad) as proposed by Gonzalez et al. (2011). We denote these sentiment tweets as L_{sent} (Table 1). Gonzalez et al. (2011) argue that it is harder to distinguish sarcastic from non-sarcastic messages where the non-sarcastic messages contain sentiment. Our results support this argument (97% F1 measure for the best result for S vs. L, compared to 84% F1 for the best result for S vs. L_{sent}; Section 4).[2]

2 Collection of Target Words

To collect a set of target words that can have either literal or sarcastic meaning depending on context, we propose a two step approach: 1) a crowdsourcing task to collect a parallel dataset of sarcastic utterances and their re-phrasings that convey the authors' intended meaning; and 2) unsupervised alignment techniques to detect semantically opposite words/phrases.

Crowdsourcing Task. Given a sarcastic message (SM), Turkers were asked to re-phrase the message so that the new message is likely to express the author's intended meaning (IM). Examples of an original sarcastic message (1) and three messages generated by the Turkers (2) is given below:

(1) [SM] I am so happy that I am going back to the emergency room.

(2) a. [IM_1] I don't like that I have to go to the emergency room again.
b. [IM_2] I am so upset I have to return to the emergency room.
c. [IM_3] I'm so unhappy that I am going back to the emergency room.

From the above examples, we can see that aligning the sarcastic message (SM) to the re-phrasings containing the author's intended meaning generated by the Turkers (IM_1, IM_2, IM_3) will allow us to detect that "happy" can be aligned to "don't like", "upset", and "unhappy". Based on this alignment, "happy" will be considered as a target word for the LSSD task.

We used 1,000 sarcastic messages collected from Twitter using the #sarcasm and #sarcastic hashtags. The Turkers were provided with detailed instructions of the task including a definition of *sarcasm*, the task description, and multiple examples. In addition, for messages that contain one or more sentences and where sarcasm is related to only a part of the message, the Turkers were instructed to consider the entire message in their rephrasing. This emphasis was added to avoid high asymmetry in the length between the original sarcastic message and the rephrasing of the intended meaning. For each original sarcastic message (SM), we asked five Turkers to do the rephrasing task. Each HIT contains 1 sarcastic message, and Turkers were paid 5 cents for each HIT. To ensure a high quality level, only qualified workers were allowed to perform the task (i.e., more than 90% approval rate and at least 500 approved HITs). In this way, we obtained a dataset of 5,000 SM-IM pairs.

Unsupervised Techniques to Detect Semantically Opposite Words/Phrases. We use two methods for unsupervised alignment. First, we use the co-training algorithm for paraphrase detection developed by Barzilay and McKeown (2001). This algorithm is used for two specific reasons. First, our dataset is similar in nature to the parallel

[2]The datasets used in the experiments is available at https://github.com/debanjanghosh/sarcasm_wsd.

monolingual dataset used in Barzilay and McKeown (2001), and thus lexical and contextual information from tweets can be used to extract the candidate targets words for LSSD. For instance, we can align the [SM] and [IM_3] (from the above examples), where except for the words happy and unhappy, the majority of the words in the two messages are anchor words and thus happy and unhappy can be extracted as paraphrases via co-training. To model contextual information, such as part of speech tagging for the co-training algorithm, we used Tweet NLP (Gimpel et al., 2011). Second, Bannard and Callison-Burch (2005) noticed that the co-training method proposed by-Barzilay and McKeown (2001) requires identical bounding substrings and has bias towards single words while extracting paraphrases. This apparent limitation, however, is advantageous to us because we are specifically interested in extracting target words. Co-training resulted in 367 extracted pairs of paraphrases.

We also considered a statistical machine translation (SMT) alignment method - IBM Model 4 with HMM alignment implemented in Giza++ (Och and Ney, 2000). We used Moses software(Koehn et al., 2007) to extract lexical translations by aligning the dataset of 5,000 SM-IM pairs. From the set of 367 extracted paraphrases using Barzilay and McKeown (2001)'s approach, we selected only those paraphrases where the lexical translation scores ϕ (resulted after running Moses) are ≥ 0.8. After filtering via translation scores and manual inspection, we obtained a set of 80 semantically opposite paraphrases. Given this set of semantically opposite words, the words that appear in the sarcastic messages were consider our target words for LSSD (70 target words after lemmatization). They range from verbs, such as "love" and "like", adjectives, such as "brilliant", "genius", and adverbs, such as "really".

3 Literal/Sarcastic Sense Disambiguation

Our Literal/Sarcastic Sense Disambiguation (LSSD) task is formulated as follows: given a candidate utterance (i.e., a tweet) that contains a target word t, identify whether the sense of t is *sarcastic* (S) or *literal* (L). In order to be able to solve this problem we need training and test data for each target word that consists of utterances where the target word is used either in the literal sense or the sarcastic sense.

love(26802), like(14995), great(14495), good(11624), really(9825), right(6771), fun(6603), best(6182), better(5960), glad(5748), yeah(5504), nice(4443), awesome(4196), excited(4027), always(3807), happy(3098), cool(2705), amazing(1952), favorite(1883), perfect(1792), wonderful(1749), wonder(1476), lovely(1424), super(1390), fantastic(1369), joy(1176), cute(1007), beautiful(981), sweet(800), hot(729), proud(703), shocked(645), interested(624), brilliant(576), genius(481), attractive(449), mature(427)

Table 2: Target words and # of training instances per sense

3.1 Data Collection

To collect training and test datasets for each of the target words, we use Twitter messages that contain those words. For the *sarcastic sense* (S), we use tweets that contain the target word and are labeled with the #sarcasm or #sarcastic hashtag. For the *literal sense* (L), we collect tweets that contain the target word and are not labeled with the #sarcastic or #sarcasm hashtags. In addition, for the *literal sense* we also consider a special case, where the tweets are labeled with either positive or negative sentiment hashtags (e.g., #happy, #sad). Thus, we consider two LSSD tasks: S vs. L and S vs. L_{sent}, and aim to collect a balanced dataset for each target word.

For the 70 target words (see Section 2), we collected a total of 2,542,249 tweets via Twitter API . We considered a setup where 80% of data is used for training, 10% for development, and 10% for test. We empirically set the number of minimum training instances for each sense of the target word to 400 without any upper restriction. This resulted in 37 target words to be used in the LSSD experiments. Table 2 shows all the target words and their corresponding number of *training* instances for each sense (S and L/L_{sent}). The size of training data ranges from 26,802 for the target word "love" to 427 for the word "mature". As we will see in the results sections, however, the size of the training data is not always the key factor in the LSSD task, especially for the methods that use word embeddings.

3.2 Learning Approaches

We consider two classical approaches used in word sense disambiguation tasks: 1) distributional approaches where each sense of a target word is represented as a context vector derived from the training data; and 2) classification approaches (S

vs. L; S vs. L_{sent}) for each target word.

3.2.1 Distributional Approaches

The Distributional Hypothesis in linguistics is derived from the semantic theory of language usage, i.e., words that are used and occur in the same contexts tend to purport similar meanings (Harris, 1954). Distributional semantic models (DSMs) use vectors that represent the contexts (e.g., co-occurring words) in which target words appear in a corpus, as proxies for meaning representations. Geometric techniques such as cosine similarity are then applied to these vectors to measure the similarity in meaning of corresponding words.

The DSMs are a natural approach to model our LSSD task. For each target word t we build two context-vectors that will represent the two senses of the target word t using the training data: one for the *sarcastic* sense S using the sarcastic training data for t ($\vec{v_s}$) and one for the *literal* sense L using the literal sense training data for t ($\vec{v_l}$).[3] Given a test message u containing a target word t, we first represent the target word as a vector $\vec{v_u}$ using all the context words inside u. To predict whether t is used in a literal or sarcastic sense in the test message u we simply apply geometric techniques (e.g., cosine similarity) between $\vec{v_u}$ and the two sense vectors $\vec{v_s}$ and $\vec{v_l}$, choosing the one with the maximum score.

To create the two sense vectors $\vec{v_s}$ and $\vec{v_l}$ for each of the target words t, we use the positive pointwise mutual information model (PPMI) (Church and Hanks, 1990). Based on t's context words c_k in a window of 10 words, we separately computed PPMI for sarcastic and literal senses using t's training data. The size of the context widow used in DSMs is generally between 5 and 10, and in our experiments we used a window of 10 words since tweets often include meaningful words/tokens at the end of the tweets (e.g., interjections, such as "yay", "ohh"; upper-case words, such as, "GREAT"; novel hashtags, such as "#notreally", "#lolol"; emoticons, such as ":("). We sorted the context words based on the PPMI scores and for each target word t we selected a maximum of 1,000 context words per sense to approximate the two senses of the target word (i.e., the vectors $\vec{v_s}$ and $\vec{v_l}$ for each target word t consist of a maximum of 1,000 words). Table 3 shows some target words and their corresponding context words that were selected based on high PPMI scores.

Targets	Senses	Context Vector
love	S	ignored, being, waking, work, sick, #not
	L	please, follow, ♡, her, :)
	L_{sent}	happy, family, blessed, cute, birthday
fun	S	work, tomorrow, homework, friday, sleep
	L	hope, join, girl, game, friend
	L_{sent}	#friends, #family, weekend, amazing, #christmas
joy	S	working, snow, waking, studying, sick
	L	yesterday, sweet, special, prayer, laughter
	L_{sent}	wishing, warmth, love, christmas, peace

Table 3: Target words and their context words

To predict whether t is used in a literal or sarcastic sense in the test message u we simply apply the cosine similarity to the $\vec{v_u}$ (vector representation of the target word t in the test message u) and the two sense vectors $\vec{v_s}$ and $\vec{v_l}$ of t, choosing the one with the maximum score. All vector elements are given by the tf-idf values of the corresponding words. This approach, denoted as the "PPMI baseline", is the baseline for our DSM experiments.

Context Vectors with Word Embedding: The above method considers that the context vectors $\vec{v_s}$ and $\vec{v_l}$ of each target word t contain the co-occurring words selected by their PPMI values. We enhance the representation of context vectors to represent each word in the context vector by its word embedding. We experiment with three different methods of obtaining word embeddings: Weighted Textual Matrix Factorization (WTMF) (Guo and Diab, 2012b); *word2vec* that implements the skip-gram and continuous bag-of-words models (CBOW) of Mikolov et al. (2013a), and GloVe (Pennington et al., 2014), a log-bilinear regression model based upon global word-word co-occurrence count in the training corpora.

After removing the tweets that are used as test sets, we build the three word embedding models in an unsupervised fashion with the remaining 2,482,763 tweets from our original data collection (Section 3.1). In each of the three models, each word w is represented by its d-dimensional vector $\vec{w}$ of real numbers, where d=100 for all of the embedding algorithms in our experiments. For the size of the embedding vectors, it is common to use

[3] In the remaining of this section we will only mention L and not L_{sent} for clarity and brevity.

100 or 300 dimensions, with larger dimensions for larger datasets. Our current dataset is smaller than the ones used in other applications of word embeddings (e.g., Pennington et al. (2014) have used billion tweets to create word embedding) so we opted for 100 dimensional vectors. Below are the short descriptions of the three word embedding models:

- *Weighted Textual Matrix Factorization (WTMF):* Low-dimensional vectors have been used in WSD tasks, since they are computationally efficient and provide better generalization than surface words. A dimension reduction method is Weighted Textual Matrix Factorization (WTMF) (Guo and Diab, 2012b), which is designed specifically for short texts, and has been successfully applied in WSD tasks (Guo and Diab, 2012a). WTMF models unobserved words, thus providing more robust embeddings for short texts such as tweets.

- *word2vec Representation:* We use both the Skip-gram model and the Continuous Bag-of-Words (CBOW) model (Mikolov et al., 2013a; Mikolov et al., 2013c) as implemented in the word2vec gensim python library. [4] Given a window size of n words around a word w, the skip-gram model predicts the neighboring words given the current word. In contrast, the CBOW model predicts the current word w, given the neighboring words in the window. We considered a context window of 10 words.

- *GloVe Representation:* GloVe (Pennington et al., 2014) is a word embedding model that is based upon weighted least-square model trained on global word-word co-occurrence counts instead of the local context used by word2vec.

Here, the LSSD task is similar to the baseline: to predict whether the target word t in the test message u is used in a literal or sarcastic sense, we simply use a similarity measure between the $\vec{v_u}$ (vector representation of the target word t in the test message u) and the two sense vectors $\vec{v_s}$ and $\vec{v_l}$ of t, choosing the one with the maximum score. The difference from the baseline is twofold: First, all vectors elements are word embeddings (i.e., 100-d vectors). Second, we use the *maximum-valued matrix-element* (MVME) algorithm introduced by Islam and Inkpen (2008), which has been shown to be particularly useful for computing the similarity of short texts. We modify this algorithm to use word embeddings ($MVME_{we}$). The idea behind the MVME algorithm is that it finds a one-to-one "word alignment" between two utterances (i.e., sentences) based on the pairwise word similarity. Only the aligned words contribute to the overall similarity score.

Algorithm 1 $MVME_{we}$

procedure $MVME_{we}(v_s, v_u)$
  $v_{s_{words}} \leftarrow v_s.elements()$
  $v_{u_{words}} \leftarrow v_u.elements()$
  $M[v_{s_{words}}.size(), v_{u_{words}}.size()] \leftarrow 0$
  for $k \leftarrow 0, v_{s_{words}}.size()$ **do**
    $c_k \leftarrow v_{s_{words}}[k]$
    $\vec{c_k} \leftarrow getEmbedding(c_k)$
    for $j \leftarrow 0, v_{u_{words}}.size()$ **do**
      $w_j \leftarrow v_{u_{words}}[j]$
      $\vec{w_j} \leftarrow getEmbedding(w_j)$
      $M[k][j] \leftarrow cosine(\vec{c_k}, \vec{w_j})$
    end for
  end for
  while True **do**
    repeat
      $max \leftarrow getMax(M)$
      $Sim \leftarrow Sim + max$
      $r_m, c_m \leftarrow getRowCol(M, max)$
  ▷ *Remove r_m row and c_m column from M*
      $remove(M, r_m, c_m)$
    until $max > 0$ Or $M.size() > 0$
  end while
  Return Sim
end procedure

procedure GETEMBEDDING(word)
  Return $we_{model}[word]$
end procedure
procedure GETROWCOL(M,max)
  $row, col \leftarrow M.indexOf(max)$
  Return row, col
end procedure

Algorithm 1 presents the pseudocode of our modified algorithm for word embeddings, $MVME_{we}$. Let the total similarity between $\vec{v_s}$ and $\vec{v_u}$ be Sim. For each context word c_k from $\vec{v_s}$ and each word w_j from $\vec{v_u}$, we compute a matrix where the value of the matrix element M_{jk}

[4] https://radimrehurek.com/gensim/models/word2vec.html

denotes the cosine similarity between the embedded vectors $\vec{c_k}$ and $\vec{w_j}$ [lines 5 -13]. Next, we first select the matrix cell that has the highest similarity value in M (max) and add this to the Sim score [lines 16-17]. Let the r_m and c_m be the row and the column of the cell containing max (maximum-valued matrix element), respectively. Next, we remove all the matrix elements of the r_m-th row and the c_m-th column from M [line 20]. We repeat this procedure until we have traversed through all the rows and columns of M or max = 0 [line 21].

3.2.2 Classification Approaches

The second approach for our LSSD task is to treat it as a binary classification task to identify the sarcastic or literal sense of a target word t. We have two classification tasks: S vs. L and S vs. L_{sent} for each of the 37 target words. We use the libSVM toolkit (Chang and Lin, 2011). Development data is used for tuning parameters.

SVM Baseline: The SVM baseline for LSSD tasks uses n-grams and lexicon-based binary-valued features that are commonly used in existing state-of-the-art sarcasm detection approaches (González-Ibáñez et al., 2011; Tchokni et al., 2014). They are derived from i) bag-of-words (BoW) representations of words, ii) LIWC dictionary (Pennebaker et al., 2001), and iii) a list of interjections (e.g., "ah", "oh", "yeah"), punctuations (e.g., "!", "?"), and emoticons collected from Wikipedia. *CMU Tweet Tokenizer* is employed for tokenization. [5] We kept unigrams unchanged when all the characters are uppercase (e.g., "NEVER" in *"A shooting in Oakland? That NEVER happens! #sarcasm"*) but otherwise words are converted to lower case. We also change all numbers to a generic number token "22". To avoid any bias during experiments, we removed the target words from the tweets as well as any hashtag used to determine the sense of the tweet (e.g., #sarcasm, #sarcastic, #happy, #sad).

SVM with $MVME_{we}$ Kernel: We propose a new kernel $kernel_{we}$ to compute the semantic similarity between two tweets u_r and u_s using the $MVME_{we}$ method introduced for the DSM approach, and the three types of word embeddings (WTMF, word2vec, and GloVe). The similarity measure in the kernel is similar to the algorithm $MVME_{we}$ described in Algorithm 1, but instead of measuring the similarity between the sense vectors of t ($\vec{v_s}$, $\vec{v_l}$) and the vector representation of t in test message ($\vec{v_u}$), now we measure the similarity between two tweets u_r and u_s. For each k-th index word w_k in u_r and l-th index word w_l in u_s we compute the cosine similarity between the embedded vectors of the words and fill up a similarity matrix M. We select the matrix cell that has the highest similarity, add this similarity score to the total similarity Sim, remove the row and column from M that has highest similarity score, and repeat the procedure (similar to Algorithm 1). We noticed that $MVME_{we}$ algorithm carefully chooses the best candidate word w_l in u_s for the w_k word in u_r since w_l is the most similar word to w_k. The algorithm continues the same procedure for all the remaining words in u_r and u_s. The final Sim is used as the kernel similarity between u_r and u_s. We augment this kernel $kernel_{we}$ into libSVM and during evaluation we run supervised LSSD classification for each target word t separately.

4 Results and Discussions

Tables 4 and 5 show the results for the LSSD experiments using distributional approaches and classification-based approaches, respectively. For brevity, we only report the average Precision (P), Recall (R), and F1 scores with their standard deviation (SD) (given by '$\pm$'), and the targets with maximum/minimum F1 scores. $w2v_{sg}$ and $w2v_{cbow}$ represent the skip-gram and CBOW models implemented in word2vec, respectively.

Table 4 presents the results of distributional approaches (Section 3.2.1). We observe that the word embedding methods have better performance than the PPMI baseline for both S vs. L and S vs. L_{sent} disambiguation tasks. Also, the average P/R/F1 scores for S vs. L are much higher than for S vs. L_{sent}. Since all tweets with L_{sent} sense were collected using sentiment hashtags (González-Ibáñez et al., 2011), they might be lexically more similar to the S tweets than the L tweets are and thus identifying the sense of a target word t between S vs. L_{sent} is a harder task. In Table 4 we also observe that the average F1 scores between WTMF, $w2v_{sg}$, $w2v_{cbow}$, and GloVe are comparable and between 84%-86%, with $w2v_{sg}$ and $w2v_{cbow}$ achieving slightly higher F1.

Table 5 outlines the LSSD experiments us-

Expr.	Senses	Avg. P	Avg. R	Avg. F1	Max. F1(Target)	Min. F1(Target)

Table 5: Evaluation of classification approaches (SVM_{bl} and $kernel_{we}$) for LSSD experiments

ing the classification approaches (Section 3.2.2): SVM baseline (SVM_{bl}) and SVM using the $kernel_{we}$ with word embeddings ($kernel_{WTMF}$, $kernel_{GloVe}$, $kernel_{w2v_{sg}}$, and $kernel_{w2v_{cbow}}$). The classification approaches give better performance compared to the distributional approaches. The SVM_{bl} is around 7-8 % higher than the $PPMI_{bl}$ and comparable with the word embeddings used in distributional approaches (Table 4). In addition, our new SVM kernel method using word embeddings shows significantly better results when compared to the SVM_{bl} (and distributional approaches). For instance, for the S vs. L task, the average F1 is 96-97%, which is more than 10% higher than SVM_{bl}. Similarly, for S vs. L_{sent} task, F1 scores reported by the kernel using word2vec embeddings are in the range of 83%-84% compared to 77% given by the SVM_{bl}, showing an absolute increase of 7%. As stated earlier, MVME algorithm aligns similar word pairs found in its inputs and this performs well for short texts (i.e., tweets). Thus, the MVME algorithm combined with word embedding in $kernel_{we}$ results in very high F1. Among the word embedding models, word2vec models give marginally better results compared to GloVe and WTMF, and GloVe outperforms marginally WTMF. Similar to Table 4, here, the average F1 scores for S vs. L task are higher than the S vs. L_{sent} results.

In terms of the best and worst performing tar-

gets, SVM_{bl} prefers targets with more training data (e.g., "yeah", "love" vs. "sweet", "attractive"; see Table 2). In contrast, word embedding models for "joy" and "mature", two targets with comparatively low number of training instances have achieved very high F1 using both distributional and classification approaches (Table 4 and 5). This can be explained by the fact that for words, such as "joy", "mature", "cute", and "brilliant", the contexts of their literal and sarcastic sense are quite different, and DSMs and word embeddings are able to capture the difference. For example, observe in the Table 3, negative sentiment words, i.e., "sick", "working", "snow" are the context words for targets "joy" and "love", where as positive sentiment words, such as, "blessed", "family", "christmas", and "peace" are the context words for L or L_{sent} senses. Overall, out of 37 targets, only 5 targets ("mature", "joy", "cute", "love", and "yeah") achieved "maximum" F1 scores in various experimental settings (Tables 4 and 5) whereas targets such as "interested", "genius", and "attractive" achieved low F1 scores.

In terms of variance in results, SVM results show low SD (0-4%). For distributional approaches, SD is slightly higher (5-8%) for several cases.

5 Related Work

Two lines of research are directly relevant to our work: sarcasm detection in Twitter and application of distributional semantics, such as word embedding techniques to various NLP tasks. In contrast to current research on sarcasm and irony detection (Davidov et al., 2010; Riloff et al., 2013; Liebrecht et al., 2013; Maynard and Greenwood, 2014), we have introduced a reframing of this task as a type of word sense disambiguation problem, where the sense of a word is sarcastic or literal. Our SVM baseline uses the lexical features proposed in previous research on sarcasm detection (e.g., LIWC lexicon, interjections, pragmatic features) (Liebrecht et al., 2013; González-Ibáñez et al., 2011; Reyes et al., 2013). Our analysis of target words where the sarcastic sense is the opposite of the literal sense is related to the idea of "positive sentiment toward a negative situation" proposed by Riloff et al. (2013) and recently studied by Joshi et al. (2015). In our approach, we chose distributional semantic approaches that learn contextual information of targets effectively from a large corpus containing both literal and sarcastic uses of words and show that word embedding are highly accurate in predicting the sarcastic or literal sense of a word (Tables 4 and 5). This approach has the potential to capture more nuanced cases of sarcasm, beyond "positive sentiment towards a negative situation" (e.g., one of our target words was "shocked" which is negative). However, our current framing is still inherently limited to cases where sarcasm is characterized as a figure of speech where the author means the opposite of what she says, due to our approach of selecting the target words.

Low-dimensional text representation, such as WTMF, have been successful in WSD disambiguation research and in computing similarity between short texts (Guo and Diab, 2012a; Guo and Diab, 2012b). word2vec and GloVe representations have provided state-of-the-art results on various word similarity and analogy detection task (Mikolov et al., 2013c; Mikolov et al., 2013b; Pennington et al., 2014). Word embedding based models are also used for other NLP tasks such as dependency parsing, semantic role labeling, POS tagging, NER, question-answering (Bansal et al., 2014; Collobert et al., 2011; Weston et al., 2015) and our work on LSSD is a novel application of word embeddings.

6 Conclusion and Future Work

We proposed a reframing of the sarcasm detection task as a type of word sense disambiguation problem, where the sense of a word is its *sarcastic* or *literal* sense. Using a crowdsourcing experiment and unsupervised methods for detecting semantically opposite phrases, we collected a set of target words to be used in the LSSD task. We compared several distributional semantics methods, and showed that using word embeddings in a modified SVM kernel achieves the best results (an increase of 10% F1 and 8% F1 for S vs. L and S vs. L_{sent} disambiguation task, respectively, against a SVM baseline). While the SVM baseline preferred larger amounts of training data (best performance achieved on the targets words with higher number of training examples), the methods using word embeddings seem to perform well on target words where there might be an inherent difference in the contextual sarcastic and literal use of a target word, even if the training data was smaller.

We want to investigate further the nature and

size of training data useful for the LSSD task. For example, to test the effect of larger training dataset, we utilized pre-trained word vectors from GloVe (trained with 2 Billion tweets, using 100 dimensions).[6] For S vs. L disambiguation, the average F1 was 88.9%, which is 7% lower than the result using GloVe on our training set of tweets (much smaller) designed for the LSSD task. This shows the training data utilized to create word embedding models in GloVe probably do not contain enough sarcastic tweets.

Regarding the size of the training data, recall that the unsupervised alignment approach had extracted 70 target words (Section 2), although we have used 37 target words as we did not have enough training data for the remaining targets. Thus, we plan to collect more training data for these targets as well as more target words (especially for the S vs. L_{sent} task). In addition, we plan to improve our unsupervised methods for detecting semantically opposite meaning (e.g., using the IM-IM dataset in addition to the SM-IM dataset).

One common criticism of research based on use of hashtags as gold labels is that the training utterances could be noisy. In other words, tweets might be sarcastic but not have #sarcasm or #sarcastic hashtags. We did a small manual validation on a dataset of 180 tweets from the L_{sent} class using 3 annotators (we asked them to say whether the tweet is sarcastic or not). For cases where all 3 coders agree none of them were considered sarcastic, while when only 2 coders agree 1 tweet out of 180 was considered sarcastic. In future, we plan to perform additional experiments to study the issue of noisy data. We hope that the release of our datasets will stimulate other studies related to the sarcasm detection problem, including addressing the issue of noisy data.

We also plan to study the effect of hyperparameters in designing the DSMs. Recently, Levy et al. (2015) have argued that parameter settings have a large impact on the success of word embedding models. We want to follow their experiments to study whether parameter tuning in PMI based disambiguation can improve its performance.

Abstract

Taxonomy plays an important role in many applications by organizing domain knowledge into a hierarchy of *is-a* relations between terms. Previous works on the taxonomic relation identification from text corpora lack in two aspects: 1) They do not consider the trustiness of individual source texts, which is important to filter out incorrect relations from unreliable sources. 2) They also do not consider collective evidence from synonyms and contrastive terms, where synonyms may provide additional supports to taxonomic relations, while contrastive terms may contradict them. In this paper, we present a method of taxonomic relation identification that incorporates the trustiness of source texts measured with such techniques as PageRank and knowledge-based trust, and the collective evidence of synonyms and contrastive terms identified by linguistic pattern matching and machine learning. The experimental results show that the proposed features can consistently improve performance up to 4%-10% of F-measure.

1 Introduction

Taxonomies which serve as backbone of structured knowledge are useful for many applications such as question answering (Harabagiu et al., 2003) and document clustering (Fodeh et al., 2011). Even though there are many hand-crafted, well-structured taxonomies publicly available, including WordNet (Miller, 1995), OpenCyc (Matuszek et al., 2006), and Freebase (Bollacker et al., 2008), they are incomplete in specific domains, and it is time-consuming to manually extend them or create new ones. There is thus a need for automatically extracting taxonomic relations from text corpora to construct/extend taxonomies.

Previous works on the task of taxonomy construction capture information about potential taxonomic relations between concepts, rank the candidate relations based on the captured information, and integrate the highly ranked relations into a taxonomic structure. They utilize such information as hypernym patterns (e.g. A is a B, A such as B) (Kozareva et al., 2008), syntactic dependency (Drumond and Girardi, 2010), definition sentences (Navigli et al., 2011), co-occurrence (Zhu et al., 2013), syntactic contextual similarity (Tuan et al., 2014), and sibling relations (Bansal et al., 2014).

They, however, lack in the three following aspects: 1) Trustiness: Not all sources are trustworthy (e.g. gossip, forum posts written by non-experts) (Dong et al., 2015). The trustiness of source texts is important in taxonomic relation identification because evidence from unreliable sources can be incorrect. For example, the invalid taxonomic relation between "American chameleon" and "chameleon" is mistakenly more popular in the Web than the valid taxonomic relation between "American chameleon" and "lizard", and statistical methods without considering the trustiness may incorrectly extract the invalid relation instead of the latter. However, to the best of our knowledge, no previous work considered this aspect.

2) Synonyms: A concept may be expressed in multiple ways, for example with synonyms. The previous works mostly assumed that a term represents an independent concept, and did not combine information about a concept, which is expressed with multiple synonyms. The lack of evidence from synonyms may hamper the ranking of candidate taxonomic relations. Navigli and Velardi (2004) combined synonyms into a concept, but only for those from WordNet, called synsets.

3) Contrastive terms: We observe that if two terms are often contrasted (e.g. A but not B, A is different from B) (Kim et al., 2006), they may

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1013–1022, Lisbon, Portugal, 17-21 September 2015.

not have a taxonomic relation.

In this paper, we present a method based on the state-of-the-art method (Tuan et al., 2014), which incorporates the trustiness of source texts and the collective evidence from synonyms/contrastive terms. Tuan et al. (2014) rank candidate taxonomic relations based on such evidence as hypernym patterns, WordNet, and syntactic contextual similarity, where the pattern matches and the syntactic contexts are found from the Web by using a Web search engine. First, we calculate the trustiness score of each data source with the four following weights: importance (if it is linked by many pages), popularity (if it is visited by many users), authority (if it is from a creditable Web site) and accuracy (if it has many facts). We integrate this score to the work of (Tuan et al., 2014) so that evidence for taxonomic relations from unreliable sources is discarded.

Second, we identify synonyms of two terms (t_1, t_2), whose taxonomic relation is being scrutinized, by matching such queries as "t_1 also known as" against the Web to find t_1's synonyms next to the query matches (e.g. t in "t_1 also known as t"). We then collect the evidence for all taxonomic relations between t'_1 and t'_2, where t'_i is either t_i or its synonym ($i \in \{1, 2\}$), and combine them to calculate the evidence score of the candidate taxonomic relation between t_1 and t_2. Similarly, for each pair of two terms (t_1, t_2), we collect their contrastive evidence by matching such queries as "t_1 is not a type of t_2" against the Web, and use them to proportionally decrease the evidence score for taxonomic relation between contrasting terms.

2 Related Work

The previous methods for identifying taxonomic relations from text can be generally classified into two categories: linguistic and statistical approaches. The former approach mostly exploits lexical-syntactic patterns (e.g. *A is a B*, *A such as B*) (Hearst, 1992). Those patterns can be manually created (Kozareva et al., 2008; Wentao et al., 2012) or automatically identified (Navigli et al., 2011; Bansal et al., 2014). The pattern matching methods show high precision when the patterns are carefully defined, but low coverage due to the lack of contextual analysis across sentences.

The latter approach, on the other hand, includes asymmetrical term co-occurrence (Fotzo and Gallinari, 2004), clustering (Wong et al., 2007), syntactic contextual similarity (Tuan et al., 2014), and word embedding (Fu et al., 2014). The main idea behind these techniques is that the terms that are asymmetrically similar to each other with regard to, for example, co-occurrences, syntactic contexts, and latent vector representation may have taxonomic relationships. Such methods, however, usually suffer from low accuracy, though showing relatively high coverage. To get the balance between the two approaches, Yang and Callan (2009), Zhu et al. (2013) and Tuan et al. (2014) combine both statistical and linguistic features in the process of finding taxonomic relations.

Most of these previous methods do not consider if the source text of evidence (e.g. co-occurrences, pattern matches) is trustworthy or not and do not combine evidence from synonyms and contrastive terms as discussed earlier. Related to synonyms, a few previous works utilize siblings for taxonomy construction. Yang and Callan (2009) use siblings as one of the features in the metric-based framework which incrementally clusters terms to form taxonomies. Wentao et al. (2012) also utilize such sibling feature that, for example of the linguistic pattern "A such as B_1, B_2, $\cdots$ and B_n", if the concept at the k-th position (e.g. B_k) from pattern keywords (e.g. such as) is a valid sub-concept (e.g. of A), then most likely its siblings from position 1 to position k-1 (e.g. B_1, $\cdots$, B_{k-1}) are also valid sub-concepts. Bansal et al. (2014) include the sibling factors to a structured probabilistic model over the full space of taxonomy trees, thus helping to add more evidence to taxonomic relations. Navigli and Velardi (2004) utilize the synonym feature (i.e. WordNet synsets) for the process of semantic disambiguation and concept clustering as mentioned above, but not for the process of inducing novel taxonomic relations.

3 Methodology

We briefly introduce (Tuan et al., 2014) in Section 3.1. We then explain how to incorporate trustiness (Section 3.2) and collective evidence from synonyms (Section 3.3) and from contrastive terms (Section 3.4) into the work of (Tuan et al., 2014).

3.1 Overview of baseline (Tuan et al., 2014)

Tuan et al. (2014) follow three steps to construct a taxonomy: term extraction/filtering, taxonomic relation identification and taxonomy induction. Because the focus of this paper is on the second step,

taxonomic relation identification, we use the same methods for the first and third steps as in (Tuan et al., 2014) and will not discuss them here.

Given each ordered pair of two terms t_1 and t_2 from the term extraction/filtering, the taxonomic relation identification of (Tuan et al., 2014) calculates the evidence score that t_1 is a hypernym of t_2 (denoted as $t_1 \gg t_2$) based on the following three measures:

String inclusion with WordNet (SIWN): This measure is to check if t_1 is a substring of t_2, considering synonymy between words using WordNet synsets. $Score_{SIWN}(t_1, t_2)$ is set to 1 if there is such evidence; otherwise, it is set to 0.

Lexical-syntactic pattern (LSP): This measure is to find how much more evidence for $t_1 \gg t_2$ is found in the Web than for $t_2 \gg t_1$. Specifically, a list of manually constructed hypernym patterns (e.g. "t_2 is a t_1") is queried with a Web search engine to estimate the number of evidence for $t_1 \gg t_2$ from the Web. The LSP measure is calculated as follows, where $C_{Web}(t_1, t_2)$ denotes the collection of search results:

$$Score_{LSP}(t_1, t_2) = \frac{log(|C_{Web}(t_1,t_2)|)}{1+log(|C_{Web}(t_2,t_1)|)}$$

Syntactic contextual subsumption (SCS): The idea of this measure is to derive the hypernymy evidence for two terms t_1 and t_2 from their syntactic contexts, particularly from the triples of (subject,verb,object). They observe that if the context set of t_1 mostly contains that of t_2 but not vice versa, then t_1 is likely to be a hypernym of t_2. To implement this idea, they first find the most common relation (or verb) r between t_1 and t_2, and use the queries "t_1 r" and "t_2 r" to construct two corpora $Corpus^{\Gamma}_{t_1}$ and $Corpus^{\Gamma}_{t_2}$ for t_1 and t_2, respectively. Then the syntactic context sets are created from these contextual corpora using a non-taxonomic relation identification method. The details of calculating $Score_{SCS}(t_1, t_2)$ can be found in (Tuan et al., 2014).

They linearly combine the three scores as follows:

$$\begin{aligned} Score(t_1, t_2) = \ & \alpha \times Score_{SIWN}(t_1, t_2) \\ & + \beta \times Score_{LSP}(t_1, t_2) + \gamma \times Score_{SCS}(t_1, t_2) \end{aligned} \quad (1)$$

If $Score(t_1, t_2)$ is greater than a threshold value, then t_1 is regarded as a hypernym of t_2. We use the same values of α, β and γ as in (Tuan et al., 2014).

3.2 Trustiness of the evidence data

We introduce our method of estimating the trustiness of a given source text in Section 3.2.1 and explain how to incorporate it into the work of (Tuan et al., 2014) in Section 3.2.2.

3.2.1 Collecting trustiness score of the evidence data

Given a data source (e.g. Web page), we consider four aspects of trustiness as follows:

- Importance: A data source may be important if it is referenced by many other sources.
- Popularity: If a data source is accessed by many people, it is considered popular.
- Authority: If the data is created by a trusted agency, such as government and education institute, it may be more trustful than others from less trusted sources such as forums and social media.
- Accuracy: If the data contains many pieces of accurate information, it seems trustful.

Importance

To measure the importance of a Web page (d) as data source, we use the Google PageRank score[1] ($Score_{PageRank}(d)$) that is calculated based on the number and quality of links to the page. The PageRank scores have the scale from 0 to 9, where the bigger score means more importance than the lower one. Using this score, the importance of a page is calculated as follows:

$$Trust_{Imp}(d) = \frac{1}{10 - Score_{PageRank}(d)} \quad (2)$$

Note that we use the non-linearity for PageRank score rather than just normalizing PageRank to 0-1. The reason is to vary the gaps between the important sites (which usually have the PageRank score value from 7-10) and majority unimportant site (which usually have the PageRank score value less than 5).

Popularity

We use Alexa's Traffic Rank[2] as the measure of popularity, ($Score_{Alexa}(d)$) which is based on the traffic data provided by users in Alexa's global data panel over a rolling 3 month period. The Traffic Ranks are updated daily. A site's rank is

[1] http://searchengineland.com/what-is-google-pagerank-a-guide-for-searchers-webmasters-11068

[2] http://www.alexa.com/

based on a combined measure of unique visitors and page views. Using this rank, the popularity of a data source is calculated as follows:

$$Trust_{Pop}(d) = \frac{1}{log(Score_{Alexa}(d) + 1)} \quad (3)$$

We use log transform in the popularity score instead of, for example, linear scoring because we want to avoid the bias of the much large gap between the Alexa scores of different sites (e.g. one site has Alexa score 1000, but the other may have score 100,000)

Authority

We rank the authority of a data source based on the internet top-level domain (TLD). We observe that the pages with limited and registered TLD (e.g. *.gov*, *.mil*, *.edu*) are often more credible than those with open domain (e.g. *.com*, *.net*). Therefore, the authority score of a data source is calculated as follows:

$$Trust_{Auth}(d) = \begin{cases} 1 & \text{if TLD of } d \text{ is } .gov, .mil \text{ or } .edu \\ 0 & \text{otherwise} \end{cases} \quad (4)$$

Note that there are some reasons we choose such implementation of Authority in an elementary way. First, we tried finer categorization of various domains, e.g. *.int* has score 1/3, *.com* has score 1/4, etc. However, the experimental results did not show much change of performance. In addition, there is controversy on which open TLD domains are more trustful than the others, e.g. it is difficult to judge whether a *.net* site is more trustful than *.org* or not. Thus, we let all open TLD domains have the same score.

Accuracy

If the data source contains many pieces of accurate information, it is trustful. Inspired by the idea of Dong et al. (2015), we estimate the accuracy of a data source by identifying correct and incorrect information in form of the triples *(Subject, Predicate, Object)* in the source, where *Subject*, *Predicate* and *Object* are normalized with regard to the knowledge base Freebase. The extraction of the triples includes six tasks: named entity recognition, part of speech tagging, dependency parsing, triple extraction, entity linkage (which maps mentions of proper nouns and their co-references to the corresponding entities in Freebase) and relation linkage. We use three information extraction (IE) tools (Angeli et al. (2014), Manning et al. (2014), MITIE[3]) for the first four tasks, and develop a method similar to Hachey et al. (2013) for the last two tasks of entity linkage and relation linkage.

Since the IE tools may produce noisy or unreliable triples, we use a voting scheme for triple extraction as follows: A triple is only considered to be true if it is extracted by at least two extractors. After obtaining all triples in the data source, we use the closed world assumption as follows: Given subject s and predicate p, $O(s, p)$ denotes the set of such objects that a triple (s,p,o) is found in Freebase. Now given a triple (s, p, o) found in the data source, if $o \in O(s, p)$, we conclude that the triple is correct; but if $o \notin O(s, p)$ and $|O(s, p)| > 0$, we conclude that the triple is incorrect. If $|O(s, p)| = 0$, we do not conclude anything about the triple, and the triple is removed from the set of facts found in the data source.

Given a data source d, we define $cf(d)$ as the number of correct facts, and $icf(d)$ as the number of incorrect facts found in d. The accuracy of d is calculated as follows:

$$Trust_{Accu}(d) = \frac{1}{1 + icf(d)^2} - \frac{1}{1 + cf(d)^2} \quad (5)$$

Combining trustiness scores

The final trustiness score of a data source is the linear combination of the four scores as follows:

$$\begin{aligned} Trust(d) = \alpha \times Trust_{Imp}(d) + \beta \times Trust_{Pop}(d) \\ + \gamma \times Trust_{Auth}(d) + \delta \times Trust_{Accu}(d) \end{aligned} \quad (6)$$

To estimate the optimal combination for parameters α, β, γ and δ, we apply linear regression algorithm (Hastie et al., 2009). For parameter learning, we manually list 50 websites as trusted sources (e.g. *stanford.edu*, *bbc.com*, *nasa.gov*), and the top 15 gossip websites listed in a site[4] as untrusted sources. Then we use the scores of their individual pages by the four methods to learn the parameters in Formula 6. The learning results are as follows: α=0.46, β=0.46, γ=2.03, δ=0.61.

3.2.2 Integrating trustiness into taxonomic relation identification methods

Given a data collection C, we define:

$$AvgTrust(C) = \frac{\sum_{d \in C} Trust(d)}{|C|}$$

[3]https://github.com/mit-nlp/MITIE

[4]http://www.ebizmba.com/articles/gossip-websites

as the average trustiness score of all data in C.

We integrate the trustiness score to the three taxonomic relation identification methods described in Section 3.1 as follows:

LSP method:
The LSP evidence score of the taxonomic relation between t_1 and t_2 is recalculated as follows:

$$Score_{LSP}^{Trust}(t_1,t_2) = Score_{LSP}(t_1,t_2)\times (AvgTrust(C_{Web}(t_1,t_2)) + AvgTrust(C_{Web}(t_2,t_1))) \quad (7)$$

The intuition of Formula 7 is that the original LSP evidence score is multiplied with the average trustiness score of all evidence documents for the taxonomic relation from the Web. If the number of Web search results is too large, we use only the first 1,000 results to estimate the average trustiness score.

SCS method:
Similarly, the SCS evidence score is recalculated as follows:

$$Score_{SCS}^{Trust}(t_1,t_2) = Score_{SCS}(t_1,t_2)\times (AvgTrust(Corpus_{t_1}^{\Gamma}) + AvgTrust(Corpus_{t_2}^{\Gamma})) \quad (8)$$

SIWN method:
This method does not use any evidence from the Web, and so its measure does not change as follows:

$$Score_{SIWN}^{Trust}(t_1,t_2) = Score_{SIWN}(t_1,t_2) \quad (9)$$

The three measures of trustiness are also linearly combined as follows:

$$Score^{Trust}(t_1,t_2) = \alpha \times Score_{SIWN}^{Trust}(t_1,t_2) + \beta \times Score_{LSP}^{Trust}(t_1,t_2) + \gamma \times Score_{SCS}^{Trust}(t_1,t_2) \quad (10)$$

The values of α, β, and γ in Formula 10 are identical to those for Formula 1.

3.3 Collective synonym evidence

3.3.1 Synonymy identification

We use the three following methods to collect synonyms: dictionaries, pattern matching, and supervised learning.

Dictionaries: Synonyms can be found in dictionaries like a general-purpose dictionary WordNet and also domain-specific ones. Since our domains of interest include virus, animals, and plants (see the next section for details), we also utilize MeSH[5], a well-known vocabulary in biomedicine.

Pattern matching: Given two terms t_1 and t_2, we use the following patterns to find their synonymy evidence from the Web:

- t_1 also [known|called|named|abbreviated] as t_2
- Other common name[s] of t_1 [is|are|include] t_2
- t_1, or t_2, is a
- t_1 (short for t_2)

, where $[a|b]$ denotes a choice between a and b. If the number of Web search results is greater than a threshold Ψ, t_1 is considered as a synonym of t_2.

Supervised learning: We randomly pick 100 pairs of synonyms in WordNet, and for each pair, we use the Web search engine to collect sample sentences in which both terms of the pair are mentioned. If the number of collected sentences is greater than 2000, we use only the first 2000 sentences for training. After that, we extract the following features from the sentences to train a logistic regression model (Hastie et al., 2009) for the synonymy identification:

- Headwords of the two terms
- Average distance between the terms
- Sequence of words between the terms
- Bag of words between the terms
- Dependency path between the terms (using Stanford parser (Klein and Manning, 2003))
- Bag of words on the dependency path

The average F-measure of the obtained model with 10-fold cross-validation is 81%. We use the learned model to identify more synonym pairs in the next step.

3.3.2 Embedding synonym information

Given a term t, we denote $Syn(t)$ as the set of synonyms of t (including t itself). The evidence scores of the SCS and LSP methods are recalculated with synonyms as follows:

$$Score_X^{Synonym}(t_1,t_2) = \sum_{\substack{t_1' \in Syn(t_1) \\ t_2' \in Syn(t_2)}} Score_X(t_1',t_2') \quad (11)$$

, where the variable X can be replaced with SCS and LSP.

[5] http://www.ncbi.nlm.nih.gov/mesh

The intuition of Formula (11) is that the evidence score of the taxonomic relation between two terms t_1 and t_2 can be boosted by adding all the evidence scores of taxonomic relations between them and their synonyms.

Again, as for the SIWN method, we do not change the evidence score as follows:

$$Score_{SIWN}^{Synonym}(t_1, t_2) = Score_{SIWN}(t_1, t_2)$$

3.4 Contrastive evidence

Given two terms t_1 and t_2, we use the following patterns to find their contrastive (thus negative) evidence from the Web:

- t_1 is not a t_2
- t_1 is not a [type|kind] of t_2
- t_1, unlike the t_2
- t_1 is different [from|with] t_2
- t_1 but not t_2
- t_1, not t_2

$WH(t_1, t_2)$ denotes the total number of Web search results, and the contrastive evidence score between t_1 and t_2 is computed as follows:

$$Contrast(t_1, t_2) = \log(WH(t_1, t_2) + 1) \quad (12)$$

Similar to the collective synonym evidence, the contrastive evidence score of taxonomic relation between t_1 and t_2 is boosted with the contrastive evidence scores of taxonomic relations between the two terms and their synonyms as follows:

$$Score^{Contrast}(t_1, t_2) = \frac{\sum_{\substack{t'_1 \in Syn(t_1) \\ t'_2 \in Syn(t_2)}} Contrast(t'_1, t'_2)}{|Syn(t_1)| * |Syn(t_2)|} \quad (13)$$

3.5 Combining trustiness, synonym and contrastive evidence

We combine all the three features into the system of (Tuan et al., 2014) as follows:

$$\begin{aligned} Score_X^{Final}(t_1, t_2) = & Score_X^{Trust}(t_1, t_2) \\ & + Score_X^{Synonym}(t_1, t_2) \end{aligned} \quad (14)$$

, where the variable X can be replaced with each of the three taxonomic relation evidence measures (i.e. SCS, LSP, SIWN). The final combined score is calculated as follows:

$$\begin{aligned} Score_{Combined}^{Final}(t_1, t_2) = & \ \alpha \times Score_{SIWN}^{Final}(t_1, t_2) \\ & + \beta \times Score_{LSP}^{Final}(t_1, t_2) + \gamma \times Score_{SCS}^{Final}(t_1, t_2) \\ & - \delta \times Score^{Contrast}(t_1, t_2) \end{aligned} \quad (15)$$

For each ordered pair of terms t_1 and t_2, if $Score_{Combined}^{Final}(t_1, t_2)$ is greater than a threshold value, then t_1 is considered as a hypernym of t_2.

We estimate the optimal values of parameters α, β, γ and δ in Formula 15 with ridge regression technique (Hastie et al., 2009) as follows: First, we randomly select 100 taxonomic relations in Animal domain as the training set. For each taxonomic relation $t_1 \gg t_2$, its evidence score is estimated as $\tau + \frac{1}{Dist(t_1,t_2)}$, where τ is the threshold value for $Score_{Combined}^{Final}$, and $Dist(t_1, t_2)$ is the length of the shortest path between t_1 and t_2 found in WordNet. Then we use our system to find evidence scores with taxonomic relation identification methods in Formulas 13 and 14. Finally, we build the training set using Formula 15, and use the ridge regression algorithm to learn that the best value for α is 1.31, β 1.57, γ 1.24 and δ 0.79, where τ=2.3.

4 Experiment

4.1 Datasets

We evaluate our method for taxonomy construction against the following collections of six domains:

- Artificial Intelligence (AI) domain: The corpus consists of 4,976 papers extracted from the IJCAI proceedings from 1969 to 2014 and the ACL archives from year 1979 to 2014.
- Finance domain: The corpus consists of 1,253 papers extracted from the freely available collection of "Journal of Financial Economics" from 1995 to 2012 and from "Review Of Finance" from 1997 to 2012.
- Virus domain: We submit the query "virus" to PUBMED search engine [6] and retrieve the first 20,000 abstracts as the corpus of the virus domain.
- Animals, Plants and Vehicles domains: Collections of Web pages crawled by using the bootstrapping algorithm described by Kozareva et al. (2008).

We report the results of two experiments in this section: (1) Evaluating the construction of new taxonomies for Finance and AI domains (Section 4.2), and (2) comparing with the curated

[6] http://www.ncbi.nlm.nih.gov/pubmed

databases' sub-hierarchies. We compare our approach with other three state-of-the-art methods in the literature, i.e. (Kozareva and Hovy, 2010), (Navigli et al., 2011) and (Tuan et al., 2014) (Section 4.3). In addition, for Animal domain, we also compare with the reported performance of Bansal et al. (2014), a recent work to construct taxonomy using belief propagation.

4.2 Constructing new taxonomies for Finance and AI domains

Referential taxonomy structures such as WordNet and OpenCyc are widely used in semantic analytics applications. However, their coverage is limited to common, well-known areas, and many specific domains like Finance and AI are not well covered in those structures. Therefore, an automatic method which can induce taxonomies for those specific domains can greatly contribute to the process of knowledge discovery.

To estimate the precision of a given method, we randomly choose 100 relations among the results of the method and manually check their correctness. The results summarized in Table 1 show that our method extracts much more relations, though with slightly lower precision, than Kozareva et al. (2008) and Navigli and Velardi (2004). Note that due to the lack of gold standards in these two domains, we do not compare the methods in terms of F-score, which we will measure with curated databases in the next section. Compared to Tuan et al. (2014), which can be considered as the baseline of our approach, our method has significant improvement in both precision and the number of extracted relations. It indicates that the three incorporated features of trustiness, and synonym and contrastive evidence are effective in improving the performance of existing taxonomy construction methods.

	Finance		AI	
	P	N	P	N
Kozareva	**90%**	753	**94%**	950
Navigli	88%	1161	93%	1711
Tuan	85%	1312	90%	1927
Our method	88%	**1570**	92%	**2168**

Table 1: Experiment result for finance and AI domains. P stands for Precision, and N indicates the number of extracted relations.

4.3 Evaluation against curated databases

We evaluate automatically constructed taxonomies for four domains (i.e. Animal, Plant, Vehicle, Virus) against the corresponding sub-hierarchies of curated databases. For Animal, Plant and Vehicle domains, we use WordNet as the gold standards, whereas for Virus domain, we use MeSH sub-hierarchy of virus as the reference.

Note that in this comparison, to be fair, we change our algorithm to avoid using WordNet in identifying taxonomic relations (i.e. SIWN algorithm), and we only use the exact string-matching comparison without WordNet. The evaluation uses the following measures:

$$Precision = \frac{\#relations\ found\ in\ database\ and\ by\ the\ method}{\#relations\ found\ by\ the\ method}$$

$$Recall = \frac{\#relations\ found\ in\ database\ and\ by\ the\ method}{\#relations\ found\ in\ database}$$

To understand the individual contribution of the three introduced features (i.e. trustiness, synonym, contrast), we also evaluate our method only with one of the three features each time, as well as with all the three features (denoted as "Combined").

Tables 2 and 3 summarize the experiment results. Our combined method achieves significantly better performance than the previous state-of-the-art methods in terms of F-measure and Recall (t-test, p-value < 0.05) for all the four domains. For Animal domain, it also shows higher performance than the reported performance of Bansal et al. (2014). In addition, the proposed method improves the baseline (i.e. Tuan et al. (2014)) up to 4%-10% of F-measure.

Furthermore, we find that the three features have different contribution to the performance improvement. The trustiness feature contributes to the improvement on both precision and recall. The synonym feature has the tendency of improving the recall further than the trustiness, whereas the contrastive evidence improves the precision. Note that we discussed these different contributions of the features in the Introduction.

4.3.1 Evaluation of individual methods for trustiness and synonymy identification

We evaluate the individual methods for trustiness measurement and synonymy identification described in Sections 3.2.1 and 3.3.1. For this purpose, we evaluate our system only with one of the individual methods at a time (i.e. importance, popularity, authority and accuracy for trustiness measure, and dictionary, pattern matching, and machine learning methods for synonymy identification).

As summarized in Table 4, the "Importance" and "Accuracy" methods for trustiness measurement based on PageRank and IE systems, respectively, have more contribution than the others. Similarly, the experiment results indicate that the "Machine learning" method has the most contribution among the three methods of synonymy identification.

In addition, we also examine the interdependence of the four introduced aspects of trustiness by running the system with the combination of only two aspects, Importance and Accuracy. The results in all domains show that when combining only the Importance and Accuracy, the system almost achieves the same performance to that of the combined system with all four criteria, except for the Plant domain. It can be explained as the Importance aspect (which is expressed as the PageRank score) may subsume the Popularity and Authority aspects. Another interesting point is that the performance of Accuracy, which is solely based on the local information from the website, when applied individually, is almost the same with that of Importance which is based on the distributed information. It shows that the method of ranking of the sites based on the knowledge-based facts can achieve the effectiveness as good as the traditional ranking method using PageRank score.

	Animal	Plant	Vehicle	Virus
Trustiness:				
Importance	74%	**70%**	81%	63%
Popularity	72%	69%	81%	61%

4.4 Discussion

4.4.1 Case studies

We give two examples to illustrate how the proposed features help to infer correct taxonomic relations and filter out incorrect relations. Our baseline (Tuan et al. (2014)) extracts an incorrect taxonomic relation between 'fox' and 'flying fox' due to the following reasons: (1) 'flying fox' includes 'fox' (SIWN) and (2) untrusted sources such as a public forum[7] support the relation. Using our proposed method, this relation is filtered out because those untrusted sources are discouraged by the trustiness feature, and also because there are contrastive evidence[8] saying that 'flying fox' is NOT a 'fox'. Specifically, the average trustiness score of LSP method of the sources for the invalid relation (i.e. $AvgTrust(C_{Web}(fox, flying\ fox)) + AvgTrust(C_{Web}(flying\ fox, fox))$) is 0.63, which is lower than the average of those scores, 0.90. Also, the collective contrastive evidence score (i.e. $Score^{Contrast}(fox, flying\ fox)$) is 1.10, which is higher than the average collective contrastive score, 0.32.

On the other hand, the true taxonomic relation between 'bat' and 'flying fox' is not identified by the baseline, mainly due to the rare mention of this relation in the Web. However, our proposed method can recognize this relation because of two reasons: (1) 'flying fox' has many synonyms such as 'fruit bat', 'pteropus', 'kalong', and 'megabat', and there are much evidence that these synonyms are kinds of 'bat' (i.e. using the collective synonym evidence). (2) The evidence for the taxonomic relation between 'fly-

[7] http://redwall.wikia.com/wiki/User:Ferretmaiden/Archive3
[8] http://en.cc-english.com/index.php?shownews-1397

ing fox' and 'bat', though rare, is from trusted sites[9] which are maintained by scientists. Thus, the trustiness feature helps to boost the evidence score for this relation over the threshold value. Specifically, the average trustiness score of LSP method (i.e. $(AvgTrust(C_{Web}(bat, flying\ fox)) + AvgTrust(C_{Web}(flying\ fox, bat)))$), 2.84, is higher than the average in total, 0.90.

We further investigate on 256 taxonomic relations that were missed by the baseline but correctly identified by the proposed method. The average $Score_{LSP}$ and the average $Score_{SCS}$ of the relations by the baseline are 0.35 and 0.60, respectively, while those by the proposed method are 1.17 and 0.82, respectively. We thus find that the proposed method is more effective in correctly improving the LSP method than the SCS method.

4.4.2 Empirical comparison with WordNet

By error analysis, we find that our results may complement WordNet. For example, in Animal domain, our method identifies 'wild sheep' as a hyponym of 'sheep', but in WordNet, they are siblings. However, many references [10] [11] consider 'wild sheep' as a species of 'sheep'. Another such example is that our system recognizes 'aquatic vertebrate' as a hypernym of 'aquatic mammal', but WordNet places them in different subtrees incorrectly [12]. Therefore, our results may help restructure and extend WordNet.

4.4.3 Threshold tuning

Our scoring methods utilize several thresholds to select relations of high ranks. Here we discuss them in details below.

The threshold value Ψ for the pattern matching method in Section 3.3.1 controls the number of synonymy relations extracted from text. The threshold value for $Score^{Final}_{Combined}$ of Formula 15 in Section 3.5 controls the number of extracted taxonomic relations. In general, the larger these threshold values are, the higher number of synonyms and taxonomic relations we can get. In our experiments, we found that the threshold values for Ψ between 100 and 120, and those for $Score^{Final}_{Combined}$ between 2.3 and 2.5 generally help the system achieve the best performance.

5 Conclusion

In this paper, we propose the features of trustiness, and synonym and contrastive collective evidence for the task of taxonomy construction, and show that these features help the system improve the performance significantly. As future work, we will investigate into the task of automatically constructing patterns for the pattern matching methods in Sections 3.3 and 3.4, to improve coverage. We will also enhance the accuracy measure of trustiness, based on the observation that some untrusted sites copy information from other sites to make them look more trustful.

Abstract

Logic grid puzzle is a genre of logic puzzles in which we are given (in a natural language) a scenario, the object to be deduced and certain clues. The reader has to figure out the solution using the clues provided and some generic domain constraints. In this paper, we present a system, LOGICIA, that takes a logic grid puzzle and the set of elements in the puzzle and tries to solve it by translating it to the knowledge representation and reasoning language of Answer Set Programming (ASP) and then using an ASP solver. The translation to ASP involves extraction of entities and their relations from the clues. For that we use a novel learning based approach which uses varied supervision, including the entities present in a clue and the expected representation of a clue in ASP. Our system, LOGICIA, learns to automatically translate a clue with 81.11% accuracy and is able to solve 71% of the problems of a corpus. This is the first learning system that can solve logic grid puzzles described in natural language in a fully automated manner. The code and the data will be made publicly available at http://bioai.lab.asu.edu/logicgridpuzzles.

1 Introduction

Understanding natural language to solve problems be it algebraic word problems (Kushman et al., 2014; Hosseini et al., 2014) or questions from biology texts (Berant et al., 2014; Kim et al., 2011), has attracted a lot of research interest over the past few decades. For NLP, these problems are of particular interest as they are concise, yet rich in information. In this paper, we attempt to solve another problem of this kind, known as Logic Grid Puzzle. Problem.1 shows an example of the same. Puzzle problems in the same spirit as the previously mentioned science problems, do not restrict the vocabulary; they use everyday language and have diverse background stories. The puzzle problems, however, are unique in their requirement of high precision understanding of the text. For a puzzle problem, the solution is never in the text and requires involved reasoning. Moreover, one needs to correctly understand each of the given clues to successfully solve a problem. Another interesting property is that only a small core of the world knowledge, noticeably spatial, temporal and knowledge related to numbers, is crucial to solve these problems.

PROBLEM .1 A LOGIC GRID PUZZLE

Waterford Spa had a full appointment calendar booked today. Help Janice figure out the schedule by matching each masseuse to her client, and determine the total price for each.

1. Hannah paid more than Teri's client.
2. Freda paid 20 dollars more than Lynda's client.
3. Hannah paid 10 dollars less than Nancy's client.
4. Nancy's client, Hannah and Ginger were all different clients.
5. Hannah was either the person who paid $180 or Lynda's client.

Clients: *Aimee, Ginger, Freda, Hannah*.
Prices: *$150, $160, $170, $180*.
Masseuses: *Lynda, Nancy, Tery, Whitney*.

A logic grid puzzle contains a set of categories and an equal number of elements in each category.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1023–1033,
Lisbon, Portugal, 17-21 September 2015.

And the goal is to find out which elements are linked together based on a series of given clues. Each element is used only once. Each puzzle has a unique solution and can be solved using logical reasoning. A logic grid puzzle is called a (n, m)-puzzle if it contains n categories and each category has m elements. For the example in Problem.1, there are three categories, namely *clients, prices, masseuses* and each category has four elements which are shown in the respective columns. A total of five clues are given in free text and the goal is to find the members of the four tuples, where each tuple shall contain exactly one element from each category such that all the members in a tuple are linked together.

To solve such a puzzle problem, it is crucial to understand the clues (for example, "Hannah paid more than Teri's client."). Each clue talks about a set of entities (for example, "Hannah", "client", "Terry") and their relations ("a greater-than relation between Hannah and the client of Terry on the basis of payment"). Our system, LOGICIA, learns to discover these entities and the underlying semantics of the relations that exist between them. Once the relations are discovered, a pair of Answer Set Programming (ASP) (Baral, 2003) rules are created. The reasoning module takes these ASP rules as input and finds a group configuration that satisfies all the clues. LOGICIA has "knowledge" about a fixed set of predicates which models different relations that hold between entities in a puzzle world. Clues in the puzzle text that are converted into ASP rules, use these predicates as building blocks. In this research, our goal is to build a system which can automatically do this conversion and then reason over it to find the solution. The set of predicates that the reasoning model is aware of is not sufficient to represent all logic grid puzzles. The family of logic grid puzzles is broad and contains variety of clues. Our future work involves dealing with such a diverse set of relations. In this work we assume that the relations in Table 1 are sufficient to represent the clues. Following are some examples of clues that cannot be modeled using the predicates in Table 1.

- *Esther's brother's* seat is at one end of the block of seven.
- The *writer* of *Lifetime Ambition* has a *first name* with more letters than that of the *tennis star*.
- *Edward* was *two places* behind *Salim* in one of the lines, *both* being in odd-numbered positions.
- *Performers* who finished in the top *three* places, in no particular order, are *Tanya* , the *person* who performed the *fox trot*, and the *one* who performed the *waltz*.

The rest of the paper is organized as follows: in section 2, we describe the representation of a puzzle problem in ASP and delineate how it helps in reasoning; in section 3, we present our novel method for learning to automatically translate a logic problem described in natural language to its ASP counterpart. In section 4, we describe the related works. In section 5, we discuss the detailed experimental evaluation of our system. Finally, section 6 concludes our paper.

2 Puzzle Representation

Answer Set Programming (ASP) (Baral, 2003; Lifschitz, 1999; Gelfond and Lifschitz, 1991) has been used to represent a puzzle and reason over it. This choice is facilitated by the two important reasons: 1) non-monotonic reasoning may occur in a puzzle (Nagy and Allwein, 2004) and 2) ASP constructs greatly simplify the reasoning module, as we will see in this section. We now briefly describe a part of ASP. Our discussion is informal. For a detailed account of the language, readers are referred to (Baral, 2003).

2.1 Answer Set Programming

An answer set program is a collection of rules of the form,

$$L_0 \mid ... \mid L_k \text{ :- } L_{k+1}, ..., L_m, \textbf{not } L_{m+1}, ..., \textbf{not } L_n$$

where each of the L_i's is a literal in the sense of a classical logic. Intuitively, the above rule means that if $L_{k+1}, ..., L_m$ are to be true and if $L_{m+1}, ..., L_n$ can be safely assumed to be false then at least one of $L_0, ..., L_k$ must be true. The left-hand side of an ASP rule is called the *head* and the right-hand side is called the *body*. A rule with no *head* is often referred to as a $constraint$. A rule with empty *body* is referred to as a $fact$ and written as,

$$L_0 \mid L_1 \mid ... \mid L_k.$$

Example

fly(X) :- bird(X), not ab(X).

The above program represents the knowledge that "Most birds fly". If we add the following rule ($fact$) to the program,

bird(penguin).

the answer set of the program will contain the belief that penguins can fly, $\{bird(penguin), fly(penguin)\}$. However, adding one more fact, '$ab(penguin)$.', to convey that the penguin is an abnormal bird, will change the belief that the penguin can fly and correspondingly the answer set, $\{bird(penguin), ab(penguin)\}$, will not contain the fact, $fly(penguin)$.

Choice Rule

$$m\ \{p(X) : q(X)\}\ n : -L_1, ..., L_k, ..., \textbf{not}\ L_n.$$

Rules of this type allow inclusion in the program's answer sets of arbitrary collections S of atoms of the form $p(t)$ such that, $m \leq \mid S \mid \leq n$ and if $p(t) \in S$ then $q(t)$ belongs to the corresponding answer set.

2.2 Representing Puzzle Entities

A (m, n)-puzzle problem contains m categories and n elements in each category. The term 'puzzle entity' is used to refer to any of them. Each category is assigned an unique index, denoted by the predicate $cindex/1$ (the number after the '/' denotes the arity of the predicate). The predicate $etype/2$ captures this association. Each element is represented, by the $element/2$ predicate which connects a category index to its element. The predicate $eindex/1$, denotes the tuple indices. The following blocks of code shows the representation of the entities for the puzzle in Problem.1.

```
cindex(1...3).
eindex(1...4).

etype(1,clients).
etype(2,prices).
etype(3,masseuses).

element(1,aimee;;1,ginger).
element(1,freda;;1,hannah).
element(2,150;;2,160).
element(2,170;;2,180).
element(3,lynda;;3,nancy).
element(3,teri;;3,whitney).
```

2.3 Representing Solution

Solution to a logic grid puzzle is a set of tuples containing related elements. The $tuple/3$ predicate captures this tuple membership information of the elements. For example, the fact, $tuple(2, 1, aimee)$, states that the element $aimee$ from the category with index 1 is in the tuple 2. The rel/m predicate captures all the elements in a tuple for a (m, n)-puzzle and is defined using the $tuple/3$ predicate.

2.4 Domain Constraints

In the proposed approach, the logic grid puzzle problem is solved as a constraint satisfaction problem. Given a puzzle problem the goal is to enumerate over all possible configurations of $tuple/3$, and select the one which does not violate the constraints specified in the clues. However, 1) each tuple in a logic grid puzzle will contain exactly one element from each category and 2) an element will belong to exactly one tuple. These constraints come from the specification of a puzzle problem and will hold irrespective of the problem instance. Following blocks of code show an elegant representation of these domain constraints in ASP along with the enumeration.

```
%enumerate over the tuple
%assignments with constraint#1
1 {
    tuple(G,Cat,Elem):
    element(Cat,Elem)
} 1 :- cindex(Cat),
       eindex(G).

%domain constraint#2
:-tuple(G1,Cat,Elem),
  tuple(G2,Cat,Elem),
  G1!=G2.
```

2.5 Representing clues

Each clue describes some entities and the relations that hold between them. In its simplest form, the relations will suggest if the entities are linked together or not. However, the underlying semantics of such relations can be deep such as the one in clue 5 of Problem.1. There are different ways to express the same relation that holds between entities. For example, in Problem.1, the *possessive* relation has been used to express the linking between clients and masseuses; and the word *paid*

expresses the linking between the clients and the prices. Depending on the puzzles the phrases that are used to express the relations will vary and it is crucial to identify their underlying semantics to solve the problems in systematic way.

In the current version, the reasoning module has knowledge of a selected set of relations and the translation module tries to represent the clue as a conjunction of these relations. All these relations and their underlying meanings are described in table 1. In this subsection, we describe the representation of a clue in terms of these relations in ASP and show how it is used by the reasoning module. In the next section, we present our approach to automate this translation.

Let us consider the clues and their representation from Problem.1:

[1] Hannah paid more than Teri's client.

```
clue1 :-
  greaterThan(hannah,1,X,1,2),
  sameTuple(X,1,teri,3).
:- not clue1.
```

The first rule $clue1$ evaluates to true (will be in the answer set) if the element from category 1 with value $hannah$ is linked to some element from category 2 which has a higher value than the element from its own category which is linked to an element from category 1 which is linked to $teri$ from category 3. Since the desired solution must satisfy the relations described in the clue, the second ASP rule is added. A rule of this form that does not have a $head$ is known as a $constraint$ and the program must satisfy it to have an answer set. As the reasoning module enumerates over all possible configurations, in some cases the $clue1$ will not hold and subsequently those branches will be pruned. Similar constraints will be added for all clues. In the below, we show some more examples. A configuration which satisfies all the clue constraints and the domain constraints described in the previous section, will be accepted as the solution to the puzzle.

[2] Nancy's client, Hannah and Ginger were all different clients.

```
clue4 :-
  diffTuple(hannah,1,ginger,1),
  diffTuple(hannah,1,X,1),
  diffTuple(X,1,ginger,1),
  sameTuple(X,1,nancy,3).
:- not clue4.
```

[3] Hannah was either the person who paid $180 or Lynda's client.

```
clue5 :-
   eitherOr(hannah,1,X,1,Y,1),
   sameTuple(X,1,180,2).
   sameTuple(Y,1,lynda,3).
:- clue5.
```

3 Learning Translation

To automate the translation of a clue to the pair of ASP rules, the translation module needs to identify the entities that are present in the clue, their category and their value; and the underlying interpretations of all the relations that hold between them. Once all the relation instances $\{R_1(arg_1, ..., arg_{p_1})$,..., $R_q(arg_1, ..., arg_{p_q})\}$, in the clue are identified, the ASP representation of the clue is generated in the following way:

$$clue : -R_1(arg_1..., arg_{p_1}), ..., R_q(arg_1..., arg_{p_q})$$

The entity classification problem for logic grid puzzles poses several challenges. First, the existence of a wide variety in the set of entities. Entities can be names of objects, time related to some event, numbers, dates, currency, some form of ID etc. And it is not necessary that the entities in puzzles are nouns. It can be verbs, adjectives etc. Second and of paramount important, the "category" of a puzzle "element" is specific to a puzzle problem. Same element may have different category in different problems. Also, a constituent in a clue which refers to an entity in a particular problem may not refer to an entity in another problem. We formalize this problem in this section and propose one approach to solve the problem. Next, we discuss the method that is used to extract relations from clues. To the best of our knowledge, this type of entity classification problem has never been studied before.

Relation	Interpretation
sameTuple(E1, C1, E2, C2)	States that two elements, (C1,E1) and (C2,E2) are in the same tuple. The dictionary also contains the negation of it, *diffTuple*(E1, C1, E2, C2).
referrent(E1, C1, E2, C2)	States that the elements are identical.
posDiff(E1, C1, E2, C2, N1, NC1)	If (C1,E1) is related to (NC1,X1) and (E2,C2) is related to (NC1,X2), then difference(X1,X2)=N1. Similarly the dictionary contains the predicate *negDiff*.
greaterThan(E1, C1, E2, C2, NC1)	Similar to *posDiff* however the difference(X1,X2) $>$ 0. The dictionary also contains its opposite predicate *lessThan*.
members(E1, C1, E2, C2,..., EN, CN)	All the elements are distinct and do not share a tuple.
eitherOr(E1, C1, E2, C2,..., EN, CN)	The first element is related to one of the last $N-1$ elements. The last $N-1$ elements are assumed to be different unless contradicts with other beliefs.
referrent22(E1, C1, E2, C2, E3, C3, E4, C4)	The first two elements are different and referring to the last two elements.

Table 1: Describes the various relations that are part of the reasoning module.

3.1 Entity Classification

The entity classification problem is defined as follows:

Problem description Given m categories C_1, ..., C_m and a text T, each category C_i, $1 \leq i \leq m$, contains a collection of elements E_i and an optional textual description d_i. The goal is to find the class information of all the constituents in the text T. Each category contributes two classes, where one of them represents the category itself and the other represents an instance of that category. Also, a constituent may not refer to any category or any instance of it, in that case the class of that constituent is $null$. So, there are a total $2m+1$ classes and a constituent will take one value from them.

Example In the puzzle of Problem.1, there are 3 categories with, C_1 = {Aimee, Freda, Ginger, Hannah}, C_2 = {\$150, \$160, \$170, \$180}, C_3 = {Lynda, Nancy, Terry, Whiteney} and d_1 = "clients", d_2 = "prices", d_3 = "masseuses". The text T, is the concatenation of all clues. In the last clue, there are a total 5 entities, namely "Hannah", "person", "\$180", "Lydia","client" and the corresponding classes are "Instance of C_1", "Instance of C_1", "Instance of C_2", "Instance of C_3" and "Instance of C_1" respectively. The remaining constituents in that clue have the class value $null$. The constituent "clients" in the fourth clue refers to the category C_1.

Our approach We model the Entity Classification problem as a decoding query on Pairwise Markov Network (Koller and Friedman, 2009; Kindermann et al., 1980; Zhang et al., 2001). A pairwise Markov network over a graph $\mathcal{H}$, is associated with a set of node potentials $\{\phi(X_i) : i = 1, ..., n\}$ and a set of edge potentials $\{\phi(X_i, X_j) : (X_i, X_j) \in \mathcal{H}\}$. Each node $X_i \in \mathcal{H}$, represents a random variable. Here, each X_i can take value from the set $\{1...2m+1\}$, denoting the class of the corresponding constituent in the text T.

In our implementation, the node potential captures the chances of that node to be classified as one of the possible categories without being affected by the given text T. And the edge potentials captures hints from the context in T for classification. After constructing the pairwise Markov network, a decoding query is issued to obtain the configuration that maximizes the joint probability distribution of the pairwise Markov network in consideration. The proposed approach is inspired by the following two observations: 1) to find the class of a constituent one needs some background knowledge; 2) however, background knowledge is not sufficient on its own, one also needs to understand the text to properly identify the class of each constituent. For example, let us consider the word "person" in clue 5 of Problem.1. Just skimming through the categories, one can discover that the word "person" is very unlikely to be a instance of the category "prices", which is from her knowledge about those constituents. However a proper

disambiguation may face an issue here as there are two different categories of human beings. To properly classify the word "person" it is necessary to go through the text.

The following paragraphs describe the construction of the grah $\mathcal{H}$, and the algorithm that is used in the computation of associated set of node potentials and edge potentials.

Construction of the graph While constructing the graph, we assign a label, L, to each edge in $\mathcal{H}$ which will be used in the edge potential computation. Let $\mathcal{D}_\mathcal{G}$ denotes the dependency graph of the text T obtained from the Stanford dependency parser (Chen and Manning, 2014) and $dep(v_1, v_2)$ denotes the grammatical relation between $(v_1, v_2) \in \mathcal{D}_\mathcal{G}$. Then the graph, $\mathcal{H}$, is constructed as follows:

1. Create a node in $\mathcal{H}$ for each constituent w_j in T if $w_j \in \mathcal{D}_\mathcal{G}$.
2. Add an edge (X_i, X_j) to $\mathcal{H}$ if the corresponding edge $(w_p, w_q) \in \mathcal{D}_\mathcal{G}$. $L(X_i, X_j) := dep(w_p, w_q)$.
3. Add an edge between a pair of nodes (X_i, X_j) if the corresponding words are synonyms. $L(X_i, X_j) := synonymy$.
4. Create a node for each element and category specified in the puzzle and add an edge from them to others if the corresponding string descriptions are 'same'. In this case, the edges are labeled as $exact\_match$.
5. If $(X_i, X_j) \in \mathcal{H}$ and $L(X_i, X_j) = exact\_match$ and both of them are referring to a verb, then add more edges (X_i', X_j') to $\mathcal{H}$ with label $spatial\_symmetry$, where $L(X_i, X_i') = L(X_j, X_j')$.

Determining Node potentials For each element in the m category, a set of naive regular-expression based taggers are used to detect it's type (For example, "am-pm time"). Each element type maps to a WordNet (Miller, 1995) representative (For example, "time_unit#n"). For each constituent w a similarity score, $sim(w,c)$, is calculated to each class $c \in \{1...2m+1\}$, in the following way:

•**Class c is denoting instance of some category C_i** Similarity scores are computed between the textual description of the constituent to both the WordNet representative of E_i and the textual description d_i using the HSO WordNet similarity algorithm (Hirst and St-Onge, 1998). The similarity score, $sim(w,c)$, is chosen to be the maximum of them.

•**Class c is denoting a category C_i :** $sim(w,c)$ is assigned the value of HSO Similarity between the textual description and d_i.

•**Class c is $null$:** In this case similarity is calculated using the following formula:

$$sim(w, null) = MAX_{HSO} - \max_{c \neq null} sim(w, c)$$

where MAX_{HSO} denotes the maximum similarity score returned by HSO algorithm, which is 16.

Node potential for each node $X_i \in \mathcal{H}$, corresponding to the constituent w_j, are then calculated by,

$$\phi(X_i = c) = 1 + sim(w_j, c), \forall c$$

Determining Edge potentials For each edge in the graph H, the edge potential, $\phi(X_i, X_j)$ is calculated using the following formula,

$$\phi(X_i = c_1, X_j = c_2) =$$
$$1 + \begin{cases} P(X_i = X_j | L(X_i, X_j)), & \text{if } c_1 = c_2 \\ P(X_i \neq X_j | L(X_i, X_j)), & \text{otherwise} \end{cases}$$

In the training phase, each entity in a clue is tagged with its respective class. The probability values are then calculated from the training dataset using simple count.

3.2 Learning To Extract Relations

The goal here is to identify all the relations $R(arg_1, ..., arg_p)$ that are present in a clue, where each relation belongs to the logical vocabulary described in Table 1 . This problem is known as *Complex relation extraction* (McDonald et al., 2005; Bach and Badaskar, 2007; Fundel et al., 2007; Zhou et al., 2014). The common approach for solving the *Complex relation extraction* problem is to first find the relation between each pair of entities and then discover the complex relations from binary ones using the definition of each relation.

Figure 1 depicts the scenario. The goal is to identify the relation $possDiff(E1, E2, E3)$, where $E1, E2, E3$ are constituents having a non-$null$ class value. However instead of identifying $posDiff(E1, E2, E3)$ directly, first the relation

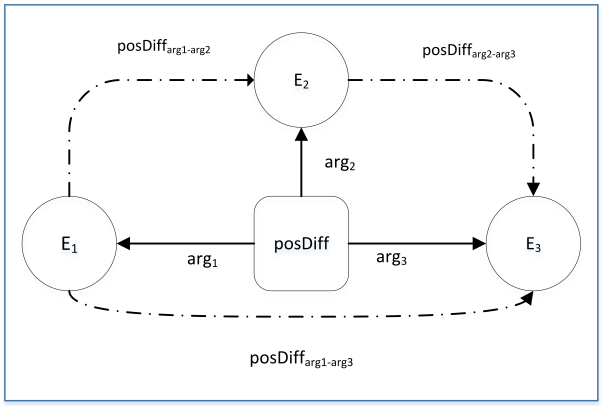

Figure 1: Binary representation of the relation $possDiff$

between each pair of entities will be identified. If the relations $\{posDiff_{arg_1-arg_2}(E_1, E_2)$, $posDiff_{arg_2-arg_3}(E_2, E_3)$, $posDiff_{arg_1-arg_3}$ (E_1,E_3) $\}$ are identified, the extraction module will infer that $posDiff(E1, E2, E3)$ holds. In a similar manner, a set of total 39 binary relations are created for all the relations described in Table 1.

In the training phase, all the relations and their respective arguments in each clue are given. Using this supervision, we have built a Maximum Entropy based model (Berger et al., 1996; Della Pietra et al., 1997) to classify the relation between a pair of entities present in a clue. Maximum entropy classifier has been successfully applied in many natural language processing applications (Charniak, 2000; Chieu and Ng, 2002; Ratnaparkhi and others, 1996) and allows the inclusion of various sources of information without necessarily assuming any independence between the features. In this model, the conditional probability distribution is given by:

$$P(c|d) = \frac{\prod_{j=1...K} e^{\lambda_i f_i(d,c)}}{\sum_{c' \in C} \prod_{j=1...K} e^{\lambda_i f_i(d,c')}} \quad (1)$$

where the denominator is the normalization term and the parameter λ_i correspond to the weight for the feature f_i. Features in Maximum Entropy model are functions from context and classes to the set of real numbers. A detailed description of the model or parameter estimation method used - Generalized Iterative Scaling, can be found at (Darroch and Ratcliff, 1972).

Table 2 describes the features that are used in the classification task. Here, $path(E_1, E_2)$ denotes all the words that occur in the path(s) connecting E_1 and $E2$ in the dependency graph of the clue.

Feature Set
Class of E_1 and E_2
All the grammatical relations between the words in $path(E_1, E_2)$
All the adjectives and adverbs in $path(E_1, E_2)$.
POS tags of all the words in $path(E_1, E_2)$
TypeMatched = [[class of E_1 = class of E_2]]
IsE_1Numeric = [[class of E_1 is Numeric]]
IsE_2Numeric = [[class of E_2 is Numeric]]
All the words that appears in the following grammatical relations $advmod$, $amod$, cop, det with the words in $path(E_1, E_2)$.
hasNegativeWord = [[$\exists$w $\in$ $path(E_1, E_2)$ s.t. w has a neg relation starting with it.]]

Table 2: Features used in the classification task

The relation between each pair of entities in a clue is the one which maximizes the conditional probability in equation (1).

3.2.1 Missing Entity

In the case of comparative relations in Table 1, such as $greaterThan$, the basis of the comparison can be hidden. For example, in clue 1 of the example problem, the two entities, "Hannah" and "client" have been compared on the basis of "price", however there is no constituent in the clue which refers to an element from that category. The basis of comparison is hidden in this case and is implied by the word "paid". In the current implementation, the translation module does not handle this case. For puzzles that contain only one category consisting of numeric elements, the translation module goes with the obvious choice. This is part of our future work.

4 Related Work

There has been a significant amount of work on the representation of puzzle problems in a formal language (Gelfond and Kahl, 2014; Baral, 2003; Celik et al., 2009). However, there has not been any work that can automatically solve a logic grid puzzle. The latest work (Baral and Dzifcak, 2012) on this problem, assumes that the entities in a clue are given and the authors manually simplify the sentences for translation. Furthermore their representation of logic grid puzzles does not consider the category of a variable in the formal representation

i.e. uses $element/1$ and $tuple/2$ predicates and thus cannot solve puzzles containing more than one numeric categories.

In the same work (Baral and Dzifcak, 2012), the authors propose to use a semantic parser to do the translation. This method works well for simple sentences such as "Donna dale does not have green fleece" however it faces several challenges while dealing with real world puzzle sentences. The difficulty arises due to the restrictions enforced in the translation models used by the existing semantic parsers. Traditional semantic parsers (Vo et al., 2015; Zettlemoyer and Collins, 2005) assign meanings to each word in a dictionary and combine the meaning of the words to characterize the complete sentence. A phrase structure grammar formalism such as Combinatory Categorial Grammar (Steedman and Baldridge, 2011; Vo et al., 2015; Zettlemoyer and Collins, 2005), Context Free Grammar (Aho and Ullman, 1972; Wong and Mooney, 2006), is normally used to obtain the way words combine with each other. In the training phase, the semantic parser learns the meanings of words given a corpus of <sentence, meaning> pairs and stores them in a dictionary. During translation, the semantic parser uses those learned meanings to obtain the meaning of the sentence. Firstly, for the puzzle problems the meaning of the words changes drastically depending on the puzzle. A word may be an entity in one puzzle, but, in a different problem it might not be an entity or might belong to a different category altogether. Thus a learned dictionary may not be useful while translating clues in a new puzzle. Secondly, in puzzles relations are normally expressed by phrases. For example, in the clue "The person who played at Eden Gardens played for India", the phrases "played at" and "played for" are used to express two different relations. Thus, using a model that assigns meaning to each word may not be suitable here. Finally, it is difficult to identify the participants of a relation with a parse tree generated following a phrase structure grammar. For example, consider the parse tree of the clue "The person who trekked for 8 miles started at Bull Creek". Even though, the relation "started at" takes the word 'person' and 'Bull Creek' as its input, it receives the entire phrase "the person who trekked for 8 miles" as its argument along with the other input 'Bull Creek'.

The entity classification problem studied in this research shares many similarity with Named Entity Recognition (Nadeau and Sekine, 2007; Zhou and Su, 2002) and the Word Sense disambiguation (Stevenson and Wilks, 2003; Sanderson, 1994) task. However, our work has a major difference; in the entity classification problem, the class of an entity varies with the problem and does not belong to a known closed set, whereas for the other two problems the possible classes are pre-specified.

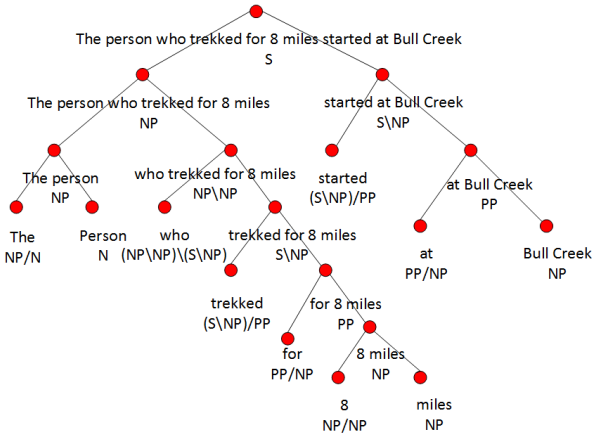

Figure 2: Parse tree of an example sentence in Combinatory categorial grammar

5 Experimental Evaluation

Dataset To evaluate our method we have built a dataset of logic grid puzzles along with their correct solutions. A total of 150 problems are collected from `logic-puzzles.org`. Out of them 100 problems are fully annotated with the entities and the relations information. The remaining 50 puzzles do not have any annotation except their solution. The set of annotated puzzles contain a total of 467 clues, 5687 words, 1681 entities and 862 relations. The set of 50 puzzles contain a total of 222 clues with 2604 words.

Tasks We evaluate LOGICIA on three tasks: 1) puzzle solving; 2) entity classification; and 3) relation extraction. We use the percentage of correct answers as the evaluation metric for all the three tasks. In case of a logic grid puzzle solving, an answer is considered correct if it exactly matches the solution of that puzzle.

Training-Testing Out of the 100 annotated puzzle problems 50 are used as training samples and remaining 50 puzzles are used in testing. The set of 50 unannotated puzzles are used solely for the task of testing puzzle solving.

	Entity classification	Binary relation classification with annotation		Relation extraction with annotation		Solution
		Yes	No	Yes	No	
Total	1766	960		450		50
Correct	1502	922	854	410	365	37
Percentage	85.05%	96.04%	88.95%	90.90%	81.11%	74%

Table 3: Accuracy on 50 annotated puzzle problems in the Test set.

Results Table 3 & 4 shows the efficacy of our approach in solving logic grid puzzles with the selected set of relations. LOGICIA is able to classify the constituents with 85.05% accuracy and is able to solve 71 problems out of the 100 test puzzles. It should be noted that puzzle problems requires precise understanding of the text and to obtain the correct solution of a puzzle problem all the entities and their relations in the puzzle need to be identified. Columns 2 and 3 in Table 3 compares the performance on relation extraction when it is used in conjunction with the entity classification and when it directly uses the annotated entity.

Puzzle Solving		
Total	Correct	Percentage
50	34	68%

Table 4: Accuracy on unannotated 50 test puzzle problems.

Error Analysis The errors in entity classification falls into two major categories. In the first category, more knowledge of similarity is needed than what is currently obtained from the WordNet. Consider for example, the categories are "class number" and "class size" and the constituent is "20 students". Even though the constituent is closer to "class size", standard WordNet based similarity methods are unable to provide such information. In the second category, the WordNet similarity of the constituent to one of the classes is quite high due to their position in the WordNet hierarchy; however with respect to the particular problem the constituent is not an entity. The relation extraction task performs fairly well, however the binary relation classification task does not jointly consider the relation between all the entities and because of that if one of the necessary binary relation of a complex relation is misclassified, the extraction of the entire relation gets affected.

6 Conclusion & Future Work

This paper presents a novel approach for solving logic grid puzzle. To the best of our knowledge, this is a novel work with respect to the fact that that it can automatically solve a given logic grid puzzle.

There are several advantages of our approach. The inclusion of knowledge in terms of a vocabulary of relations makes it scalable. For puzzles which make use of a different set of constraints, such as "Lynda *sat on an even numbered position*", can be easily integrated into the vocabulary and the system can then be trained to identify those relations for new puzzles. Also, the proposed approach separates the representation from reasoning. The translation module only identifies the relation and their arguments; it is not aware of the meaning of those relations. The reasoning module, on the other hand, knows the definition of each relation and subsequently prunes those possibilities when relations appearing in a clue does not hold. This separation of representation from reasoning allows the system to deal with the complex relations that appear in a clue.

There are a few practical and theoretical issues which need to be addressed. One of those is updating the logical vocabulary in a scalable manner. Logic grid puzzle is a wide family of puzzles and it will require more knowledge of relations than what is currently available. Another challenge that needs to be addressed is the computation of similarity between complex concepts such as "size of class" and "20 students". Also, the case of "missing entity" (3.2) needs to be modeled properly. This work is the first step towards further understanding these important issues.

Improving fast_align by Reordering

Abstract

fast_align is a simple, fast, and efficient approach for word alignment based on the IBM model 2. fast_align performs well for language pairs with relatively similar word orders; however, it does not perform well for language pairs with drastically different word orders. We propose a *segmenting-reversing reordering* process to solve this problem by alternately applying fast_align and reordering source sentences during training. Experimental results with Japanese-English translation demonstrate that the proposed approach improves the performance of fast_align significantly without the loss of efficiency. Experiments using other languages are also reported.

1 Introduction

Aligning words in a parallel corpus is a basic task for almost all state-of-the-art statistical machine translation (SMT) systems. Word alignment is used to extract translation rules in various way, such as the phrase pairs used in a phrase-based (PB) SMT system (Koehn et al., 2003), the hierarchical rules used in a HIERO system (Chiang, 2007), and the sophisticated translation templates used in tree-based SMT systems (Liu et al., 2006).

Among different approaches, GIZA++[1] (Och and Ney, 2003), which is based on the IBM translation models, is the most widely used word alignment tool. Other well-known tools are the BerkeleyAligner[2], Nile[3] (Riesa et al., 2011), and pialign[4] (Neubig et al., 2011).

fast_align[5] (Dyer et al., 2013) is a recently proposed word alignment approach based on the reparameterization of the IBM model 2, which is usually referred to as a *zero-order* alignment model (Och and Ney, 2003). Taking advantage of the simplicity of the IBM model 2, fast_align introduces a "*tension*" parameter to model the overall accordance of word orders and an efficient parameter re-estimation algorithm is devised. It has been reported that the fast_align approach is more than 10 times faster than baseline GIZA++, with comparable results in end-to-end French-, Chinese-, and Arabic-to-English translation experiments.

However, the simplicity of the IBM model 2 also leads to a limitation. As demonstrated in this study, fast_align does not perform well when applied to language pairs with drastically different word orders, e.g., Japanese and English. The problem is because of the IBM model 2's intrinsic inability to handle complex distortions. In this study, we propose a simple and efficient reordering approach to improve the fast_align's performance in such situations, referred to as *segmenting-reversing* (seg_rev). Our motivation is to apply a rough but robust reordering to make the source and target sentences have more similar word orders, where fast_align can show its power. Specifically, seg_rev first segments a source-target sentence pair into a sequence of *minimal monotone* chunk pairs[6] based on the automatically generated word alignment. Within the chunk pairs, source word sequences are examined to determine whether they should be *completely reversed* or the original order should be retained. The objective of this step is to convert the source sentence to a roughly target-like word order. The seg_rev process is applied recursively but not deeply (only twice in our ex-

[6] same as the "*tuple*" used in Mariño et al. (2006)

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1034–1039,
Lisbon, Portugal, 17-21 September 2015.

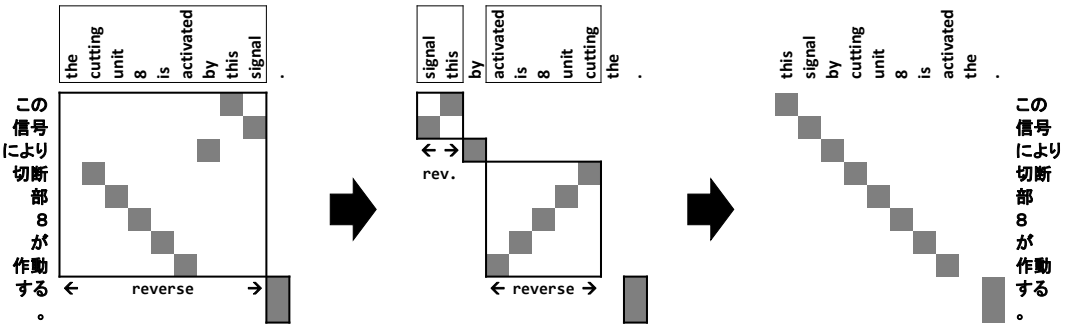

Figure 1: Example of `seg_rev` applied to a word-aligned English-Japanese sentence pair. Based on the word alignment, the source sentence is reordered in a target-like order after applying `seg_rev` **twice**.

periments) for each source sentence in the training data. Consequently, the `seg_rev` process is lightweight and shallow. Local word sequences, except those at chunk boundaries, are not scrambled, while global word orders are re-arranged if there are *large* chunks.

Our primary experimental results for Japanese-English translation show that applying `seg_rev` significantly improves `fast_align`'s performance to a level comparable to `GIZA++`. The training time becomes 2–4 times that of a baseline `fast_align`, which is still at least $2-4$ times faster than the training time required by baseline `GIZA++`. Results for German-, French-, and Chinese-English translations are also reported.

2 Segmenting-Reversing Reordering

The `seg_rev` is inspired by the "*REV preorder*" (Katz-Brown and Collins, 2008), which is a simple pre-reordering approach originally designed for the Japanese-to-English translation task. More efficient pre-reordering approaches usually require trained parsers and sophisticated machine learning frameworks (de Gispert et al., 2015; Hoshino et al., 2015). We adopt the `REV` method in Katz-Brown and Collins (2008) considering it is the simplest and lightest pre-reordering approach (to our knowledge), which may bring a minimal effect on the efficiency of `fast_align`.

An example `seg_rev` process, where the word alignment is generated by `fast_align`, is illustrated in Fig. 1. The example we selected has relatively correct word alignment and `seg_rev` performs well. In general cases, the alignment has significant noise and the reordering is rougher .

Algorithm 1 describes the repeated (δ times) application of the `seg_rev` process, and Algorithm 2 describes a single application. Specifically, Algorithm 1 applies Algorithm 2 δ times. For each application of Algorithm 2, source sentence S and source indices in alignment A are reordered, and the overall permutation R_I is updated and recorded. In Fig. 1, the original English sentence had 10 words (including the period), being indexed as $[0,1,2,3,4,5,6,7,8,9]$. After the first application of `seg_rev`, R_I was $[\boxed{8,7,6,5,4,3,2,1,0},9]$, and after the second application, R_I was $[\boxed{7,8},6,\boxed{1,2,3,4,5},0,9]$ (reversed parts are boxed).

In Algorithm 2, the main **for** loop (line 3) scans the source sentence from the beginning to the end to obtain monotone segmentation. The **foreach** (line 5) and **if** (line 11) are general phrase pair extraction process. The **if** (line 13) guarantees that the chunk is monotone on the target side. The `rev` function (line 16), which is described in Algorithm 3, determines whether the sub-sequence from s_{start} to s_{end} should be reversed by examining the related alignment A_{sub}. For example, in the first application shown in Fig.1, two sub-sequences $[0:8]$ and $[9:9]$ are processed by `rev` and $[0:8]$ is reversed. Four sub-sequences $[0:1]$, $[2:2]$, $[3:7]$, and $[9:9]$ are processed in the second application and $[0:1]$ and $[3:7]$ are reversed.[7] Finally, source sentence S and source indices in alignment A are reordered (lines 19 – 20).[8]

Algorithm 3 performs the reversal. We count the concordant and discordant pairs[9] and reverse

[7] The sub-sequences are based on the input, not the original sentence, e.g., sub-sequence $[0:1]$ contains the 8th and 7th word of the original source sentence in the 2nd application.

[8] Unaligned words between chunks on the source side are problematic. They are not touched by line 18. Although they can be attached to preceding or succeeding chunks, we do not use further heuristics to handle them. An example is the drifting "*the*" in the English sentence in Fig. 1, which our approach cannot handle properly.

[9] As used in Kendall's τ or Goodman and Kruskal's γ.

Algorithm 1: `seg_rev`$^{\delta}$

input : *same as Algorithm 2 and a depth δ;*
output : *same as Algorithm 2 except R_A;*

$R_I \leftarrow [0, \cdots, I]$; $R_S \leftarrow S$; $R_A \leftarrow A$;
for $i \leftarrow 1$ **to** δ **do**
  $R_S, R_A, R_{I'} \leftarrow$ `seg_rev` (R_S, T, R_A);
  permute R_I with $R_{I'}$;
return R_S, R_I;

Algorithm 2: `seg_rev`

input : source sentence $S = s_0, \cdots, s_I$;
target sentence $T = t_0 \cdots, t_J$;
word alignment $A = \{(i,j)|$
s_i, t_j are aligned, $i \in [0, I], j \in [0, J]\}$;
output : reordered source sentence R_S;
source index reordered alignment R_A;
reordered indices $R_I = \pi(0, \cdots, I)$,
which is a permutation from 0 to I;

1 $R_I \leftarrow [0, \cdots, I]$;
2 $s_{start} \leftarrow 0$; $t_{pre\_end} \leftarrow -1$;
3 **for** $s_{end} \leftarrow s_{start}$ **to** I **do**
4 $t_{start} \leftarrow J+1$; $t_{end} \leftarrow -1$;
5 **foreach** $(i,j) \in A$ **do**
6 **if** $i \in [s_{start}, s_{end}]$ **then**
7 **if** $j < t_{start}$ **then**
8 $t_{start} \leftarrow j$;
9 **if** $j > t_{end}$ **then**
10 $t_{end} \leftarrow j$;
11 **if** $\exists (i,j) \in A :$
$j \in [t_{start}, t_{end}] \wedge i \notin [s_{start}, s_{end}]$ **then**
12 **continue**;
13 **if** $\exists (i,j) \in A : j \in (t_{pre\_end}, t_{start})$ **then**
14 **continue**;
15 $A_{sub} \leftarrow \{(i,j)|(i,j) \in A,$
$i \in [s_{start}, s_{end}] \wedge j \in [t_{start}, t_{end}]\}$;
16 `rev` $(R_I[s_{start} : s_{end}], A_{sub})$;
17 $t_{pre\_end} \leftarrow t_{end}$;
18 $s_{start} \leftarrow min(\{i | i > s_{end} \wedge \exists (i,j) \in A\})$;
19 $R_S \leftarrow$ permute S according to R_I;
20 $R_A \leftarrow$ permute i in A according to R_I;
21 **return** R_S, R_A, R_I;

Algorithm 3: `rev`

input : index sequence I_{sub}; word alignment A_{sub};

$con \leftarrow 0$; $dis \leftarrow 0$;
foreach unordered tuple $((i_0, j_0), (i_1, j_1)) :$
$(i_0, j_0) \in A_{sub} \wedge (i_1, j_1) \in A_{sub}$ **do**
  $x \leftarrow (i_1 - i_0) \times (j_1 - j_0)$;
  if $x > 0$ **then**
  $con \leftarrow con + 1$;
  else if $x < 0$ **then**
  $dis \leftarrow dis + 1$;
  else
  continue;
if $dis > con$ **then**
  $I_{sub} \leftarrow$ reverse I_{sub};

Algorithm 4: `fast_align` with `seg_rev`

input : parallel corpus $\mathcal{C}$ with N sentence pairs
$\mathcal{C} = \{(S^1, T^1) \cdots, (S^N, T^N)\}$;
maximum iteration M; depth δ for `seg_rev`;
output : word alignment $\mathcal{A} = \{A^1, \cdots, A^N\}$;

$\mathcal{A} \leftarrow \varnothing$;
for $iter \leftarrow 1$ **to** M **do**
  $\mathcal{I} \leftarrow \varnothing$; $\mathcal{C}' \leftarrow \varnothing$;
  if $\mathcal{A} \neq \varnothing$ **then**
  for $n \leftarrow 1$ **to** N **do**
  $R_S, R_I \leftarrow$ `seg_rev`$^{\delta}(S^n, T^n, A^n)$;
  append (R_S, T^n) to $\mathcal{C}'$;
  append R_I to $\mathcal{I}$;
  else
  $\mathcal{C}' \leftarrow \mathcal{C}$;
  $\mathcal{A} \leftarrow$ `sym` $\circ$ `fast_align` $(\mathcal{C}')$;
  if $\mathcal{I} \neq \varnothing$ **then**
  for $n \leftarrow 1$ **to** N **do**
  recover A^n by $\mathcal{I}[n]$;
return $\mathcal{A}$;

the sub-sequence if and only if there are more discordant pairs than the concordant pairs. In Fig.1, the sub-sequence $[0:8]$ in the first application has $C_8^2 = 28$ pairs of aligned word pair (i.e., 28 gray block pairs for eight gray blocks); however, only 11 pairs are concordant ($C_5^2 = 10$ pairs in $[1:5]$ and one pair in $[7:8]$), Consequently, the sub-sequence $[0:8]$ is reversed because there are more discordant pairs ($17 = 28 - 11$). The two reversed subsequences in the second application are obvious.

Algorithm 4 describes the training framework, where `fast_align` and `seg_rev` are applied alternately. To generate word alignment, `fast_align` is run bi-directionally and symmetrization heuristics are applied to reduce noise (line 11). In each iteration, the source sentences for `seg_rev` are the original sentences, and `fast_align` uses the reordered sentences with the exception of the first iteration. The word alignment generated is thus based on the reordered source sentences; consequently, the recorded permutation (line 14) is used to recover word alignment before the next iteration. The permutation is a one-to-one mapping; therefore, recovering is realized by the inverse mapping of the permutation, which transfers the source-side word alignment indices to match the original source sentences.

The time complexity of Algorithm 3 is $O(l^2)$, where l is the size of A_{sub} that is related to the chunk size. If the average chunk size is a constant C depending on languages pairs or data sets, then the time complexity of Algorithm 2 is $O(C \cdot I^2)$ assuming J and the size of A are both linear against I. The average chunk size will be reduced when `seg_rev` is applied successively; therefore, the time required for subsequent `seg_rev` processes will decrease. In practice, compared with the training time required by `fast_align`,

seg_rev processing time is negligible. Note that seg_rev processes are accelerated easily by parallel processing.

3 Experiments and Discussion

We applied the proposed approach to Japanese-English translation, a language pair with dramatically different word orders. In addition, we applied the approach to German-English translation, a language pair with relatively different word orders among European languages.

For Japanese-English translation, we used the **NTCIR-7 PAT-MT** data (Fujii et al., 2008). For German-English translation, we used the **Europarl v7** corpus[10] (Koehn, 2005) for training, the **WMT 08**[11] **/ WMT 09**[12] test sets for development / testing, respectively. Default settings for the PB SMT in MOSES[13] (Koehn et al., 2007) were used, except for Japanese-English translations where the *distortion-limit* was set to 12 to reach a recently reported baseline (Isozaki et al., 2012). MERT (Och, 2003) was used to tune development set parameter weights and BLEU (Papineni et al., 2002) was used on test sets to evaluate the translation performance. *Bootstrap sampling* (Koehn, 2004) was employed to test statistical significance using bleu_kit[14].

We compared GIZA++ and fast_align with default settings. GIZA++ was used as a module of MOSES. The bi-directional outputs of fast_align were symmetrized by atools in cdec[15] (Dyer et al., 2010), and further training steps were conducted using MOSES. *grow-diag-final-and* symmetrization was used consistently in the experiments. For the the proposed approach, we set $\delta = 2$ and $M = 4$ in Algorithm 4. Note that δ can be set to a larger value and seg_rev could be applied repeatedly until no additional reordering is possible. As mentioned, the word alignment is noisy and our intention is a robust and rough process; therefore, we restricted seg_rev to two applications and did not consider the difference in sentence lengths or different languages during training. Within each iteration, fast_align was run with default settings, except *initial diagonal-tension* (λ^{ini}) was set to 0.1 in the first iteration, to avoid overly strong monotone preference at the beginning of training.

	ja-en	**en-ja**	**de-en**	**en-de**
GIZA++	**28.8**	**30.8**	**18.2**	**12.9**
$\text{FA}_{\lambda^{ini}=4.0}$	$28.1^{\ddagger}$	$29.5^{\ddagger}$	$18.0^{\dagger}$	$12.7^{\dagger}$
$\text{FA}_{\lambda^{ini}=0.1}$	$28.0^{\ddagger}$	$29.8^{\ddagger}$	$17.5^{\ddagger}$	$12.5^{\ddagger}$
iteration 2	$28.3^{\dagger}$	**30.9**	$17.9^{\ddagger}$	**12.8**
iteration 3	$28.4^{\dagger}$	$30.1^{\ddagger}$	**18.1**	$12.7^{\dagger}$
iteration 4	**28.8**	**30.7**	**18.1**	$12.7^{\dagger}$

Table 1: Test set BLEU scores for Japanese-English and German-English translations. (‡, statistical significance at $p < 0.01$; †, at $p < 0.05$; boldface, no significance; all compared with GIZA++)

Experimental results for Japanese-English and German-English translations in both directions are listed in Table 1. The first two rows show the baseline performance. fast_align (using a default $\lambda^{ini} = 4.0$) performance was statistically significantly lower than GIZA++, particularly for Japanese-English translation. The following four rows show the results of the proposed approach. For the first iteration, λ^{ini} was set to 0.1, and the performance did not change significantly. The translations **from** English improved (equal to GIZA++) at the second iteration. However, translations **to** English improved more slowly. We attribute the difference in improvement rates between translation to and from English to the relatively fixed word order of English, whereby the reordering process is easier and more consistent. Note that once translations **from** English improved in the second iteration, performance decreased in the following iterations. The results in Table 1 were obtained using *predictable-seed* for tuning, which generated determinate results. Another attempt using random seeds to tune returned test set BLEU scores of **30.5**, **30.4** on **en-ja** and **12.8**, **12.8** on **en-de**, for iterations 3 and 4, respectively. These four scores had no statistical significance against GIZA++. The instability is largely due to the alignment of function words, which affects translation performance (Riesa et al., 2011). The alignment does not change significantly after the second iteration; however, it is unstable around function words,[16] because seg_rev does not process

$\text{FA}_{\lambda^{ini}=4.0}$	23.1	31.7
iteration 2	23.1	31.7

Table 2: Test set BLEU scores for French-to-English and Chinese-to-English translations. For **fr-en**, the data sets were the same as for **de-en**. For **zh-en**, NIST 2006 OpenMT data were used for training and test; test data from 2002 to 2005 OpenMT were used for tuning.

unaligned function words between chunks. Our approach is too rough to handle function words precisely. We plan to address this in future.

We also tested our approach on French- and Chinese-to-English translations. The results are listed in Table 2. GIZA++ and fast_align showed no statistically significant difference in performance, which is consistent with Dyer et al. (2013). The proposed approach did not affect performance for French- and Chinese-to-English translations. These results are expected as these language pairs have similar word orders.

With regard to processing time, a naïve, single-thread implementation of seg_rev in C++ took approximately $60s$ / $40s$ in the first / second application on the entire Japanese-English corpus[17]. The recover process took less than $30s$ in each iteration. In contrast, fast_align, although very fast, took approximately one hour for one round of training (using five iterations for its log-linear model) on the same corpus. Therefore, the additional time required in our approach is quite small and can be ignored compared with the training time of fast_align.[18]

4 Conclusion and Future Work

We have proposed a simple and efficient approach to improve the performance of fast_align on language pairs with drastically different word orders. With the proposed approach, fast_align obtained results comparable with GIZA++, and its efficiency is retained. We are investigating further properties of seg_rev and plan to extend it to achieve greater stability and efficiency.[19]

[17] 1.8 *M* sentence pairs with an average length of 35 words.

[18] GIZA++ actually took around 18 hours to align the Japanese-English corpus (parallel processes for two directions, including mkcls, five iterations for the model 1 and the HMM model, three iteration for the model 3 and 4).

[19] Ongoing experiments using seg_rev with GIZA++ returned negative results. BLEU decreases by approx. 1 point.

Abstract

We introduce *pre-post-editing*, possibly the most basic form of interactive translation, as a touch-based interaction with iteratively improved translation hypotheses prior to classical post-editing. We report simulated experiments that yield very large improvements on classical evaluation metrics (up to 21 BLEU) as well as on a parameterized variant of the TER metric that takes into account the cost of matching/touching tokens, confirming the promising prospects of the novel translation scenarios offered by our approach.

1 Introduction

As shown by oracle studies (Wisniewski et al., 2010; Turchi et al., 2012; Marie and Max, 2013), Statistical Machine Translation (SMT) systems produce results that are of significantly lower quality than what could be produced from their available resources. As a pragmatic solution, human intervention is commonly used for improving automatic draft translations, in so-called *post-editing* (PE), but is also studied earlier in the translation process in a variety of interactive strategies, including e.g. completion assistance and local translation choices (e.g. (Foster et al., 2002; Koehn and Haddow, 2009; González-Rubio et al., 2013)). Although *interactive machine translation* does facilitate the work of the SMT system in certain situations by allowing it to make efficient use of knowledge contributed by the human translator, post-editing has been shown to remain a faster alternative (Green et al., 2014). Nevertheless, this activity usually requires complex intervention from an expert translator (Carl et al., 2011).

In this work we reduce interaction with an SMT system to its most basic form: similarly to what a human translator is likely to do when first reading a draft translation to post-edit, we require a user to simply *spot* those segments of a draft translation that can participate in an acceptable translation. The corresponding information is then used by a SMT system in a soft way to improve the draft translation. This process may be iteratively repeated as long as enough improvements are obtained, and terminates with classical post-editing on the obtained translation, hence we dub it *pre-post-editing* (PPE). We resort to simulated pre-post-editing and post-editing, as in other works (Carl et al., 2011; Denkowski et al., 2014), to measure translation performance on some available reference translation using both classical metrics and a variant of the TER metric (Snover et al., 2006), where, essentially, the cost of a token *matching* operation is a parameterized fraction of the cost of the other token edit operations. With the implementation of appropriate strategies in the SMT system, we show under reasonable assumptions that this approach has the potential to significantly reduce the amount of human effort required to obtain a final translation.

In the remainder of this article, we describe the technical details of pre-post-editing (Section 2), report experiments conducted on two translation directions and two domains (Section 3), and finally discuss our proposal and introduce our future work (Section 4).

2 Touch-based pre-post-editing

In our PPE framework, the human *pre-post-editor* has to mark n-grams from a translation hypothesis that can take part in a correct translation.[1] The annotated n-grams are counted, as an n-gram can appear more than once in the same sentence, and a "positive" 6-gram language model (LM)

[1] A touch-based interface when a keyboard is not available or typing is inconvenient lends itself particularly well to PPE.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1040–1045,
Lisbon, Portugal, 17-21 September 2015.

(positive-lm) is trained on these counts[2]. A "negative" LM (negative-lm) is also trained on the counted n-grams left unannotated. Then, all bi-phrases from the SMT system's phrase table that match an annotated n-gram, according to the source token alignments provided by the decoder, are removed from the main phrase table and stored in a separate "positive" phrase table (positive-pt). Conversely, n-grams containing at least one token left unannotated are considered as incorrect, and the set of bi-phrases matching these n-grams are removed and stored in a "negative" phrase table (negative-pt).

As source tokens can appear more than once in a source text, they are *located*: an identifier is concatenated to each token to make it unique in the source text. Tokens of the source phrases in the phrase table are accordingly also located, so each bi-phrase is duplicated as needed to cover all located tokens. Using located tokens allows our PPE framework to treat differently source tokens that are correctly translated from incorrectly translated ones in the same sentence or text. Figure 1 shows an example of phrase table extraction, using located source tokens[3], for one iteration of PPE.

If an n-gram is annotated as correct, all its inner n-grams of lower order are also deemed correct. Although annotating translations of high quality may be less expensive by explicitely annotating *incorrect* n-grams instead of correct ones, such annotations would not permit to identify correct n-grams inside incorrect ones, as illustrated in Figure 2. PPE can thus be worded as a simple problem for the pre-post-editor: *which sequences of tokens should appear in the final translation?*

The newly extracted phrase tables and LMs[4], along with the remainder of the original phrase table and the original LM, are used to re-decode the source text in a first iteration of PPE. A new PPE annotation can then be performed on the new translations. The newly extracted "positive" and "negative" phrase tables are merged with the corresponding phrase table of the previous iteration. The extracted n-gram counts from the current iteration and the counts of the previous iterations are summed, and the LMs are re-trained with the updated counts. A new iteration of PPE is then performed with the updated models. The weights for all, old or new, models in the log-linear combination are found by tuning on a development set for each PPE iteration.[5] Figure 3 illustrates 4 iterations of PPE from an initial translation hypothesis assuming a given target reference translation.

Figure 2: Annotation example for two correct tokens forming an incorrect n-gram. At the first PPE iteration a reordering is performed and the new hypothesis now matches the reference translation.

3 Experiments

3.1 Data and systems

We ran experiments on two translation tasks of different domains: the WMT'14 Medical translation task (medical) and the WMT'11 news translation task (news) for the language pair en-fr on both translation directions. For both tasks we trained two competitive phrase-based SMT systems using Moses (Koehn et al., 2007) and WMT data[6] (see Table 1). The tuning for all systems, including our iteration-specific PPE systems, was performed with kb-mira (Cherry and Foster, 2012).

3.2 An adapted evaluation metric: TER_{PPE}

Classical MT evaluation metrics cannot take into account the interactive cost of PPE, and thus do

[2] We used SRILM (Stolcke, 2002) to train the LMs with Witten-Bell smoothing.

[3] Subsequent examples do not use located tokens.

[4] The extracted LMs are sentence-level, and are only used on their specific sentence during PPE.

[5] In this work, we did not exceed 5 iterations.

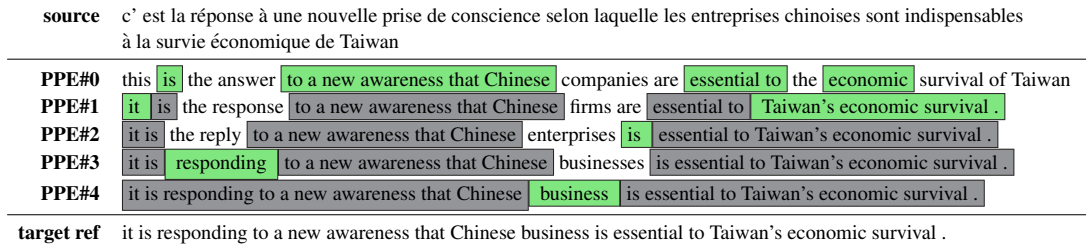

Figure 3: Example of a pre-post-edition trace for French to English translation (using the `news` task, cf. Section 3) using a given implicit target reference translation for simulating pre-post-editing and post-editing. Each newly touched phrase is indicated with a green background. Phrases with a gray background indicate previously touched phrases but their tokens remain individually touchable by the user.

Tasks	Corpus	Sentences	Tokens (fr-en)
`news`	train	12M	383M - 318M
	dev	2,525	73k - 65k
	test	3,003	85k - 74k
`medical`	train	4.9M	91M - 78M
	dev	500	12k - 10k
	test	1,000	26k - 21k
	specialized LM		146M - 78M
for both tasks	LM		2.5B - 6B

Table 1: Data used in this work.

not allow us to make direct comparisons with PE. We thus adapt the TER (Snover et al., 2006) metric, which typically uses 4 types of token edits: `substitution` (s), `insertion` (i), `deletion` (d) and `shift` (f). While these edit types all have a (debatable) uniform cost of 1, the operation of `matching` (m) a correct token is ignored. We posit that this operation is in fact performed by a human translator during PE (at the minimum, by recognizing and skipping tokens), and that it can be directly compared to our touch-based selection of tokens for PPE. However, we cannot at this stage of our work provide a realistic cost value for this operation, and so we introduce a match cost parameter α, and use the following as our PPE-aware metric:

$$\text{TER}_{\text{PPE}} = \frac{\#s + \#d + \#i + \#f + \alpha\#m}{r + \alpha r} \quad (1)$$

where r is the number of tokens in the reference translation. Note that a null value for α makes TER_{PPE} correspond to TER, while a value of 1 would indicate that a token matching/touch (m) is e.g. as costly as a token rewriting (s). We anticipate that a realistic value for α given a reasonably skilled user should be rather small, but we will provide TER_{PPE} results for the full range $[0, 1]$.

3.3 Experimental results

To validate our approach, we initially used a simulated post-editing paradigm (Carl et al., 2011; Denkowski et al., 2014) in which non-post-edited reference translations are used in lieu of human post-editions. Results on TER (Snover et al., 2006) and BLEU (Papineni et al., 2002), tuning on both metrics, are provided in Tables 2 (`news`) and 3 (`medical`).

First, we observe that whatever the metric and the task, the first iteration of PPE always yields a significant improvement over the `Moses` initial system (e.g. up to +9.8 BLEU and -8.2 TER for `news` fr→en). Unsurprisingly, tuning on a metric yields better results for the same metric for the first iteration; however, we note that this is not always true for the TER metric at later iterations (cf. `news` en→fr). More generally, tuning on the TER metric results in lower improvements for `news`, which are mostly concentrated on the first iterations; as systems tuned on BLEU have been found to produce better translations than systems tuned on TER (Cer et al., 2010), only BLEU tuning was used for `medical`.[7]

Improvements follow an interesting pattern over PPE iterations: for instance, on `news` fr→en, BLEU scores steadily increase after each new touch-based iteration and reach a gain of +21.1 BLEU and -12.3 TER over the initial `Moses` translation after 5 PPE iterations. Results are very comparable on both language pairs and both domains, e.g. gains of +12.1 BLEU and -9.7 TER are obtained on fr→en `medical`. The lesser amplitude of the gains obtained after 5 iterations may be attributed to the higher ini-

[7] We have observed a tendency of the TER tuning to shrink the size of hypotheses, resulting in higher brevity penalty values for BLEU and a higher number of insertions for TER.

Iteration	fr→en				en→fr			
	tuned with TER		tuned with BLEU		tuned with TER		tuned with BLEU	
	TER	BLEU	TER	BLEU	TER	BLEU	TER	BLEU
Moses	51.1	28.2	52.7	28.6	52.3	29.7	51.8	31.1
PPE iteration 1	42.9	35.4	46.7	38.4	44.4	35.0	47.3	39.6
PPE iteration 2	40.8	37.3	43.7	43.4	43.0	36.3	44.6	43.9
PPE iteration 3	40.8	37.8	42.2	46.2	42.5	36.4	43.5	46.6
PPE iteration 4	39.9	37.9	40.9	48.3	42.3	36.5	42.3	48.2
PPE iteration 5	39.9	37.9	40.4	49.7	42.2	36.6	41.0	49.5

Table 2: PPE results on the news task.

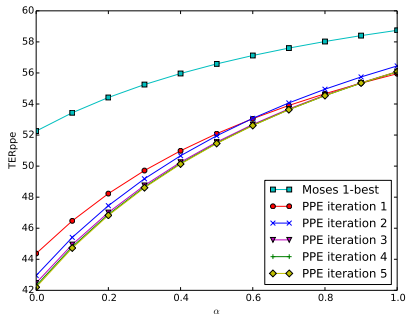
tial quality of the translations in the medical task (e.g. 37.1 BLEU vs 28.6 BLEU in fr→en for Moses with BLEU tuning).

Iteration	fr→en		en→fr	
	tuned with BLEU		tuned with BLEU	
	TER	BLEU	TER	BLEU
Moses	42.2	37.1	44.0	38.8
PPE iteration 1	36.9	44.9	37.2	48.3
PPE iteration 2	34.8	47.5	35.3	51.1
PPE iteration 3	34.1	48.5	33.5	52.9
PPE iteration 4	32.9	49.2	32.4	54.0
PPE iteration 5	32.5	49.2	32.1	54.8

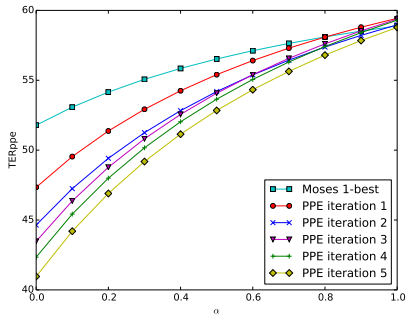
Table 3: PPE results on the medical task.

Figures 4 and 5 show how our TER_{PPE} metric varies for different values of our α parameter (recall that $\alpha = 0$ corresponds to TER). Essentially, whatever the value of α, we observe that any iteration of PPE dominates PE (Moses 1-best), but with a tendency to become as costly as PE for high, but probably unrealistic values of α. Tuning with BLEU allows us to bring regular improvements as the number of iteration increases, while tuning with TER makes the amplitude of the gains decrease faster.

Furthermore, results shown in Table 4 point out the complementarity between negative models (negative-lm and negative-pt) and positive models (positive-lm and positive-pt), with a drop of almost 10 BLEU points compared to the corresponding configuration using all models when removing one type of models on both translation directions. The language models (negative-lm and positive-lm) seem to play a more important role during PPE than the phrase tables (negative-pt and positive-pt), with a drop of 9.6 BLEU points on news fr→en when removing the language models against a significantly lower drop of 4.4 BLEU points when removing the phrase tables.



(a) Tuned with TER



(b) Tuned with BLEU

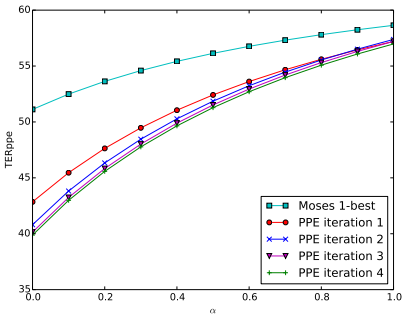
Figure 4: PPE results on the en→fr news task.

4 Discussion and future work

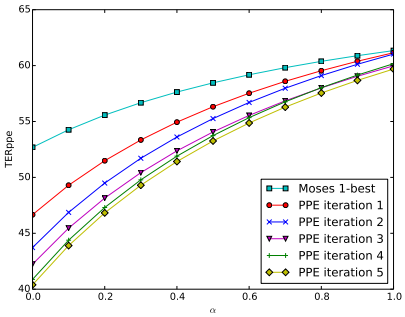
We have introduced *pre-post-editing*, a minimalist interactive machine translation paradigm where a user is only asked to spot text fragments that may be used in the final translation. Our approach is quite comparable to the two-pass procedure described by Luong et al. (2014) using word-level confidence estimation (e.g. (Bach et al., 2011)) to update the cost of the search graph hypotheses. However, contrarily to Luong et al.'s work, our PPE framework is efficiently multi-pass, updates the models over iterations and relies on more informative annotations made at n-gram-level. Our evaluation based on simulated post-editing has revealed a large potential for translation improvement. Interestingly, the type of interaction defined

Configuration	fr→en tuned with BLEU TER	fr→en tuned with BLEU BLEU	en→fr tuned with BLEU TER	en→fr tuned with BLEU BLEU
`Moses`	52.7	28.6	51.8	31.1
PPE w/ all models	40.4	49.7	41.0	49.5
PPE w/o `negative-pt` and `negative-lm`	45.2	39.4	47.1	39.0
PPE w/o `positive-pt` and `positive-lm`	46.7	39.8	48.3	39.8
PPE w/o `negative-pt` and `positive-pt`	45.0	45.3	46.5	44.9
PPE w/o `negative-lm` and `positive-lm`	42.7	40.1	43.2	42.0

Table 4: PPE results for the `news` task after 5 iterations using various configurations.



(a) Tuned with TER



(b) Tuned with BLEU

Figure 5: PPE results on the fr→en `news` task.

is very different from that expected of a post-editor or in existing interactive translation modes, and lends itself nicely to touch-based interaction. Furthermore, our proposal may in fact define a new *role* in Computer-Assisted Translation, with PPE being performed on-the-go on mobile devices by more people than available human translators, and even possibly by monolinguals of the target language whose contribution may be more efficiently exploited than that of monolinguals of the source language (e.g. (Resnik et al., 2010)).

In terms of usability, our future work will focus on two important questions: (*a*) study the actual use of PPE in an interactive setting and tune the α parameter for our TER_{PPE} metric on HTER (Snover et al., 2006) traces, and (*b*) study whether PPE alters in any positive way the work of the human translator performing the residual post-editing, hoping that PE *could become a less tedious task by nature*. We further anticipate that some additions would improve our approach, including dealing early with out-of-vocabulary phrases, proposing local drop-down options (e.g. (Koehn and Haddow, 2009)), possibly clustered by senses, allowing the user to easily fix reordering issues, and adapting PPE to be discourse-aware (e.g. (Ture et al., 2012)).

Abstract

Continuous-space translation models have recently emerged as extremely powerful ways to boost the performance of existing translation systems. A simple, yet effective way to integrate such models in inference is to use them in an N-best rescoring step. In this paper, we focus on this scenario and show that the performance gains in rescoring can be greatly increased when the neural network is trained jointly with all the other model parameters, using an appropriate objective function. Our approach is validated on two domains, where it outperforms strong baselines.

1 Introduction

Over the past few years, research on neural networks (NN) architectures for Natural Language Processing has been rejuvenated. Boosted by early successes in language modelling for speech recognition (Schwenk, 2007; Le et al., 2011), NNs have since been successufully applied to many other tasks (Socher et al., 2013; Huang et al., 2012; Yang et al., 2013). In particular, these techniques have been applied to Statistical Machine Translation (SMT), first to estimate continuous-space translation models (CTMs) (Schwenk et al., 2007; Le et al., 2012; Devlin et al., 2014), and more recently to implement end-to-end translation systems (Cho et al., 2014; Sutskever et al., 2014).

In most SMT settings, CTMs are used as an additional feature function in the log-linear model, and are conventionally trained by maximizing the regularized log-likelihood on some parallel training corpora. Since this objective function requires to normalize scores, several alternative training objectives have recently been proposed to speed up training and inference, a popular and effective choice being the Noise Contrastive Estimation (NCE) introduced in (Gutmann and Hyvärinen, 2010). In any case, NN training is typically performed (a) in isolation from the other components of the SMT system and (b) using a criterion that is unrelated to the actual performance of the SMT system (as measured for instance by BLEU). It is therefore likely that the resulting NN parameters are sub-optimal with respect to their intended use.

In this paper, we study an alternative training regime aimed at addressing problems (a) and (b). To this end, we propose a new objective function used to discriminatively train or adapt CTMs, along with a training procedure that enables to take the other components of the system into account. Our starting point is a non-normalized extension of the n-gram CTM of (Le et al., 2012) that we briefly restate in section 2. We then introduce our objective function and the associated optimization procedure in section 3. As will be discussed, our new training criterion is inspired both from max-margin methods (Watanabe et al., 2007) and from pair-wise ranking (PRO) (Hopkins and May, 2011; Simianer et al., 2012). This proposal is evaluated in an N-best rescoring step, using the framework of n-gram-based systems, within which they integrate seamlessly. Note, however that it could be used with any phrase-based system. Experimental results for two translation tasks (section 4) clearly demonstrate the benefits of using discriminative training on top of an NCE-trained model, as it almost doubles the performance improvements of the rescoring step in all settings.

2 n-gram-based CTMs

The n-gram-based approach in Machine Translation is a variant of the phrase-based approach (Zens et al., 2002). Introduced in (Casacuberta and Vidal, 2004), and extended in (Mariño et al., 2006; Crego and Mariño, 2006), this approach is based on a specific factorization of the joint probability of parallel sentence pairs, where the

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1046–1052,
Lisbon, Portugal, 17-21 September 2015.

source sentence has been reordered beforehand.

2.1 n-gram-based Machine Translation

Let $(\mathbf{s}, \mathbf{t})$ denote a sentence pair made of a source $\mathbf{s}$ and target $\mathbf{t}$ sides. This sentence pair is decomposed into a sequence of L bilingual units called *tuples* defining a joint segmentation. In this framework, tuples constitute the basic translation units: like phrase pairs, they represent a matching between a source and a target chunk . The joint probability of a *synchronized* and *segmented* sentence pair can be estimated using the n-gram assumption. During training, the segmentation is obtained as a by-product of source reordering, (see (Crego and Mariño, 2006) for details). During the inference step, the SMT decoder will compute and output the best derivation in a small set of pre-defined reorderings.

Note that the n-gram translation model manipulates bilingual tuples. The underlying set of events is thus much larger than for word-based models, while the training data (parallel corpora) are typically order of magnitude smaller than monolingual resources. As a consequence, data sparsity issues for such models are particularly severe. Effective workarounds consist in factorizing the conditional probabitily of tuples into terms involving smaller units: the resulting model thus splits bilingual phrases in two sequences of respectively source and target words, synchronised by the tuple segmentation. Such bilingual word-based n-gram models were initially described in (Le et al., 2012). We assume here a similar decomposition.

2.2 Neural Architectures

The estimation of n-gram probabilities can be performed via multi-layer NN structures, as described in (Bengio et al., 2003; Schwenk, 2007) for a monolingual language model. The standard *feed-forward* structure is used to estimate the translation models sketched in the previous section. We give here a brief description, more details are in (Le et al., 2012): first, each context word is projected into language dependent continuous spaces, using two projection matrices for the source and target languages. The continuous representations are then concatenated to form the representation of the context, which is used as input for a feed-forward NN predicting a target word.

In such architecture, the size of output vocabulary is a bottleneck when normalized distributions are expected. Various workarounds have been proposed, relying for instance on a structured output layer using word-classes (Mnih and Hinton, 2008; Le et al., 2011). A more effective alternative, which however only delivers *quasi-normalized* scores, is to train the network using the *Noise Contrastive Estimation* or NCE (Gutmann and Hyvärinen, 2010; Mnih and Teh, 2012). This technique is readily applicable for CTMs and has been adopted here. We therefore assume that the NN outputs a positive score $\mathbf{b}_{\boldsymbol{\theta}}(w, \mathbf{c})$ for each word w given its context $\mathbf{c}$; this score is simply computed as $\mathbf{b}_{\boldsymbol{\theta}}(w, \mathbf{c}) = \exp(\mathbf{a}_{\boldsymbol{\theta}}(w, \mathbf{c}))$, where $\mathbf{a}_{\boldsymbol{\theta}}(w, \mathbf{c})$ is the activation at the output layer; $\boldsymbol{\theta}$ denotes all the network free parameters.

3 Discriminative Training of CTMs

In SMT, the primary role of CTMs is to help the system in ranking a set of hypotheses so that the top scoring hypotheses correspond to the best translations, where quality is measured using automatic metrics such as BLEU (Papineni et al., 2002). Given the computational burden of continuous models, the prefered use of CTMs is to rescore a list of N-best hypotheses, a scenario we favor here; note that their integration in a first pass search is also possible (Niehues and Waibel, 2012; Vaswani et al., 2013; Devlin et al., 2014). The important point is to realize that the CTM score will in any case be composed with several scores computed by other components: reordering model(s), monolingual language model(s), etc. In this section, we propose a discriminative training framework which implements a tight integration of the CTM with the rest of the system.

3.1 A Discriminative Training Framework

The decoder generates a list of N hypotheses for each source sentence $\mathbf{s}$. Each hypothesis $\mathbf{h}$ is composed of a target sentence $\mathbf{t}$ along with its associated derivation and is evaluated as follows:

$$G_{\boldsymbol{\lambda},\boldsymbol{\theta}}(\mathbf{s}, \mathbf{h}) = \sum_{k=1}^{M} \lambda_k f_k(\mathbf{s}, \mathbf{h}) + \lambda_{M+1} f_{\boldsymbol{\theta}}(\mathbf{s}, \mathbf{h}),$$

where M conventional feature functions[1] $f_1 ... f_M$, estimated during the training phase, are scaled by coefficients $\lambda_1 ... \lambda_M$. The introduction of a continuous model during the rescoring step is implemented by adding the feature $f_{\boldsymbol{\theta}}(\mathbf{s}, \mathbf{h})$, which ac-

[1]The functions used in our experiments are similar to the ones used in other phrase-based systems (Crego et al., 2011).

end for
```

cumulates, over all contexts $\mathbf{c}$ and word w, the CTM log-score $\log \mathbf{b}_{\boldsymbol{\theta}}(w, \mathbf{c})$.

$G_{\boldsymbol{\lambda},\boldsymbol{\theta}}$ depends both on the NN parameters $\boldsymbol{\theta}$ and on the log-linear coefficients $\boldsymbol{\lambda}$. We propose to train these two sets of parameters, by alternatively updating $\boldsymbol{\theta}$ through SGD on the training corpus, and updating $\boldsymbol{\lambda}$ using conventional algorithms on the development data. This procedure, which has also been adopted in recent studies (e.g. (He and Deng, 2012; Gao and He, 2013)) is sketched in algorithm 1. In practice, the training data is successively divided into mini-batches of 128 sentences. Each mini-batch is used to compute the sub-gradient of the training criterion (see section 3.2) and to update $\boldsymbol{\theta}$. After each training iteration of the CTM, $\boldsymbol{\lambda}$s are retuned on the development set; we use here the *K-Best Mira* algorithm of Cherry and Foster (2012) as implemented in MOSES.[2]

3.2 Loss function

The training criterion considered here draws inspiration both from max-margin methods (Watanabe et al., 2007) and from the pair-wise ranking (PRO) (Hopkins and May, 2011; Simianer et al., 2012). The choice of a ranking loss seems to be the most appropriate in our setting; as in many recent studies on discriminative training for MT (e.g. (Chiang, 2012; Flanigan et al., 2013)), the integration of the translation metric into the loss function is critical to obtain parameters that will yield good translation performance.

Translation hypotheses $\mathbf{h}_i$ are scored using a sentence-level approximation of BLEU denoted $SBLEU(\mathbf{h}_i)$. Let r_i be the rank of hypothesis $\mathbf{h}_i$ when hypotheses are sorted according to their sentence-level BLEU. *Critical hypotheses* are defined as follows:[3]

$$\mathcal{C}^{\alpha}_{\delta}(\mathbf{s}) = \{(i,k) : 1 \leq k, i \leq N, r_k - r_i \geq \delta, \\ \Delta_{i,k} G_{\boldsymbol{\lambda},\boldsymbol{\theta}}(\mathbf{s}, \mathbf{h}) < \alpha \Delta_{i,k} SBLEU(\mathbf{h}).$$

A pair of hypotheses is thus deemed critical when a large difference in $SBLEU$ is not reflected by the difference of scores, which falls below a threshold. This threshold is defined by the difference between their sentence-level BLEU, multiplied by α. Our loss function $\mathcal{L}(\boldsymbol{\theta})$ is defined with respect to this critical set and can be written as:[4]

$$\sum_{(i,k) \in \mathcal{C}^{\alpha}_{\delta}(\mathbf{s})} \alpha \Delta_{i,k} SBLEU(\mathbf{h}) - \Delta_{i,k} G_{\boldsymbol{\lambda},\boldsymbol{\theta}}(\mathbf{s}, \mathbf{h}_i)$$

Initialization is an important issue when optimizing NN. Moreover, our training procedure depends heavily on the log-linear coefficients $\boldsymbol{\lambda}$. To initialize $\boldsymbol{\theta}$, preliminary experiments (Do et al., 2014; Do et al., 2015) show that it is more efficient to start from a NN pre-trained using NCE, while the discriminative loss is used only in a fine-tuning phase. Given the pre-trained CTM's scores, we initialize $\boldsymbol{\lambda}$ by optimizing it on the development set. This strategy forces the training of $\boldsymbol{\theta}$ to focus on errors made by the system as a whole.

4 Experiments

4.1 Tasks and Corpora

The discriminative optimization framework is evaluated both in a training and in an adaptation scenario. In the *training* scenario, the CTM is trained on the same parallel data as the one used for the baseline system. In the *adaptation* scenario, large out-of-domain corpora are used to train the baseline SMT system, while the CTM is trained on a much smaller, in-domain corpus and only serves for rescoring. An intermediate situation (*partial training*) is when only a fraction of the training data is re-used to estimate the CTM: this situation is interesting because it allows us to train the CTM much faster than in the training scenario.[5]

Two domains are investigated. For the TED Talkstask[6] the only parallel in-domain data contains 180K sentence pairs; the out-of-domain

Table 2: BLEU scores for the medical tasks.

data is much larger and contains all corpora allowed in the translation shared task of WMT'14 (English-French), amounting to 12M parallel sentences. The second task is the medical translation task of WMT'14[7] (English to French) for which we use all authorized corpora. The Patent-Abstract corpus, made of 200K parallel sentence pairs, is used either for adaptation or partial training for the CTM. Experimental results are reported on official evaluation sets, as well as on the CTM training set.

All translation systems are based on the open source implementation[8] of the bilingual n-gram approach to MT. For the NN structure, each vocabulary's word is projected into a 500-dimension space followed by two hidden layers of 1000 and 500 units. For the discriminative training and adaptation tasks, baseline SMT systems are used to generate respectively 600 and 300 best hypotheses for each sentence of the in-domain corpus. [9]

4.2 Experimental results

Results in Table 1 measure the impact of discriminative training on top of an NCE-trained model for the two TED Talks conditions. In the adaptation task, the discriminative training of the CTM gives a large improvement of 0.9 BLEU score over the CTM only trained with NCE and 1.9 over the baseline system. However, for the training scenario, these gains are reduced respectively to 0.4 and 1.2 BLEU points. The BLEU scores (in the **train** column) measured on the N-best lists used to train the CTM provide an explanation for this difference: in training, the N-best lists contain hypotheses with an overoptimistic BLEU score, to be compared with the ones observed on unseen data. As a result, adding the CTM significantly worsens the performance on the discriminative training data, contrarily to what is observed on the development and test sets. Even if the results of these two conditions cannot be directly compared (the baselines are different), it seems that the proposed discriminative training has a greater impact on performance in the adaptation scenario, even though the out-of-domain system initially yields lower BLEU scores.

The medical translation task represents a different situation, in which a large-scale system is built from multiples but domain-related corpora, among which, one is used to train the CTM. Nevertheless, results reported in Table 2 exhibit a similar trend. For both conditions, the discriminative training gives a significant improvement, up to 0.7 BLEU score over the one only trained with NCE and up to 1.7 over the baseline system. Arguably, the difference between the two conditions is much smaller than what was observed with the TED Talks task, due to the fact that the Patent-Abstract corpus used to discriminatively train the CTM only corresponds to a small subset of the parallel data. However, the best strategy seems, here again, to exclude the data used for the CTM from the data used to train the baseline system.

5 Related work

It is important to notice that similar discriminative methods have been used to train phrase table's scores (He and Deng, 2012; Gao and He, 2013; Gao et al., 2014), or a recurrent NNLM (Auli and Gao, 2014). In recent studies, the authors tend to limit the number of iterations to 1 (Gao et al., 2014; Auli and Gao, 2014), while we still advocate the general iterative procedure sketched in Algo. 1. Initialization is also an important issue when optimizing NN. In this work, we initialize CTM's parameters by using a pre-training procedure based on the model's probabilistic in-

[7] www.statmt.org/wmt14/medical-task/

[9] The threshold δ is set to 250 for 300-best and to 500 for 600-best lists, while α is set empirically.

terpretation and NCE algorithm to produce *quasi-normalized scores*, while similar work in (Auli and Gao, 2014) only uses *un-normalized scores*. The initial values of $\boldsymbol{\lambda}$ also needs some investigation. Gao et al. (2014) and Auli and Gao (2014) initialize λ_{M+1} to 1, and normalize all other coefficients; here we initialize $\boldsymbol{\lambda}$ by optimizing it on the development set using the pre-trained CTM's scores. This strategy forces the training of $\boldsymbol{\theta}$ to focus on errors made by the system as a whole. The fundamental difference of this work hence lays in the use of the ranking loss described in Section 3.2, whereas previous works use expected BLEU loss. We plan a systematic comparison between these two criteria, along with some other discriminative losses in a future work.

About the CTM's structure, our used model is based on the feed-forward CTM described in (Le et al., 2012) and extended in (Devlin et al., 2014). This structure, though simple, have been shown to achieve impressive results, and with which efficient tricks are available to speed up both training and inference. While models in (Le et al., 2012) employ a structured output layer to reduce *softmax* operation's cost, we prefer the NCE *self-normalized* output which is very efficient both in training and inference. Another form of self-normalization is presented in (Devlin et al., 2014) but does not seem to have fast training. Finally, although N-best rescoring is used in this work to facilitate the discriminative training, other CTM's integration into SMT systems exist, such as lattice reranking (Auli et al., 2013) or direct decoding with CTM (Niehues and Waibel, 2012; Devlin et al., 2014; Auli and Gao, 2014).

6 Conclusions

In this paper, we have proposed a new discriminative training procedure for continuous-space translation models, which correlates better with translation quality than conventional training methods. This procedure has been validated using an n-gram-based CTM, but the general idea could be applied to other continuous models which compute a score for each translation hypothesis. The core of the method lays in the definition of a new objective function inspired both from max-margin and Pairwise Ranking approach in MT, which enables us to effectively integrate the CTM into the SMT system through N-best rescoring. A major difference with most past efforts along these lines is the joint training of the CTM and the log-linear parameters. In all our experiments, discriminative training, when applied on a CTM initially trained with NCE, yields substantial performance gains.

Abstract

In this paper, we propose a paraphrasing model to address the task of system combination for machine translation. We dynamically learn hierarchical paraphrases from target hypotheses and form a synchronous context-free grammar to guide a series of transformations of target hypotheses into fused translations. The model is able to exploit phrasal and structural system-weighted consensus and also to utilize existing information about word ordering present in the target hypotheses. In addition, to consider a diverse set of plausible fused translations, we develop a hybrid combination architecture, where we paraphrase every target hypothesis using different fusing techniques to obtain fused translations for each target, and then make the final selection among all fused translations. Our experimental results show that our approach can achieve a significant improvement over combination baselines.

1 Introduction

In the past several years, many machine translation (MT) combination approaches have been developed. Word-level combination approaches, such as the confusion network decoding model, have been quite successful (Matusov et al., 2006; Rosti et al., 2007a; He et al. 2008; Karakos et al. 2008; Chen et al. 2009a; Narsale 2010; Leusch 2011; Freitag et al. 2014).

In addition to word-level combination approaches, some phrase-level combination approaches have also recently been developed; the goal is to retain coherence and consistency between the words in a phrase. The most common phrase-level combination approaches are re-decoding methods: by constructing a new phrase table from each MT system's source-to-target phrase alignments, the source sentence can also be re-decoded using the new translation table (Rosti et al., 2007b; Huang and Papineni, 2007; Chen et al., 2007; Chen et al., 2009b). One problem with these approaches is that, just with a new phrase table, existing information about word ordering present in the target hypotheses is not utilized; thus the approaches are likely to make new mistakes of word reordering which do not appear in the target hypotheses of MT engines. Huang and Papineni (2007) attacked this issue through a reordering cost function that encourages search along with decoding paths from all MT engines' decoders.

Another phrase-level combination approach relies on a lattice decoding model to carry out the combination (Feng et al 2009; Du and Way 2010; Ma and McKeown 2012). In a lattice, each edge is associated with a phrase (a single word or a sequence of words) rather than a single word. The construction of the lattice is based on the extraction of phrase pairs from word alignments between a selected best MT system hypothesis (the backbone) and the other translation hypotheses. One challenge of the lattice decoding model is that it is difficult to consider structural consensus among target hypotheses from multiple MT engines, i.e, the consensus among occurrences of discontinuous words.

In this paper, we propose another phrase-level combination approach – a paraphrasing model using hierarchical paraphrases (paraphrases contain subparaphrases), to fuse target hypotheses. We dynamically learn hierarchical paraphrases from target hypotheses without any syntactic annotations and form a synchronous context-free grammar (SCFG) (Aho and Ullman 1969) to

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1053–1058,
Lisbon, Portugal, 17-21 September 2015.

guide a series of transformations of target hypotheses into fused translations. Through these structural transformations, the paraphrasing model is able to exploit phrasal and structural system-weighted consensus and also able to utilize existing information about word ordering present in the target hypotheses. In addition, to consider a diverse set of plausible fused translations, we develop a hybrid combination architecture, where we paraphrase every target hypothesis using different fusing techniques to obtain fused translations for each target, and then make the final selection among all fused translations through a sentence-level selection-based model.

In short, compared with other related work, our approach features the following advantages:

1. It can consider structural system-weighted consensus among target hypotheses from multiple MT engines through its hierarchical paraphrases, which non-hierarchical paraphrases are not able to do.

2. It can utilize existing information about word ordering present in the target hypotheses.

3. It can retain coherence and consistency between the words in a phrase.

4. The hybrid combination architecture enables us to consider a diverse set of plausible fused translations produced by different fusing techniques.

2 Hybrid Combination Architecture

In the context of system combination, discriminative reranking or post editing, MT researchers (Rosti et al., 2007a; Huang and Papineni, 2007; Devlin and Matsoukas, 2012, Matusov et al., 2008; Gimpel et al., 2013) have recently shown many positive results if more diverse translations are considered. Inspired by them, we develop a hybrid combination architecture in order to consider more diverse fused translations. We paraphrase every target hypothesis to obtain the corresponding fused translation, and then make the final selection among all fused translations through a sentence-level selection-based model, shown in Figure 1. In the architecture, different fusing techniques can be used to generate fused translations for the further sentence-level selection, enabling us to exploit more sophisticated information of the whole sentence.

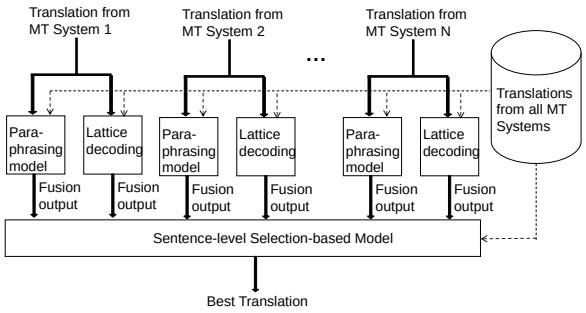

Figure 1. An example of *hybrid combination architecture*

3 Paraphrasing Model

In this section, we introduce our paraphrasing model. For each single target hypothesis, we extract a set of hierarchical paraphrases from monolingual word alignments between the hypothesis and other hypotheses. Each set of hierarchical paraphrases forms a synchronous context-free grammar to guide a series of transformations of that target hypothesis into a fused translation.

Any monolingual word aligner can be used to produce the monolingual word alignments. In our system, we adopt TERp (Snover et al. 2009), one of the state-of-the-art alignment tools, to serve this purpose. TERp is an extension of TER (Snover et al. 2006). Both TERp and TER are automatic evaluation metrics for MT, based on measuring the ratio of the number of edit operations between the reference sentence and the MT system hypothesis. The edit operations of TERp include TER's Matches, Insertions, Deletions, Substitutions and Shifts—as well as three new edit operations: Stem Matches, Synonym Matches and Paraphrases. A valuable side product of TERp is the monolingual word alignment. A constructed example is shown in Figure 2.

3.1 Hierarchical Paraphrase Extraction

We first introduce our notation. For a given sentence *i*, we use E_h^i to denote the target hypothesis from MT system *h*, use EP_h^i to denote E_h^i attached with related word positions, use e_h^i to denote a phrase within E_h^i, and use ep_h^i to denote e_h^i attached with related word positions. For instance, If E_h^i is "you buy the book", then EP_h^i would be "you[1] buy[2] the[3] book[4]". If e_h^i is "the book", then ep_h^i is "the[3] book[4]".

For a given sentence *i*, a MT system *h* and a MT system *k*, we use a SCFG denoted by $Q_{h,k}^i$ to represent the set of hierarchical paraphrases learned from EP_h^i and EP_k^i. Adapting (Chiang

2007), we design the following rules to obtain $Q^i_{h,k}$, based on the monolingual word alignment, obtained by a aligner, such as TERp.

- If $< ep^i_h , ep^i_k >$ is consistent[1] with the monolingual word alignment, then $X \rightarrow < ep^i_h , e^i_k >$ is added to $Q^i_{h,k}$.
- If $X \rightarrow < \gamma , \alpha >$ is in $Q^i_{h,k}$, and $< ep^i_h , ep^i_k >$ is consistent with monolingual word alignment such that $\gamma = \gamma_1 ep^i_h \gamma_2$ and $\alpha = \alpha_1 e^i_k \alpha_2$, then $X \rightarrow < \gamma_1 X_a \gamma_2 , \alpha_1 X_a \alpha_2 >$ is added to $Q^i_{h,k}$, where *a* is an index.

Please note that for each extracted hierarchical paraphrase - $X \rightarrow < \gamma , \alpha >$, γ would include information of word positions while α would not.

For a certain target hypothesis - EP^i_h, our goal is to paraphrase it to get the fusion output by using a set of hierarchical paraphrases, denoted by Q^i_h. Thus we create the union of all related hierarchical paraphrases learned from EP^i_h and other target hypotheses. Two special "glue" rules - $S \rightarrow < S_1 X_2 , S_1 X_2 >$ and $S \rightarrow < X_1 , X_1 >$ are also added to Q^i_h. The process can be represented formally in the following:

$$Q^i_h = \bigcup_{k=1}^{N} Q^i_{h,k} \bigcup \{ S \rightarrow < S_1 X_2 , S_1 X_2 > , S \rightarrow < X_1 , X_1 > \}$$

where *N* is the total number of MT systems.

3.1.1 An Example

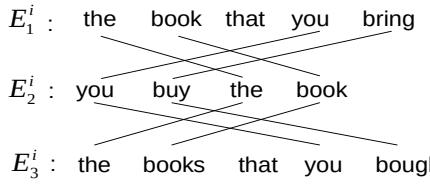

Figure 2. A constructed example of a sentence - "你買的書 (the book that you bought)" and its translations from three MT systems – E^i_1, E^i_2 and E^i_3, and word alignments between E^i_2 and E^i_1, and between E^i_2 and E^i_3, obtained through TERp.

We use a Chinese-to-English example in Figure 2 to illustrate the extraction process. The extracted hierarchical paraphrases to paraphrase EP^i_2 - "you[1] buy[2] the[3] book[4]" are shown in Table 1. Because of limited space, only part of the paraphrases, i.e, part of the rules of Q^i_2, are shown.

part of rules of Q^i_2		in $Q^i_{2,1}$?	in $Q^i_{2,2}$?	in $Q^i_{2,3}$?
X →< you[1] , you>	(a)	✔	✔	✔
X →< you[1] buy[2] , you buy >	(b)		✔	
X →< you[1] buy[2] , you bought >	(c)			✔
X →< you[1] buy[2] , you bring >	(d)	✔		
X →< book[4] , book >	(e)	✔	✔	
X →< book[4] , books >	(f)			✔
X →< the[3] book[4] , the book >	(g)	✔	✔	
X →< the[3] book[4] , the books >	(h)			✔
X →< you[1] buy[2] the[3] book[4] , the books that you bought >	(i)			✔
X →< X_1 the[3] book[4] , the books that X_1 >	(j)			✔
X →< you[1] buy[2] the[3] X_1 , the X_1 that you bought >	(k)			✔
X →< X_1 the[3] X_2 , the X_2 that X_1 >	(l)	✔		✔

Table 1. Part of extracted hierarchical paraphrases to paraphrase EP^i_2, i.e, part of the rules of Q^i_2.

Note that, in Table 1, the rules (j), (k) and (l) can be regarded as structural paraphrases, and they utilize existing information about word ordering present in the target hypotheses. Since rule (l) is included in both $Q^i_{2,1}$ and $Q^i_{2,3}$, we can say that rule (l) has more structural consensus than rule (j) and (k). And rule (l) also models the word reordering through reversing the order of X_1 and X_2. By the example, we can see the reason why our model is able to exploit structural consensus and also to utilize existing information about word ordering present in the target hypotheses.

3.2 Decoding

Given a certain target hypothesis - EP^i_h, and its set of hierarchical paraphrases - Q^i_h, the decoder aims to paraphrase EP^i_h using Q^i_h by performing a search for the single most probable derivation via the CKY algorithm with a Viterbi approximation. The derivation is the paraphrased result, i.e, the fusion result indicated in Figure 1. The single most probable derivation can be represented as

$$\arg\max_{\overline{E}^i_h} \log p(\overline{E}^i_h \mid EP^i_h) = \arg\max_{\overline{E}^i_h} \sum_{j=1}^{J} \left(\sum_{k=1}^{N} \lambda_k * f(q^{i,j}_h , k) \right) + \lambda_p * J + \lambda_l * \log(LM(\overline{E}^i_h)) + \lambda_w * length(\overline{E}^i_h)$$

$$f(q^{i,j}_h , k) = \begin{cases} 1 \text{ if } q^{i,j}_h \in Q^i_{h,k} \\ 0 \text{ otherwise} \end{cases}$$

[1] This means that words in a legal paraphrase are not aligned to words outside of the paraphrase, and should include at least one pair of words aligned with each other.

where $q_h^{i,j}$ is the jth paraphrase in Q_h^i used to generate $\overline{E}_h^i$, J is the number of paraphrases used to generate $\overline{E}_h^i$. N is the total number of MT systems. λ_k is the weight of MT system k, in charge of the system-weighted consensus. λ_p is phrase penalty. λ_l is the LM weight and λ_w is word penalty. All weights are trained discriminatively for Bleu score using Minimum Error Rate Training (MERT) procedure (Och 2004).

The ideal result of paraphrasing EP_2^i is shown in the following, which is supposed to be generated with a higher chance if, regardless of system weights. That is because of the use of the rules with higher degree of structural consensus, such as (l) and (e).

$< S_1 >$
$\Rightarrow < X_2, X_2 >$ using glue rule
$\Rightarrow < X_3 \text{ the}^3 X_4, \text{the } X_4 \text{ that } X_3 >$ using rule (l)
$\Rightarrow < \text{you}^1 \text{ buy}^2 \text{ the}^3 X_4, \text{the } X_4 \text{ that you bought} >$ using rule (c)
$\Rightarrow < \text{you}^1 \text{ buy}^2 \text{ the}^3 \text{ book}^4, \text{the book that you bought} >$ using rule (e)

4 Sentence-Level Selection-based Model

For a given sentence i and its M multiple fusion outputs - $\overline{E}_f^i$, $1 \le f \le M$ generated by the paraphrasing model or the lattice decoding model, the goal here is to select the best one among them, as shown in Figure 1 (For the case shown in the figure, M is $2N$). The idea is to compare system-weighted consensus among all fusion outputs and translations from all MT systems, and then select the one with the highest consensus. We adopt Minimum Bayes Risk (MBR) decoding (Kumar and Byrne, 2004; Sim et al., 2007) to serve our purpose and develop the following TER-based MBR:

$$\arg\max_f \log p(\overline{E}_f^i) = \arg\max_f \omega_l * \log(LM(\overline{E}_f^i)) + \sum_{m=1}^{M}\left(\omega_m * \log(1 - TER(\overline{E}_f^i, \overline{E}_m^i))\right) + \sum_{k=1}^{N}\left(\omega_k * \log(1 - TER(\overline{E}_f^i, E_k^i))\right)$$

where *TER* is Translation Tdit Ratio. ω_m is the fusion weight specific to a certain MT system and a certain fusion model, ω_k is the weight of MT system k and ω_l is the LM weight. All weights are trained discriminatively for Bleu score using MERT.

5 Experiments

Our experiments are conducted and reported on three datasets: The first dataset includes Chinese-English system translations and reference translations from DARPA GALE 2008 (GALE Chi-Eng). The second dataset includes Chinese-English system translations and reference translations and from NIST 2008 (NIST Chi-Eng). And the third dataset includes Arabic-English system translations and reference translations and from NIST 2008 (NIST Ara-Eng).

	MTSystem#	TuneSent#	TestSent#
GALE Chi-Eng	5	422	422
NIST Chi-Eng	5	524	788
NIST Ara-Eng	5	592	717

Table 2. Experimental setting

MT System	Approach	Bleu
nrc	phrase-based SMT	30.95
rwth-pbt-aml	phrase-based SMT + source reordering	31.83
rwth-pbt-jx	phrase-based SMT + word segmentation	31.78
rwth-pbt-sh	phrase-based SMT + source reordering + rescoring	32.63
sri-hpbt	hierarchical phrase-based SMT	32.00

Table 3: Techniques of top five MT of GALE Chi-Eng Dataset

Table 3 lists distinguishing machine translation approaches of top five MT of GALE Chi-Eng Dataset. And "rwth-pbt-sh" performs the best in Bleu score.

Two combination baselines are implemented for comparison: one is an implementation based on confusion network decoding, and the other is Lattice Decoding from (Ma and McKeown 2012), both of which are using TERp to obtain word alignments between a selected backbone hypothesis and other target hypotheses. The former uses these word alignments to construct a confusion network while the latter extracts phrases which are consistent with these word alignments to construct a lattice. For both baselines, backbone hypotheses are selected sentence by sentence based on system-weighted consensus among translation of all MT systems.

5.1 Results

In Table 4, CN represents confusion network; LD represents Lattice Decoding (Ma and McKeown 2012); PARA represents paraphrasing model proposed in this paper; Backbone_* represents that * is carried out on selected backbones, in contrast with the hybrid combination architecture. Arch_LD represents that only lattice decoding is carried out using hybrid combination architecture. Arch_PARA represents that only paraphrasing model is carried out using hybrid combination

architecture. Arch_LD_PARA represents that LD and PARA are both carried out using hybrid combination architecture, which is the example shown in Figure 2.

	GALE Chi-Eng	NIST Chi-Eng	NIST Ara-Eng
Best MT system	32.63	30.16	48.40
Backbone_CN (baseline)	33.04	31.21	48.56
Backbone_LD (baseline)	33.16	32.65	49.33
Backbone_PARA	33.09	32.59	49.46
Arch_LD	33.24	32.66	50.48
Arch_PARA	33.32	32.90	50.20
Arch_LD_PARA	33.72	33.42	50.44

Table 4. Experimental results in Bleu score

From Table 4, we can first observe that, for the three datasets, Backbone_PARA and Backbone_LD outperform Backbone_CN, which shows the advantage of using phrases over words in combination. However, Backbone_PARA does not show improvement over Backbone_LD. The reason could be that selected backbones already have a high level of quality and fewer words need to be replaced or re-ordered in contrast with other target hypotheses.

We find that Arch_PARA performs better than Backbone_PARA, and Arch_LD performs better than Backbone_LD. This observation supports our claim that it is beneficial to consider more diverse sets of plausible fused translations.

Arch_LD_PARA achieves the best performance among all techniques used in this paper. It not only supports our claim, but also brings a conclusion that the paraphrasing model and lattice decoding can compensate for the weaknesses of the other in our architecture.

Since the paraphrasing model uses hierarchical paraphrases to carry out the fusion, it is able to make a bigger degree of word-reordering or structural change on the input hypothesis in comparison with lattice decoding. We suppose that when more word-reordering and structural changes are needed, paraphrasing model can bring more benefits than lattice decoding. Because the quality of a given translation hypothesis is highly related to word reordering and structural change, it can be expected that when a poorly translated hypothesis is paraphrased, paraphrasing model can bring more benefits than lattice decoding. In order to obtain the evidence to support this hypothesis, we carried out the following experiment on NIST Chi-Eng Dataset.

For each MT system from the selected top 5 system A-E, we paraphrase its translations using the paraphrasing model and lattice decoding separately, aiming to compare the performances of the two models on each MT system. In other words, we do not first do backbone selection. Every MT system's translation is regarded as a backbone. The results are shown in Table 5.

	MT	Lattice Decoding	Paraphrasing model
Sys A	30.16	32.17	31.76
Sys B	30.06	31.93	31.72
Sys C	**28.15**	**30.66**	**31.00**
Sys D	29.94	31.86	31.46
Sys E	**29.52**	**31.52**	**31.92**

Table 5. The Bleu score of each MT system, the Bleu score of paraphrasing each MT system using lattice decoding and the Bleu score of paraphrasing each MT system using paraphrasing model.

Among the five MT systems, "Sys C" and "Sys D" perform poorer than the other three MT systems. When we paraphrase the two systems, we find that paraphrasing model outperforms lattice decoding. These results support our hypothesis that when more word-reordering and structural changes are needed, paraphrasing model can bring more benefits than lattice decoding.

6 Conclusion

We view MT combination as a paraphrasing process using a set of hierarchical paraphrases, in which more complicated paraphrasing phenomena are able to be modeled, such as phrasal and structural consensus. Existing information about word ordering present in the target hypotheses are also considered. The experimental results show that our approach can achieve a significant improvement over combination baselines.

There are many possibilities for enriching the simple framework. Many ideas from recent translation developments can be borrowed and modified for combination. Our future work aims to incorporate syntactic or semantic information into our paraphrasing framework.

Abstract

We present an incremental adaptation approach for statistical machine translation that maintains a flexible hierarchical domain structure within a single consistent model. Both weights and rules are updated incrementally on a stream of post-edits. Our multi-level domain hierarchy allows the system to adapt simultaneously towards local context at different levels of granularity, including genres and individual documents. Our experiments show consistent improvements in translation quality from all components of our approach.

1 Introduction

Suggestions from a machine translation system can increase the speed and quality of professional human translators (Guerberof, 2009; Plitt and Masselot, 2010; Green et al., 2013a, *inter alia*). However, querying a single fixed model for all different documents fails to incorporate contextual information that can potentially improve suggestion quality. We describe a model architecture that adapts simultaneously to multiple genres and individual documents, so that translation suggestions are informed by two levels of contextual information.

Our primary technical contribution is a hierarchical adaptation technique for a post-editing scenario with incremental adaptation, in which users request translations of sentences in corpus order and provide corrected translations of each sentence back to the system (Ortiz-Martínez et al., 2010). Our learning approach resembles Hierarchical Bayesian Domain Adaptation (Finkel and Manning, 2009), but updates both the model weights and translation rules in real time based on these corrected translations (Mathur et al., 2013; Denkowski et al., 2014). Our adapted system can provide on-demand translations for any genre and document to which it has ever been exposed, using weights and rules for domains associated with each translation request.

Our weight adaptation is performed using a hierarchical extension to fast and adaptive online training (Green et al., 2013b), a technique based on AdaGrad (Duchi et al., 2011) and forward-backward splitting (Duchi and Singer, 2009) that can accurately set weights for both dense and sparse features (Green et al., 2014b). Rather than adjusting all weights based on each example, our extension adjusts offsets to a fixed baseline system. In this way, the system can adapt to multiple genres while preventing cross-genre contamination.

In large-scale experiments, we adapt a multi-genre baseline system to patents, lectures, and news articles. Our experiments show that sparse models, hierarchical updates, and rule adaptation all contribute consistent improvements. We observe quality gains in all genres, validating our hypothesis that document and genre context are important additional inputs to a machine translation system used for post-editing.

2 Background

The log-linear appoach to statistical machine translation models the predictive translation distribution $p(e|f; w)$ directly in log-linear form (Och and Ney, 2004):

$$p(e|f;w) = \sum_{\substack{r: \\ src(r)=f \\ tgt(r)=e}} \frac{1}{Z(f)} \exp\left[w^\top \phi(r;c)\right] \quad (1)$$

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1059–1065,
Lisbon, Portugal, 17-21 September 2015.

where $f \in \mathcal{F}$ is a string in the set of all source language strings $\mathcal{F}$, $e \in \mathcal{E}$ is a string in the set of all target language strings $\mathcal{E}$, r is a phrasal derivation with source and target projections $src(r)$ and $tgt(r)$, $w \in \mathbb{R}^d$ is the vector of model parameters, $\phi(\cdot) \in \mathbb{R}^d$ is a feature map computed using corpus c, and $Z(f)$ is an appropriate normalizing constant. During search, the maximum approximation is applied rather than summing over the derivations r.

Model. We extend a phrase-based system for which $\phi(r; c)$ includes 16 dense features:

- Two phrasal channel models and two lexical channel models (Koehn et al., 2003), the (log) count of the rule in the training corpus c, and an indicator for singleton rules in c.
- Six orientation models that score ordering configurations in r by their frequency in c (Koehn et al., 2007).
- A linear distortion penalty that promotes monotonic translation.
- An n-gram language model score, $p(e)$, which scores the target language projection of r using statistics from a monolingual corpus.
- Fixed-value phrase and word penalties.

The elements of $\phi(r; c)$ may also include sparse features that have non-zero values for only a subset of rules, but typically do not depend on c (Liang et al., 2006). In this paper, we use four types of sparse features: rule indicators, discriminative lexicalized reordering indicators, rule shape indicators and alignment features (Green et al., 2014b).

The model parameters w are chosen to maximize translation quality on a tuning set.

Adaptation. Domain adaptation for machine translation has improved quality using a variety of approaches, including data selection (Ceauşfu et al., 2011), regularized online learning (Simianer et al., 2012; Green et al., 2013b), and input classification (Xu et al., 2007; Banerjee et al., 2010; Wang et al., 2012) and has also been investigated for multi-domain tasks (Sennrich et al., 2013; Cui et al., 2013; Simianer and Riezler, 2013). Even without domain labels at either training or test time, multi-task learning can boost translation quality in a batch setting (Duh et al., 2010; Song et al., 2011).

Post-editing with incremental adaptation describes a particular mixed-initiative setting (Ortiz-Martínez et al., 2010; Hardt and Elming, 2010). For each f in a corpus, the machine generates a hypothesis e, then a human provides a corrected translation e^* to the machine. Observing e^* can affect both the model weights w and corpus c used for rule extraction and dense feature estimation.[1] To translate the ith sentence f_i, the system uses weights w_{i-1} and corpus c_{i-1}. The new corpus c_i results from adding (f_i, e_i^*) to c_{i-1}. For incremental adaptation, speed is essential, and so w_i is typically computed with a single online update from w_{i-1} using (f_i, e_i^*) as the tuning example.

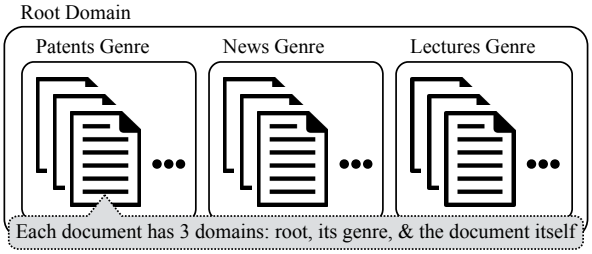

Figure 1: The weights used to translate a document in the patent genre include three domains.

To alleviate the need for human intervention in the experiment cycle, *simulated post-editing* (Hardt and Elming, 2010; Denkowski et al., 2014) replaces each e^* with a reference that is not a corrected variant of e. Thus, a standard test corpus can be used as an adaptation corpus. Prior work on online learning from post-edits has demonstrated the benefit of adjusting only c (Ortiz-Martínez et al., 2010; Hardt and Elming, 2010) and further benefit from adjusting both c and w (Mathur et al., 2013; Denkowski et al., 2014). Incremental adaptation of both c and the weights w for sparse features is reported to yield large quality gains by Wäschle et al. (2013).[2]

3 Hierarchical Incremental Adaptation

Our hierachical approach to incremental adaptation uses document and genre information to adapt appropriately to multiple contexts. We assume that each sentence f_i has a known set D_i of domains, which identify the genre and individual document origin of the sentence. This set could be extended to include topics, individual translators, etc.

Figure 1 shows the domains that we apply in experiments. All sentences in the baseline training corpus, the tuning corpus, and the adaptation corpus share a ROOT domain.

[1] For the purpose of our description, the corpus c is equivalent to the set of phrases and their scores in the rule table. We prefer this notation because it is consistent with our stream-based rule table, where the models are computed on-the-fly from the indexed training corpus c.

[2] Language model adaptation also has a rich literature, but it is beyond the scope of this paper.

Our adaptation is conceptually similar to hierarchical Bayesian domain adaptation (Finkel and Manning, 2009), but both weights and feature values depend on D_i, and we use L_1 regularization.

Weight Updates. Model tuning and adaptation are performed with AdaGrad, an online subgradient method with an *adaptive learning rate* that comes with good theoretical guarantees. AdaGrad makes the following update:

$$w_t = w_{t-1} - \eta \Sigma_t^{1/2} \nabla \ell_t(w_{t-1}) \quad (2)$$

$$\Sigma_t^{-1} = \Sigma_{t-1}^{-1} + \nabla \ell_t(w_{t-1}) \nabla \ell_t(w_{t-1})^\top$$

$$= \sum_{i=1}^{t} \nabla \ell_i(w_{i-1}) \nabla \ell_i(w_{i-1})^\top \quad (3)$$

The loss function ℓ reflects the pairwise ordering between hypotheses. For feature selection, we apply an L_1 penalty via forward-backward splitting (Duchi and Singer, 2009). η is the initial learning rate. See (Green et al., 2013b) for details.

Our adaptation schema is an extension of *frustratingly easy domain adaptation* (FEDA) (Daumé III, 2007) to multiple domains with different regularization parameters, similar to (Finkel and Manning, 2009). Each feature value is replicated for each domain. Let $\mathcal{D}$ denote the set of all domains present in the adaptation set. Given an original feature vector $\phi(r; c)$ for derivation r of sentence f_i with $D_i \subseteq \mathcal{D}$, the replicated feature vector includes $|\mathcal{D}|$ copies of $\phi(r; c)$, one for each $d \in |\mathcal{D}|$, such that

$$\phi_d(r; c) = \begin{cases} \phi(r; c), & d \in D_i \\ 0, & \text{otherwise.} \end{cases} \quad (4)$$

The weights of this replicated feature space are initialized using the weights w tuned for the baseline $\phi(r; c)$.

$$w_d = \begin{cases} w, & d \text{ is ROOT} \\ 0, & \text{otherwise.} \end{cases} \quad (5)$$

In this way, the ROOT domain corresponds to the unadapted baseline weights, denoted as Θ_* in (Finkel and Manning, 2009). The idea is that we simultaneously maintain a generic set of weights that applies to all domains as well as their domain-specific "offsets", describing how a domain differs from the generic case. Model updates during adaptation are performed according to the same procedure as tuning updates, but now in the replicated space.

Different from (Finkel and Manning, 2009), this generalized FEDA model does not restrict the domains to be strictly hierarchically structured. We could, for example, include a domain for each translator that crossed different genres. However, all of our experimental evaluations maintain a hierarchical domain structure, leaving more general setups to future work.

Rules and Feature Values. A derivation r of sentence f_i has features that are computed from the combination of the baseline training corpus c_0 and a genre-specific corpus that includes all sentence pairs from the tuning corpus as well as from the adaptation corpus (f_j, e_j^*) with $j < i$ sharing f_i's genre. We refer to this combined corpus as c_i. The tuning corpus is the same that is used for parameter tuning in the baseline system. The adaptation corpus is our test set. Note that in our evaluation, each sentence is translated before it is used for adaptation, so that there is no contamination of results.

In order to extend the model efficiently within a streaming data environment, we make use of a suffix-array implementation for our phrase table (Levenberg et al., 2010).

Rather than combining corpus counts across these different sources, separate rules extracted from the baseline corpus and the genre-specific corpus exist independently in the derivation space, and features of each are computed only with one corpus. In this configuration, a large amount of out-of-domain evidence from the baseline model will not dampen the feature value adaptation effects of adding new sentence pairs from the adaptation corpus. The genre-specific phrases are distinguished by an additional binary provenance feature.

In order to extract features from the genre-specific corpus, a word-level alignment must be computed for each (f_j, e_j^*). We force decode using the adapted translation model for f_j. In order to avoid decoding failures, we insert high-cost single-word translation rules that allow any word in f_j to align to any word in e_j^*.

Sparse Features. Applying a large number of sparse features would compromise responsiveness of our translation system and is thus a poor fit for real-time adaptive computer-assisted translation. However, features that can be learned on a single document are limited in number and can be discarded after the document has been processed. Therefore, document-level sparse features are a powerful means to fit our model to local context with a comparatively small impact on efficiency.

4 Experiments

We performed two sets of German→English experiments; Table 1 contains the results for both. Our first set of experiments was performed on the *PatTR* corpus (Wäschle and Riezler, 2012). We divided the corpus into training and development data by date and selected 2.4M parallel segments dated before 2000 from the "claims" section as bilingual training data, taking equal parts from each of the eight patent types A–H as classified by the Cooperative Patent Classification (CPC). From each type we further drew separate test sets and a single tune set, selecting documents with at least 10 segments and a maximum of 150 source words per segment, with around 2,100 sentences per test set and 400 sentences per type for the tune set. The "claims" section of this corpus is highly repetitive, which makes it ideal for observing the effects of incremental adaptation techniques.

To train the language and translation model we additionally leveraged all available bilingual and monolingual data provided for the *EMNLP 2015 Tenth Workshop on Machine Translation*[3]. The total size of the bitext used for rule extraction and feature estimation was 6.4M sentence pairs. We trained a standard 5-gram language model with modified Kneser-Ney smoothing (Kneser and Ney, 1995; Chen and Goodman, 1998) using the *KenLM* toolkit (Heafield et al., 2013) on 4 billion running words. The bitext was word-aligned with *mgiza* (Och and Ney, 2003), and we used the *phrasal* decoder (Green et al., 2014a) with standard German-English settings for experimentation.

Our second set of experiments was performed on a mixed-genre corpus containing lectures, patents, and news articles. The standard dev and test sets of the IWSLT 2014 shared task[4] were used for the *lecture* genre. Each document corresponded to an entire lecture. For the *news* genre, we used *newstest2012* for tuning, *newstest2013* for meta-parameter optimization, and *newstest2014* for testing. The tune set for the *patent* genre is identical to the first set of experiments, while the test set consists of the first 300 sentence pairs of each of the patent type specific test sets of the previous experiment. The documents in the news and patent genres contain around 20 segments on average.

Our evaluation proceeded in multiple stages. We first trained a set of background weights on the concatenated tune sets (*baseline*). Keeping these weights fixed, we performed an additional tuning run to estimate genre-level weights (+ *genre weights*).[5] In the patent-only setup, we used patent CPC type as genre. Next, we trained a genre-specific translation model for each genre by first feeding the tune set and then the test set into our incremental adaptation learning method as a continuous stream of simulated post edits (+ *genre TM*). After each sentence, we performed an update on the genre-specific weights. In separate experiments, we also included document-level weights as an additional domain (+ *doc. weights*) and included sparse features at the document level (+ *sparse features*).[6]

	PatTR	**heterogeneous data**		
	avg	lecture	news	patent
repetition rate	*27.80*	*5.46*	*3.13*	*27.42*
baseline	48.89	25.82	24.92	48.97
+ genre weights	49.05	26.64	25.12	49.39
+ genre TM	53.25	27.67	25.66	53.22
+ doc. weights	53.56	27.98	25.71	53.40
+ sparse features	54.53	28.09	25.89	54.30

Table 1: Results in uncased BLEU [%]. Each component is added on top of the previous line. All results in line + *genre TM* and below are statistically significant improvements over the baseline with 95% confidence. We also report the repetition rate of the test corpora as propsed by Bertoldi et al. (2013).

Table 1 demonstrates that each component of this approach offered consistent incremental quality gains, but with varying magnitudes. For the patent experiments we report the average over our eight test sets (A-H) due to lack of space, but total improvement varied from +4.92 to +6.46 BLEU. In the mixed-genre experiments, BLEU increased by +2.27 on *lectures*, +0.97 on *news*, and +5.33 on *patents*. On all tasks, we observed statistically significant improvements over the baseline (95% confidence level) in the + *genre TM*, + *doc. weights* and + *sparse features* experiments using bootstrap resampling (Koehn, 2004).

These results demonstrate the efficacy of hierarchical incremental adaptation, although we would like to stress that the patent data was selected specifically for its high level of repetitiveness, and the

[3] http://www.statmt.org/wmt15/

[4] http://workshop2014.iwslt.org/

[5] Learning rates and regularization weights for this step were selected on *newstest2013*.

[6] Learning rates and regularization weights for each genre were selected on the genre-specific tune sets.

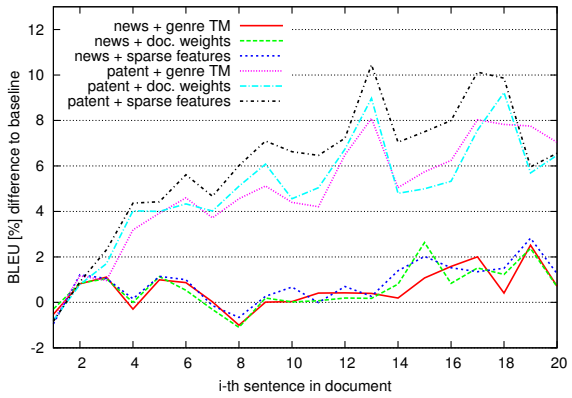

Figure 2: BLEU difference between *baseline + genre weights* and our incremental adaptation approach, computed on a single segment from each document according to their order, i.e. the first segment from each document, then the second segment from each document, etc.

large improvement in this genre would only be expected to arise in similarly structured domains. This property is quantified by the *repetition rate* measure (RR) (Bertoldi et al., 2013) reported in Table 1, which confirms the finding by Cettolo et al. (2014) that RR correlates with the effectiveness of adaptation.

Analysis. Figure 2 shows BLEU score differences to the *baseline + genre weights* system for different subsets of the news and patent test sets. Each point is computed by document slicing, i.e. on a single segment from each document. The rightmost data point is the BLEU score we obtain by evaluating on the 20th segment of each document, grouped into a pseudo-corpus. Note that this group does not correspond to any number in Table 1, which reports BLEU on the entire test sets. Thus, we evaluate on all sentences that have learned from exactly $(i-1)$ segments of the same document, with $i = 1, \ldots, 19$. Although the graph is naturally very noisy (each score is computed on roughly 150 segments), we can clearly see that incremental adaptation learns on the document level: on average, the improvement over the baseline increases when proceeding further into the document.

Decoding speed. In our real-time computer-assisted translation scenario, a certain translation speed is required to allow for responsive user interaction. Table 2 reports the speed in words per second on the lecture data. Adding a genre-specific translation model results in a speed reduction by a factor of 12.6 due to the additional (forced) decoding run and weight updates. Sparse features slows the system down further by a factor of 2.4. However, the largest part of the computation time incurs only when the user has finalized collaborative translation of one sentence and is busy reading the next source sentence. Further, the speed/quality tradeoff can be adjusted with pruning parameters.

	words / sec
baseline	177.6
+ genre weights	58.5
+ genre TM	14.1
+ doc. weights	9.8
+ sparse features	5.8

Table 2: Decoding speed on the lecture data.

5 Conclusion

We have presented an incremental learning approach for MT that maintains a flexible hierarchical domain structure within a single consistent model. In our experiments, we define a three-level hierarchy with a global root domain as well as genre- and document-level domains. Further, we perform incremental adaptation by training a genre-specific translation model on the stream of incoming post-edits and adding document-level sparse features that do not significantly compromise efficiency. Our results show consistent contributions from each level of adaptation across multiple genres.

Abstract

Many state-of-the-art Machine Translation (MT) evaluation metrics are complex, involve extensive external resources (e.g. for paraphrasing) and require tuning to achieve best results. We present a simple alternative approach based on dense vector spaces and recurrent neural networks (RNNs), in particular Long Short Term Memory (LSTM) networks. For WMT-14, our new metric scores best for two out of five language pairs, and overall best and second best on all language pairs, using Spearman and Pearson correlation, respectively. We also show how training data is computed automatically from WMT ranks data.

1 Introduction

Deep learning approaches have turned out to be successful in many NLP applications such as paraphrasing (Mikolov et al., 2013b; Socher et al., 2011), sentiment analysis (Socher et al., 2013b), parsing (Socher et al., 2013a) and machine translation (Mikolov et al., 2013a). While dense vector space representations such as those obtained through Deep Neural Networks (DNNs) or RNNs are able to capture semantic similarity for words (Mikolov et al., 2013b), segments (Socher et al., 2011) and documents (Le and Mikolov, 2014) naturally, traditional MT evaluation metrics can only achieve this using resources like WordNet and paraphrase databases. This paper presents a novel, efficient and compact MT evaluation measure based on RNNs. Our metric is simple in the sense that it does not require much machinery and resources apart from the dense word vectors. This cannot be said of most of the state-of-the-art MT evaluation metrics, which tend to be complex and require extensive feature engineering. Our metric is based on RNNs and particularly on Tree Long Short Term Memory (Tree-LSTM) networks (Tai et al., 2015). LSTM (Hochreiter and Schmidhuber, 1997) is a sequence learning technique which uses a memory cell to preserve a state over a long period of time. This enables distributed representations of sentences using distributed representations of words. Tree-LSTM is a recent approach, which is an extension of the simple LSTM framework (Zaremba and Sutskever, 2014). To provide the required training data, we also show how to automatically convert the WMT-13 (Bojar et al., 2013) human evaluation rankings into similarity scores between the reference and the translation. Our metric including training data is available at https://github.com/rohitguptacs/ReVal.

2 Related Work

Many metrics have been proposed for MT evaluation. Earlier popular metrics are based on n-gram counts (e.g. BLEU (Papineni et al., 2002) and NIST (Doddington, 2002)) or word error rate. Other popular metrics like METEOR (Denkowski and Lavie, 2014) and TERp (Snover et al., 2008) also use external resources like WordNet and paraphrase databases. However, system-level correlation with human judgements for these metrics remains below 0.90 Pearson correlation coefficient (as per WMT-14 results, BLEU-0.888, NIST-0.867, METEOR-0.829, TER-0.826, WER-0.821).

Recent best-performing metrics in the WMT-14 metric shared task (Machácek and Bojar, 2014) used a combination of different metrics. The top performing system DISKOTK-PARTY-TUNED (Joty et al., 2014) in the WMT-14 task uses five different discourse metrics and twelve different metrics from the ASIYA MT evaluation toolkit (Giménez and Màrquez, 2010). The metric computes the number of common sub-trees between a reference and a translation using a convolution

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1066–1072,
Lisbon, Portugal, 17-21 September 2015.

tree kernel (Collins and Duffy, 2001). The basic version of the metric does not perform well but in combination with the other 12 metrics from the ASIYA toolkit obtained the best results for the WMT-14 metric shared task. Another top performing metric LAYERED (Gautam and Bhattacharyya, 2014), uses linear interpolation of different metrics. LAYERED uses BLEU and TER to capture lexical similarity, Hamming score and Kendall Tau Distance (Birch and Osborne, 2011) to identify syntactic similarity, and dependency parsing (De Marneffe et al., 2006) and the Universal Networking Language[1] for semantic similarity. Recently, Guzmán et al. (2015) presented a metric based on word embeddings and neural networks. However, this metric is limited to ranking the available systems and does not provide an absolute score.

In this paper we propose a compact MT evaluation metric. We hypothesize that our model learns different notions of similarity (which other metrics tend to capture using different metrics) using input, output and forget gates of an LSTM architecture.

3 LSTMs and Tree-LSTMs

Recurrent Neural Networks allow processing of arbitrary length sequences, but early RNNs had the problem of vanishing and exploding gradients (Bengio et al., 1994). RNNs with LSTM (Hochreiter and Schmidhuber, 1997) tackle this problem by introducing a memory cell composed of a unit called constant error carousel (CEC) with multiplicative input and output gate units. Input gates protect against irrelevant inputs and output gates against current irrelevant memory contents. This architecture is capable of capturing important pieces of information seen in a bigger context. Tree-LSTM is an extension of simple LSTM. A typical LSTM processes the information sequentially whereas Tree-LSTM architectures enable sentence representation through a syntactic structure. Equation (1) represents the composition of a hidden state vector for an LSTM architecture. For a simple LSTM, c_t represents the memory cell and o_t the output gate at time step t in a sequence. For Tree-LSTM, c_t represents the memory cell and o_t represents the output gate corresponding to node t in a tree. The structural processing of Tree-LSTM makes it better suited to representing sentences. For example, dependency tree structure captures syntactic features and model parameters the importance of words (content vs. function words).

$$h_t = o_t \odot \tanh c_t \tag{1}$$

Figure 1 shows simple LSTM and Tree-LSTM architectures.

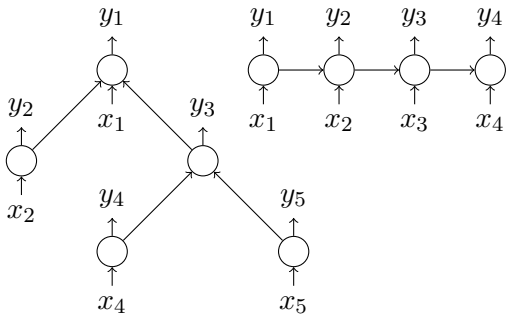

Figure 1: Tree-LSTM (left) and simple LSTM (right)

4 Evaluation Metric

We represent both the reference (h_{ref}) and the translation (h_{tra}) using an LSTM and predict the similarity score $\hat{y}$ based on a neural network which considers both distance and angle between h_{ref} and h_{tra}:

$$\begin{aligned} h_\times &= h_{ref} \odot h_{tra} \\ h_+ &= |h_{ref} - h_{tra}| \\ h_s &= \sigma\left(W^{(\times)} h_\times + W^{(+)} h_+ + b^{(h)}\right) \\ \hat{p}_\theta &= \text{softmax}\left(W^{(p)} h_s + b^{(p)}\right) \\ \hat{y} &= r^T \hat{p}_\theta \end{aligned} \tag{2}$$

where, σ is a sigmoid function, $\hat{p}_\theta$ is the estimated probability distribution vector and $r^T = [1\ 2 ... K]$. The cost function $J(\theta)$ is defined over probability distributions p and $\hat{p}_\theta$ using regularised Kullback-Leibler (KL) divergence.

$$J(\theta) = \frac{1}{n} \sum_{i=1}^{n} \text{KL}\left(p^{(i)} \middle|\middle| \hat{p}_\theta^{(i)}\right) + \frac{\lambda}{2} ||\theta||_2^2 \tag{3}$$

In Equation 3, i represents the index of each training pair, n is the number of training pairs and p is the sparse target distribution such that $y = r^T p$ is defined as follows:

$$p_j = \begin{cases} y - \lfloor y \rfloor, & j = \lfloor y \rfloor + 1 \\ \lfloor y \rfloor - y + 1, & j = \lfloor y \rfloor \\ 0 & \text{otherwise} \end{cases}$$

[1] http://www.undl.org/unlsys/unl/unl2005/UW.htm

for $1 \leq j \leq K$, where, $y \in [1, K]$ is the similarity score of a training pair. For example, for $y = 2.7$, $p^T = [0\ 0.3\ 0.7\ 0\ 0]$. In our case, the similarity score y is a value between 1 and 5.

For our work, we use *glove* word vectors (Pennington et al., 2014) and the simple LSTM, the dependency Tree-LSTM and neural network implementations by Tai et al. (2015). [2] The system uses the scientific computing framework Torch[3]. Training is performed on the data computed in Section 5. The system uses a mini batch size of 25 with learning rate 0.05 and regularization strength 0.0001. The compositional parameters for our Tree-LSTM systems with memory dimensions 150 and 300 are 203,400 and 541,800, respectively. The training is performed for 10 epochs. System-level scores are computed by aggregating and normalising segment-level scores.

5 Computing Similarity Scores from WMT Rankings

As we do not have access to any dataset which provides scores to segments on the basis of translation quality, we used the WMT-13 ranks corpus to automatically derive training data. This corpus is a by-product of the manual systems evaluation carried out in the WMT-13 evaluation. In the evaluation, the annotators are presented with a source segment, the output of five systems and a reference translation. The annotators are given the following instructions: "*You are shown a source sentence followed by several candidate translations. Your task is to rank the translations from best to worst (ties are allowed)*". Using the WMT-13 ranked corpus, we derived a corpus where the reference and corresponding translations are assigned similarity scores. The fact that *ties are allowed* makes it more suitable to generate similarity scores. If all translations are bad, annotators can mark all as rank 5 and if all translations are accurate, annotators can mark all as rank 1. The selection of the WMT-13 corpus over other WMT workshops is motivated by the fact that it is the largest among them. It contains ten times more ranks than WMT-12 and three to four times more than WMT-14. This also makes it possible to obtain enough reference translation pairs which are evaluated several times.

[2]The adapted code for MT evaluation scenarios is available at https://github.com/rohitguptacs/ReVal.

[3]http://torch.ch

Our hypothesis is that if a translation is given a certain rank many times, this reflects its similarity score with the reference. A better ranked translation among many systems will be close to the reference whereas a worse ranked translation among many systems will be dissimilar from the reference. To remove noisy pairs, we collect reference translation pairs below a certain variance only. We determined appropriate variance values using Algorithm 1 below for $n = 3, 4, 5, 6, 7$ and ≥ 8, separately. The computed variance values are given in Table 1.

n	3	4	5	6	7	≥ 8
Var	0.65	1.0	1.2	1.2	1.3	0.85

Table 1: Variances computed using Algorithm 1

Algorithm 1 Variance Computation

```
procedure GETVARIANCE(judgements)
    V, v ← −1, 0.25                          ▷ Initialise N
    for v ≤ max do
        prs ← pairs with variance below v
        score ← kendall(prs, judgements)
        if score ≥ 0.78 then
            V ← v
            v ← v + 0.05
        else
            break
    Return V                                 ▷ Return variance
```

In Algorithm 1, the $kendall$ function calculates Kendall tau correlation using the WMT-13 human judgements. We select a set for which the correlation coefficient is greater than 0.78.[4] The correlation is computed using the annotations for which scores are available in the corpus (prs). In other words, the corpus acts as a scoring function for the available reference translation pairs, which gives a similarity score between a reference and a translation. We selected pairs below the variance values obtained for $n = 4, 5, 6, 7$ and ≥ 8. Finally, all the pairs are merged to obtain a set (L). Apart from this set, we created three other sets for our experiments. The last two also use the SICK data (Marelli et al., 2014) which was developed for evaluating semantic similarity. All four sets are described below:

L: contains the set generated by selecting the pairs ranked *four or more times* and filtering the segments based on the variance

LNF: contains the set generated by selecting the pairs ranked *four or more times* without any filtering depending on the variance

[4]The score was decided so that we obtain around 10K pairs which are annotated at least four times.

L+Sick: Added 4500 sentence pairs from the SICK training set to Set L in the training set and 500 pairs in the development set.

XL+Sick: Added also the pairs ranked *three times* to Set L+Sick.

	Train	Dev	Test
L	9559	1000	1000
LNF	17855	1000	1000
L+Sick	14059	1500	1000
XL+Sick	21356	1500	1000

Table 2: Derived Corpus statistics

Table 2 shows the number of pairs extracted for each set to train our LSTM based models.[5]

6 Results

We evaluate our approach trained on the four different datasets obtained from WMT-13 (as given in Table 2) on WMT-14. Table 3 shows system-level Pearson correlation obtained on different language pairs as well as average Pearson correlation (PAvg) over all language pairs. The last column of the table also shows average Spearman correlation (SAvg). The 95% confidence level scores are obtained using bootstrap resampling as used in the WMT-2014 metric task evaluation. The scores in bold show best scores overall and the scores in bold italic show best scores in our variants.

In Table 3 and Table 4, the first section (L+Sick(lstm)) shows the results obtained using simple LSTM (layer 1, hidden dimension 50, memory dimension 150, compositional parameters 203400). The second section shows the scores of our Tree-LSTM metric trained on different training sets and dimensions. Dimensions are shown in brackets, e.g L(50,150) shows the results on set 'L' with the hidden dimension 50 and the memory dimension 150. L+Sick(mix) shows results of combining the two systems: L+Sick(50,150) and L+Sick(100,150). For the sentences longer than 20 words, the system uses scores of L+Sick(100,150) and scores of L+Sick(50,150) for the rest. The third section shows the best three overall systems from the WMT-14 metric task. The fourth section in Table 3 shows the systems from the WMT-14 task which obtained best results for certain languages but do not preform well overall. The last section in Tables 3 and 4 shows systems implementing BLEU (or variants for the segment level) and METEOR in the WMT-14 metric task.

Tables 3 and 4 contain a deluge of evaluation data, mainly to explore the effect of different training data and model parameter settings for our models. The main messages can be summarised as follows: 1. Tree LSTM models significantly outperform the LSTM model (L+Sick(lstm) and L+Sick(50,150) have the same data and parameter settings). 2. For Tree-LSTM models different parameter settings have only a minor impact on performance (in fact only for a few language pairs (e.g. hi-en at system-level, L+Sick(100, 300) and L+Sick(100,150)) results are statistically significantly different). This is reassuring as it indicates that the metric is not overly sensitive to extensive and delicate parameter tuning. 3. For the system level evaluation Tree-LSTM models are fully competitive with the best of the current complex models that combine many different metrics, substantial external resources and may require a significant amount of feature engineering and tuning. 4. For the segment level evaluation our metric outperforms BLEU based approaches and the other three systems[6] but lags behind some other approaches. We investigate this further below.

Tables 3 and 4 show that set L is able to obtain similar results compared to set LNF even though we filter out almost half of the pairs. Table 3 shows that for L+Sick(50, 150) and L+Sick(mix), we obtained an average second best Pearson correlation and best Spearman correlation coefficient. We also obtained better results for the Russian-English and Czech-English language pairs compared to any other systems in the WMT-14 task.

We also evaluate our setting L-Sick(50,150) on the WMT-12 task dataset. Our metric performs best for two out of four language pairs and best overall at the system level with 0.950 and 0.926 Pearson and Spearman correlation coefficient, respectively. At the segment level, we obtained 0.222 Kendall tau correlation which was better than seven out of the total ten metrics in the WMT-12 task.

One of the reasons for the difference in segment-level and system-level correlations is that Kendall Tau segment-level correlation is calcu-

[5]For testing our approach we use WMT-12 and WMT-14 rankings instead of the test sets in this table.

[6]These three systems are not given in this paper. Please refer (Machácek and Bojar, 2014) for results of these systems.

Table 4: Results: Segment-Level Correlations on WMT-14

lated based on rankings and does not consider the amount of difference between scores. Here is an example similar to that given in (Hopkins and May, 2013). Suppose four systems produce the translations T0, T1, T2 and T3. Suppose we have two metrics M1 and M2 and they produce scores and rankings as follows. GS represents the correct ranking and scores; Scores are in a scale [0, 1] with a higher score indicating a better translation:

M1: T0 (0.10), T3 (0.71), T1 (0.72), T2 (0.73)

M2: T1 (0.71), T0 (0.72), T2 (0.73), T3 (0.74)

GS: T0 (0.10), T1 (0.71), T2 (0.72), T3 (0.73)

Certainly, M1 produces better scores and ranking than M2. But, Kendall Tau segment-level correlation is higher for M2. (There are four concordant pairs in the M1 rank and five in the M2 rank.) Therefore, if a metric does not scale well as per the quality of translations, it may still obtain a good Kendall Tau segment-level correlation and a better metric may end up getting a low correlation. Another reason for the discrepancy between segment and system-level scores may be a low agreement on annotations. For the WMT-14 dataset, inter-annotator and intra-annotator agreement were 0.367 and 0.522. These problems should not occur with Pearson correlation at the system level because system-level scores are calculated using more sophisticated approaches (Koehn, 2012; Hopkins and May, 2013; Sakaguchi et al., 2014). For example, Hopkins and May (2013) model the differences among annotators by adding random Gaussian noise.

7 Conclusion

We conclude that our dense-vector-space-based ReVal metric is simple, elegant and effective with state-of-the-art results. ReVal is fully competitive with the best of the current complex alternative approaches that involve system combination, extensive external resources, feature engineering and tuning.

Abstract

We present novel features designed with a deep neural network for Machine Translation (MT) Quality Estimation (QE). The features are learned with a Continuous Space Language Model to estimate the probabilities of the source and target segments. These new features, along with standard MT system-independent features, are benchmarked on a series of datasets with various quality labels, including post-editing effort, human translation edit rate, post-editing time and METEOR. Results show significant improvements in prediction over the baseline, as well as over systems trained on state of the art feature sets for all datasets. More notably, the addition of the newly proposed features improves over the best QE systems in WMT12 and WMT14 by a significant margin.

1 Introduction

Quality Estimation (QE) is concerned with predicting the quality of Machine Translation (MT) output without reference translations. QE is addressed with various features indicating fluency, adequacy and complexity of the translation pair. These features are used by a machine learning algorithm along with quality labels given by humans to learn models to predict the quality of unseen translations.

A variety of features play a key role in QE. A wide range of features from source segments and their translated segments, extracted with the help of external resources and tools, have been proposed. These go from simple, language-independent features, to advanced, linguistically motivated features. They include features that summarise how the MT systems generate translations, as well as features that are oblivious to the systems. The majority of the features in the literature are extracted from each sentence pair in isolation, ignoring the context of the text. QE performance usually differs depending on the language pair, the specific quality score being optimised (e.g., post-editing time vs translation adequacy) and the feature set. Features based on n-gram language models, despite their simplicity, are among those with the best performance in most QE tasks (Shah et al., 2013b). However, they may not generalise well due to the underlying discrete nature of words in n-gram modelling.

Continuous Space Language Models (CSLM), on the other hand, have shown their potential to capture long distance dependencies among words (Schwenk, 2012; Mikolov et al., 2013). The assumption of these models is that semantically or grammatically related words are mapped to similar geometric locations in a high-dimensional continuous space. The probability distribution is thus much smoother and therefore the model has a better generalisation power on unseen events. The representations are learned in a continuous space to estimate the probabilities using neural networks with single (called shallow networks) or multiple (called deep networks) hidden layers. Deep neural networks have been shown to perform better than shallow ones due to their capability to learn higher-level, abstract representations of the input (Arisoy et al., 2012). In this paper, we explore the potential of these models in context of QE for MT. We obtain more robust features with CSLM and improve the overall prediction power for translation quality.

The paper is organised as follows: In Section 2 we briefly present the related work. Section 3 describes the CSLM model training and its various settings. In Section 4 we propose the use of CSLM features for QE. In Section 5 we present our experiments along with their results.

2 Related Work

For a detailed overview of various features and algorithms for QE, we refer the reader to the

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1073–1078,
Lisbon, Portugal, 17-21 September 2015.

WMT12-14 shared tasks on QE (Callison-Burch et al., 2012; Bojar et al., 2013; Ling et al., 2014). Most of the research work lies on deciding which aspects of quality are more relevant for a given task and designing feature extractors for them. While simple features such as counts of tokens and language model scores can be easily extracted, feature engineering for more advanced and useful information can be quite labour-intensive.

Since their introduction in (Bengio et al., 2003), neural network language models have been successfully exploited in many speech and language processing problems, including automatic speech recognition (Schwenk and Gauvain, 2005; Schwenk, 2007) and machine translation (Schwenk, 2012).

Recently, (Banchs et al., 2015) used a Latent Semantic Indexing approach to model sentences as bag-of-words in a continuous space to measure cross language adequacy. (Tan et al., 2015) proposed to train models with deep regression for machine translation evaluation in a task to measure semantic similarity between sentences. They reported positive results on simple features; larger feature sets did not improve these results.

In this paper, we propose to estimate the probabilities of source and target segments with continuous space language models based on a deep architecture and to use these estimated probabilities as features along with standard feature sets in a supervised learning framework. To the best of our knowledge, such approach has not been studied before in the context of QE for MT. The result shows significant improvements in many prediction tasks, despite its simplicity. Monolingual data for source and target language is the only resource required to extract these features.

3 Continuous Space Language Models

A key factor for quality inference of a translated text is to determine the fluency of such a text and how well it conforms to the linguistic regularities of the target language. It involves grammatical correctness, idiomatic and stylistic word choices that can be derived by using n-gram language models. However, in high-order n-grams, the parameter space is sparse and conventional modelling is inefficient. Neural networks model the non-linear relationship between the input features and target outputs. They often outperform conventional techniques in difficult machine learning tasks. Neural network language models (CSLM) alleviate the curse of dimensionality by projecting words into a continuous space, and modelling and estimating probabilities in this space.

The architecture of a deep CSLM is illustrated in Figure 1. The inputs to a CSLM model are the $(K-1)$ left-context words $(w_{i-K+1}, \ldots, w_{i-2}, w_{i-1})$ to predict w_i. A one-hot vector encoding scheme is used to represent the input w_{i-k} with an N-dimensional vector. The output of CSLM is a vector of posterior probabilities for all words in vocabulary, $P(w_i|w_{i-1}, w_{i-2}, \ldots, w_{i-K+1})$. Due to the large output layer (vocabulary size), the complexity of a basic neural network language model is very high. Schwenk (2007) proposed efficient training strategies in order to reduce the computational complexity and speed up the training time. They process several examples at once and use a *short-list* vocabulary V with only the most frequent words.

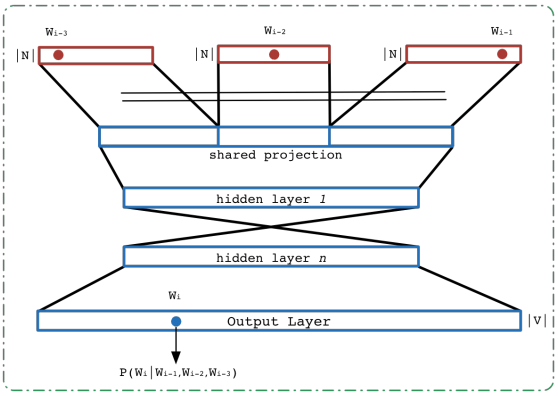

Figure 1: Deep CSLM architecture.

Following the settings mentioned in (Schwenk et al., 2014), all CSLM experiments described in this paper are performed using deep networks with four hidden layers: first layer for the projection (320 units for each context word) and three hidden layers of 1024 units with *tanh* activation. At the output layer, we use a *softmax* activation function applied to a *short-list* of the 32k most frequent words. The probabilities of the out-of-vocabulary words are obtained from a standard back-off n-gram language model. The projection of the words onto the continuous space and the training of the neural network is done by the standard back-propagation algorithm and outputs are the converged posterior probabilities. The model parameters are optimised on a development set.

4 CSLM and Quality Estimation

In the context of MT, CSLMs are generally trained on the target side of a given language pair to ex-

press the probability that the generated sentence is "correct" or "likely", without looking at the source sentence. However, QE is also concerned with how well the source segments can be translated. Therefore, we trained two models, one for each side of a given language pair. We extracted the probabilities for QE training and test sets for both source and its translation with their respective models and used them as features, along with other features, in a supervised learning setting.

Finally, we also used CSLM in a spoken language translation (SLT) task. In SLT, an automatic speech recogniser (ASR) is used to decode the source language text from audio. This creates an extra source of variability, where different ASR models and configurations give different outputs. In this paper, we use QE to exploit different ASR outputs (i.e. MT inputs) which in turn can lead to different MT outputs.

5 Experiments

We focus on experiments with sentence level QE tasks. Our English-Spanish experiments are based on the WMT QE shared task data from 2012 to 2015.[1] These tasks are diverse in nature, with different sizes and labels such as post-editing effort (PEE), post-editing time (PET) and human translation error rate (HTER). The results reported in Section 5.5 are directly comparable with the official systems submitted for each of the respective tasks. We also performed experiments on the IWSLT 2014 English-French SLT task [2] to study the applicability of our models on n-best ASR (MT inputs) comparison.

5.1 QE Datasets

In Table 1 we summarise the data and tasks for our experiments. We refer readers to the WMT and IWSLT websites for detailed descriptions of these datasets. All datasets are publicly available.

WMT12: English-Spanish news sentence translations produced by a Moses "baseline" statistical MT (SMT) system, and judged for perceived post-editing effort in 1–5 (highest-lowest), taking a weighted average of three annotators (Callison-Burch et al., 2012).

WMT13 (Task-1): English-Spanish sentence translations of news texts produced by a Moses "baseline" SMT system. These were then post-edited by a professional translator and labelled using HTER. This is a superset of the WMT12 dataset, with 500 additional sentences for test, and a different quality label (Bojar et al., 2013).

WMT14 (Task-1.1): English-Spanish news sentence translations. The dataset contains source sentences and their human translations, as well as three versions of machine translations: by an SMT system, a rule-based system system and a hybrid system. Each translation was labelled by professional translators with 1-3 (lowest-highest) scores for perceived post-editing effort.

WMT14 (Task-1.3): English-Spanish news sentence translations post-edited by a professional translator, with the post-editing time collected on a sentence-basis and used as label (in milliseconds).

WMT15 (Task-1): Large English-Spanish news dataset containing source sentences, their machine translations by an online SMT system, and the post-editions of the translation by crowdsourced translators, with HTER used as label.

IWSLT14: English-French dataset containing source language data from the 10-best (sentences) ASR system output. On the target side, the 1-best MT translation is used. The ASR system leads to different source segments, which in turn lead to different translations. METEOR (Banerjee and Lavie, 2005) is used to label these alternative translations against a reference (human) translation. Both ASR and MT outputs come from a system submission in IWSLT 2014 (Ng et al., 2014). The ASR system is a multi-pass deep neural network tandem system with feature and model adaptation and rescoring. The MT system is a phrase-based SMT system produced using Moses.

Dataset	Lang.	Train	Test	Label
WMT12	en-es	1,832	422	PEE 1-5
WMT13	en-es	2,254	500	HTER 0-1
WMT14$_{task1.1}$	en-es	3,816	600	PEE 1-3
WMT14$_{task1.3}$	en-es	650	208	PET (ms)
WMT15	en-es	11,271	1,817	HTER 0-1
IWSLT14	en-fr	8,180	11,240	MET. 0-1

Table 1: QE datasets: # sentences and labels.

5.2 CSLM Dataset

The dataset used for CSLM training consists of Europarl, News-commentary and News-crawl corpus. We used a data selection method (Moore

[1] http://www.statmt.org/wmt[12,13,14,15]/quality-estimation-task.html

[2] https://sites.google.com/site/iwsltevaluation2014/slt-track

and Lewis, 2010) to select the most relevant training data with respect to a development set. For English-Spanish, the development data is the concatenation of newstest2012 and newstest2013 of the WMT translation track. For English-French, the development set is the concatenation of the IWSLT dev2010 and eval2010. In Table 2 we show statistics on the selected monolingual data used to train back-off LM and CSLM.

Lang.	Train	Dev	LM ppl	CSLM ppl
en	4.3G	137.7k	164.63	116.58 (29.18%)
fr	464.7M	54K	99.34	64.88 (34.68%)
es	21.2M	149.4k	145.49	87.14 (40.10%)

Table 2: Training data size (number of tokens) and language models perplexity (ppl). The values in parentheses in last column shows percentage decrease in perplexity.

5.3 Feature Sets

We use the `QuEst` [3] toolkit (Specia et al., 2013; Shah et al., 2013a) to extract two feature sets for each dataset:

- **BL**: 17 features used as baseline in the WMT shared tasks on QE.
- **AF**: 80 augmented MT system-independent features[4] (superset of **BL**). For the En-Fr SLT task, we have additional 36 features (21 ASR + 15 MT-dependent features)

The resources used to extract these features (corpora, etc.) are also available as part of the WMT shared tasks on QE. The CSLM features for each of the source and target segments are extracted using the procedure described in Section 3 with the CSLM toolkit. [5]

We trained QE models with following combination of features:

- **BL + CSLM**$_{src,tgt}$: CSLM features for source and target segments, plus the baseline features.
- **AF + CSLM**$_{src,tgt}$: CSLM features for source and target segments, plus all available features.

For the WMT12 task, we performed further experiments to analyse the improvements with CSLM:

- **CSLM**$_{src}$: Source side CSLM feature only.
- **CSLM**$_{tgt}$: Target side CSLM feature only.
- **CSLM**$_{src,tgt}$: Source and target CSLM features by themselves.
- **FS(AF) + CSLM**$_{src,tgt}$: CSLM features in addition to the best performing feature set (**FS(AF)**) selected as described in (Shah et al., 2013b; Shah et al., 2015).

5.4 Learning algorithms

We use the Support Vector Machines implementation of the `scikit-learn` toolkit to perform regression (SVR) with either Radial Basis Function (RBF) or linear kernel and parameters optimised via grid search. To evaluate the prediction models we use Mean Absolute Error (MAE), its squared version – Root Mean Squared Error (RMSE), and Pearson's correlation (r) score.

Task	System	#feats	MAE	RMSE	r
WMT12	BL	17	0.6821	0.8117	0.5595
	AF	80	0.6717	0.8103	0.5645
	BL + CSLM$_{src,tgt}$	19	0.6463	0.7977	0.5805
	AF + CSLM$_{src,tgt}$	82	0.6462	0.7946	0.5825
WMT13	BL	17	0.1411	0.1812	0.4612
	AF	80	0.1399	0.1789	0.4751
	BL + CSLM$_{src,tgt}$	19	0.1401	0.1791	0.4771
	AF + CSLM$_{src,tgt}$	82	0.1371	0.1750	0.4820
WMT14 Task 1.1	BL	17	0.5241	0.6591	0.2502
	AF	80	0.4896	0.6349	0.3310
	BL + CSLM$_{src,tgt}$	19	0.4931	0.6351	0.3545
	AF + CSLM$_{src,tgt}$	82	0.4628*	0.6165*	0.3824*
WMT14 Task 1.3	BL	17	0.1798	0.2865	0.5661
	AF	80	0.1753	0.2815	0.5871
	BL + CSLM$_{src,tgt}$	19	0.1740	0.2758	0.6243
	AF + CSLM$_{src,tgt}$	82	0.1701**	0.2734	0.6201
WMT15	BL	17	0.1562	0.2036	0.1382
	AF	80	0.1541	0.1995	0.2205
	BL + CSLM$_{src,tgt}$	19	0.1501	0.1971	0.2611
	AF + CSLM$_{src,tgt}$	82	0.1471	0.1934	0.2862

5.5 Results

Table 3 presents the results with different feature sets for data from various shared tasks. It can be noted that CSLM features always bring significant improvements whenever added to either baseline or augmented feature set. A reduction in both error scores (MAE and RMSE) as well as an increase in Pearson's correlation with human labels can be observed on all tasks. It is also worth noticing that the CSLM features bring improvements over all tasks with different labels, evidencing that different optimisation objectives and language pairs can benefit from these features. However, the improvements are more visible when predicting post-editing effort for WMT12 and WMT14's Task 1.1. For these two tasks, we are able to achieve state-of-the-art performance by adding the two CSLM features to all available or selected feature sets.

For WMT12, we performed another set of experiments to study the effect of CSLM features by themselves and in combination. The results in Table 4 show that the target side CSLM feature bring larger improvements than its source side counterpart. We believe that it is because the target side feature directly reflects the fluency of the translation, whereas the source side feature (regarded as a translation complexity feature) only has indirect effect on quality. Interestingly, the two CSLM features alone give comparable results (slightly worse) than the BL feature set [6] despite the fact that these 17 features cover many complexity, adequacy and fluency quality aspects. CSLM features bring further improvements on pre-selected feature sets, as shown in Table 3. We also performed feature selection over the full feature set along with CSLM features, following the procedure in (Shah et al., 2013b). Interestingly, both CSLM features were selected among the top ranked features, confirming their relevance.

In order to investigate whether our CSLM features results hold for other feature sets, we experimented with the feature sets provided by most teams participating in the WMT12 QE shared task. These feature sets are very diverse in terms of the types of features, resources used, and their sizes. Table 5 shows the official results from the shared task (Off.) (Callison-Burch et al., 2012), those from training an SVR on these features with and without CSLM features. Note that the official scores are often different from the results obtained with our SVR models because of differences in the learning algorithms. As shown in Table 5, we observed similar improvements with additional CSLM features over all of these feature sets.

System	#feats	Off.	SVR without CSLM	SVR with CSLM

Table 5: MAE score on official WMT12 feature sets using SVR with and without CSLM features.

6 Conclusions

We proposed novel features for machine translation quality estimation obtained using a deep continuous space language models. The proposed features led to significant improvements over standard feature sets for a variety of datasets, outperforming the state-of-art on two official WMT QE tasks. These results showed that different optimisation objectives and language pairs can benefit from the proposed features. The proposed features have been shown to also perform well on QE within a spoken language translation task.

Both source and target CSLM features improve prediction quality, either when used separately or in combination. They proved complementary when used together with other feature sets and produce comparable results to high performing baseline features when used alone for prediction. Finally, results comparing all official WMT12 QE feature sets showed significant improvements in the predictions when CSLM features were added to those submitted by participating teams. These findings provide evidence that the proposed features bring valuable information into prediction models, despite their simplicity and the fact that they require only monolingual data as resource, which is available in abundance for many languages.

As future work, it would be interesting to explore various distributed word representations for quality estimation and joint models that look at both the source and the target sentences simultaneously.

Supervised Phrase Table Triangulation with Neural Word Embeddings for Low-Resource Languages

Tomer Levinboim and **David Chiang**

University of Notre Dame
{levinboim.1,dchiang}@nd.edu

Abstract

In this paper, we develop a supervised learning technique that improves noisy phrase translation scores obtained by phrase table triangulation. In particular, we extract word translation distributions from small amounts of source-target bilingual data (a dictionary or a parallel corpus) with which we learn to assign better scores to translation candidates obtained by triangulation. Our method is able to gain improvement in translation quality on two tasks: (1) On Malagasy-to-French translation via English, we use only 1k dictionary entries to gain +0.5 B over triangulation. (2) On Spanish-to-French via English we use only 4k sentence pairs to gain +0.7 B over triangulation interpolated with a phrase table extracted from the same 4k sentence pairs.

1 Introduction

Phrase-based statistical machine translation systems require considerable amounts of source-target parallel data to produce good quality translation. However, large amounts of parallel data are available for only a fraction of language pairs, and mostly when one of the languages is English.

Phrase table triangulation (Utiyama and Isahara, 2007; Cohn and Lapata, 2007; Wu and Wang, 2007) is a method for generating source-target phrase tables without having access to any source-target parallel data. The intuition behind triangulation (and pivoting techniques in general) is the transitivity of translation: if a source language phrase **s** translates to a pivot language phrase **p** which in turn translates to a target language phrase **t**, then **s** should likely translate to **t**. Following this intuition, a triangulated source-target phrase table $\hat{T}$ can be composed from a source-pivot and pivot-target phrase table (§2).

However, the resulting triangulated phrase table $\hat{T}$ contains many spurious phrase pairs and noisy probability estimates. Therefore, early triangulation work (Wu and Wang, 2007) already realistically assumed access to a limited source-target parallel data from which a relatively high-quality source-target phrase table T can be directly estimated. The two phrase tables were then combined, resulting in a higher quality phrase table that proposes translations for many source phrases not found in T. Wu and Wang (2007) report that interpolation of the two phrase tables T and $\hat{T}$ leads to higher quality translations. However, the triangulated phrase table $\hat{T}$ is obtained without using the source-target bilingual data, which suggests that the source-target data is not used as fully as it could be.

In this paper, we develop a supervised learning algorithm that corrects triangulated word translation probabilities by relying on word translation distributions w^{sup} derived from the limited source-target data. In particular, we represent source and target words using word embeddings (Mikolov et al., 2013) and learn a transformation between the two embedding spaces in order to approximate w^{sup}, thus down-weighting incorrect translation candidates proposed by triangulation (§3). By representing words as embeddings, our model can generalize the information contained in the source-target data (as encoded in the distributions w^{sup}) to a much larger vocabulary, and can assign lexical-weighting probabilities to most of the phrase pairs in $\hat{T}$.

Fixing English as the pivot language (the most realistic pivot language choice), on a low-resource Spanish-to-French translation task our model gains +0.7 B on top of standard phrase table interpolation. On Malagasy-to-French translation, our model gains +0.5 B on top of triangulation when using only 1k Malagasy-French dictionary entries (§4).

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1079–1083,
Lisbon, Portugal, 17-21 September 2015.

2 Preliminaries

Let s, p, t denote words and $\mathbf{s}, \mathbf{p}, \mathbf{t}$ denote phrases in the source, pivot, and target languages, respectively. Also, let T denote a phrase table estimated over a parallel corpus and $\hat{T}$ denote a triangulated phrase table. We use similar notation for their respective phrase translation features ϕ, lexical-weighting features *lex*, and the word translation probabilities w.

2.1 Triangulation (weak baseline)

In phrase table triangulation, a source-target phrase table T_{st} is constructed by combining a source-pivot and pivot-target phrase table $T_{\text{sp}}, T_{\text{pt}}$, each estimated on its respective parallel data. For each resulting phrase pair $(\mathbf{s}, \mathbf{t})$, we can also compute an alignment $\hat{\mathbf{a}}$ as the most frequent alignment obtained by combining source-pivot and pivot-target alignments $\mathbf{a_{sp}}$ and $\mathbf{a_{pt}}$ across all pivot phrases $\mathbf{p}$ as follows: $\{(s,t) \mid \exists p : (s,p) \in \mathbf{a_{sp}} \wedge (p,t) \in \mathbf{a_{pt}}\}$.

The triangulated source-to-target lexical weights, denoted $\widehat{lex}_{\text{st}}$, are approximated in two steps: First, word translation scores $\hat{w}_{\text{st}}$ are approximated by marginalizing over the pivot words:

$$\hat{w}_{\text{st}}(t \mid s) = \sum_p w_{\text{sp}}(p \mid s) \cdot w_{\text{pt}}(t \mid p). \quad (1)$$

Next, given a (triangulated) phrase pair $(\mathbf{s}, \mathbf{t})$ with alignment $\hat{\mathbf{a}}$, let $\hat{\mathbf{a}}_{s,:} = \{t \mid (s,t) \in \hat{\mathbf{a}}\}$; the lexical-weighting probability is (Koehn et al., 2003):

$$\widehat{lex}_{\text{st}}(\mathbf{t} \mid \mathbf{s}, \hat{\mathbf{a}}) = \prod_{s \in \mathbf{s}} \frac{1}{|\hat{\mathbf{a}}_{s,:}|} \sum_{t \in \hat{\mathbf{a}}_{s,:}} \hat{w}_{\text{st}}(t \mid s). \quad (2)$$

The triangulated phrase translation scores, denoted $\hat{\phi}_{\text{st}}$, are computed by analogy with Eq. 1.

We also compute these scores in the reverse direction by swapping the source and target languages.

2.2 Interpolation (strong baseline)

Given access to source-target data, an ordinary source-target phrase table T_{st} can be estimated directly. Wu and Wang (2007) suggest interpolating phrase pairs entries that occur in both tables:

$$T_{\text{interp}} = \alpha T_{\text{st}} + (1 - \alpha)\hat{T}_{\text{st}}. \quad (3)$$

Phrase pairs appearing in only one phrase table are added as-is. We refer to the resulting table as the interpolated phrase table.

3 Supervised Word Translations

While interpolation (Eq. 3) may help correct some of the noisy triangulated scores, its effect is limited to phrase pairs appearing in both phrase tables. Here, we suggest a discriminative supervised learning method that can affect all phrase pairs.

Our idea is to regard word translation distributions derived from source-target bilingual data (through word alignments or dictionary entries) as the correct translation distributions, and use them to learn discriminately: correct target words should become likely translations, and incorrect ones should be down-weighted. To generalize beyond the vocabulary of the source-target data, we appeal to word embeddings.

We present our formulation in the source-to-target direction. The target-to-source direction is obtained simply by swapping the source and target languages.

3.1 Model

Let c^{sup}_{st} denote the number of times source word s was aligned to target word t (in word alignment, or in the dictionary). We define the word translation distributions $w^{\text{sup}}(t \mid s) = c^{\text{sup}}_{st}/c^{\text{sup}}_{s}$, where $c^{\text{sup}}_{s} = \sum_t c^{\text{sup}}_{st}$. Furthermore, let $q(t \mid s)$ denote the word translation probabilities we wish to learn and consider maximizing the log-likelihood function:

$$\arg\max_q L(q) = \arg\max_q \sum_{(s,t)} c^{\text{sup}}_{st} \log q(t \mid s).$$

Clearly, the solution $q(\cdot \mid s) := w^{\text{sup}}(\cdot \mid s)$ maximizes L. However, we would like a solution that generalizes to source words s beyond those observed in the source-target corpus – in particular, those source words that appear in the triangulated phrase table $\hat{T}$, but not in T.

In order to generalize, we abstract from words to vector representations of words. Specifically, we constrain q to the following parameterization:

$$q(t \mid s) = \frac{1}{Z_s} \exp\left(v_s^T A v_t + f_{st}^T h\right)$$
$$Z_s = \sum_{t \in \mathcal{T}(s)} \exp\left(v_s^T A v_t + f_{st}^T h\right).$$

Here, the vectors v_s and v_t represent monolingual features and the vector f_{st} represents bilingual features. The parameters A and h are to be learned.

In this work, we use monolingual word embeddings for v_s and v_t, and set the vector f_{st} to contain only the value of the triangulated score, such

that $f_{st} := \hat{w}_{\text{st}}$. Therefore, the matrix A is a linear transformation between the source and target embedding spaces, and h (now a scalar) quantifies how the triangulated scores $\hat{w}$ are to be trusted.

In the normalization factor Z_s, we let t range only over possible translations of s suggested by either w^{sup} or the triangulated word probabilities. That is:

$$\mathcal{T}(s) = \{t \mid w^{\text{sup}}(t \mid s) > 0 \ \vee \ \hat{w}(t \mid s) > 0\}.$$

This restriction makes efficient computation possible, as otherwise the normalization term would have to be computed over the entire target vocabulary.

Under this parameterization, our goal is to solve the following maximization problem:

$$\max_{A,h} L(A, h) = \max_{A,h} \sum_{s,t} c_{st}^{\text{sup}} \log q(t \mid s). \quad (4)$$

3.2 Optimization

The objective function in Eq. 4 is concave in both A and h. This is because after taking the log, we are left with a weighted sum of linear and concave (negative log-sum-exp) terms in A and h. We can therefore reach the global solution of the problem using gradient descent.

Taking derivatives, the gradient is

$$\frac{\partial L}{\partial A} = \sum_{s,t} m_{st} v_s v_t^{\text{T}} \qquad \frac{\partial L}{\partial h} = \sum_{s,t} m_{st} f_{st}$$

where the scalar $m_{st} = c_{st}^{\text{sup}} - c_s^{\text{sup}} q(t \mid s)$ for the current value of q.

For quick results, we limited the number of gradient steps to 200 and selected the iteration that minimized the total variation distance to w^{sup} over a held out dev set:

$$\sum_s \|q(\cdot \mid s) - w^{\text{sup}}(\cdot \mid s)\|_1. \quad (5)$$

We obtained better convergence rate by using a batch version of the effective and easy-to-implement Adagrad technique (Duchi et al., 2011). See Figure 1.

3.3 Re-estimating lexical weights

Having learned the model (A and h), we can now use $q(t \mid s)$ to estimate the lexical weights (Eq. 2) of any aligned phrase pairs $(\mathbf{s}, \mathbf{t}, \hat{\mathbf{a}})$, assuming it is composed of embeddable words.

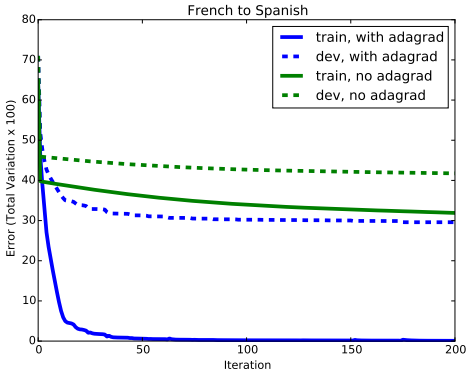

Figure 1: The (target-to-source) objective function per iteration. Applying batch Adagrad (blue) significantly accelerates convergence.

However, we found the supervised word translation scores q to be too sharp, sometimes assigning all probability mass to a single target word. We therefore interpolated q with the triangulated word translation scores $\hat{w}$:

$$q_\beta = \beta q + (1 - \beta)\hat{w}. \quad (6)$$

To integrate the lexical weights induced by q_β (Eq. 2), we simply appended them as new features in the phrase table in addition to the existing lexical weights. Following this, we can search for a β value that maximizes B on a tuning set.

3.4 Summary of method

In summary, to improve upon a triangulated or interpolated phrase table, we:

1. Learn word translation distributions q by supervision against distributions w^{sup} derived from the source-target bilingual data (§3.1).

2. Smooth the learned distributions q by interpolating with triangulated word translation scores $\hat{w}$ (§3.3).

3. Compute new lexical weights and append them to the phrase table (§3.3).

4 Experiments

To test our method, we conducted two low-resource translation experiments using the phrase-based MT system Moses (Koehn et al., 2007).

4.1 Data

Fixing the pivot language to English, we applied our method on two data scenarios:

1. **Spanish-to-French:** two related languages used to simulate a low-resource setting. The baseline is phrase table interpolation (Eq. 3).

2. **Malagasy-to-French:** two unrelated languages for which we have a small dictionary, but no parallel corpus (aside from tuning and testing data). The baseline is triangulation alone (there is no source-target model to interpolate with).

Table 1 lists some statistics of the bilingual data we used. European-language bitexts were extracted from Europarl (Koehn, 2005). For Malagasy-English, we used the Global Voices parallel data available online.[1] The Malagasy-French dictionary was extracted from online resources[2] and the small Malagasy-French tune/test sets were extracted[3] from Global Voices.

	lines of data		
language pair	train	tune	test
sp-fr	4k	1.5k	1.5k
mg-fr	1.1k	1.2k	1.2k
sp-en	50k	–	–
mg-en	100k	–	–
en-fr	50k	–	–

Table 1: Bilingual datasets. Legend: sp=Spanish, fr=French, en=English, mg=Malagasy.

Table 2 lists token statistics of the monolingual data used. We used word2vec[4] to generate French, Spanish and Malagasy word embeddings. The French and Spanish embeddings were (independently) estimated over their combined tokenized and lowercased Gigaword[5] and Leipzig news corpora.[6] The Malagasy embeddings were similarly estimated over data form Global Voices,[7] the Malagasy Wikipedia and the Malagasy Common Crawl.[8] In addition, we estimated a 5-gram French language model over the French monolingual data.

language	words
French	1.5G
Spanish	1.4G
Malagasy	58M

Table 2: Size of monolingual corpus per language as measured in number of tokens.

4.2 Spanish-French Results

To produce w^{sup}, we aligned the small Spanish-French parallel corpus in both directions, and symmetrized using the intersection heuristic. This was done to obtain high precision alignments (the often-used *grow-diag-final-and* heuristic is optimized for phrase extraction, not precision).

We used the skip-gram model to estimate the Spanish and French word embeddings and set the dimension to $d = 200$ and context window to $w = 5$ (default). Subsequently, to run our method, we filtered out source and target words that either did not appear in the triangulation, or, did not have an embedding. We took words that appeared more than 10 times in the parallel corpus for the training set (~690 words), and between 5–9 times for the held out dev set (~530 words). This was done in both source-target and target-source directions.

In Table 3 we show that the distributions learned by our method are much better approximations of w^{sup} compared to those obtained by triangulation.

Method	source→target	target→source
triangulation	71.6%	72.0%
our scores	30.2%	33.8%

Table 3: Average total variation distance (Eq. 5) to the dev set portion of w^{sup} (computed only over words whose translations in w^{sup} appear in the triangulation). Using word embeddings, our method is able to better generalize on the dev set.

We then examined the effect of appending our supervised lexical weights. We fixed the word level interpolation $\beta := 0.95$ (effectively assigning very little mass to triangulated word translations $\hat{w}$) and searched for $\alpha \in \{0.9, 0.8, 0.7, 0.6\}$ in Eq. 3 to maximize B on the tuning set.

Our MT results are reported in Table 4. While interpolation improves over triangulation alone by +0.8 B , our method adds another +0.7 B on top of interpolation, a statistically significant gain ($p < 0.01$) according to a bootstrap resampling significance test (Koehn, 2004).

Method	α	tune	test
source-target	–	26.8	25.3
triangulation	–	29.2	28.4
interpolation	0.7	30.2	29.2
interpolation+our scores	0.6	30.8	**29.9**

Table 4: Spanish-French B scores. Appending lexical weights obtained by supervision over a small source-target corpus significantly outperforms phrase table interpolation (Eq. 3) by +0.7 B .

4.3 Malagasy-French Results

For Malagasy-French, the w^{sup} distributions used for supervision were taken to be uniform distributions over the dictionary translations. For each training direction, we used a 70%/30% split of the dictionary to form the train and dev sets.

Having significantly less Malagasy monolingual data, we used $d = 100$ dimensional embeddings and a $w = 3$ context window to estimate both Malagasy and French words.

As before, we added our supervised lexical weights as new features in the phrase table. However, instead of fixing $\beta = 0.95$ as above, we searched for $\beta \in \{0.9, 0.8, 0.7, 0.6\}$ in Eq. 6 to maximize B on a small tune set. We report our results in Table 5. Using only a dictionary, we are able to improve over triangulation by +0.5 B , a statistically significant difference ($p < 0.01$).

Method	β	tune	test
triangulation	–	12.2	11.1
triangulation+our scores	0.6	12.4	**11.6**

Table 5: Malagasy-French B . Supervision with a dictionary significantly improves upon simple triangulation by +0.5 B .

5 Conclusion

In this paper, we argued that constructing a triangulated phrase table independently from even very limited source-target data (a small dictionary or parallel corpus) underutilizes that parallel data.

Following this argument, we designed a supervised learning algorithm that relies on word translation distributions derived from the parallel data as well as a distributed representation of words (embeddings). The latter enables our algorithm to assign translation probabilities to word pairs that do not appear in the source-target bilingual data.

We then used our model to generate new lexical weights for phrase pairs appearing in a triangulated or interpolated phrase table and demonstrated improvements in MT quality on two tasks. This is despite the fact that the distributions (w^{sup}) we fit our model to were estimated automatically, or even naïvely as uniform distributions.

Abstract

This work focuses on the task of finding latent vector representations of the words in a corpus. In particular, we address the issue of what to do when there are multiple languages in the corpus. Prior work has, among other techniques, used canonical correlation analysis to project pre-trained vectors in two languages into a common space. We propose a simple and scalable method that is inspired by the notion that the learned vector representations should be invariant to translation between languages. We show empirically that our method outperforms prior work on multilingual tasks, matches the performance of prior work on monolingual tasks, and scales linearly with the size of the input data (and thus the number of languages being embedded).

1 Introduction

Representing words as vectors in some latent space has long been a central idea in natural language processing. The *distributional hypothesis*, perhaps best stated as "You shall know a word by the company it keeps" (Firth, 1957), has had a long and productive history, as well as a recent revival in neural-network-based models (Mikolov et al., 2013). These methods generally construct a word by context matrix, then either use the vectors directly (often weighted by term frequency and inverse document frequency), perform some factorization of the matrix, or use it as input to a neural network which produces vectors for each word. The resultant vectors can be used in a wide array of tasks, from information retrieval to part-of-speech tagging and parsing.

There has also been some recent work addressing how to create these vectors when information from multiple languages is available. Two recent attempts involve using canonical correlation analysis (CCA) to project pre-trained vectors from each of two languages into a common space (Faruqui and Dyer, 2014b) and using an alignment matrix to heuristically project the vectors from one language onto the words in another language (Guo et al., 2015). These methods generally only work with two languages at a time, however.

In this paper, we introduce a technique for constructing multilingual word embeddings that is inspired by the notion of translational invariance. CCA and the heuristic projection mentioned above both attempt to construct vectors such that words that are translations of each other are close in the vector space, but the method we introduce formalizes this as part of the objective function of the *original decomposition*. We further show how to optimize this objective function with a method that scales linearly in the size of the input data. This results in a scalable, single-step method that is informed by both the monolingual corpus statistics and the multilingual alignment data. We show experimentally that this results in vectors that outperform prior work on multilingual tasks and match the performance of prior work on monolingual tasks.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1084–1088,
Lisbon, Portugal, 17-21 September 2015.

The contributions of this paper are the following:

- **Problem formulation:** we formalize the notion of translation-invariance, *regardless of the number of languages*, as part of the objective function of a standard matrix decomposition;
- **Scalable algorithm:** we introduce scalable means of optimizing this augmented objective functions; and
- **Effectiveness:** we present state-of-the-art results on a multilingual task using the vectors obtained by these methods.

The code and data used in this paper are publicly available at `https://sites.google.com/a/umn.edu/huang663/`.

2 Problem Definition

The informal problem definition is the following:

Informal Problem. Given *a set of cooccurrence statistics between words in each of several languages, and a translation table containing alignment counts between words in each of these languages,* **Find** *a latent representation for each word in each language that (1) captures information from the cooccurrence statistics and (2) is* invariant *to translations of the cooccurrence statistics between languages.*

More formally, suppose we have M_1 words and N_1 contexts in the first language ("English"), and M_2 and N_2 for the second language ("Spanish"). Then, we are given two matrices of cooccurrence statistics (one for each language), with dimensions $M_1 \times N_1$ and $M_2 \times N_2$, and two dictionary matrices containing translations from English to Spanish, and from Spanish to English, repesctively. A more detailed description on how the data is obtained can be found in (Faruqui and Dyer, 2014b). For simplicity in what follows, we denote these matrices as

- $\mathbf{X}$: a single multilingual cooccurrence matrix (with all the $M_1 + M_2$ words as the rows, and $N_1 + N_2$ contexts as columns). Entries in this matrix specify the cooccurrence between a word in any language and a context in any language.
- $\mathbf{D}_1$: a word dictionary matrix (with all the $M_1 + M_2$ English and Spanish words as both rows and columns). Entries in this matrix specify which words are translations of which other words, and is generally block-normalized, so that (e.g.) each Spanish word has a probability distribution over English words.
- $\mathbf{D}_2$: a context dictionary matrix (with all the N_1+N_2 English and Spanish contexts as both rows and columns). This is similar to $\mathbf{D}_1$ in its construction.

We seek decompositions of $\mathbf{X}$ that are invariant to multiplications along each mode by its respective $\mathbf{D}$ matrix. Note that, while we only described the case where we have two languages, it is straightforward to extend this to having many languages in the combined $\mathbf{X}$, $\mathbf{D}_1$ and $\mathbf{D}_2$ matrices, and we do this in some of the experiments described below.

3 Translation-invariant LSA

Without the side information provided by the dictionary matrices, the classic method for generating word vectors finds a low-rank decomposition of the data matrix $\mathbf{X}$:

$$\min_{\mathbf{U},\mathbf{V}} \|\mathbf{X} - \mathbf{U}\mathbf{V}^T\|_F^2.$$

With proper scaling (see our discussion in §4.2), the rows of $\mathbf{U}$ (or rows of $\mathbf{V}$) are the word embeddings (or "context embeddings"). It is well-known that the solution is given by the principal components of the singular value decomposition (SVD) of $\mathbf{X}$. Generating word embeddings in this way is known as latent semantic analysis (LSA) (Deerwester et al., 1990).

Our method extends LSA to incorporate information from many languages at a time, with the constraint that the decomposition should be invariant to translation between these languages. We call this method *translation-invariant LSA* (TI-LSA).

In order to take the dictionary matrices $\mathbf{D}_1$ and $\mathbf{D}_2$ into consideration, we propose to seek a decomposition that can simultaneously explain the original matrix $\mathbf{X}$ and various translations of it. We can formalize this in the following objective function:

$$\min_{\mathbf{U},\mathbf{V}} \|\mathbf{X} - \mathbf{U}\mathbf{V}^T\|_F^2 + \|\mathbf{D}_1\mathbf{X} - \mathbf{U}\mathbf{V}^T\|_F^2 + \|\mathbf{X}\mathbf{D}_2^T - \mathbf{U}\mathbf{V}^T\|_F^2 + \|\mathbf{D}_1\mathbf{X}\mathbf{D}_2^T - \mathbf{U}\mathbf{V}^T\|_F^2. \quad (1)$$

By expanding and combining all four quadratic terms, we can see that the above problem is equivalent to (up to a constant difference)

$$\min_{\mathbf{U},\mathbf{V}} \|\tilde{\mathbf{X}} - \mathbf{U}\mathbf{V}^T\|_F^2, \quad (2)$$

where

$$\tilde{\mathbf{X}} = \frac{1}{4}\left(\mathbf{X} + \mathbf{D}_1\mathbf{X} + \mathbf{X}\mathbf{D}_2^T + \mathbf{D}_1\mathbf{X}\mathbf{D}_2^T\right)$$
$$= \frac{1}{4}(\mathbf{I} + \mathbf{D}_1)\mathbf{X}(\mathbf{I} + \mathbf{D}_2)^T.$$

Taking the SVD of $\tilde{\mathbf{X}}$ does not seem numerically appealing at first glance: even though $\mathbf{D}_1$, $\mathbf{D}_2$, and $\mathbf{X}$ are all very sparse, forming $\tilde{\mathbf{X}}$ explicitly will introduce a significant amount of nonzeros. However, as we will explain below, it is not necessary to explicitly form $\tilde{\mathbf{X}}$ in order to find a few principal components of it.

We propose to use the Lanczos algorithm (Golub and Van Loan, 1996, Chapter 9) to calculate the SVD of $\tilde{\mathbf{X}}$. The Lanczos method can be viewed as a generalization of the power method for computing an arbitrary number of principal components, and the basic operation required is only matrix-vector multiplication. For our problem specifically, the required matrix-vector multiplications $\tilde{\mathbf{X}}\boldsymbol{\mu}$ and $\tilde{\mathbf{X}}^T\boldsymbol{\nu}$ can be carried out very efficiently with three sparse matrix-vector multiplications, each with complexity linear in the number of nonzeros in the sparse matrix involved, so that any dense intermediate matrix is avoided. As a result, by using our implementation of the Lanczos method, the time required for calculating the SVD of $\tilde{\mathbf{X}}$ is not much more than that of $\mathbf{X}$, even though $\tilde{\mathbf{X}}$ is significantly denser than $\mathbf{X}$.

4 Experiments

We present three experiments to evaluate the method introduced in this paper. The first experiment uses our word embeddings in a cross-lingual dependency parsing task; the second experiment looks at monolingual (English) performance on a series of word-similarity tasks; and the final experiment shows the scalability of our method by applying it to multiple languages.

4.1 Cross-lingual evaluation

Guo et al. (2015) recently introduced a method for using multilingual word embeddings to perform cross-lingual dependency parsing. They train a neural-network-based dependency parsing model using word vectors from one language, and then test the model using data and word vectors from another language. They used the embeddings obtained by Faruqui and Dyer (2014b), along with a heuristic projection. Because we used the same data to obtain our embeddings, our method is directly comparable to the CCA method of Faruqui and Dyer, and the projection method of Guo et al.

Embedding method	LAS	UAS
CCA (Faruqui & Dyer)	60.7	69.8
Projection (Guo et al.)	61.3	71.1
TI-LSA	**62.8**	**72.5**

Table 1: Labeled and unlabeled attachment score (LAS/UAS) on a cross-lingual dependency task. TI-LSA outperforms prior work on this task.

We used code and data graciously provided by Guo to run experiments, training a dependency parsing model on their English treebank, and testing it on the Spanish treebank. We report the results below for the methods used by Guo et al. and the method introduced in this paper. We could not exactly reproduce Guo's result with the code we were provided, so we report all results from our use of the provided code, in case some parameter settings are different from those used in Guo's paper. The results are shown in Table 1. As can be seen in the table, our first method for obtaining multilingual embeddings outperforms both the CCA method of Faruqui and Dyer, and the heuristic projection used by Guo et al.

4.2 Monolingual evaluation

While our focus is on generating embeddings that are invariant to translations (and thus most suited to multi- or cross-lingual tasks), we would hope that the addition of multiple languages would not hurt performance on monolingual tasks. We used wordvectors.org (Faruqui and Dyer, 2014a) to evaluate our learned vectors on a variety of English-language word similarity tasks. The tasks are mostly all variations on performing word similarity judgments, finding the correlation between the system's output and human responses. We used the same data as that used by Faruqui and Dyer (2014b) (English-Spanish only), and thus our method for obtaining multilingual embeddings is directly comparable to their technique for doing the same (CCA). We used the first 11 tasks on wordvectors.org, and obtained Faruqui and Dyer's results from that website. Due to space constraints, we only report the average performance across these 11 tasks for each of the methods we tested. The results are shown in Table 2. To test statistical significance, we performed a paired permutation test, treating performance on each task as

Method	Average Correlation
CCA (Faruqui & Dyer)	0.638
LSA	0.626
TI-LSA	0.628

Table 2: Average correlation with human similarity judgments on 11 word-similarity tasks. The differences between these methods are not statistically significant, showing that the gains we see in cross-lingual tasks are not at the expense of monolingual tasks.

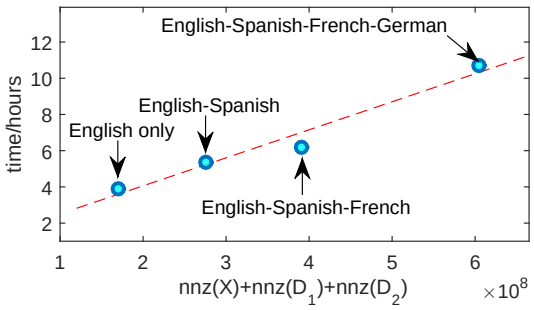

Figure 1: TI-LSA is linear in the number of nonzeros in the data matrices, and can easily scale to many languages.

paired data. The important thing to note from the table is that the differences between the methods are all quite small, and none of them are statistically significant.

Note that LSA on just the *English* data performs on par with all of the other methods presented; we have not found a way to improve performance on this monolingual task from using multilingual data.[1] However, it is also important to note that our multilingual methods do not *hurt* performance on these monolingual tasks, either—we get the benefits described in our other evaluations without losing performance on English-only tasks.

4.3 Scalability

We mentioned in Section 3 that our method is linear in the number of nonzeros in the data, as we are simply using the Lanczos algorithm to compute a sparse SVD. To show this in practice, we briefly present how the running time of our algorithm scales with the number of languages used. Each additional language adds roughly the same amount of data to the $\mathbf{X}$ matrix. Figure 1 shows that our method does indeed scale linearly with the number of nonzeros in the matrix, and thus also with the number of languages used (assuming each language has roughly the same amount of data). All the experiments are performed in MATLAB 2013a on a Linux server with 32 Xeon 2.00GHz cores and 128GB memory.

5 Discussion

We discuss here two points on the flexibility of the method we have introduced. First, note that the dictionary matrices we used contained information about translations between languages. It is also possible to include information about *paraphrases* in this dictionary. For instance, a resource such as the Paraphrase Database (Ganitkevitch et al., 2013) could be used to further constrain the embeddings obtained; this could be useful if the resource used to obtain a paraphrase dictionary contained more or different information than the corpus statistics used in the decomposition.

Second, note that we have two dictionaries, one for the words and one for the contexts. These dictionaries correspond to the modes of the matrix; we have one dictionary matrix per mode, and we always multiply the dictionary along its corresponding mode. It would be easy to extend this method to a setting where the data is a 3-mode tensor instead of a matrix, e.g., if the data were (subject, verb, object) triples, or relation triples in some knowledge base. In these settings, the dictionaries used for each mode might be more different; in the subject-verb-object example, one of the dictionaries would only have verbs, while the other two would only have nouns, for instance. Standard tensor decompositions could be augmented with a translation-invariance term, similar to what we have done with matrices in this work.

6 Related Work

The most closely related work is that of Faruqui and Dyer (2014b), whose CCA-based method we have already mentioned; however, it is not obvious how CCA-based methods can be applied to more than two languages at a time. Our work is also similar to prior work on multilingual latent semantic analysis; Bader and Chew (2008) also include a translation dictionary when decomposing the $\mathbf{X}$ matrix, though their formulation uses a term-document matrix instead of a word-context

[1] This is in contrast to the results reported by Faruqui and Dyer, who by our evaluation also do not improve performance using multilingual data. To obtain word vectors from our decomposition, we used only the U component of the SVD; including the singular values, as Faruqui and Dyer did, gives worse performance. We confirmed this with the authors, and replicated their result for English-only LSA when using the singular values.

matrix, and the way they use the translation dictionary is quite different.

7 Conclusions

We have presented a new technique for generating word embeddings from multilingual corpora. This technique formalizes the notion of translation invariance into the objective function of the matrix decomposition and provides flexible and scalable means for obtaining word vectors where words that are translations of each other are close in the learned vector space. Through three separate evaluations, we showed that our technique gives superior performance on multilingual tasks, matches prior work on monolingual tasks, and scales linearly in the size of the input data. The code and data used in this paper are available at `https://sites.google.com/a/umn.edu/huang663/`.

Abstract

This paper proposes a method for hierarchical phrase-based stream decoding. A stream decoder is able to take a continuous stream of tokens as input, and segments this stream into word sequences that are translated and output as a stream of target word sequences. Phrase-based stream decoding techniques have been shown to be effective as a means of simultaneous interpretation. In this paper we transfer the essence of this idea into the framework of hierarchical machine translation. The hierarchical decoding framework organizes the decoding process into a chart; this structure is naturally suited to the process of stream decoding, leading to an efficient stream decoding algorithm that searches a restricted subspace containing only relevant hypotheses. Furthermore, the decoder allows more explicit access to the word re-ordering process that is of critical importance in decoding while interpreting. The decoder was evaluated on TED talk data for English-Spanish and English-Chinese. Our results show that like the phrase-based stream decoder, the hierarchical is capable of approaching the performance of the underlying hierarchical phrase-based machine translation decoder, at useful levels of latency. In addition the hierarchical approach appeared to be robust to the difficulties presented by the more challenging English-Chinese task.

1 Introduction

Statistical machine translation traditionally operates on sentence segmented input. This technology has advanced to the point where it is becoming capable enough to be useful for many applications. However, this approach may be unsuitable for simultaneous interpretation where the machine translation system is required to provide translations within a reasonably short space of time after words have been spoken. Under this type of constraint, it may not be possible to wait for the end of the sentence before translating, and segmentation at the sub-sentential level may be required as a consequence. This segmentation process is difficult, even for skilled human interpreters, and presents a major challenge to a machine since in addition to the translation process, decisions need to be made about when to commit to outputting a partial translation. Such decisions are critical since once such an output is made it can be difficult and highly undesirable to correct it later if it is in error.

2 Related Work

In order to automatically perform segmentation for interpretation, two types of strategy have be proposed. In the first, which we will call presegmentation, the stream is segmented prior to the start of the machine translation decoding process, and the machine translation system is constrained to translate using the given segmentation. This approach has the advantage that it can be implemented without the need to modify the machine translation decoding software. In the second type of strategy, which we will call incremental decoding, the segmentation process is performed during the decoding of the input stream. In this approach the segmentation process is able to exploit segmentation cues arising from the decoding process itself. That is to say, the order in which the decoder would prefer to generate the target sequence is taken into account.

A number of diverse strategies for presegmentation were studied in (Sridhar et al., 2013). They studied both non-linguistic techniques, that included fixed-length segments, and a "hold-output" method which identifies contiguous blocks of text that do not contain alignments to words outside them, and linguistically-motivated segmentation techniques beased on segmenting on

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1089–1094,
Lisbon, Portugal, 17-21 September 2015.

conjunctions, sentence boundaries and commas. Commas were the most effective segmentation cue in their investigation.

In (Oda et al., 2014) a strategy for segmentation prior to decoding based on searching for segmentation points while optimizing the BLEU score was presented. An attractive characteristic of this approach is that the granularity of the segmentation could be controlled by choosing the number of segmentation boundaries to be inserted, prior to the segmentation process. In (Matusov et al., 2007) it was shown that the prediction and use of soft boundaries in the source language text, when used as re-ordering constraints can improve the quality of a speech translation system.

(Siahbani et al., 2014) used a pre-segmenter in combination with a left-to-right hierarchical decoder (Watanabe et al., 2006) to achieve a considerably faster decoder in return for a small cost in terms of BLEU score.

A phrase-based incremental decoder called the stream decoder was introduced in (Kolss et al., 2008b), and further studied in (Finch et al., 2014). Their results, conducted on translation between European languages, and also on English-Chinese, showed that this approach was able to maintain a high level of translation quality for practically useful levels of latency. The hierarchical decoding strategy proposed here is based on this work.

2.1 Stream Decoding

The reader is referred to the original paper (Kolss et al., 2008a) for a complete description of the stream decoding process; in this section we provide a brief summary.

Figure 1 depicts a stream decoding process, and the figure applies to both the original phrase-based technique, and the proposed hierarchical method. The input to the stream decoder is a stream of tokens (it is also possible for the decoder to operate on tuples of confusable token sequences from a speech recognition decoder). As new tokens arrive, states in the search graph are extended with the new possible translation options arising from the new tokens. Periodically the stream decoder will commit to outputting a sequence of target tokens. At this point a state from the search graph is selected, the search graph leading from this state is kept, and the remainder discarded. The search then continues using the pruned search graph. The language model context is preserved at this state for use during the subsequent decoding. In this manner the stream decoder is able to jointly segment and translate a continuous stream of tokens that contains no segment boundary information; the segmentation occurs as a natural by-product of the decoding process. Re-ordering occurs in exactly the same manner as the sentence-by-sentence hierarchical decoder, and word re-ordering within segments is possible.

2.1.1 Latency Parameters

The stream decoding process is governed by two parameters L_{max} and L_{min}. These parameters are illustrated in Figure 1. The L_{max} parameter controls the maximum latency of the system. That is, the maximum number of tokens the system is permitted to fall behind the current position. If interpreting from speech, the parameter represents the number of words the system is allowed to fall behind the speaker, before being required to provide an output translation. This parameter is a hard constraint that guarantees the system will always be within L_{max} tokens of the current last token in the stream of input tokens. The parameter L_{min} represents the minimum number of words the system will lag behind the last word spoken. It serves as a means of preventing the decoder from committing to a translation too early.

Both the phrase-based and hierarchical phrase-based stream decoders maintain a sequence of tokens that represent the sequence of untranslated tokens from the input stream (see Figure 1). As new tokens arrive from the input stream, they are added to the end of the sequence. When the length of this sequence reaches L_{max}, the decoder is forced to provide an output.

2.1.2 Phrase-based Segmentation

When forced to commit to a translation, the phrase-based decoder rolls back the best hypothesis state by state, until the remaining state sequence translates a contiguous sequence of source words starting from beginning of the sequence of untranslated words, and the number of words that would remain in the sequence of untranslated words after the translation is made, is at least L_{min}. It is possible that no such state exists, in which case since the stream decoder is required to make an output, it must use an alternative strategy.

In this alternative strategy, the stream decoder will undertake a new decoding pass in which it is forced to make a monotonic step as the first step in the decoding process. Then, a state is selected from the best hypothesis using the roll-back strategy above. This process may also fail if the monotonic step would lead to the violation of L_{min}. In the implementation of (Finch et al., 2014), the decoder is permitted to violate L_{min} only in this case.

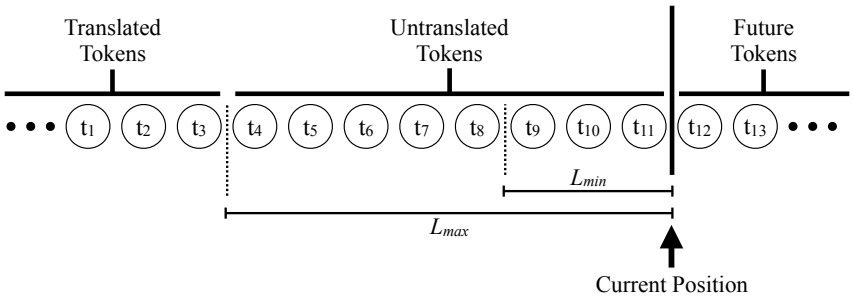

Figure 1: The stream decoding process.

2.1.3 The Proposed Method

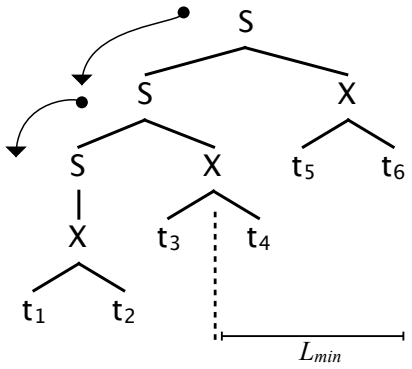

Figure 2: Selecting a segmentation point during hierarchical decoding.

The proposed hierarchical method attempts to capture the spirit of the phrase-based method. When forced to commit to a translation of a sequence of n words, the segmentation process is simple and guided direcly by the chart.

As in the phrase-based approach, the best hypothesis at the top of the chart is used to provide the partial translation and segmentation point. This hypothesis has a span of $[1, n]$ over the source words. The left child of the rule (defined in accordance with the binarized grammar used by the decoder) that was applied to create this hypothesis is examined; let its span be $[1, k]$. If $n - k \geq L_{min}$, then this partial hypothesis represents a translation of the first k words of the sentence that leaves at least L_{min} words untranslated, and therefore the target word sequence from this partial hypothesis is output, and the associated source words are removed from the sequence of untranslated words. If this hypothesis is not able to meet the constraint, the parse tree traversal continues in the same manner: depth first along the left children until either a translation can be made, or no further traversal is possible.

Following the translation of of word sequence, similar to the phrase-based stream decoder of (Finch et al., 2014), the hierarchical stream decoder proceeds from an initial state in which the language model context is preserved. The decoding process relies on an implicit application of the glue grammar to connect the past and future nodes. An visual example of this selection process is given in Figure 2. In this example, the neither the root of the tree (spanning $t_1t_2t_3t_4t_5t_6$) nor its left child (spanning $t_1t_2t_3t_4$) are not able to generate an output since they both span sequences of words that would violate L_{min}, which is 3 in this example. The left child two levels down from the root node spans only t_1t_2 and would leave 4 words untranslated, therefore it defines an acceptable segmentation point.

Instead of forcing a monotonic decoding step in the event of a failure to find a segmentation point during the decoding, the hierarchical stream decoder directly eliminates hypotheses that would lead to such a failure. The search process is constrained such that all parse trees that cover the first word of the source sentence, must contain a subtree that can give rise to a translation that does not violate L_{min} (constituents that can produce translations cannot span more than $L_{max} - L_{min}$ words). Any search state that would violate this constraint is not allowed to enter the chart. This property is recursively propagated up the chart during the parsing process ensuring that each entry placed into the first column of the chart contains a constituent that could be used to produce a translation.

This approach is more appealing than the forced monotonic step in that it will also allow non-monotonic translations that are guaranteed to be usable. Similar to the phrase-based approach, in some circumstances it may not be possible to produce a parse that does not violate L_{min}, and only in this rare case is the decoder allowed to violate L_{min} in order to guarantee maximum latency.

Figure 3: Stream decoding performance for several language pairs. The baseline was the same hierarchical phrase-based decoder, but decoded in the usual manner sentence-by-sentence without the stream decoding process. The baseline used the sentence segmentation provided by the corpus.

3 Experiments

3.1 Corpora

In all experiments, we used the TED[1] talks data sets from the IWSLT2014 campaign. We evaluated on English-to-Spanish, and English-to-Chinese translation using the same data sets that were used in (Finch et al., 2014). These pairs were chosen to include language pairs with a relatively monotonic translation process (English-Spanish) and (English-French), and also language pairs that required a greater amount of word re-ordering for example (English-Chinese). The Chinese corpus was segmented using the Stanford Chinese word segmenter (Tseng et al., 2005) according to the Chinese Penn Treebank standard.

3.2 Experimental Methodology

Our stream decoder was implemented within the framework of the AUGUSTUS decoder, a hierarchical statistical machine translation decoder (Chiang, 2007) that operates in a similar manner to the moses-chart decoder provided in the Moses machine translation toolkit (Koehn et al., 2007). The training procedure was quite typical: 5-gram language models were used, trained with modified

Figure 4: Example translation segmentation from the English-Spanish task ($L_{max} = 8$ and $L_{min} = 4$).

Kneser-Ney smoothing; MERT (Och, 2003) was used to train the log-linear weights of the models; the decoding was performed with a distortion limit of 20 words.

To allow the results to be directly comparable to those in (Finch et al., 2014), the talk level BLEU score (Papineni et al., 2001) was used to evaluate the machine translation quality in all experiments.

3.3 Results

The results for decoding with various values of the latency parameters are shown in Figure 3 for English-French, English-Spanish, English-Arabic, English-Hebrew, English-Russian and English-Chinese. Overall the behavior of the system was quite similar in character to the published results for phrase-based stream decoding for English-Spanish (Kolss et al., 2008b; Finch et al., 2014). The hierarchical system seemed to be more sensitive to small values of minimum latency, and less sensitive to larger values. The results for the more challenging English-Chinese pair were more surprising. In (Finch et al., 2014), the performance of the phrase-based decoder suffered as expected in comparison to pairs of European languages. This was in line with the increase in difficulty of the task due to word order differences. However, in comparison to prior results published on the phrase-based stream decoder, the hierarchical stream decoder seems less affected by the differences between these languages; the curves are higher at the optimal values of minimum latency, and seem less sensitive to its value. The character of the results appears to be very similar to those from English-Spanish. This result is encouraging and suggests that the hierarchical method may be better suited to interpreting between the more difficult language pairs. Figure 4 shows the segmentation given by the system with $L_{max} = 8$ and $L_{min} = 4$, on a sequence of English words which is a subsequence of an unseen test stream of words being decoded.

4 Conclusion

In this paper we propose and evaluate the first hierarchical phrase-based steam decoder. The standard hierarchical phrase-based decoding process generates from the source in left-to-right order, making it naturally suited for incremental decoding. The hierarchical decoder organizes the search process in a chart which can be directly exploited to perform stream decoding. The proposed hierarchical stream decoding process only searches a subset of the search space that is capable of generating useful partial translation hypothesis. This eliminates the necessity for the forced monotonic step necessary in the phrase-based counterpart. Hypotheses that are not useful are discarded, and are therefore not able to compete with useful hypotheses in the search. Additionally, a beneficial side-effect of the pruning of the search space is that decoding speed increased by a factor of approximately 8 over the baseline sentence-by-sentence decoder. Looking to the future, one important benefit of taking a hierarchical approach is that the re-ordering process is made explicit, and in further research we wish to explore the possibility of introducing of new interpretation-oriented rules into the stream decoding process.

Abstract

In syntax-based machine translation, rule selection is the task of choosing the correct target side of a translation rule among rules with the same source side. We define a discriminative rule selection model for systems that have syntactic annotation on the target language side (string-to-tree). This is a new and clean way to integrate soft source syntactic constraints into string-to-tree systems as features of the rule selection model. We release our implementation as part of Moses.

1 Introduction

Syntax-based machine translation is well known for its ability to handle non-local reordering. Syntax-based models either use linguistic annotation on the source language side (Huang, 2006; Liu et al., 2006), target language side (Galley et al., 2004; Galley et al., 2006) or are syntactic in a structural sense only (Chiang, 2005). Recent shared tasks have shown that systems integrating information on the target language side, also called *string-to-tree* systems, achieve the best performance on several language pairs (Bojar et al., 2014). At the same time, soft syntactic features significantly improve the translation quality of hierarchical systems (Hiero) as shown in (Marton et al., 2012; Chiang, 2010; Liu et al., 2011; Cui et al., 2010). Improving the performance of string-to-tree systems through the integration of soft syntactic constraints on the source language side is therefore an interesting task.

So far, all approaches on this topic include soft syntactic constraints into the rules of string-to-tree (Zhang et al., 2011; Huck et al., 2014) or string-to-dependency (Huang et al., 2013) systems and define heuristics to determine to what extent these constituents match the syntactic structure of the source sentence. We propose a novel way to integrate soft syntactic constraints into a string-to-tree system. We define a discriminative rule selection model for string-to-tree machine translation. We consider rule selection as a multi-class classification problem where the task is to select the correct target side of a rule given its source side as well as contextual information about the source sentence and the considered rule. So far, such models have been applied to systems without syntactic annotation on the target language side. He et al. (2008), He et al. (2010) and Cui et al. (2010) apply such rule selection models to hierarchical machine translation, Liu et al. (2008) to tree-to-string systems and Zhai et al. (2013) to systems based on predicate argument structures. When target side syntactic annotations are taken into account, the task of rule selection has to be reformulated (see Section 2) while the same type of model can be used in approaches without target annotations. This work is the first attempt to define a rule selection model for a string-to-tree system. We make our implementation publicly available as part of Moses.[1]

We show in Section 2 that string-to-tree rule selection is different from the hierarchical case addressed by previous work and define our rule selection model. In Section 3 we present the training procedure before providing a proof-of-concept evaluation in Section 4.

2 Rule selection for string-to-tree SMT

2.1 String-to-tree machine translation

We present string-to-tree machine translation as implemented in Moses (which is the framework that we use). String-to-tree rules have the form $X/A \rightarrow \langle \alpha, \gamma, \sim \rangle$. On the source language side,

[1] We use the string-to-tree component of Moses (Williams and Koehn, 2012; Hoang et al., 2009) in which we integrate the high-speed classifier Vowpal Wabbit http://hunch.net/~vw/.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1095–1101,
Lisbon, Portugal, 17-21 September 2015.

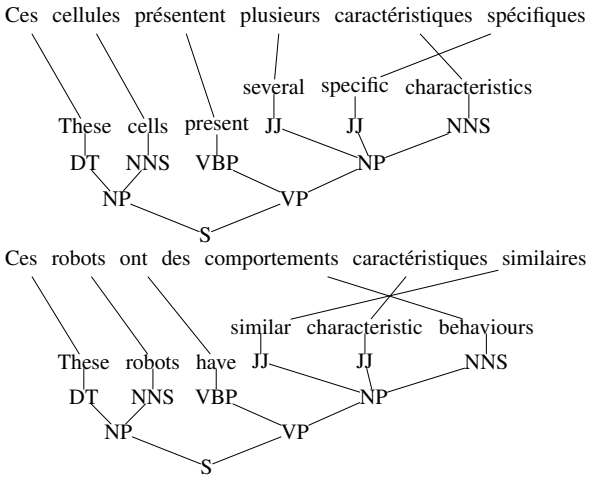

Figure 1: Word-aligned sentence pairs with target-side parse.

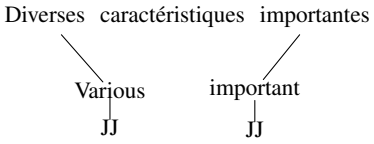

Figure 2: Partial translation during decoding.

all non-terminals have the unique label X while on the target language side non-terminals are annotated with syntactic labels $n_t \in N_t$. The left-hand side X/A consists of source and target non-terminals. In the right hand side (rhs), α is a string of source terminal symbols and the non-terminal X. The string γ consists of target terminals and non-terminals $n_t \in N_t$. The alignment $\sim$ is a one-to-one correspondence between source and target non-terminal symbols. String-to-tree rules are extracted from pairs of strings and trees as exemplified in Figure 1. Rules r_1 and r_2 are example rules extracted from this data.

(r_1) $X/NP \rightarrow \langle\ X_1$ caractéristiques X_2, $JJ_1\ JJ_2$ characteristics $\rangle$
(r_2) $X/NP \rightarrow \langle\ X_1$ caractéristiques X_2, NNS_1 characteristic $JJ_2\ \rangle$

During decoding, CYK+ chart parsing (Chappelier et al., 1998) with cube pruning and language model scoring is performed on an input sentence such as F below. Each time a rule is applied to the input sentence, candidate target trees are built. Figure 2 shows the partial translations built after the segments *Diverses* and *importantes* have been decoded. Given these partial translations, rule r_1 can be applied in a further decoding step.

F (Diverses)$_{X1}$ caractéristiques (importantes)$_{X2}$ n'ont pas été prises en compte.
(Various)$_{X_1}$ ***characteristics*** *(important)*$_{X_2}$ *were not considered.*

2.2 String-to-tree rule selection

Rule selection is the problem of selecting the rule with the correct target side among rules with the same source side. For hierarchical machine translation (Hiero), the rule selection problem consists of choosing, among r_3 and r_4, the rule that correctly applies to F (r_3 in our example).

(r_3) $X/X \rightarrow \langle\ X_1$ caractéristiques X_2, $X_1\ X_2$ characteristics $\rangle$
(r_4) $X/X \rightarrow \langle\ X_1$ caractéristiques X_2, X_1 characteristic $X_2\ \rangle$

Rule selection models disambiguate between these rules using context information about the source sentence and the shape of the rules.

In string-to-tree machine translation, the rule selection problem is different. Because the decoding process is guided by target side syntactic annotation, partial trees built during decoding must be considered when new rules are applied. For instance, when a rule is selected to translate sentence F given the partial translations in Figure 2, then the non-terminals in the target side of this rule must match the constituents selected so far. Consequently, rules r_1 and r_2 (Section 2.1) are not competing during rule selection.[2] Competing rules for r_1 would be r_5 and r_6 below.

(r_5) $X/NP \rightarrow \langle\ X_1$ caractéristiques X_2, JJ_1 properties $JJ_2\ \rangle$
(r_6) $X/NP \rightarrow \langle\ X_1$ caractéristiques X_2, $JJ_1\ JJ_2$ features $\rangle$

For consistency with decoding, we redefine the rule selection problem for the string-to-tree case. In this setup, it is the task of disambiguating rules with the same source side *and aligned target non-terminals*. As a consequence, our rule selection model (presented next) is not only normalized over the source rhs of the rules but also takes target non-terminals into account. The default rule scoring procedure for string-to-tree rules implemented in Moses uses the same normalization as we do. However, Williams and Koehn (2012) propose to normalize string-to-tree rules over the source rhs only.

[2]This is because their target side non-terminals are different.

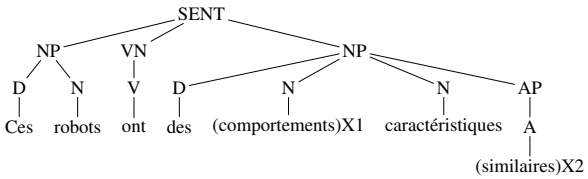

Figure 3: French sentence with input parse tree.

2.3 Rule selection model

We denote string-to-tree rules with $X/A \rightarrow \langle \alpha, \gamma, \sim \rangle$, as in Section 2.1. By $\tilde{N}t_t$, we denote target non-terminals with their alignment to source non-terminals.[3] $C(f, \alpha)$ is context information in the source sentence f and the source side α. $R(\alpha, \gamma)$ represents features on string-to-tree rules. The rule selection model estimates $P(\gamma \mid C(f, \alpha), R(\alpha, \gamma), \alpha, \tilde{N}t_t)$ and is normalized over the set G' of candidate target sides γ' for a given α *and* $\tilde{N}t_t$. The function $GTO : \alpha \rightarrow G'$ generates, given the source side α and target non-terminals $\tilde{N}t_t$, the set G' of all corresponding target sides γ'. The estimated distribution can be written as:

$$P(\gamma \mid C(f,\alpha), R(\alpha,\gamma), \alpha, \tilde{N}t_t) = \frac{\exp(\sum_i \lambda_i h_i(C(f,\alpha), R(\alpha,\gamma), \alpha, \tilde{N}t_t)))}{\sum_{\gamma' \in GTO(\alpha, \tilde{N}t_t)} \exp(\sum_i \lambda_i h_i(C(f,\alpha), R(\alpha,\gamma'), \alpha, \tilde{N}t_t))}$$

In the same fashion as (Cui et al., 2010) do for the hierarchical case, we define a global rule selection model instead of a model that is local to the source side of each rule.

To illustrate the feature templates $C(f, \alpha)$ and $R(\alpha, \gamma)$ of our rule selection model, we suppose that rule r_1 has been extracted from the French sentence in Figure 3. The syntactic features are:

- Does α match a constituent: *no_match*
- Type of matched constituent: *None*
- Lowest parent of unmatched constituent: *NP*
- Span width covered by α: *3*

The rule internal features are:

- Source side α: *X1_caractéristiques_X2* (one feature)
- Target side γ: *JJ1_JJ2_characteristics*
- Aligned terminals in α and γ: *caractéristiques↔characteristics*
- Aligned non-terminals in α and γ: *X1↔JJ1_X2↔JJ2*
- Best baseline translation probability: *Most_Frequent*

Our rule selection model is integrated in the Moses string-to-tree system as an additional feature of the log-linear model.

[3]For rule r_1,r_5 and r_6, $\tilde{N}t_t$ would be JJ_1 and JJ_2.

3 Model Training

We create training examples using the rule extraction procedure in (Williams and Koehn, 2012).[4] We begin by generating a rule-table using this procedure. Then, each time a rule $r : X/A \rightarrow \langle \alpha, \gamma, \sim \rangle$ can be extracted from the training data, we generate a new training example. The target side γ of the extracted rule is a positive instance and gets a loss of 0. To generate negative samples, we collect all rules $r_2, \ldots, r_n$ that have the same source language side as r as well as the same aligned target non-terminals $\tilde{N}t_t$. Each of these rules is a negative example and gets a cost of 1. As an example, suppose that rule r_1 introduced in Section 2.1 has been extracted from the training example in Figure 1. The target side "JJ_1 JJ_2 characteristics" is a correct class and gets a cost of 0. The target side of all other rules having the same source side *and aligned target non-terminals*, such as rule r_5 and r_6, are incorrect classes.

For model training, we use the cost-sensitive one-against-all-reduction (Beygelzimer et al., 2005) of Vowpal Wabbit (VW).[5] We avoid overfitting to training data by employing early stopping once classifier accuracy decreases on a held-out dataset.[6]

4 Experiments

4.1 Experimental Setup

Our baseline system is a syntax-based system with linguistic annotation on the target language side (*string-to-tree*). We use the version implemented in the Moses open source toolkit (Hoang et al., 2009; Williams and Koehn, 2012) with standard parameters. Rule extraction is performed as in (Galley et al., 2004) with rule composition (Galley et al., 2006; DeNeefe et al., 2007). Non-lexical unary rules are removed (Chung et al., 2011) and scope-3 pruning (Hopkins and Langmead, 2010) is performed. Rule scoring is done using relative frequencies normalized over the source rhs and aligned non-terminals in the target rhs. The contrastive system is the same string-to-tree system but augmented with our rule selection model as a feature of the log-linear model.

[4]Which is based on (Galley et al., 2004; Galley et al., 2006; DeNeefe et al., 2007).

[5]Specifically, the label dependent version of *Cost Sensitive One Against All* which uses classification.

[6]We use the development set which is also used for MIRA tuning.

System	science	medical	news
Baseline	34.06	49.87	18.35
Contrastive	34.36	49.57	18.59

Table 2: String-to-tree system evaluation results.

We evaluate the baseline and our global model on three domains: (1) news, (2) medical, and (3) science. The training data for news is taken from Europarl-v4. Development and test sets are from the news translation task of WMT 2009 (Callison-Burch et al., 2009). For medical we use the biomedical data from EMEA (Tiedemann, 2009). Since this is a parallel corpus only, we first removed duplicate sentences and then constructed development and test sets by randomly selecting sentence pairs. As training data for science we use the scientific abstracts data provided by Carpuat et al. (2013). Table 1 gives an overview of the corpora sizes.

Berkeley parser (Petrov et al., 2006) is used to parse the English side of each parallel corpus (for string-to-tree rule extraction) as well as for parsing the French source side (for feature extraction). We trained a 5-gram language model on the English side of each training corpus using the SRI Language Modeling Toolkit (Stolcke, 2002). We train the model in the standard way and generate word alignments using GIZA++. After training, we reduced the number of translation rules by only keeping the 30-best rules with the same source side according to the direct rule translation rule probability. Our rule selection model was trained with VW. All systems were tuned using batch MIRA (Cherry and Foster, 2012). We measured the overall translation quality with 4-gram BLEU (Papineni et al., 2002), which was computed on tokenized and lowercased data for all systems. Statistical significance is computed with the pairwise bootstrap resampling technique of Koehn (2004).

4.2 Results

Table 2 displays the BLEU scores for our experiments. On science and news, small improvements are achieved while for medical a small decrease is observed. None of these differences is statistically significant.

An analysis of the system outputs for each domain showed that the small improvements are due to the fact that in string-to-tree systems there is not enough ambiguity between competing rules during decoding. To support this conjecture, we first analyzed rule diversity by looking at the negative samples collected during training example acquisition. In a second step, we compared the results of the string-to-tree systems in Table 2 with a system where the translation rules are much more ambiguous. To this aim, we applied our approach to a hierarchical system in the same line as (Cui et al., 2010). Finally, we further tested the ability of our system to disambiguate between competing rules by training a model on the concatenation of all domains.

4.3 Analysis of Rule Diversity

The amount of competing rules during decoding can be estimated by looking at the negative samples collected for each training example. This analysis showed that the diversity of rules containing non-terminal symbols is limited. We present rules q_1 to q_3 (taken from science) to illustrate the poor diversity observed in our training examples.

(q_1) $X/PP \rightarrow \langle$ à X_1 X_2 éventail X_3, to DT_1 JJ_2 variety $PP_3 \rangle$
(q_2) $X/PP \rightarrow \langle$ à X_1 X_2 éventail X_3, to DT_1 JJ_2 range $PP_3 \rangle$
(q_3) $X/PP \rightarrow \langle$ à X_1 X_2 éventail X_3, to DT_1 JJ_2 array $PP_3 \rangle$

Rules q_1 to q_3 are the only rules with source side *à* X_1 X_2 *éventail* X_3. This number is very low given that the source side contains three non-terminal symbols out of which two are adjacent. Moreover, the difference between these rules is limited to the lexical translation of *éventail*. This lack of diversity is due to the constraint that competing string-to-tree rules must have the same aligned non-terminal symbols, which is taken into account when collecting negative samples. In other words, the ambiguity between translation rules in a string-to-tree system is heavily restricted by the target side syntax.

The observed lack of diversity could be minimized by allowing rules with the same source rhs to have different aligned target non-terminals. In this perspective, rule scoring should be done by normalizing over the source rhs only as in Williams and Koehn (2012). The rule selection model in Section 2.3 should then be redefined and normalized over all rules with the same source rhs. Another way to improve rule diversity would be to remove target non-terminals and use preference

grammars as in Huck et al. (2014).

4.4 Comparison with Hierarchical Rule Selection

We applied our approach in a hierarchical phrase-based setting (Hiero). To this end, we trained 3 Hiero baseline systems and 3 Hiero systems augmented with our rule selection model on the data given in Section 4.1. The results of these experiments are shown in Table 3. Our augmented system largely outperforms the baselines. Interestingly, hierarchical rule selection significantly helps on the medical and scientific domain but still yields results that are significantly lower than those of the string-to-tree systems. This indicates that systems with target side syntax better disambiguate than hierarchical models with improved rule selection. Overall, we find the results of both types of systems promising and we will consider how to introduce more diversity into the rules of string-to-tree systems.

4.5 Concatenation of Training Data

In order to further evaluate the ability of our model to disambiguate string-to-tree rules, we trained a system using the concatenated training data of all 3 domains as presented in Section 4.1. This global model was then used to tune and decode using the development and test data of each domain. The results in Table 4 show that even on concatenated data our rule selection model does not improve over the baseline.

System	science	medical	news
Baseline	33.78	49.48	19.12
Contrastive	33.87	49.14	19.00

Table 4: String-to-tree system evaluation results with concatenated training data.

5 Conclusion and future work

We presented the first attempt to define a rule selection model with syntactic features for string-to-tree machine translation. We have shown that in order to be applied to the string-to-tree case, the rule selection problem must be redefined. An extensive evaluation on French-English translation tasks for different domains has shown that rule selection cannot significantly improve string-to-tree systems. An analysis of rule diversity and an empirical comparison with hierarchical rule selection indicate that the low improvements are due to the fact that the ambiguity between string-to-tree rules is too small to be improved with a rule selection model. In future work, we will use different techniques to improve the diversity of the string-to-tree rules considered during decoding in our system.

Acknowledgements

We thank all members of the DAMT team of the 2012 JHU Summer Workshop. We are especially grateful to Hal Daumé III and Ales Tamchyna for their ongoing support in the implementation of our system. We also thank Andreas Maletti for his shared expertise on tree grammars. Abstract

Language use is known to be influenced by personality traits as well as by socio-demographic characteristics such as age or mother tongue. As a result, it is possible to automatically identify these traits of the author from her texts. It has recently been shown that knowledge of such dimensions can improve performance in NLP tasks such as topic and sentiment modeling. We posit that machine translation is another application that should be personalized. In order to motivate this, we explore whether translation preserves demographic and psychometric traits. We show that, largely, both translation of the source training data into the target language, and the target test data into the source language has a detrimental effect on the accuracy of predicting author traits. We argue that this supports the need for personal and personality-aware machine translation models.

1 Introduction

Computational personality recognition is garnering increasing interest with a number of recent workshops exploring the topic (Celli et al., 2014; Tkalčič et al., 2014). The addition of personality as target traits in the PAN Author Profiling challenge in 2015 (Rangel et al., 2015) is further evidence. Such user modeling – when performed on text – is built on a long-standing understanding that language use is influenced by socio-demographic characteristics such as age, gender, education level or mother tongue and personality traits like agreeableness or openness (Tannen, 1990; Pennebaker et al., 2003).

In this work we explore *multilingual* user modelling. The motivation is not only to enable modeling in multiple languages, but also to enable modeling multilingual users who may express different sides of their personality in each language. One way to address multilinguality in this context is to create models separately in each language, and then fuse the resulting models. However, labelled data of this nature, particularly in non-English languages, is often not available. Personality labelling is time consuming, requiring the completion of psychometric questionnaires which may be considered invasive by many. An alternative is the use of machine translation (MT) to bootstrap corpora in resource poor languages, and to translate the user's content into a single language before modeling. Translated text, either manually or automatically generated, is known to have different characteristics than native text. Yet, MT was shown to be of use within traditional NLP tasks such as sentiment analysis (Balahur and Turchi, 2012). We explore the utility of MT for classification of demographic and personality traits.

MT models, even domain-specific, are user-generic. Thus, the linguistic signals of user traits which are conveyed in the original language may not be preserved over translation. In other words, the attributes on which we wish to rely for modelling may be lost. This concern is perhaps most observable with gender, a trait of the speaker that is encoded in the morphology of many languages, though not in English. Gendered translation was the topic of research for many years. However, the gender of the author is largely ignored by MT systems, and specifically statistical ones, that would often arbitrarily (or rather statistically-based) translate into one gender form or another. Other demographic and personality traits have not yet been investigated.

One way to address this concern is *personalized* translation, or *author-aware* translation.[1] The first step toward this goal would be to consider the author traits in the model. Such an approach has already shown to be useful for several NLP tasks (Volkova et al., 2013; Hovy, 2015). However, before embarking on this challenging task, we explore if the above concerns are founded by addressing the research question: does MT has an impact on the classification of demographic and personality traits?

2 Background

Oberlander and Nowson (2006) motivated their study of computational personality recognition by arguing that automatically understanding an author's personality would permit the personalization of sentiment analysis. Such personalized NLP has recently been

*This work was mostly done while the first author was at Xerox Research Centre Europe.

[1] In this work we investigate MT awareness of the author; in (Mirkin and Meunier, 2015) we address the task of reader-aware MT.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1102–1108,
Lisbon, Portugal, 17-21 September 2015.

explored by Volkova et al. (2013). They incorporated age and gender features for sentiment analysis, and show improvements in three different languages. Hovy (2015) extends this work to other languages and NLP tasks. Using demographically-informed word embeddings, they show improvements in sentiment analysis, topic classification and trait detection. None of these works, however, addressed cross-lingual issues.

Yet, personality projection goes beyond automatic detection of traits – there is also human perception to be considered. The casual reader may not be aware of personality related linguistic cues. Yet, studies have shown that traits can be reliably detected following cold readings of texts from unknown authors (Mehl et al., 2006; Gill et al., 2012) without such explicit knowledge. Although personality projection in different languages is under-explored, it has been shown that the relationship between language use and personality traits varies between domains (Nowson and Gill, 2014). Thus, while it would seem that there are cues which translate directly between languages, this may not always be the case. In English, for example, women tend to use first-person pronouns such as "*I*" more than men (Newman et al., 2008); but this does not guarantee a gender-based usage difference for, say, "*je*" in French. Furthermore, what happens with more subtle, language-specific indicators of personality? For instance, Nowson (2006) showed that use of contractions (e.g. *don't* vs. *do not*) is a marker for the Agreeableness trait. These different forms do not naturally translate into other languages. It is doubtful that even a human translator would always pay attention to such subtleties. In investigating whether these cues are preserved when a text is translated, we are also beginning to address the question of consistency in cues between languages.

MT systems do not explicitly consider demographic or personality traits. Instead, they often exploit "in-domain" data to create translation models that are adapted for the domain of interest (Lu et al., 2007; Foster et al., 2010; Axelrod et al., 2011; Gong et al., 2012; Mirkin and Besacier, 2014). The term "domain" has a wide interpretation in the MT literature and may refer to topic, dialect, genre or style (Chen et al., 2013). However, to the best of our knowledge, MT domain adaptation does not extend to consider demographic or personality traits of the author. Gender in translation has been researched extensively; in human translation studies, it has been shown that the gender of translators impact the translation. In SMT, phrase-based models (Koehn et al., 2003) can correctly pick-up translations of gender-inflected words, and rule-based MT systems and factored models (Koehn and Hoang, 2007) provide more explicit ways for gender translation. Yet, most SMT systems are unaware of the gender of the author, neither in the training nor in the test data, and are therefore unable to adapt their translation beyond the local inflectional level; in particular when no such evidence exists, as in English. To a much greater extent, this is the case with other demographics, such as age, and with personality traits.

3 Methodology

3.1 Hypothesis

The hypothesis of our broader vision is that personalized MT or author-aware translation is an important necessity. We believe the human understanding of translated text (of its explicit and implicit meanings, of its author and of the full context) would be improved if author traits are better conveyed.

In order to motivate this future work, this paper explores a supporting hypothesis: that author traits are not conveyed accurately under machine translation. We assess this by investigating whether trait detection performs as well on translated data as on native text.

3.2 Experimental Framework

To explore our hypothesis, we require data in multiple languages which is labelled with socio-demographic or personality traits. Using English as the base language (as typically the most resource-rich language in NLP studies), we perform three comparative experiments on several non-English ("foreign") corpora. In these experiments we train a classification model:

1. Using only foreign language data. This provides a baseline, as no translated data is used.
2. Augmenting the foreign training data with English data translated into the foreign language. Here, the goal is to assess a scenario where translations from a resource-rich language supplement scarce training data in the foreign language, under the assumption that more training data can be beneficial.
3. Translating the foreign test data into English and classifying it using a model trained on the English data. This allows us to explore another practical scenario, where an English model already exists and we wish to use it to classify data from another language for which we do not have a robust model.

For this task we use the data from the 2015 PAN workshop (Rangel et al., 2015) which is labelled for author gender and personality traits. For more details see Section 4.1. We also wish to explore if any affect was due strictly to the use of MT or to translation (or language change) in general. The PAN corpus is multi-lingual but does not contain parallel data. Such parallel corpora, however, are not typically labelled with the type of author information we wish to investigate. Therefore we required such a corpus to which we could easily add labels. For these we used a selection of TED talks which we labelled for gender (see Section 4.2). The full details of our approach to text processing, translation and classification can be found in our technical paper at the PAN workshop (Nowson et al., 2015); in the interests of space a compressed version is presented here.

3.3 Preprocessing and feature extraction

We use the multilingual parser described by Ait-Mokhtar et al. (2001) to preprocess the texts and extract a wide range of features. The parser has been customized to handle social media data, e.g. by detecting hashtags, mentions, and emoticons. For English, we have integrated a normalization dictionary by Han et al. (2012) in the preprocessing. The English and French grammars also include a polarity lexicon to recognize sentiment bearing words or expressions. The features we extract include: 1-, 2-, 3-grams of surface, normalized and lemmatized forms; part-of-speech tagged forms, and n-grams of POS; named entities (places, persons, organization, dates, time expressions), emoticons, hashtags, mentions and URLs.

3.4 Learning framework

To train classification models we first prune features with a frequency threshold. Next, the remaining set of features is compressed using truncated singular value decomposition (SVD). SVD (Golub and Reinsch, 1970) is a widely used technique in sparse dataset situations. This method copes with noise present in the data by extracting the principal dimensions describing the data and projecting the data to a latent space. In the truncated version, a low-rank approximation, all but the top-k dimensions are removed. The result is a dense, low-dimension representation of the data. Finally, ensemble models (Schapire, 1990; Dietterich, 2000) are used to predict trait values: for gender, we use the majority vote of 10 classifiers; for each personality trait, we use the mean of 10 regression estimators.

3.5 Machine translation models

We created standard machine translation models between English and each one of Spanish, Italian, French and Dutch. The details are described below.

Parallel corpora We wished to use the same setting for all language pairs. To that end, we chose parallel corpora that are available for all of them, namely Europarl (Koehn, 2005)[2] and WIT3 (Cettolo et al., 2012), from the IWSLT 2014 evaluation campaign (Cettolo et al., 2014). WIT3, consisting of spoken-language transcripts, represents an in-domain corpus for the TED dataset and a "near-domain" for PAN. The data consisted of approximately 2 million parallel sentences for each language pair, with 50 million tokens for each language. The Europarl corpus comprised more than 90% of that data. The two corpora were concatenated to create the training data for the MT models.

Translation System Moses (Koehn et al., 2007), an open-source phrase-based MT system,[3] was used to train translation models and translate the data.

Preprocessing We used the standard Moses tools to preprocess the data, including tokenization, lowercasing and removal of sentence pairs where at least one of the sentences is empty or longer than 80 tokens.

Recasing and Language models We used SRILM (Stolcke, 2002) version 1.7.1 to train 5-gram language models on the target side of the parallel corpus, with modified Kneser-Ney discounting (Chen and Goodman, 1996). A recasing model was trained from the same corpus, with a 3-gram KenLM language model (Heafield, 2011).

Tuning We tuned the translation models using MERT (Och, 2003), using the development set of the above mentioned campaign (*dev2010*), consisting of 887 sentence pairs for each language pair.

Translation and post-processing Each of the tweets of the PAN training set was preprocessed in the same fashion as the training data. It was then translated with the trained model of the corresponding language pair, and finally underwent quick post-processing, namely recasing and detokenization.

4 Data

Personality-tagged datasets in multiple languages are scarce. We used two datasets, with content from twitter and TED talks, as described in this section.

4.1 PAN

The first corpus we used was the data of the PAN 2015 Author Profiling task (Rangel et al., 2015), drawn from Twitter (PAN15). For each user, the data consists of tweets (average $n = 100$) and gold standard labels: gender (Male or Female), and personality. The labels are provided by the author, with scores on five traits being calculated via self-assessment responses to the short Big 5 test, BFI-10 (Rammstedt and John, 2007)), then normalized between -0.5 and +0.5. Table 1 shows the volume of data per language for the training set.

Language	Authors	Tweets
English (en)	152	14166
Spanish (es)	100	9879
Italian (it)	38	3687
Dutch (nl)	34	3350

Table 1: Number of authors and tweets across the four languages of the PAN dataset.

4.2 TED

The PAN15 data allows us to assess personality projection in multilingual data. In addition to exploring automatic translation, we wish to compare with manual translation. We turned to TED talks[4] for such comparative evaluation. We chose the English-French lan-

[2] Version 7, www.statmt.org/europarl

[3] We used version 3.0, downloaded on 16 Feb 2015 from www.statmt.org/moses.

[4] www.ted.com

guage pair, because French is not a language in PAN15, but also due to the difficulties in obtaining such data, as described below.

4.2.1 TED English-French

We use data of the MT track of the IWSLT 2014 Evaluation Campaign, which includes parallel corpora from transcripts of TED talks. The English-French (*en-fr*) corpus consists of 1415 talks, with approximately 190k sentence pairs and 3 million tokens for each of the source and target sides (before preprocessing). We annotated the gender of each speaker with a simple web interface. Any talk with multiple speakers or where the majority is not a speech (e.g. a performance) is discarded. After discarding 59 talks, 1012 (75%) were annotated as male and 344 (25%) as female.[5]

4.2.2 TED French-English

The WIT3 data seems to also include data in the *fr-en* direction. However, in practice, TED hosts only talks in English and all foreign to English corpora were collected from the translated versions of the site. We therefore turned to TEDx[6] for *fr-en* data. TEDx are independent TED-style events, often including talks in languages other than English. Unlike *en-fr*, there is no easily accessible parallel data available for *fr-en*, where the source is native French. We applied the following procedure to collect the necessary data. We used the Google YouTube Analytics API[7] to search for videos of talks in French. We have extracted the list of TEDx events in France and their dates via `www.tedxenfrance.fr`.[8] Each event-name and year is used as a query in YouTube, e.g. "TEDx Paris 2011". For each talk, we download the **manual** French and English subtitles, i.e. the transcript and the translation, respectively. These files were annotated using the same process and criteria described above. This resulted with a small corpus (TED61$_{fr-en}$) of 61 talks of which 32 are annotated as male and 29 as female.

TED61$_{en}$ In order to account for any potential effect of length, we created a subset of the *en-fr* corpus, that is of the same size of the *fr-en* dataset. We matched files from the French side of the *en-fr* corpus to each of those in the *fr-en* for gender and length (in tokens). The French *en-fr* files were truncated after the nearest line break to the desired size; the corresponding English *en-fr* files were truncated at the same point.

5 Experiments

It has been shown that standard approaches to gender classification on English texts can be sub-optimal for non-English language data (Ciot et al., 2013). However, state-of-the-art classification results are not our focus; rather, our intention is to understand the impact of translation on classification of socio-demographic and personality traits. Therefore, we fix our models with a set of parameters selected via cross-validation (CV) on the native language: the occurrence threshold is set to 5 and the SVD dimensionality to 500.

5.1 PAN

For each of the three non-English languages of PAN15 we train classification models as explained in Section 3: using the original training data, adding training data translated from English, and translating the test data into English to use the English-trained model.

Results can be seen in Table 2. For the majority of the traits, the native results outperform both translation settings, in some cases by considerable margin. The assumption posited earlier that more training data is be beneficial appears not to have held up in this context. The alternative scenario seems to be doing even worse.

The most distinct results are perhaps the accuracy of gender prediction (for which each corpora is balanced, thus a baseline of 50%). One explanation may be that the translation is done from and into English, which does not express gender via morphology, in contrast to Italian and Spanish. An interesting exception is that adding translated English texts into Dutch considerably improves performance. This may be explained by the lesser expression of gender in Dutch morphology, much like English. In this instance it appears that adding more data – when translation is between two gender-agnostic languages – does indeed help. For both Italian and Dutch, English adds a very substantial amount of data; the outcomes, however, are opposite.

5.2 TED

Though the TED data is currently only labelled for gender, it allows us to make comparisons between manual and machine translation. First we explored if there were gender signals in the English corpus which a classifier could uncover. For this, we performed leave-one-out CV on each of the following three versions: native English, manually and machine translated into French. The results, presented in Table 3, show that some gender signal is lost between manual and machine translation. In the manual translation, the translator, who is aware of the speaker's gender is able to reflect that through morphological and lexical cues, that exist in French much more than in English. The MT's ability to project these features properly was more limited. Note that the results between English and French are not directly comparable, since any text classification on different languages may yield different results.

One interesting observation is the low performance relative to the baseline and that of PAN15. Though we do not discuss this in detail here, we suspect this may be an effect of genre muting (Argamon et al., 2003; Herring and Paolillo, 2006).

Next, we explore another setting: The English corpus is modified to exclude the speakers of the

Table 4: Results when classifying gender on native, manually translated and machine translated English texts, from 61 TEDx and TED talks.

TED61_{en} dataset (leaving $n = 1295$ speakers), and this data is used to train a classification model. We then test our three smaller English datasets on this model: TED61_{en}, TED61_{fr-en} manual translated and TED61_{fr-en} machine translated. The results in this case are more comparable since we use the same model for all datasets and since their sizes are similar. The classification results are presented in Table 4. Again, signal is lost in automatic translation in comparison to manual translation. Interestingly, the manual translation scores higher than the native English, as if the translators are adding more gender indications to the text. Further analysis is required to clarify whether this is indeed a consequence of the manual translation or an artifact of the setting.

Author-aware translation may be viewed as a human-centric domain adaptation task: we can consider the two genders as two different domains, and apply domain adaptation techniques to train a better-suited model for each one. To assess this approach, we conducted a set of experiments with standard domain adaptation techniques for *en-fr*, including: separating the translation models and the language models by gender in various configurations, using only the target gender's training data from WIT3 (on top of the Europarl data), and separating tuning sets by gender. We split the IWSLT test sets by gender, and applied on each part the respective gender's model before concatenating the translations to compute a BLEU (Papineni et al., 2002) score. Unfortunately, none of these models showed a significant improvement, if at all, in comparison to our baseline that used both genders together. This suggests that alternative methods should be used for our task. We cannot say, however, that these results are conclusive; specifically, one difficulty in our experiments was obtaining enough female data, due to the relative small number of female speakers in WIT3.

6 Discussion

We are interested in understanding the impact which the consideration of author traits might have on automatic translation, in order to preserve projection of those traits in a target language. However, it is first necessary to understand the inverse: the effect of current translation approaches on the computational recognition of these traits. In the initial studies reported here we have explored two corpora: one of social media data; one of scripted speeches. Although linguistic signals of traits are weaker in the latter case, so far it appears that machine translation is detrimental to the automatic recognition of these traits. Though we have tried to account for as many confounding factors in this work as we could – particularly the availability of data – naturally there are still some open questions, and some obvious next steps. We fixed the learning parameters across languages and traits for comparative reasons, but would independent optimization provide better results? What is the impact of the translation quality on the subsequent classification performance? We would also like to understand the true relationship between linguistic features and traits across languages, along with how native speakers naturally observe these traits. Overall, however, we are encouraged to pursue our goal of personalized machine translation.

Acknowledgments

We would like to gratefully acknowledge the comments and feedback we received from the EMNLP reviewers.

Abstract

We introduce *Trans-gram*, a simple and computationally-efficient method to simultaneously learn and align word-embeddings for a variety of languages, using only monolingual data and a smaller set of sentence-aligned data. We use our new method to compute aligned word-embeddings for twenty-one languages using English as a pivot language. We show that some linguistic features are aligned across languages for which we do not have aligned data, even though those properties do not exist in the pivot language. We also achieve state of the art results on standard cross-lingual text classification and word translation tasks.

1 Introduction

Word-embeddings are a representation of words with fixed-sized vectors. It is a distributed representation (Hinton, 1984) in the sense that there is not necessarily a one-to-one correspondence between vector dimensions and linguistic properties. The linguistic properties are distributed along the dimensions of the space.

A popular method to compute word-embeddings is the Skip-gram model (Mikolov et al., 2013a). This algorithm learns high-quality word vectors with a computation cost much lower than previous methods. This allows the processing of very important amounts of data. For instance, a 1.6 billion words dataset can be processed in less than one day.

Several authors came up with different methods to align word-embeddings across two languages (Klementiev et al., 2012; Mikolov et al., 2013b; Lauly et al., 2014; Gouws et al., 2015).

In this article, we introduce a new method called Trans-gram, which learns word embeddings aligned across many languages, in a simple and efficient fashion, using only sentence alignments rather than word alignments. We compare our method with previous approaches on a cross-lingual document classification task and on a word translation task and obtain state of the art results on these tasks. Additionally, word-embeddings for twenty-one languages are learned simultaneously - to our knowledge - for the first time, in less than two and a half hours. Furthermore, we illustrate some interesting properties that are captured such as cross-lingual analogies, e.g $\vec{\text{rey}}_{\text{es}} - \vec{\text{Mann}}_{\text{de}} + \vec{\text{femme}}_{\text{fr}} \approx \vec{\text{regina}}_{\text{it}}$ which can be used for disambiguation.

2 Review of Previous Work

A number of methods have been explored to train and align bilingual word-embeddings. These methods pursue two objectives: first, similar representations (i.e. spatially close) must be assigned to similar words (i.e. "semantically close") within each language - this is the **mono-lingual objective**; second, similar representations must be assigned to similar words across languages - this is the **cross-lingual objective**.

The simplest approach consists in separating the mono-lingual optimization task from the cross-lingual optimization task. This is for example the case in (Mikolov et al., 2013b). The idea is to separately train two sets of word-embeddings for each language and then to do a parametric estimation of the mapping between word-embeddings across languages. This method was further extended by (Faruqui and Dyer, 2014). Even though those algorithms proved to be viable and fast, it is not clear whether or not a simple mapping between whole languages exists. Moreover, they require word alignments which are a rare and expensive resource.

*These authors contributed equally.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1109–1113,
Lisbon, Portugal, 17-21 September 2015.

Another approach consists in focusing entirely on the cross-lingual objective. This was explored in (Hermann and Blunsom, 2013; Lauly et al., 2014) where every couple of aligned sentences is transformed into two fixed-size vectors. Then, the model minimizes the Euclidean distance between both vectors. This idea allows processing corpus aligned at sentence-level rather than word-level. However, it does not leverage the abundance of existing mono-lingual corpora .

A popular approach is to jointly optimize the mono-lingual and cross-lingual objectives simultaneously. This is mostly done by minimizing the sum of mono-lingual loss functions for each language and the cross-lingual loss function. (Klementiev et al., 2012) proved this approach to be useful by obtaining state-of-the-art results on several tasks. (Gouws et al., 2015) extends their work with a more computationally-efficient implementation.

3 From Skip-Gram to Trans-Gram

3.1 Skip-gram

We briefly introduce the Skip-gram algorithm, as we will need it for further explanations. Skip-gram allows to train word embeddings for a language using mono-lingual data. This method uses a dual representation for words. Each word w has two embeddings: a target vector, $\vec{w}$ ($\in \mathbb{R}^D$), and a context vector, $\overleftarrow{w}$ ($\in \mathbb{R}^D$). The algorithm tries to estimate the probability of a word w to appear in the context of a word c. More precisely we are learning the embeddings $\vec{w}, \overleftarrow{c}$ so that: $\sigma(\vec{w} \cdot \overleftarrow{c}) = P(w|c)$ where σ is the sigmoid function.

A simplified version of the loss function minimized by Skip-gram is the following:

$$J = \sum_{s \in C} \sum_{w \in s} \sum_{c \in s[w-l:w+l]} -\log \sigma(\vec{w} \cdot \overleftarrow{c}) \quad (1)$$

where C is the set of sentences constituting the training corpus, and $s[w-l:w+l]$ is a word window on the sentence s centered around w. For the sake of simplicity this equation does not include the "negative-sampling" term, see (Mikolov et al., 2013a) for more details.

Skip-gram can be seen as a materialization of the distributional hypothesis (Harris, 1968): "Words used in similar contexts have similar meanings". We will now see how to extend this idea to cross-lingual contexts.

3.2 Trans-gram

In this section we introduce Trans-gram, a new method to compute aligned word-embeddings for a variety of languages.

Our method will minimize the summation of mono-lingual losses and cross-lingual losses. Like in BilBOWA (Gouws et al., 2015), we use Skip-gram as a mono-lingual loss. Assuming we are trying to learn aligned word vectors for languages e (e.g. English) and f (e.g. French), we note J_e and J_f the two mono-lingual losses.

In BilBOWA, the cross-lingual loss function is a distance between bag-of-words representations of two aligned sentences. But as (Levy and Goldberg, 2014) showed that the Skip-gram loss function extracts interesting linguistic features, we wanted to use a loss function for the cross-lingual objective that will be closer to Skip-gram than BilBOWA.

Therefore, we introduce a new task, Trans-gram, similar to Skip-gram. Each English sentence s_e in our aligned corpus $A_{e,f}$ is aligned with a French sentence s_f. In Skip-gram, the context picked for a target word w_e in a sentence s_e is the set of words c_e appearing in the window centered around w_e: $s_e[w_e - l : w_e + l]$. In Trans-gram, the context picked for a target word w_e in a sentence s_e will be all the words c_f appearing in s_f. The loss can thus be written as:

$$\Omega_{e,f} = \sum_{(s_e,s_f) \in A_{e,f}} \sum_{w_e \in s_e} \sum_{c_f \in s_f} -\log \sigma(\vec{w_e} \cdot \overleftarrow{c_f}) \quad (2)$$

This loss isn't symmetric with respect to the languages. We, therefore, use two cross-lingual objectives: $\Omega_{e,f}$ aligning e's target vectors and f's context vectors and $\Omega_{f,e}$ aligning f's target vectors and e's context vectors. By comparison BilBOWA only aligns e's target vectors and f's target vectors. The figure 1 illustrates the four objectives.

Notice that we make the assumption that the meaning of a word is uniformly distributed in the whole sentence. This assumption, although a naive one, gave us in practice excellent results. Also our method uses only sentence-aligned corpus and not word-aligned corpus which are rarer.

To add a third language i (e.g. Italian), we just have to add 3 new objectives (J_i, $\Omega_{e,i}$ and $\Omega_{i,e}$) to the global loss. If available we could also add $\Omega_{f,i}$ or $\Omega_{i,f}$ but in our case we only used corpora aligned with English.

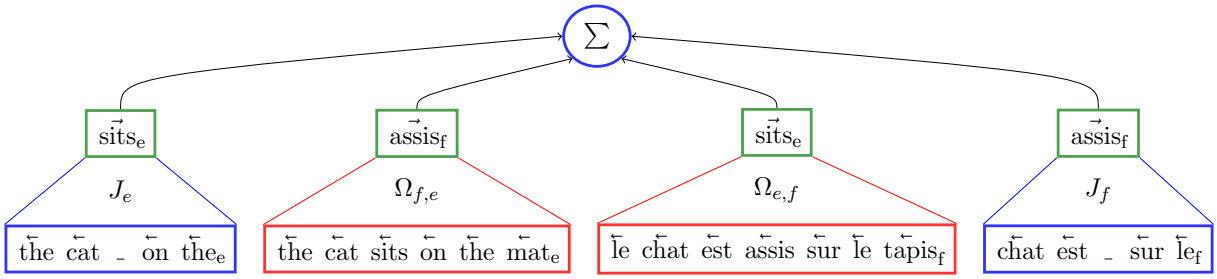

Figure 1: The four partial objectives contributing to the alignment of English and French: a Skip-gram objective per language (J_e and J_f) over a window surrounding a target word (blue) and two Trans-gram objectives ($\Omega_{e,f}$ and $\Omega_{f,e}$) over the whole sentence aligned with the sentence from which the target word is extracted (red).

4 Implementation

In our experiments, we used the Europarl (Koehn, 2005) aligned corpora. Europarl-v7 has two peculiarities: firstly, the corpora are aligned at sentence-level; secondly each pair of languages contains English as one of its members: for instance, there is no French/Italian pair. In other words, English is used as a pivot language. No bi-lingual lexicons nor other bi-lingual datasets aligned at the word level were used.

Using only the Europarl-v7 texts as both mono-lingual and bilingual data, it took 10 minutes to align 2 languages, and two and a half hours to align the 21 languages of the corpus, in a 40 dimensional space on a 6 core computer. We also computed 300 dimensions vectors using the Wikipedia extracts provided by (Al-Rfou et al., 2013) as monolingual data for each language. The training time was 21 hours.

5 Experiments

5.1 Reuters Cross-lingual Document Classification

We used a subset of the English and German sections of the Reuters RCV1/RCV2 corpora (Lewis and Li, 2004) (10000 documents each), as in (Klementiev et al., 2012), and we replicated the experimental setting. In the English dataset, there are four topics: CCAT (Corporate/Industrial), ECAT (Economics), GCAT (Government/Social), and MCAT (Markets). We used these topics as our labels and we only selected documents labeled with a single topic. We trained our classifier on the articles of one language, where each document was represented using an IDF weighted sum of the vectors of its words, we then tested it on the articles of the other language. The classifier used was an averaged perceptron, and we used the implementation from (Klementiev et al., 2012)[1]. The word vectors were computed on the Europarl-v7 parallel corpus with size 40 like other methods. For this task only the target vectors where used.

We report the percentage precision obtained with our method, in comparison with other methods, in Table 1. The table also include results obtained with 300 dimensions vectors trained by Trans-gram with the Europarl-v7 as parallel corpus and the Wikipedia as mono-lingual corpus. The previous state of the art results were detained (Gouws et al., 2015) with BilBOWA and (Lauly et al., 2014) with their Bilingual Auto-encoder model. This model learns word embeddings during a translation task that uses an encoder-decoder approach. We also report the scores from Klementiev et al. who introduced the task and the BiCVM model scores from (Hermann and Blunsom, 2013).

The results show an overall significant improvement over the other methods, with the added advantage of being computationally efficient.

5.2 P@k Word Translation

Next we evaluated our method on a word translation task, introduced in (Mikolov et al., 2013b) and used in (Gouws et al., 2015). The words were extracted from the publicly available WMT11[2] corpus. The experiments were done for two sets of translation: English to Spanish and Spanish to English. (Mikolov et al., 2013b) extracted the top $6K$ most frequent words and translated them with Google Translate. They used the top $5K$ pairs to train a translation matrix, and evaluated their method on the remaining $1K$. As our English and

Method	En → Es P@1	En → Es P@5	Es → En P@1	Es → En P@5
Edit distance	13%	18%	24%	27%
Bing	55%		71%	
Translation Matrix	33%	35%	51%	52%
BilBOWA	39%	44%	**51%**	55%
Trans-gram	**45%**	**61%**	47%	**62%**

Table 2: Results on the translation task

Spanish vectors are already aligned we don't need the $5K$ training pairs and use only the $1K$ test pairs.

The reported score, the translation precision $P@k$, is the fraction of test-pairs where the target translation (Google Translate) is one of the k translations proposed by our model. For a given English word, w, our model takes its target vectors $\vec{w}$ and proposes the k closest Spanish word using the co-similarity of their vectors to $\vec{w}$. We compare ourselves to the "translation matrix" method and to the BilBowa aligned vectors. We also report the scores obtained by a trivial algorithm that uses edit-distance to determine the closest translation and by the Bing Translator service.

6 Interesting properties

6.1 Cross-lingual disambiguation

We now present the task of cross-lingual disambiguation as an example of possible uses of aligned multilingual vectors. The goal of this task is to find a suitable representation of each sense of a given polysemous word. The idea of our method is to look for a language in which the undesired senses are represented by unambiguous words and then to perform some arithmetic operation.

Let's illustrate the process with a concrete example: consider the French word "train", $\mathrm{train}_{\mathrm{fr}}$. The three closest Polish words to $\vec{\mathrm{train}}_{\mathrm{fr}}$ translate in English into "now", "a train" and "when". This seems a poor matching. In fact, $\mathrm{train}_{\mathrm{fr}}$ is polysemous. It can name a line of railroad cars, but it is also used to form progressive tenses. The French "Il est *en train de* manger" translates into "he is eat*ing*", or in Italian "*sta* mangiando".

As the Italian word "sta" is used to form progressive tenses, it's a good candidate to disambiguate $\mathrm{train}_{\mathrm{fr}}$. Let's introduce the vector $\vec{v} = \vec{\mathrm{train}}_{\mathrm{fr}} - \vec{\mathrm{sta}}_{\mathrm{it}}$. Now the three polish words closest to $\vec{v}$ translate in English into "a train", "a train" and "railroad". Therefore $\vec{v}$ is a better representation for the railroad sense of $\mathrm{train}_{\mathrm{fr}}$.

6.2 Transfer of linguistic features

Another interesting property of the vectors generated by Trans-gram is the transfer of linguistic features through a pivot language that does not possess these features.

Let's illustrate this by focusing on Latin languages, which possess some features that English does not, like rich conjugations. For example, in French and Italian the infinitives of "eat" are $\mathrm{manger}_{\mathrm{fr}}$ and $\mathrm{mangiare}_{\mathrm{it}}$, and the first plural persons are $\mathrm{mangeons}_{\mathrm{fr}}$ and $\mathrm{mangiamo}_{\mathrm{it}}$. Actually in our models we observe the following alignments: $\vec{\mathrm{manger}}_{\mathrm{fr}} \approx \vec{\mathrm{mangiare}}_{\mathrm{it}}$ and $\vec{\mathrm{mangeons}}_{\mathrm{fr}} \approx \vec{\mathrm{mangiamo}}_{\mathrm{it}}$. It is thus remarkable to see that features not present in English match in languages aligned through English as the only pivot language. We also found similar transfers for the genders of adjectives and are currently studying other similar properties captured by Trans-gram.

7 Conclusion

In this paper we provided the following contributions: Trans-gram, a new method to compute cross-lingual word-embeddings in a single word space; state of the art results on cross-lingual NLP tasks; a sketch of a cross-lingual calculus to help disambiguate polysemous words; the exhibition of linguistic features transfers through a pivot-language not possessing those features.

We are still exploring promising properties of the generated vectors and their applications in other NLP tasks (Sentiment Analysis, NER...).

The Overall Markedness of Discourse Relations

Lifeng Jin and Marie-Catherine de Marneffe
Department of Linguistics
The Ohio State University
{jin, mcdm}@ling.osu.edu

Abstract

Discourse relations can be categorized as continuous or discontinuous in the hypothesis of continuity (Murray, 1997), with continuous relations expressing normal succession of events in discourse such as temporal, spatial or causal. Asr and Demberg (2013) propose a markedness measure to test the prediction that discontinuous relations may have more unambiguous connectives, but restrict the markedness calculation to relations with explicit connectives only. This paper extends their measure to explicit and implicit relations and shows that results from this extension better fit the continuity hypothesis predictions both for the English Penn Discourse (Prasad et al., 2008) and the Chinese Discourse (Zhou and Xue, 2015) Treebanks.

1 Introduction

Discourse relations between units of text are crucial for the production and understanding of discourse. Different taxonomies of discourse relations have been proposed (i.a. Hobbs (1985), Lascarides and Asher (1993) and Knott and Sanders (1998)). One taxonomy is based on deictic continuity (Segal et al., 1991; Murray, 1997): continuity in the sense of Segal et al. (1991) means that the same frame of reference is maintained, for example by subsequent sentences talking about the same event, without a shift in perspective (Asr and Demberg, 2012). For instance, a causal relation such as *I was tired, so I drank a cup of coffee.* is continuous, and adversatives show discontinuous relations: *I drank a cup of coffee but I was still tired.* Other continuous relations include temporal succession, topic succession and so on. The continuity hypothesis predicts that sentences connected by continuous relations are easier to understand than ones connected by discontinuous relations.

Previous work on continuity hypothesis (Maury and Teisserenc, 2005; Cain and Nash, 2011; Hoek and Zufferey, 2015) suggests that discourse connectives are indicators of the continuity of discourse and help the interlocutors predict the level of continuity of upcoming sentences. Segal et al. (1991) propose that connectives which signal discontinuous discourse relations, such as *but*, are the marked ones because they indicate harder-to-comprehend content. Asr and Demberg (2012, 2013) extend this idea to discourse relations, proposing that discourse relations which are discontinuous, or posing a conceptual difficulty (Haspelmath, 2006), may be less explicitly conveyed in text, or more explicitly marked by a connective which unambiguously conveys that specific relation than continuous ones. They propose a new measure called markedness to capture this, but when computed on the Penn Discourse Treebank, results do not fit the continuity theory well. This paper improves on Asr and Demberg (2013)'s measure and shows that the results on the Penn Discourse and the Chinese Discourse Treebanks fit the continuity hypothesis very well.

2 Discourse Treebanks

Penn Discourse Treebank The Penn Discourse Treebank (PDTB) is a corpus of Wall Street Journal articles annotated with discourse relations (Prasad et al., 2008). The discourse relations are organized in a hierarchical structure with three levels: a level 1 (e.g. TEMPORAL), level 1/level 2 (e.g. TEMPORAL.Asynchronous) or level 1/level 2/level 3 (e.g. TEMPORAL.Asynchronous.succession) relation can appear between two clauses within a sentence. Discourse relations with overt discourse connectives are annotated as "Explicit", whereas the relations with no discourse connective are annotated as "Implicit". The "AltLex" category is used when a non-connective expression conveys the relation. Table 1 gives the distribution of the

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1114–1119,
Lisbon, Portugal, 17-21 September 2015.

relation categories in the corpus.

Some connectives are labeled with multiple relations when it was difficult to pinpoint exactly one exact discourse relation for it. We follow Asr and Demberg (2013) and treat these cases as if there are multiple instances of the connective, each with one of the labels it received. This gives us a total of 35,870 relation instances.

	PDTB		CDTB	
Relation Category	**Count**	**%**	**Count**	**%**
Explicit	18459	45.5	1219	22.0
Implicit	16053	39.5	3935	71.1
AltLex	633	1.6	116	2.1
EntRel and NoRel	5464	13.4	264	4.8

Table 1: Relation category counts for the Penn Discourse and Chinese Discourse Treebanks.

Chinese Discourse Treebank The Chinese Discourse Treebank (CDTB, Zhou and Xue 2014) follows the PDTB annotation style and has annotations for 164 documents from Xinhua News. The main difference between CDTB and PDTB is that CDTB has a flat structure of only ten relations compared to the hierarchical relation structure in PDTB. Table 1 gives the distribution of the relation categories.

3 Rethinking the Markedness Measure

To quantify the conceptual difficulty of discourse relations, Asr and Demberg (2013) propose an information-theoretic measure "markedness", which tells us how tightly and uniquely a relation is associated with a connective. The measure uses normalized point-wise mutual information:

$$npmi(r;c) = \frac{\log p(r)p(c)}{\log p(r,c)} - 1 \qquad (1)$$

to get the markedness of a discourse relation:

$$markedness(r) = \sum_c p(c|r)\frac{npmi(r;c)+1}{2} \qquad (2)$$

where r is a relation and c is a discourse connective. Asr and Demberg (2013) propose this measure in the surprisal framework of Levy (2008), and restrict the scope of the data to only Explicit relations in PDTB. We will call this measure with only explicit relations "M-exp". Since surprisal is defined as the probability of a word given previous words and context (3), this restriction on the scope of relations does not seem reasonable. Surprisal is defined as

$$surprisal \propto -\log p(w_i|w_{1\ldots i-1}, CONTEXT) \qquad (3)$$

It can be argued that at the current word w_{i-1}, the distribution of upcoming discourse relations, available in CONTEXT, should play a role in determining the probability of the upcoming word w_i. In the surprisal model, the domain for w_i should be the same as w_{i-1}, which is all possible words. However, if we only calculate the distribution of explicit connectives as proposed by Asr and Demberg (2013), the candidates for w_i will change according to the prediction of whether an explicit relation is coming up or not. If the upcoming relation is an implicit relation, one then has access to a distribution of words without the connectives, whereas if one predicts an explicit relation, then one predicts the next word using a distribution of all the connectives as in M-exp. However surprisal should not be a model of deterministic decision making. It is more likely the case that given CONTEXT, one assigns probabilities to all words given the preceding context, which includes the case where no connective, in other words a zero or null connective, is predicted. The null connective may also be viewed as the probability mass for all the non-connective words predicted by CONTEXT where the connective is predicted to be omitted (Asr and Demberg, 2015).

The markedness measure can be analyzed in terms of point-wise mutual information (*pmi*), indicating the amount of information one relation has for the distribution of the words that follow it (Hume, 2011). Because *pmi* is proportionate to *npmi*, we can rewrite (2) as

$$markedness(r) \propto \sum_c p(c|r)pmi(r;c) \qquad (4)$$

We also have the mutual information measure:

$$I(X;Y) = \sum_y \sum_x p(x,y)pmi(x;y) \qquad (5)$$

For the mutual information of y_i in Y :

$$\begin{aligned} I(X;Y=y_i) &= \frac{\sum_x p(x,y_i)pmi(x;y_i)}{p(y_i)} \\ &= D_{KL}(p(x|y_i) \parallel p(x)) \\ &= \sum_x p(x|y_i)pmi(x;y_i) \\ &\propto markedness(y_i) \end{aligned} \qquad (6)$$

Level 1 Relation	Level 2 Relation	Level 3 Relation	Continuity
TEMPORAL	Asynchronous	precedence	Discontinuous
		succession	Discontinuous
	Synchronous		Ambiguous
CONTIGENCY	Cause		Continuous
	Condition		Unidentified
COMPARISON			Discontinuous
EXPANSION	Instantiation		Continuous
	Restatement		Continuous
	List		Continuous
	Alternative		Discontinuous
	Exception		Discontinuous
	Conjunction		Ambiguous

Table 2: Continuity of relations according to the continuity hypothesis (Asr and Demberg, 2012).

Therefore, the markedness measure can be understood as the Kullback-Leibler divergence of the univariate distribution of X from the conditional distribution of X given y_i (a discourse relation in our case). This shows the influence a relation has on the unigram distribution of words. Discourse relations strongly associated with certain connectives will have larger values of this measure than the ones with a weak association. In the previous discussion of surprisal, we have seen that one may treat the implicit cases as predicting a null connective, which will then expand the domain of X from explicit cases to all implicit and explicit cases. With this setup, we calculate "M-all" using all explicit and implicit relations, with a null connective accompanying all the implicit relations.

Continuity hypothesis has been linked with cognitive difficulties in discourse processing in previous studies (Segal et al., 1991; Murray, 1997). The markedness measure can also be linked to processing difficulties through surprisal theory. Surprisal theory proposes that processing difficulty during sentence processing can be seen as the work incurred by resource allocation during parallel disambiguation (Levy, 2008). If a relation has a high markedness value, it indicates that this relation has a strong influence on the distribution of upcoming candidate words. The stronger the influence is, the higher the resource allocation cost will be for the relation, thus more difficult to process.

4 Results on PDTB

Figure 1 compares the markedness of the PDTB level 1 relations as computed by the M-exp and M-all measures. According to the continuity hypothesis, the TEMPORAL relation is discontinuous (see Table 2 which gives the classification of discourse relations according to the continuity hypothesis). It should therefore have a high markedness value. However, M-exp assigns a low markedness to TEMPORAL, which Asr and Demberg (2013) note is unexpected. They ascribe this to the fact that temporal discourse connectives are often used to mark CONTINGENCY relations. However because of the high counts of Explicit connectives in TEMPORAL, whenever there is a connective that can indicate CONTINGENCY or TEMPORAL, one is more likely to predict TEMPORAL because of fewer null connective cases for TEMPORAL. In surprisal terms, whenever one predicts that there is a TEMPORAL relation next, one will more likely predict that there is an explicit discourse connective signaling the relation.

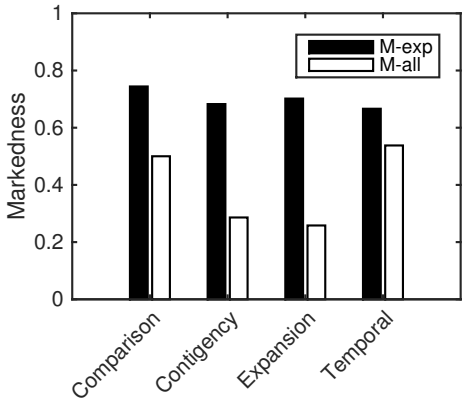

Figure 1: Comparison of markedness measures for PDTB level 1 relations.

EXPANSION is the least marked of all the relations in Figure 1 with M-all. An analysis of the level 2 relations explains this fact. Figure 2 com-

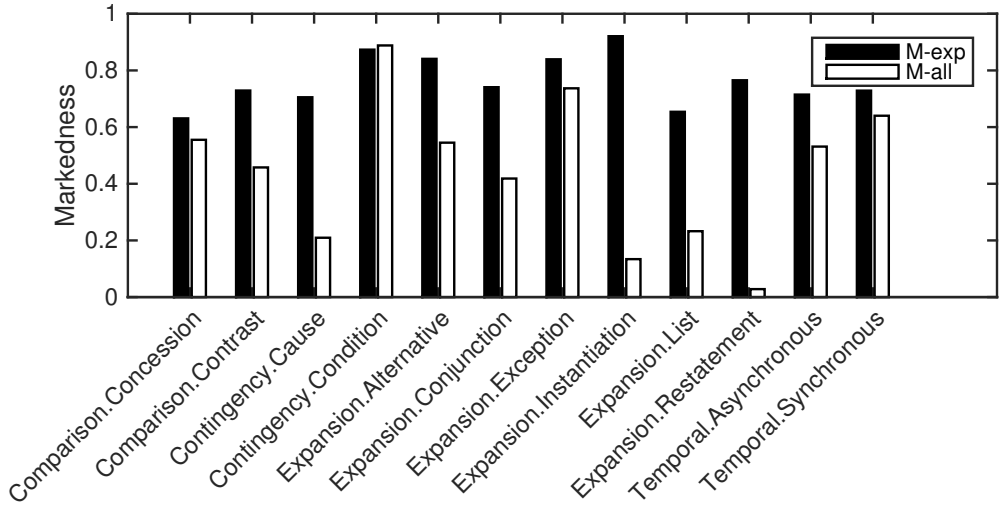

Figure 2: Comparison of markedness measures for PDTB level 2 relations.

pares both measures for the level 2 relations.[1] Using M-all, it is easy to see that discontinuous relations and ambiguous relations are more marked than the continuous ones. In the case of EXPANSION, the level 2 continuous relations are among the least marked ones, which are keeping the overall markedness low. Also, the ones which are discontinuous, especially *Exception*, are rare, so their influence to the overall score for EXPANSION is small. The most frequent relation, *Conjunction*, can be viewed as sometimes continuous and sometimes discontinuous, therefore the overall markedness rating for it is in the middle. All these factors contribute to the lowest markedness for EXPANSION. For CONTINGENCY, *Condition* is not classified as continuous or discontinuous, and it is highly marked, thus driving the overall score high. However if *Condition* is removed, then CONTINGENCY will be the least marked relation at the level 1.

At the level 3, there are two discontinuous relations of interest: *precedence* (e.g. *I had a cup of coffee before I took a bath*) and *succession* (e.g. *I took a bath after I had a cup of coffee*) under the TEMPORAL.Asynchronous relation. Table 3 compares the markedness measures for both relations. Asr and Demberg (2013) mention that there is no significant markedness distinction for them and we can see that *precedence* is slightly more marked than *succession* in M-exp, but the difference is small. M-all however shows that *succession* is more marked than *precedence*, reflecting the fact that *precedence* is easier to understand.

Metric	Precedence	Succession
M-exp	0.799	0.783
M-all	0.494	0.687

Table 3: Precedence and Succession Markedness.

	Arg1-Conn-Arg2		Conn-Arg2-Arg1	
	Implicit	Explicit	Implicit	Explicit
Precedence	567	931	0	55
Succession	171	867	0	234

Table 4: Counts for different argument orders of Precedence and Succession.

For *precedence*, the arguments can be in a normal temporal order, i.e. a forward temporal order (Arg1-Conn-Arg2, e.g. *I had some coffee before I went out.*) or in a backward temporal order (Conn-Arg2-Arg1, e.g. *Before I went out, I had some coffee.*). For *succession*, the temporal order and the argument order are reversed. Table 4 gives the counts in PTDB for both *precedence* and *succession* with different argument orders, showing that Arg1-Conn-Arg2 is the most frequent construction for both relations, which is forward temporal order for *precedence* and backward temporal order for *succession*, despite the fact that both of the relations can follow a forward temporal order. Therefore the results from M-all match the continuity hypothesis prediction that events in for-

[1]Pragmatic relations are not shown due to their small number of occurrences.

ward temporal order are easier to understand, thus less marked, than events in backward temporal order. Asr and Demberg (2012) explain that the relatively high count of Conn-Arg2-Arg1 constructions in *succession* is due to the fact that this construction actually places the events in the forward temporal order. We also notice that *precedence* has a lot more implicit occurrences than *succession*, meaning that inferring a normal temporal relation is much easier than inferring a reversed temporal relation.

5 Results on CDTB and Comparison

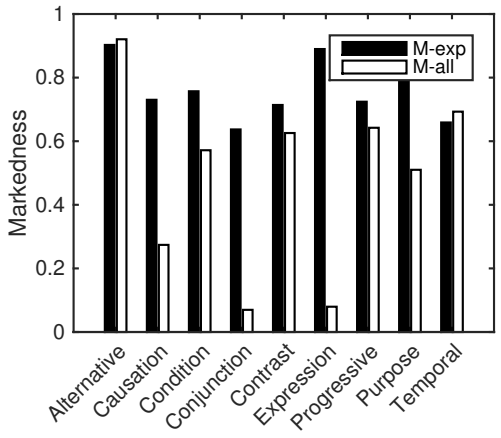

Figure 3: Markedness comparison for CDTB.

The results for CDTB, in Figure 3, shows the same trends as for English: overall, the markedness computed by M-all better fits the continuity hypothesis. EXPANSION is considered by M-exp as the second highest marked relation, whereas the continuity hypothesis predicts it to be one of the lowest marked relation, which is correctly captured by M-all. The reason for it to be low may be that discontinuous relations included by EXPANSION are rare so the frequent continuous relations dominate, just as for English. Using M-exp, CAUSATION is around the middle, but M-all correctly lowers it to the third least marked relation. TEMPORAL is now the second highest marked relation among all relations, as opposed to the second least marked one. Importantly, M-all correctly shows that discourses relations in English and Chinese behave similarly in terms of markedness, which indicates that the continuity hypothesis is valid across languages.

Sanders (2005) proposes the causality-by-default hypothesis, claiming that CAUSATION is the default discourse relation when processing discourse. However, looking at M-all scores for both languages, it is clear that CAUSATION is not the least marked relation in either language. In fact, EXPANSION can actually be seen as the least marked common relation in both languages, which may indicate that EXPANSION is the default discourse relation cross-linguistically, yet more investigations are needed to decide which one in EXPANSION is the default. CONJUNCTION is also among the least marked relations in Chinese, with 89% of its instances being implicit, but in English, CONJUNCTION has an average markedness score. This shows that there are also differences among languages on judgments of continuity of specific relations.

6 Conclusion

The continuity hypothesis predicts that discontinuous discourse relations are less expected than continuous relations and should be more marked. We expand Asr and Demberg (2013)'s measure from explicit relations only to explicit and implicit relations. We show that the results from that expansion fit the predictions of the theory very well, and such evidence demonstrates that discontinuous relations are indeed cognitively more difficult to process. Further we show that such difficulty is consistent across languages, indicating that discourse relations may not be influenced by idiosyncrasies of specific languages. Apart from the markedness measure, Asr and Demberg (2012) proposed an "implicitness" measure, modeling the continuity of a relation using the ratio of implicit cases to all cases. Incorporating explicit and implicit relations into the markedness measure has the advantage of not only providing a single measure but also one which better fits the continuity hypothesis and surprisal theory.

Abstract

The widespread use of deception in online sources has motivated the need for methods to automatically profile and identify deceivers. This work explores deception, gender and age detection in short texts using a machine learning approach. First, we collect a new open domain deception dataset also containing demographic data such as gender and age. Second, we extract feature sets including n-grams, shallow and deep syntactic features, semantic features, and syntactic complexity and readability metrics. Third, we build classifiers that aim to predict deception, gender, and age. Our findings show that while deception detection can be performed in short texts even in the absence of a predetermined domain, gender and age prediction in deceptive texts is a challenging task. We further explore the linguistic differences in deceptive content that relate to deceivers gender and age and find evidence that both age and gender play an important role in people's word choices when fabricating lies.

1 Introduction

Given the potential ethical and security risks associated with deceitful interactions, it is important to build computational tools able not only to detect deceivers but also to provide insights into the nature of deceptive behaviors. In particular, information related to the demographics of the deceivers could be potentially useful, as recent studies have shown that online users lie frequently about their appearance, gender, age or even education level.

There are multiple scenarios where it would be desirable to identify deceivers' demographics; for instance, identifying the age and gender of SMS senders or Twitter users might help improve parental controls, spam filtering, and user's security and privacy.

In this paper, we present a study on deception detection in an open domain, and also present an analysis of deceptive behavior in association with gender and age. Unlike previous studies, where domain-specific conversational transcripts and reviews have been used, this research targets the identification of deceit in short texts where domain and context are not available. We aim to build deception, age, and gender classifiers using short texts, and also explore the prediction of gender and age in deceptive content. Moreover, we present an analysis of the topics discussed by deceivers given their age and gender based on the assumption that, when lying in an open domain setting, deceivers will show natural bias towards specific topics related to gender and age.

2 Related work

To date, several studies have explored the identification of deceptive content in a variety of domains, including online dating, forums, social networks, and consumer reviews. (Toma and Hancock, 2010) conducted linguistic analyses in online dating profiles and identified correlations between deceptive profiles and self references, negations, and lower levels of words usage. A study for deception detection on essays and product reviews is presented in (Feng et al., 2012). (Ott et al., 2011) addressed the identification of spam in consumer reviews and also studied the human capability of detecting deceptive reviews, which was found not better than chance. In a following study, (Ott et al., 2013) presented an analysis of the sentiment associated to deceitful reviews focusing particularly in those containing negative

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1120–1125,
Lisbon, Portugal, 17-21 September 2015.

sentiment as it largely affects consumer purchase decisions. More recently (Yu et al., 2015) presented a study where authors analyze the role of deception in online networks by detecting deceptive groups in a social elimination-game.

This previous work has shown the effectiveness of features derived from text analysis, which frequently includes basic linguistic representations such as n-grams and sentence counts statistics (Mihalcea and Strapparava, 2009; Ott et al., 2011) and also more complex linguistic features derived from syntactic context free grammar trees and part of speech tags (Feng et al., 2012; Xu and Zhao, 2012). Other studies have focused on deception clues inspired from psychological studies. For instance, following the hypothesis that deceivers might create less complex sentences (DePaulo et al., 2003), researchers have incorporated syntactic complexity measures into the analysis. (Yancheva and Rudzicz, 2013) presented a study based on the analysis of syntactic units and found that syntactic complexity correlates with deceiver's age. Psycholinguistics lexicons, such as Linguistic Inquiry and Word Count (LIWC) (Pennebaker and Francis, 1999), have also been used to build deception models using machine learning approaches (Mihalcea and Strapparava, 2009; Almela et al., 2012) and showed that the use of semantic information is helpful for the automatic identification of deceit.

While there is a significant body of work on computational deception detection, except for (Yancheva and Rudzicz, 2013) who considered the relation between syntactic constructs and deceivers' age, to our knowledge there are no computational analyses of demographics in deceptive content. However, there have been a number of psychological studies on the role of gender and age in deceptive behavior. These studies have found interesting associations between deception and gender. For instance, (Toma et al., 2008) identified differences in self-presentation among genders. In this study men were found to lie more about their height and women lied more about their weight. (Kaina et al., 2011) found that females are more easily detectable when lying than their male counterparts. (Tilley et al., 2005) reported that females are more successful in deception detection than male receivers.

3 Open Domain Deception Dataset

We started our study by collecting a new open domain deception dataset consisting of freely contributed truths and lies. We used Amazon Mechanical Turk and asked each worker to contribute seven lies and seven truths, on topics of their own choice, each of them consisting of one single sentence. In an attempt to obtain truths and lies that represent everyday lying behavior, we asked our contributors to provide plausible lies and avoid non-commonsensical statements such as "I can fly." Since we did not enforce a particular topic, resulting truths and lies are open domain. Sample truths and lies are presented in Table 1. Note that the collected lies might include statements that are somehow unrealistic, even if plausible, e.g., "I own two Ferraris, one red and one black". We decided to also include these statements in order to aid the identification of differences in deceivers and true-tellers language, as we hypothesize that they might help reveal topics that naturally occur in truths and lies.

Additionally, we collect demographic data from the contributors, including their gender, age, country of origin, and education level. To avoid spam, contributions were manually verified by one of the paper authors. The final dataset consists of 7168 sentences from 512 unique contributors. Since each contributor provided seven lies and seven truths the dataset contains a total of 3584 truths and 3584 lies respectively. Participant's ages range from 18 to 72 years, with an average age of 34.14 and a standard deviation of 12.67.

4 Features

In this section, we describe the sets of features extracted, which will then be used to build our classifiers.

Unigrams We extract unigrams derived from the bag of words representation of truths and lies present in our dataset.

Shallow and deep syntax features These features consist of part of speech (POS) tags and lexicalized production rules derived from Probabilistic Context Free Grammar (PCFG) trees, obtained with the Berkeley Parser (Petrov et al., 2006).

Female	
Lie	Truth
I won 1 billion dollars in the Illinois state lottery last year and gave it all away to my mother.	My daughter is my best friend in the whole wide world, and i would give my life for hers.
On my last birthday i turned 119 years old and went sky diving as a gift to myself.	I graduated with a degree in information systems 10 years ago and still can't find a good job.
I'm allergic to alcohol	Giraffes are taller than zebras.
Male	
Lie	Truth
Barak obama was my guest last night; he offered me the administrative assistant job at white house in Washington.	Internet is one of the greatest invention of history of humankind with its ability to speed up the communication.
I own two Ferraris, one red and one black	I love to play soccer with my friends
I wake up at 11 o clock every day	I wake up at 6 am because I have to work at 7 am

Table 1: Sample open-domain lies and truths provided by male and a female participants

Semantic features These features include the 80 semantic classes present in the LIWC lexicon. Each feature represents the number of words in a sentence belonging to a specific semantic class.

Readability and Syntactic Complexity features This set includes the Flesch-Kincaid and Gunning Fog readability scores and 14 indexes of syntactic complexity derived from the syntactic analysis of each sentence; performed with the tool provided by Lu (Lu, 2010).

5 Classification of Deception, Gender, and Age in Short Texts

Our first experiment seeks to evaluate whether deception detection can be conducted using the open domain deception dataset described above. We performed the evaluations at user level, by collapsing all the lies from one user into one instance, and all the truths into another instance.

We build deception classifiers using the SVM algorithm[1] and the different sets of features. We performed a five-fold cross-validation, by training each time on 80% of the users and testing on the remaining 20%. During our evaluations truths and lies pertaining to a particular user were either on the training or testing set. Classification results on individual and combined sets of features are presented in Table 3. The best performing set of features are the POS tags, followed by features derived from production rules. The remaining sets of features achieved accuracy values ranging from 54% to 65%, which still represent a noticeable improvement over the random baseline. Note that we experimented with a few more feature sets combinations, including the use of all the features together, however we did not observe significant improvements.

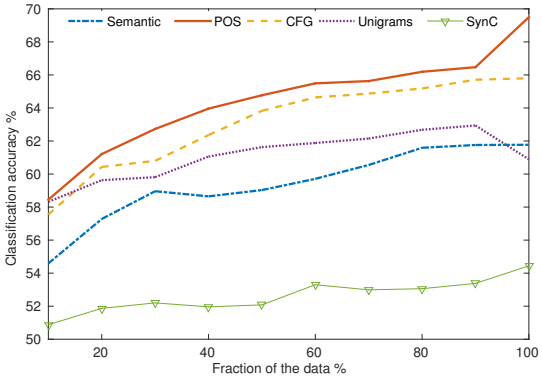

Figure 1: Learning curves for deception detection using five feature sets

To analyze the impact of the amount of data on the classifier learning process, we plot the learning curves on the different sets of features using incremental amounts of data as shown in Figure 1. Evaluations were conducted using five-fold cross validations on each incremental fraction of data. The learning trend suggests that most classifiers benefit from increasing amounts of training data.

[1] As implemented in the Weka toolkit, with default parameter settings.

Gender	Female	298
	Male	214
Age	Young ($\leq$ 35 years)	319
	Middle-aged/Elder (>35 years)	193

Table 2: Class distribution for gender and age

Feature set	Deception	Gender	Age
Baseline	50.00%	58.00%	62.00%
Unigrams	60.89%	54.25%	51.12%
Semantic	60.21%	57.28%	61.83%
POS	69.50%	49.95%	52.39%
CFG	65.39%	52.19%	54.74%
Readability	54.44%	58.16%	62.26%
Uni+Semantic	62.17%	63.04%	51.51%

Table 3: SVM classifiers trained for three prediction tasks: deception, gender, and age.

However, except for the POS features, the overall performance seems to stabilize when using 90% of the training data.

As a second experiment, we evaluate the ability of the classifier to predict gender and age in short open domain deceptive texts. Given the contributors' age distribution, which lies mainly in the range of 30-45 years, we opted to cluster the participants age into into two groups: young ($\leq$ 35 years) and middle-aged/elder (>35 years). Class distributions for age and gender are shown in Table 2. We performed the age prediction task on the two groups using the different sets of features and SVM classifiers. Classification accuracies are shown in Table 3. Reported baselines consist of a majority class baseline. Results show low to moderate improvement over the baseline for gender classification, with the combination of semantic features and unigrams being the best performing feature set. However, our classifiers performed poorly in the age prediction task, with accuracies below the majority class baseline.

Overall, the results suggest that age and gender prediction are challenging tasks when conducted in open domain deception data. One possible explanation for this is that the lack of context introduces noise into the analysis. For instance, the following sentence: "I'm 50 years old" can belong to either a male or a female, and it might be a lie for younger people or a truth for older people.

Lies			
Male		Female	
Other	2.22	Certain	1.87
Negate	2.08	Negate	1.63
Certain	2.06	You	1.59
Death	2.04	Motion	1.47
Anger	2.03	Down	1.45
You	1.77	Money	1.35
Friends	1.71	Anger	1.28
Othref	1.67	Future	1.20
Truths			
Male		Female	
Religion	1.67	Sleep	1.64
Family	1.65	Religion	1.61

School	1.42	Posfeel	1.33
Posfeel	1.35	Metaphor	1.33
Feel	1.32	TV	1.31

Table 4: Results from LIWC word class analysis for short open domain truths and lies.

6 Analyzing Language Used by Deceivers Given Age and Gender

In order to explore language differences among deceivers and true-tellers, we use the linguistic ethnography method (Mihalcea and Pulman, 2009) and obtain the most dominant semantic word classes in the LIWC lexicon associated to truth and lies provided by males and females. Results are shown in Table 4. From this table, we observe interesting patterns in word usage that are shared among genders. For instance, spontaneous lies often include *negation*, *certain*, and *you* words, which is in line with previous work on domain-specific deception (Mihalcea and Strapparava, 2009) that suggested that liars try to reinforce their lies through the use of stronger wording and detachment from the self. On the other hand, people appear to be less likely to lie when talking about their *family*, *religion*, and describing *positive* experiences. There are also LIWC classes associated to a specific gender. Male lies contain references to friends and others, while female lies contain references to money and future. Similarly, female true-tellers use metaphor words while male true-tellers use words related to sports and music.

Lies			
Age 18-34		Age 35-65	
Certain	2.04	Assent	2.13
Anger	1.98	Certain	1.83
Negate	1.82	Negate	1.68
Other	1.76	Anxiety	1.64
You	1.72	You	1.64
Down	1.64	Motion	1.54
Othref	1.53	Money	1.50
Death	1.49	Optim	1.38
Truths			
Age 18-34		Age 35-65	
Religion	1.83	Music	1.43
Tv	1.48	Sleep	1.42
Anxiety	1.45	Feel	1.34
Posfeel	1.37	Posfeel	1.33
See	1.30	See	1.31
Music	1.30	Sexual	1.28
School	1.29	Religion	1.27
Inhib	1.28	Family	1.25

Table 5: Results from LIWC word class analysis for short open domain truths and lies.

We also evaluate differences in word usage that might be attributed to deceiver's age. Resulting dominant classes and their scores are presented in Table 5. The analyses show interesting differences for deceiver's word usage across age. For instance, regardless of their gender, older deceivers use references to *anxiety*, *money*, and *motion*. On the other hand, younger deceivers language includes *anger*, *negate*, and *death* words. These differences suggest that indeed gender and age play a role on people words choices while fabricating lies.

7 Conclusions

In this paper, we presented our initial experiments in open domain deception detection. We targetted the deception detection on short text to address the cases where context is not available. In real settings, this can be useful when receiving a text message or when looking at anonymous posts in forums. We collected a new deception dataset consisting of one-sentence truths and lies, along with the demographics of the deceivers. Through several experiments, we showed that this data can be used to build deception classifiers for short open domain text. However, the classifiers do not perform very well while trying to predict gender and age. We further explored linguistic differences in deceptive content that relate to deceivers gender and age and found evidence that both age and gender play an important role on people's word choices when fabricating lies.

The dataset introduced in this paper is publicly available from http://lit.eecs.umich.edu.

A model of rapid phonotactic generalization

Abstract

The phonotactics of a language describes the ways in which the sounds of the language combine to form possible morphemes and words. Humans can learn phonotactic patterns at the level of abstract classes, generalizing across sounds (e.g., "words can end in a voiced stop"). Moreover, they rapidly acquire these generalizations, even before they acquire sound-specific patterns. We present a probabilistic model intended to capture this early-abstraction phenomenon. The model represents both abstract and concrete generalizations in its hypothesis space from the outset of learning. This—combined with a parsimony bias in favor of compact descriptions of the input data—leads the model to favor rapid abstraction in a way similar to human learners.

1 Introduction

Natural languages place restrictions on the ways in which sounds can combine to form words (the *phonotactics* of the language). The velar nasal [ŋ], for example, occurs at the end of English syllables, as in *ring* [ɹɪŋ] or *finger* [fɪŋgəɹ], but never at the beginning of a syllable: English does not have words like **ngir* [ŋɪɹ]. English speakers are aware of this constraint, and judge forms that start with a [ŋ] as impossible English words.

Sounds that share articulatory and/or perceptual properties often have similar phonotactic distributions. German, for example, allows voiced obstruents,[1] such as [b] and [g], to occur anywhere in the word except at its end: [bal] is a valid German word, but [lab] isn't.

Speakers use such features of sounds to form phonotactic generalizations, which can then apply to sounds that do not appear in their language. Although no English words start with either [sɹ] or [mb], English speakers judge *srip* to be a better potential word of English than *mbip* (Scholes, 1966); this is likely because [sɹ] shares properties with strident-liquid clusters that do exist in English, such as [sl] as in *slip* and [ʃɹ] as in *shrewd*, whereas [mb] does not benefit from any sonorant-stop onset sequences (*[nt])—none exist in English.

Recent studies have investigated how humans acquire generalizations over phonological classes in an artificial language paradigm (Linzen and Gallagher, 2014; Linzen and Gallagher, 2015). The central finding of these studies was that participants rapidly learned abstract phonotactic constraints and exhibited evidence of generalizations over classes of sounds before evidence of phoneme-specific knowledge.

This paper presents a probabilistic generative model, the Phonotactics As Infinite Mixture (PAIM) model, which exhibits similar behavior. This behavior arises from the combination of two factors: the early availability of abstract phonological classes in the learner's hypothesis space; and a parsimony bias implemented as a Dirichlet process mixture, which favors descriptions of the data using a single pattern over ones that make reference to multiple specific patterns.

2 Summary of behavioral data

The experiments are described in detail in Linzen and Gallagher (2014) and Linzen and Gallagher (2015); we summarize the main details here.

Design: Participants were exposed to varying numbers of auditorily-presented words in one of two artificial languages, VOICING and IDENTITY.

[1] See Hayes (2011) for an introduction to phonological features.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1126–1131,
Lisbon, Portugal, 17-21 September 2015.

Exposure		Test		
ganu	gimi	CONF-	CONF-	NONCONF-
balu	bini	ATT	UNATT	UNATT
vimu	voni	zonu	dila	tumu
zalu	zili	zini	dimu	talu
ðano	ðamu			

Table 1: VOICING: Design for one of the lists (voiced exposure, [d] held out). The table shows the complete list of exposure words that a participant in the two exposure sets group might receive.

Exposure	Test	
	CONF-	CONF-
	ATT	UNATT

ʃuʃe	ʃeʃu	sasi
gapu	gugi	dʒidʒe
nuni	nanu	mamu
	NONCONF-	NONCONF-
	ATT	UNATT
kesa	kasi	pina
mudʒe	medʒa	nage
dʒuki	dʒuke	gaʃe
semi	sami	ʃipu

Table 2: IDENTITY: A complete list of exposure and test words that a participant in the one exposure set group might receive.

Following the exposure phase, they were asked to judge for a set of novel test words whether those words could be part of the language they had learned (the possible answers were "yes" or "no").

In the VOICING experiment, all exposure words began with consonants that had the same value for their voicing feature (all voiced or all voiceless, e.g., $A_1 = \{$g, v, z, ð, b$\}$ or $A_2 = \{$k, f, s, θ, p$\}$). Some of the sounds with the relevant voicing were held out to be used during testing (e.g., [d] for A_1 or [t] for A_2). All exposure and test words had the form CVMV (*tumi*), where C stands for the onset consonant, V for a randomized vowel, and M for [m], [n] or [l] (see Table 1).

Participants judged three types of novel test words: ones with the same onset as one or more of the words in exposure (CONF-ATT;[2] e.g., *zonu* for A_1); ones whose onset was not encountered in exposure but had the same voicing as the exposure onsets (CONF-UNATT; e.g., *dila*); and ones whose onset had different voicing from the exposure words (NONCONF-UNATT, e.g., *tomu*). The vowels and the second consonant were randomized across conditions such that only the onsets reliably discriminated the three conditions.

In the IDENTITY language, words had the form C_1VC_2V. The generalization in this language was $C_1 = C_2$ (e.g., *pipa*). Here it was probabilistic: only half of the words in the exposure stage conformed to the generalization. As such, there was a fourth test condition, NONCONF-ATT, of exposure words that did not conform to the generalization.

Participants were recruited on Amazon Mechanical Turk (280 participants in the VOICING experiment and 288 in the IDENTITY experiment). They were divided into four groups, which received 1, 2, 4 or 8 sets of words. In the VOICING experiment, each of the sets contained five words, one starting with each of the five CONF-ATT onsets; in the IDENTITY experiment, each of the sets contained eight words, one with each of the CONF-ATT and NONCONF-ATT consonant pairs (Tables 1 and 2).

Results: Human experimental results are plotted in Figure 1. Endorsement rates represent the proportion of trials in which participants judged the word to be well-formed. Participants learned generalizations involving abstract classes of sounds after a single exposure set: in the VOICING experiment, they judged voiced word onsets to be better than voiceless ones, and in the IDENTITY experiment they judged words with identical consonants as better than words with nonidentical ones.[3] Participants did not start distinguishing CONF-ATT from CONF-UNATT patterns until they received two or more sets of exposure to the language.

Participants continued to generalize to CONF-UNATT patterns even after significant exposure to the language. Endorsement rates were higher than 50% across the board, likely because even words with NONCONF-UNATT consonant patterns were similar to the exposure words in all other respects (e.g., length, syllable structure, number of vowels

[2] ATT (attested): the consonants in the word (though not the full word) were encountered in exposure; UNATT (unattested): consonants were not encountered in exposures; CONF (conforming): the consonants conform to the abstract pattern (voicing or identity); NONCONF (nonconforming): consonants don't conform to the abstract pattern.

[3] All differences discussed in this section are statistically significant.

and consonants).

3 The model

PAIM is a generative model: it describes the probabilistic process by which the phonological forms of words are generated. Phonotactic knowledge is expressed as a set of word-form templates, represented as sequences of phonological classes. For example, the template ⟨[+voiced], V, C, V⟩ captures a generalization over words beginning with a voiced consonant.

Prior over phonological classes: Phonemes are represented as phonological feature-value matrices.[4] We generate a phonological class for each position in the template using this feature system and a parameter $p \in [0, 1]$, which controls the model's willingness to consider more or less abstract phonological classes: low values of p encourage underspecified classes, such as [] or [+voice], whereas high values of p favor highly specified classes, such as [+voice, labial, -continuant]. Given a particular value of p, we define the distribution $G(c)$ over classes as follows:

- For each phonological feature f whose set of possible values is V_f:
  1. Draw $P \sim \text{Bernoulli}(p)$.
  2. If $P = 1$, draw $v \sim \text{Uniform}(V_f)$ and include it in c.
  3. Otherwise, leave the feature unspecified, allowing the class to be abstract.

[4]The particular feature system is treated as a parameter of the model. In the simulation below we used a simplified version of the phonological feature inventory described in Hayes (2011), which only included features that are distinctive in English consonants.

Generating words from templates: Given a choice of phonological template t, we assume that each of the segments that instantiate t has the same probability of being sampled (cf. the "size principle" of Tenenbaum and Griffiths (2001)). Consider again the class c_0 = [+continuant, labial]. Under the assumption that the model's segment inventory is the English one, there are only two segments that are labial continuants: [v] and [f]. The probability of each one of them being generated from c_0 will be $P(s|c_0) = 1/2$.

Prior over template sets: The sounds of the language can be generated from a variety of templates at varying levels of abstraction. We therefore extend the model to be a mixture of template distributions of the type described above. The number of templates is inferred from the data using a Dirichlet process mixture model (Antoniak, 1974).

This prior can be constructed as a process. Suppose that s_i is an ordering of the input sounds, and that we know which templates generated the first $n-1$ sounds $s_1, \ldots, s_{n-1}$. If K is the number of templates that have been posited so far and $n_1, \ldots, n_K$ indicate the number of sounds that have been drawn from each template, then the probability distribution over the template z_n that the sound s_n will be drawn from is given by

$$P(z_n = k|z_{1:n-1}) \propto \begin{cases} n_k & \text{if } k \leq K \\ \alpha & \text{otherwise} \end{cases} \quad (1)$$

Since the probability that an existing template generated s_n is proportional to the number of segments currently assigned to that template, this prior encourages partitions in which a few templates explain most of the sounds (the "rich get richer" property), which amounts to a parsimony bias. Higher values of α can make this bias weaker.

Modeling phoneme spreading: To simulate the generalization made by participants in the IDENTITY experiment, templates must be able to state that two phonemes need to be identical. This is analogous to mechanisms of "spreading" widely assumed in phonology (Colavin et al., 2010; Goldsmith, 1976; McCarthy, 1986). For our simulations below, we simplify by only considering identity constraints between the initial and medial consonants in exposure and test forms. We sample a template over these positions as follows:

1. Draw a class $c_1 \sim G$, where G is the distribution over phonological classes defined above.
2. Draw $Q \sim \text{Bernoulli}(q)$.
3. If $Q = 1$, return an identity template, i.e., $\langle s, s \rangle$ such that $s \in c_1$.
4. Otherwise, draw $c_2 \sim G$ and return the template $\langle s_1, s_2 \rangle$ such that $s_1 \in c_1$ and $s_2 \in c_2$.

Inference: We perform inference to find the posterior over template sets given the exposure datasets used in the human experiments described above. We also infer the hyperparameters using the following prior distributions:

$$\begin{aligned} p &\sim \text{Beta}(1,1) \\ \alpha &\sim \text{Gamma}(2,4) \\ q &\sim \text{Beta}(1,1) \end{aligned} \tag{2}$$

Inference for the Dirichlet process mixture was performed using the Gibbs sampler described in Neal (2000). After each Gibbs sweep, slice sampling (Neal, 2003) was used to obtain a new value for p and q. A new value for α was sampled using the method described by Escobar and West (1995). We ran the sampler for 3000 iterations, discarded the first 100 samples and kept every fifth sample of the remaining samples, for a total of 580 samples from the posterior distribution.

Predicting human data: Participants in the behavioral experiments gave binary judgments ("could the word be part of the language?") rather than probability estimates. To link our model's predictions to participants' binary responses, we sample m template instantiations from the posterior predictive distribution.[5] If the relevant part of the test word appeared in these m samples, the model responds "yes"; this can be understood to be related to a sampling-based view of human inference (Vul et al., 2014). In the simulations below we fix m to be 10.

Human endorsement rates were consistently above 50%, while the model's ratings were often close to 0%. This is likely to be because human ratings were also informed by the unmodeled (fixed) parts of the templates, such as word length or number of vowels. We therefore linearly transform the model's ratings to the range exhibited by human participants: if the untransformed rate is r, the ultimate simulated rate will be $(1 + r)/2$.

[5]Template instantiations only include the modeled (specified) part of the template: an onset consonant in our model of the VOICING language or a consonant pair for the IDENTITY language.

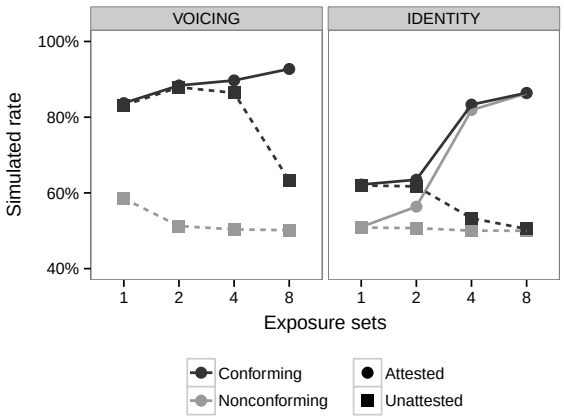

Figure 2: PAIM: Simulated endorsement rates.

4 Simulations

We only modeled those aspects of phonotactic templates that are relevant to the experimental results. For the VOICING experiment, we constrained the template to be ⟨_, V, C, V⟩ (inference is only performed on the first consonant); for the IDENTITY experiment, we constrained it to be ⟨_, V, _, V⟩.

Figure 2 shows the simulated endorsement rates. After a single exposure to each pattern (one exposure set), PAIM behaved in a qualitatively similar way to participants in both experiments: it distinguished CONF from NONCONF words, but did not distinguish ATT from UNATT words.

PAIM was less willing than humans to generalize to CONF-UNATT items after multiple exposure sets: in the IDENTITY experiment the generalization had no effect by the eighth exposure set; in the VOICING experiment its effect was weaker after eight than after four exposures sets. By contrast, human generalization in both languages showed no sign of weakening after multiple exposure sets.

5 Comparison to related models

Hayes and Wilson (2008) propose a Maximum Entropy model of phonotactics (MaxEnt; see also Goldwater and Johnson (2003)). Like PAIM, MaxEnt is based on phonological classes defined as feature matrices. Each class c is assigned a weight w_c. The predicted probability in MaxEnt of a sound s is

$$\hat{p}(s) = \frac{1}{Z} e^{\sum_c w_c I_c(s)} \tag{3}$$

where $Z = \sum_s \hat{p}(s)$ and $I_c(s) = 1$ if $s \in c$ and 0 otherwise.

We simulated endorsement rates from a MaxEnt model for the VOICING language. Following Hayes and Wilson (2008), we used l_2 regularization; that is, if the exposure words were $s_1, \ldots, s_n$, the objective function was

$$\sum_{i=1}^{n} \log \hat{p}(s_i) - \sum_{c} \frac{(w_c - \mu)^2}{2\sigma^2} \qquad (4)$$

Figure 3 shows the simulated endorsement rates for different values of σ (we set $\mu = 0$ in all simulations). For $\sigma = 0.05$, the model showed little learning after a single exposure set. When σ was set to higher values, MaxEnt rapidly preferred attested to unattested items, failing to reproduce the human early generalization pattern. Like PAIM, but unlike humans, generalization to CONF-UNATT items diminished after multiple exposure sets (in particular for $\sigma = 0.5$). A straightforward implementation of MaxEnt is therefore incapable of simulating the human results; better results could potentially be achieved with a regularization method that encouraged sparsity (Goodman, 2004; Johnson et al., 2015).

Another proposed model of phonotactics is the Minimal Generalization Learner, or MGL (Albright, 2009); Linzen and Gallagher (2014) showed that MGL can simulate relevant human behavioral data in some circumstances. In contrast with PAIM and MaxEnt, which converge to the empirical distribution given sufficient data, MGL reserves a fixed amount of probability mass to unseen events. It would therefore able to simulate a sustained generalization pattern.

Our prior over phonological classes bears some resemblance to the Rational Rules model of visual categorization (Goodman et al., 2008). In that model, classes are generated from a probabilistic context free grammar (PCFG); highly specified rules are therefore implicitly less probable, as in our model. Relatedly, Hayes and Wilson (2008) use a greedy feature selection procedure that starts from simpler phonological classes and gradually adds more complex ones; this procedure also encodes an implicit bias in favor of simple classes. Finally, our implementation of a parsimony bias using a Dirichlet process is related to similar biases incorporated into other models of language learning (Frank and Tenenbaum, 2011; Johnson et al., 2007; O'Donnell, 2015).

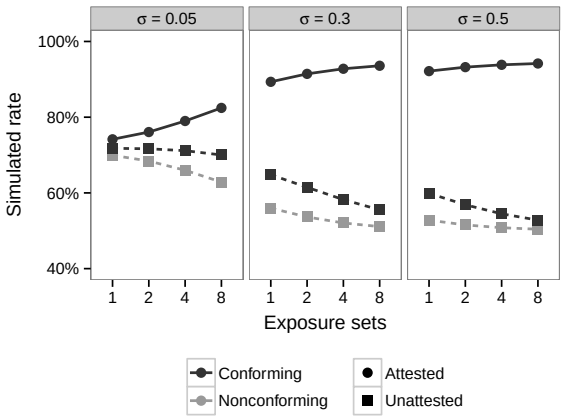

Figure 3: Maximum entropy model: Simulated endorsement rates for the VOICING language, with different values of the regularization parameter σ.

6 Discussion

We have presented a probabilistic model of phonotactic generalization that captures the pattern of rapid, abstract generalization characteristic of human learners. The model's performance is driven by two crucial assumptions. First, it allows hypotheses that make reference to abstract, broad classes of phones from the beginning of the learning process. Second, it prefers to learn compact or parsimonious explanations of the input corpus, using a small number of phonotactic templates. This second property is enforced by our use of the Dirichlet process as a prior over template sets.

These two properties interact. When the model has seen only a few data items, the availability of abstract generalizations allows it to explain all items using a single template, and the prior bias towards parsimony drives it to do so. As the number of data items increases, repeated instances of specific phonemes no longer seem like accidental observations from a more general template, but rather like significant templates in their own right; the model begins to capture such item-specificity.

The model stopped generalizing earlier than humans did; we intend to explore ways to explain this discrepancy. Additional human data would need to be collected to determine whether humans keep generalizing indefinitely, or eventually converge on the attested sounds. Finally, to facilitate inference, we only tested our model on the parts of the word that were relevant to the human data. In future work, we intend to extend the model to learn larger templates that include syllable structure and phonological tiers (Goldsmith, 1976).

Abstract

This paper presents a semantic parsing and reasoning approach to automatically solving math word problems. A new meaning representation language is designed to bridge natural language text and math expressions. A CFG parser is implemented based on 9,600 semi-automatically created grammar rules. We conduct experiments on a test set of over 1,500 number word problems (i.e., verbally expressed number problems) and yield 95.4% precision and 60.2% recall.

1 Introduction

Computers, since their creation, have exceeded human beings in (speed and accuracy of) mathematical calculation. However, it is still a big challenge nowadays to design algorithms to automatically solve even primary-school-level math word problems (i.e., math problems described in natural language).

Efforts to automatically solve math word problems date back to the 1960s (Bobrow, 1964a, b). Previous work on this topic falls into two categories: symbolic approaches and statistical learning methods. In symbolic approaches (Bobrow, 1964a, b; Charniak, 1968; Bakman, 2007; Liguda & Pfeiffer, 2012), math problem sentences are transformed to certain structures by pattern matching or verb categorization. Equations are then derived from the structures. Statistical learning methods are employed in two recent papers (Kushman et al., 2014; Hosseini et al., 2014).

Most (if not all) previous symbolic approaches suffer from two major shortcomings. First, natural language (NL) sentences are processed by simply applying pattern matching and/or transformation rules in an ad-hoc manner (refer to the related work section for more details). Second, surprisingly, they seldom report evaluation results about the effectiveness of the methods (except for some examples for demonstration purposes). For the small percentage of work with evaluation results available, it is unclear whether the patterns and rules are specially designed for specific sentences in a test set.

1). One number is 16 more than another. If the smaller number is subtracted from 2/3 of the larger, the result is 1/4 of the sum of the two numbers. Find the numbers.

2). Nine plus the sum of an even integer and its square is 3 raised to the power of 4. What is the number?

3). The tens digit of a two-digit number is 3 more than the units digit. If the number is 8 more than 6 times the sum of the digits, find the number.

4). If the first and third of three consecutive even integers are added, the result is 12 less than three times the second integer. Find the integers.

Figure 1: Number word problem examples

In this paper, we present a computer system called SigmaDolphin which automatically solves math word problems by semantic parsing and reasoning. We design a meaning representation language called DOL (abbreviation of dolphin language) as the structured semantic representation of NL text. A semantic parser is implemented to transform math problem text into DOL trees. A reasoning module is included to derive math expressions from DOL trees and to calculate final answers. Our approach falls into the symbolic category, but makes improvements over previous symbolic methods in the following ways,

* Work done while this author was an intern at Microsoft Research

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1132–1142,
Lisbon, Portugal, 17-21 September 2015.

1) We introduce a systematic way of parsing NL text, based on context-free grammar (CFG).

2) Evaluation is enhanced in terms of both data set construction and evaluation mechanisms. We split the problem set into a development set (called dev set) and a test set. Only the dev set is accessible during our algorithm design (especially in designing CFG rules and in implementing the parsing algorithm), which avoids over-tuning towards the test set. Three metrics (precision, recall, and F1) are employed to measure system performance from multiple perspectives, in contrast to all previous work (including the statistical ones) which only measures accuracy.

We target, in experiments, a subtype of word problems: number word problems (i.e., verbally expressed number problems, as shown in Figure 1). We hope to extend our techniques to handle general math word problems in the future.

We build a test set of over 1,500 problems and make a quantitative comparison with state-of-the-art statistical methods. Evaluation results show that our approach significantly outperforms baseline methods on our test set. Our system yields an extremely high precision of 95.4% and a reasonable recall of 60.2%, which shows promising application of our system in precision-critical situations.

2 Related Work

2.1 Math word problem solving

Most previous work on automatic word problem solving is symbolic. STUDENT (Bobrow, 1964a, b) handles algebraic problems by first transforming NL sentences into *kernel sentences* using a small set of transformation patterns. The kernel sentences are then transformed to math expressions by recursive use of pattern matching. CARPS (Charniak, 1968, 1969) uses a similar approach to solve English rate problems. The major difference is the introduction of a tree structure as the internal representation of the information gathered for one object. Liguda & Pfeiffer (2012) propose modeling math word problems with augmented semantic networks. Addition/subtraction problems are studied most in early research (Briars & Larkin, 1984; Fletcher, 1985; Dellarosa, 1986; Bakman, 2007; Ma et al., 2010). Please refer to Mukherjee & Garain (2008) for a review of symbolic approaches before 2008.

No empirical evaluation results are reported in most of the above work. Almost all of these approaches parse NL text by simply applying pattern matching rules in an ad-hoc manner. For example, as mentioned in Bobrow (1964b), due to the pattern "($, AND $)", the system would incorrectly divide "Tom has 2 apples, 3 bananas, and 4 pears." into two "sentences": "Tom has 2 apples, 3 bananas." and "4 pears."

WolframAlpha[1] shows some examples[2] of automatically solving elementary math word problems, with technique details unknown to the general public. Other examples on the web site demonstrate a large coverage of short phrase queries on math and other domains. By randomly selecting problems from our dataset and manually testing on their web site, we find that it fails to handle most problems in our problem collection.

Statistical learning methods have been proposed recently in two papers: Hosseini et al. (2014) solve single step or multi-step homogenous addition and subtraction problems by learning verb categories from the training data. Kushman et al. (2014) can solve a wide range of word problems, given that the equation systems and solutions are attached to problems in the training set. The method of the latter paper (referred to as KAZB henceforth) is used as one of our baselines.

2.2 Semantic parsing

There has been much work on analyzing the semantic structure of NL strings. In semantic role labeling and frame-semantic parsing (Gildea & Jurafsky, 2002; Carreras & Marquez, 2004; Marquez et al., 2008; Baker et al., 2007; Das et al., 2014), predicate-argument structures are discovered from text as their shallow semantic representation. In math problem solving, we need a deeper and richer semantic representation from which to facilitate the deriving of math expressions.

Another type of semantic parsing work (Zelle & Mooney, 1996; Zettlemoyer & Collins, 2005; Zettlemoyer & Collins, 2007; Wong & Mooney, 2007; Cai & Yates, 2013; Berant et al., 2013; Kwiatkowski et al., 2013; Berant & Liang, 2014) maps NL text into logical forms by supervised or semi-supervised learning. Some of them are based on or related to combinatory categorial grammar (CCG) (Steedman, 2000). Abstract Meaning Representation (AMR) (Banarescu et al., 2013) keeps richer semantic information than CCG and logical

[1] http://www.wolframalpha.com

[2] https://www.wolframalpha.com/examples/Elementary-Math.html (bottom-right part)

forms. In Section 3.1.4, we discuss the differences between DOL, AMR, and CCG, and explain why we choose DOL as the meaning representation language for math problem solving.

3 Approach

Consider the first problem in Figure 1 (written below for convenience),

One number is 16 more than another. If the smaller number is subtracted from 2/3 of the larger, the result is 1/4 of the sum of the two numbers. Find the numbers.

To automatically solve this problem, the computer system needs to figure out, somehow, that 1) two numbers x, y are demanded, and 2) they satisfy the equations below,

$$x = 16 + y \quad (1)$$

$$(2/3)x - y = (x + y) / 4 \quad (2)$$

To achieve this, *reasoning* must be performed based on common sense knowledge and the information provided by the source problem. Given the difficulty of performing reasoning directly on unstructured and ambiguous natural language text, it is reasonable to transform the source text into a structured, less ambiguous representation.

Our approach contains three modules:

1) A *meaning representation language* called DOL newly designed by us as the semantic representation of natural language text.
2) A *semantic parser* which transforms natural language sentences of a math problem into DOL representation.
3) A *reasoning* module to derive math expressions from DOL representation.

English: Nine plus the sum of an even integer and its square is 3 raised to the power of 4. What is the number?

DOL trees:

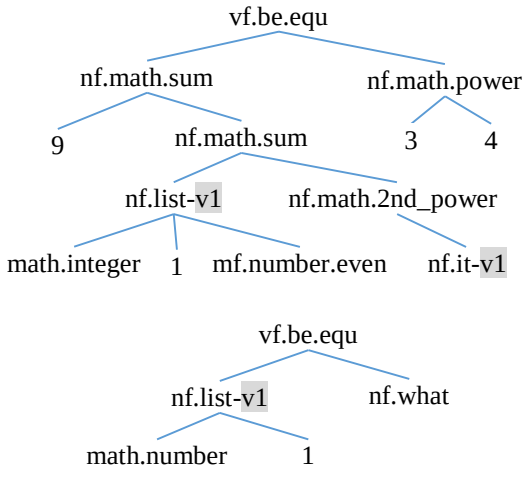

Figure 2: DOL example

3.1 DOL: Meaning representation language

Every meaningful piece of NL text is represented in DOL as a semantic tree of various node types. Figure 2 shows the DOL representation of the second problem of Figure 1. It contains two semantic trees, corresponding to the two sentences.

3.1.1 Node types

Node types of a DOL tree include *constants*, *classes*, and *functions*. Each interim node of a tree is always a function; and each leaf node can be a constant, a class, or a zero-argument function.

Constants in DOL refer to specific objects in the world. A constant can be a number (e.g., 3.57), a lexical string (like "New York"), or an entity.

Classes: An entity class refers to a category of entities sharing common semantic properties. For example, all cities are represented by the class *location.city*; and *math.number* is a class for all numbers. It is clear that,

3.14159 ∈ math.number
city.new_york ∈ location.city

A class C_1 is a *sub-class* (denoted by ⊆) of another class C_2 if and only if every instance of C_1 are in C_2. The following holds according to common sense knowledge,

math.number ⊆ math.expression
person.pianist ⊆ person.performer

Template classes are classes with one or more parameters, just like template classes in C++. The most important template class in DOL is

t.list<*c*,*m*,*n*>

where *c* is a class; *m* and *n* are integers. Each instance of this class is a list containing at least *m* and at most *n* elements of type *c*. For example, each instance of t.list<math.number,2,+∞> is a list containing at least 2 numbers.

Functions are used in DOL as the major way to form larger language units from smaller ones. A function is comprised of a *name*, a list of *core arguments*, and a *return type*. DOL enables function overloading (again borrowing ideas from programming languages). That is, one function name can have multiple core-argument specifications. Below are two specifications for fn.math.sum (which appears in the example of Figure 2).

nf.math.sum!1: $1: math.expression; $2: math.expression return type: math.expression return value: The sum of its arguments
nf.math.sum!2: $1: t.list<math.expression,2,+∞> return type: math.expression return value: The sum of the elements in $1

Here "$1: math.expression" means the first argument has type math.expression.

DOL supports three kinds of functions: noun functions, verb functions, and modifier functions.

Noun functions map entities to their properties or to other entities having specific relations with the argument(s). For example, *nf.math.sum* maps math expressions to their sum. Noun functions are used to represent noun phrases in natural language text. More noun functions are shown in Table 1.

Among all noun functions, *nf.list* has a special important position due to its high frequency in DOL trees. The function is specified below,

nf.list
$1: class; $2: math.number
return type: t.list<$1>
return value: An entity list with cardinality $2 and element type $1

For example nf.list(math.number,5) returns a list containing 5 elements of type math.number. It is the semantic representation of "five numbers".

Pronoun functions are special zero-argument noun functions. Examples are nf.it (representing an already-mentioned entity or event) and nf.what (denoting an unknown entity or entity list).

Verb functions act as sentences or sub-sentences in DOL. As an example, vf.be.equ (in Figure 2) is a verb function that has two arguments of the quantity type.

vf.be.equ
$1: quantity.generic; $2: quantity.generic
return type: t.vf
Meaning: Two quantities $1 and $2 have the same value

In addition to core arguments ($1, $2, etc.), many functions can take additional *extended arguments* as their modifiers. Our last function type called *modifier functions* often take the role of extended arguments, to modify noun functions, verb functions, or other modifier functions. Modifier functions are used in DOL as the semantic representation of adjectives, adverb phrases (including conjunctive adverb phrases), and prepositional phrases in natural languages. In the example of Figure 2, the function mf.number.even modifies the noun function nf.list as its extended argument.

3.1.2 Entity variables

Variables are assigned to DOL sub-trees for indicating the co-reference of sub-trees to entities and for facilitating the construction of logical forms and math expressions from DOL. In Figure 2, the same variable v1 (meaning a variable with ID 1) is assigned to two sub-trees in the first sentence and one sub-tree in the second sentence. Thus the three sub-trees refer to the same entity.

Function	Remarks
nf.math.numerator $1: math.fraction ret: math.number	Get the numerator of fraction $1
nf.math.gcd $1: t.list<math.integer,2,+∞> ret: math.integer	Get the greatest common divisor of the elements of $1
nf.e.height $1: e.concrete ret: quantity.length	Get the height of $1 which is a concrete entity
vf.believe $1: e.agent; $2: t.vf.std ret: t.vf	Agent $1 believes that $2 is true as a predicate
mf.number.even ret: t.mf.adj	Indicating the property of being an even number

Table 1: Example DOL functions

3.1.3 Key features of DOL

DOL has some nice characteristics that are critical to building a high-precision math problem solving system. That is why we invent DOL as our meaning representation language instead of employing an existing one.

First, DOL is a strongly typed language. Every function has clearly defined argument types and a return type. A valid DOL tree must satisfy the *type-compatibility* property:

Type-compatibility: The type of each child of a function node should match the corresponding argument type of the function.

For example, in Figure 2, the return type of nf.math.power is math.expression, which matches the second argument of vf.be.equ. However, the following two trees (yielded from the corresponding pieces of text) are invalid because they do not satisfy type-compatibility.

sum of 100 [unreasonable text]
~~nf.math.sum!2(100)~~ [invalid DOL tree]

sum of 3 and Jordan [unreasonable text]
~~nf.math.sum!2({3, "Jordan"})~~ [invalid tree]

Second, we maintain in DOL an open-domain type system. The type system contains over 1000 manually verified classes and more automatically generated ones (refer to Section 3.2.1 for more details). Such a comprehensive type system makes it possible to define various kinds of functions and to perform type-compatibility checking. In contrast, most previous semantic languages have at most 100+ types at the grammar level. In addition, by introducing template classes, we avoid maintaining a lot of potentially duplicate types and reduce the type system management efforts. To the best of our knowledge, template classes are not

available in other semantic representation languages.

Third, DOL has built-in data structures like t.list and nf.list which greatly facilitate both function declaration and text representation (especially math text representation). For example, the two variants of nf.math.sum (refer to Section 3.1.1 for their specifications) are enough to represent the following English phrases:

3 plus 5 → nf.math.sum!1(3, 5)
sum of 3, 5, 7, and 9 → nf.math.sum!2(nf.list(3, 5, 7, 9))
sum of ten thousand numbers → nf.math.sum!2(nf.list(math.number,10000))

Without t.list or nf.list, we would have to define a lot of overloaded functions for nf.math.sum to deal with different numbers of addends.

3.1.4 Comparing with other languages

Among all meaning representation languages, AMR (Banarescu et al., 2013) is most similar to DOL. Their major differences are: First, they use very different mechanisms to represent noun phrases. In AMR, a sentence (e.g., "the boy destroyed the room") and a noun phrase (e.g., "the boy's destruction of the room") can have the same representation. While in DOL, a sentence is always represented by a verb function; and a noun phrase is always a noun function or a constant. Second, DOL has a larger type system and is stricter in type compatibility checking. Third, DOL has template classes and built-in data structures like t.list and nf.list to facilitate the representation of math concepts.

CCG (Steedman, 2000) provides a transparent interface between syntax and semantics. In CCG, semantic information is defined on words (e.g., "λx.odd(x)" for "odd" and "λx.number(x)" for "number"). In contrast, DOL explicitly connects NL text patterns to semantic elements. For example, as shown in Table 2 (Section 3.2.1), one CFG grammar rule connects pattern "{$1} raised to the power of {$2}" to function nf.math.power.

Logical forms are another way of meaning representation. We choose not to transform NL text directly to logical forms for two reasons: On one hand, state-of-the-art methods for mapping NL text into logical forms typically target short, one-sentence queries in restricted domains. However, many math word problems are long and contain multiple sentences. On the other hand, variable-id assignment is a big issue in direct logical form construction for many math problems. Let's use the following problem (i.e., the first problem of Figure 1) to illustrate,

One number is 16 more than another. If the smaller number is subtracted from 2/3 of the larger, the result is 1/4 of the sum of the two numbers. Find the numbers.

For this problem, it is difficult to determine whether "the smaller number" refers to "one number" or "another" in directly constructing logical forms. It is therefore a challenge to construct a correct logical form for such kinds of problems.

Our solution to the above challenge is assigning a new variable ID (which is different from the IDs of "one number" and "another") and to delay the final variable-ID assignment to the reasoning stage. To enable this mechanism, the meaning representation language should support a lazy variable ID assignment and keep as much information (e.g., determiners, plurals, modifiers) from the noun phrases as possible. DOL is a language that always keeps the structure information of phrases, whether or not it has been assigned a variable ID.

In summary, compared with other languages, DOL has some unique features which make it more suitable for our math problem solving scenario.

3.2 Semantic Parsing

Our parsing algorithm is based on context-free grammar (CFG) (Chomsky, 1956; Backus, 1959; Jurafsky & Martin, 2000), a commonly used mathematical system for modeling constituent structure in natural languages.

3.2.1 CFG for connecting DOL and NL

The core part of a CFG is the set of grammar rules. Example English grammar rules for building syntactic parsers include "S → NP VP", "NP → CD | DT NN | NP PP", etc. Table 2 shows some example CFG rules in our system for mapping DOL nodes to natural language word sequences. The left side of each rule is a DOL element (a function, class, or constant); and the right side is a sequence of words and arguments. The grammar rules are consumed by our parser for building DOL trees from NL text.

So far there are 9,600 grammar rules in our system. For every DOL node type, the lexicon and grammar rules are constructed together in a semi-automatic way. Math-related classes, functions, and constants and their grammar rules are manually built by referring to text books and online tu-

torials. About 35 classes and 200 functions are obtained in this way. Additional instances of each element type are constructed in the ways below.

Classes: Additional classes and grammar rules are obtained from two data sources: Freebase[3] types, and automatically extracted lexical semantic data. By treating Freebase types as DOL classes and the mapping from types to lexical names as grammar rules, we get the first version of grammar for classes. To improve coverage, we run a term peer similarity and hypernym extraction algorithm (Hearst, 1992; Shi et al., 2010; Zhang et al., 2011) on a web snapshot of 3 billion pages, and get a peer-similarity graph and a collection of is-a pairs. An is-a pair example is (Megan Fox, actress), where "Megan Fox" and "actress" are instance and type names respectively. In our peer similarity graph, "Megan Fox" and "Britney Spears" have a high similarity score. The peer similarity graph is used to clean the is-a data collection (with the idea that peer terms often share some common type names). Given the cleaned is-a data, we sort the type names by weight and manually create classes for top-1000 type names. For example, create a class person.actress and add a grammar rule "person.actress → actress". For the other 2000 type names in the top 3000, we create classes and rules automatically, in the form of "class.TN → TN", where TN is a type name. For example, create rule "class.succulent → succulent" for name "succulent".

vf.be.equ($1,$2) → {$1} be equal to {$2} | {$1} equal {$2} | {$1} be {$2}
vf.give($1,$2,$3) → {$1} give {$2} to {$3} | {$1} give {$3} {$2}
nf.math.sum!1($1,$2) → {$1} plus {$2} | {$2} added to {$1}
nf.math.sum!2($1) → sum of {$1} | addition of {$1}
nf.math.power($1,$2) → {$1} raised to the {power|exponent} of {$2}
nf.list($1,$2) → {$2} {$1}
mf.number.even → even
mf.condition.if($1) → if {$1}
mf.approximately → approximately | roughly
education.university → university
math.number → number
math.integer → integer

Table 2: Example grammar for connecting DOL and NL

Functions: Additional noun functions are automatically created from Freebase properties and attribute extraction results (Pasca et al., 2006; Durme et al., 2008), using a similar procedure with creating classes from Freebase types and is-a extraction results. We have over 50 manually defined math-related verb functions. Our future plan is automatically generating verb functions from databases like PropBank (Kingsbury & Palmer, 2002), FrameNet (Fillmore et al., 2003), and VerbNet[4] (Schuler, 2005). Additional modifier functions are automatically created from an English adjective and adverb list, in the form of "mf.adj.TN → TN" and "mf.adv.TN → TN" where TN is the name of an adjective or adverb.

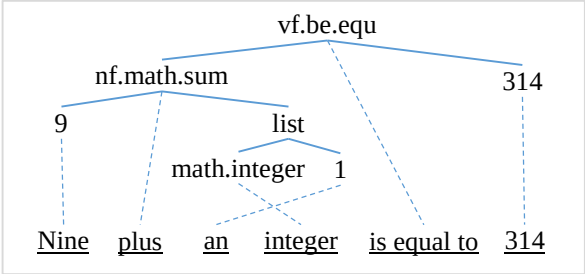

Figure 3: The DOL semantic parse tree for "Nine plus an integer is equal to 314"

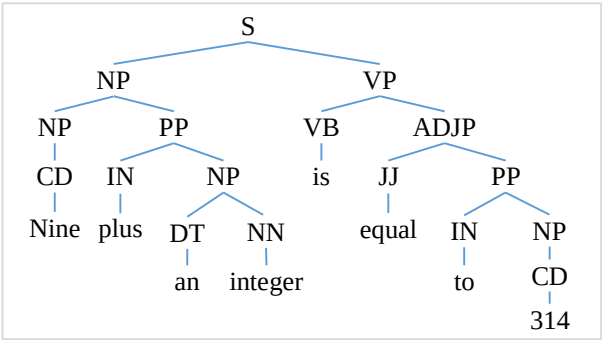

Figure 4: A syntactic parse tree

3.2.2 Parsing

Parsing for CFG is a well-studied topic with lots of algorithms invented (Kasami, 1965; Earley, 1970). The core idea behind almost all the algorithms is exploiting dynamic programming to achieve efficient search through the space of possible parse trees. For syntactic parsing, a well-known serious problem is ambiguity: the appearance of many syntactically correct but semantically unreasonable parse trees. Modern syntactic parsers reply on statistical information to reduce

[3] Freebase: http://www.freebase.com/

[4] VerbNet: http://verbs.colorado.edu/~mpalmer/projects/verbnet.html

ambiguity. They are often based on probabilistic CFGs (PCFGs) or probabilistic lexicalized CFGs trained on hand-labeled TreeBanks.

With the new set of DOL-NL grammar rules (examples in Table 2) and the type-compatibility property (Section 3.1.3), ambiguity can hopefully be greatly reduced, because semantically unreasonable parsing often results in invalid DOL trees.

We implement a top-down parser for our new CFG of Section 3.2.1, following the Earley algorithm (Earley, 1970). No probabilistic information is attached in the grammar rules because no Treebanks are available for learning statistical probabilities for the new CFG. Figure 3 shows the parse tree returned by our parser when processing a simple sentence. The DOL tree can be obtained by removing the dotted lines (corresponding to the non-argument part in the right side of the grammar rules). A traditional syntactic parse tree is shown in Figure 4 for reference.

During parsing, a score is calculated for each DOL node. The score of a tree *T* is the weighted average of the scores of its sub-trees,

$$\boldsymbol{S}(\boldsymbol{T}) = \frac{\sum_{i=1}^{k} \boldsymbol{L}(\boldsymbol{T_i}) \cdot \boldsymbol{S}(\boldsymbol{T_i})}{\sum_{i=1}^{k} \boldsymbol{L}(\boldsymbol{T_i})} \cdot \boldsymbol{p}(\boldsymbol{T}) \qquad (3)$$

where T_i is a sub-tree, and $L(T_i)$ is the number of words to which the sub-tree corresponds in the original text. If the type-compatibility property for *T* is satisfied, $p(T)$=1; otherwise $p(T)$=0.

All leaf nodes are assigned a score of 1.0, except for pure lexical string nodes (which are used as named entity names). The score of a lexical string node is set to $1/(1+\mu n)$, where *n* is the number of words in the node, and μ (=0.2 in experiments) is a parameter whose value does not have much impact on parsing results. Such a score function encourages interpreting a word sequence with our grammar than treating it as an entity name.

Among all candidate DOL trees yielded during parsing, we return the one with the highest score as the final parsing result. A null tree is returned if the highest score is zero.

3.3 Reasoning

The reasoning module is responsible for deriving *math expressions* from DOL trees and calculating problem answers by solving equation systems. Math expressions have different definitions in different contexts. In some definitions, equations and inequations are excluded from math expressions. In this paper, equations and inequations (like "*a*=*b*" and "*ax*+*b*>0") are called s-expressions because they represent mathematical sentences, while other math expressions (like "*x*+5") are named n-expressions since they are essentially noun phrases. Our definition of "*math expressions*" therefore includes both n-expressions and s-expressions.

Different types of nodes may generate different types of math expressions. In most cases, s-expressions are derived from verb function nodes and modifier function nodes, while n-expressions are generated from constants and noun function nodes. For example, the s-expression "9+*x*=314" can be derived from the DOL tree of Figure 3, if variable *x* represents the integer. In the same Figure, The n-expression "9+x" is derived from the left sub-tree.

The pseudo-codes of our math expression derivation algorithm are shown in Figure 5. The algorithm generates the math expression for a DOL tree T by first calling the expression derivation procedure of sub-trees, and then applying the semantic interpretation of T. All the s-expressions derived so far are stored in an expression list named XL.

```
Algorithm MathExpDerivation
   Input: DOL tree T
   Output: Math expression X(T)
   Global data structure: Expression list XL
1: For each child Ci of T
2:    X(Ci) = MathExpDerivation(Ci)
3:    If X(Ci) is an s-expression
4:       Add X(Ci) to XL
5: X(T) ← Applying the semantic interpretation
of T
6: Return X(T)
```

Figure 5: Math expression derivation algorithm

vf.be.equ($1,$2) → X($1) = X($2)	(1)
nf.math.sum!1($1,$2) → X($1) + X($2)	(2)
nf.math.sum!2($1) → $\sum_{\mathbf{e}\in\$\mathbf{1}} \mathbf{X}(\mathbf{e})$	(3)
nf.math.gcd($1) → gcd({X(e) | **e** ∈ $**1**})	(4)
nf.list($1,$2) → V = (v_1, v_2…, v_n), *n*=X($2)	(5)
mf.number.even → X($↑) % 2 = 0	(6)

Table 3: Example semantic interpretations

The semantic interpretation of DOL nodes plays a critical role in the algorithm. Table 3 shows some example interpretations of some representative DOL functions. In the table, $1, $2 etc. are function arguments, and $↑ for a modifier node denotes the node which the modifier modifies. So far the semantic interpretations are built manually. Please note that it is not necessary to make semantic interpretations for every DOL

node in solving number word problems. For example, most class nodes and many adverb nodes can have null interpretations at the moment.

4 Experiments

4.1 Experimental setup

Datasets: Our problem collection[5] contains 1,878 math number word problems, collected from two web sites: algebra.com[6] (a web site for users to post math problems and get help from tutors) and answers.yahoo.com[7]. Problems on both sites are organized into categories. For algebra.com, problems are randomly sampled from the number word problems category; for answers.yahoo.com, we first randomly sample an initial set of problems from the math category and then ask human annotators to manually choose number word problems from them. Math equations[8] and answers to the problems are manually added by human annotators.

We randomly split the dataset into a dev set (for algorithm design and debugging) and a test set. More subsets are extracted to meet the requirements of the baseline methods (see below). Table 4 shows the statistics of the datasets.

Baseline methods: We compare our approach with two baselines: KAZB (Kushman et al., 2014) and BasicSim.

KAZB is a learning-based statistical method which solves a problem by mapping it to one of the *equation templates* determined by the annotated equations in the training data. We run the ALLEQ version of their algorithm since it performs much better than the other two (i.e., 5EQ and 5EQ+ANS). Their codes support only linear equations and require that there are at least two problems for each equation template (otherwise an exception will be thrown). By choosing problems from the collection that meet these requirements, we build a sub-dataset called LinearT2. In the dataset of KAZB, each equation template corresponds to at least 6 problems. So we form another sub-dataset called LinearT6 by removing from the test set the problems for which the associated equation template appears less than 6 times.

BasicSim is a simple statistical method which works by computing the similarities between a testing problem and those in the training set, and then applying the equations of the most similar problem. This method has similar performance with KAZB on their dataset, but does not have the two limitations mentioned above. Therefore we adopt it as the second baseline.

For both baselines, experiments are conducted using 5-fold cross-validation with the dev set always included in the training data. In other words, we always use the dev set and 4/5 of the test set as training data for each fold.

Evaluation metrics: Evaluation is performed in the setting that a system can choose NOT to answer all problems in the test set. In other words, one has the flexibility of generating answers only when she knows how to solve it or she is confident about her answer. In this setting, the following three metrics are adopted in reporting evaluation results (assuming, in a test set of size n, a system generates answers for m problems, where k of them are correct):

Precision: k/m

Recall (or coverage): k/n

F1: $2PR/(P+R) = 2k/(m+n)$

Dataset		#problems	#sentences (average)	#words (average)
All	dev	374	1.79	20.3
	test	1,504	1.75	22.5
Linear	dev	247	1.78	19.6
	test	986	1.72	19.0
LinearT2	dev	172	1.85	18.8
	test	669	1.71	17.4
LinearT6	dev	71	1.96	16.8
	test	348	1.80	16.1

Table 4: Dataset statistics (Linear: problems with linear equations; T2: problems corresponding to template size ≥ 2)

4.2 Experimental results

The Overall evaluation results are summarized in Table 5, where "Dolphin" represents our approach. The results show that our approach significantly outperforms (with $p<<0.01$ according to two-tailed t-test) the two baselines on every test set, in terms of precision, recall, and F-measure. Our approach achieves a particularly high precision of 95%. That means once an answer is provided by our approach, it has a very high probability of being correct.

Please note that our grammar rules and parsing algorithm are NOT tuned for the evaluation data. Only the dev set is referred to in system building.

[5] Available from http://research.microsoft.com/en-us/projects/dolphin/

[6] http://www.algebra.com

[7] https://answers.yahoo.com/

[8] Math equations are used in the baseline approaches as part of training data.

Since the baselines generate results for *all* problems, the precision, recall, and F1 are all the same for each dataset.

Dataset	Method	Precision (%)	Recall (%)	F1 (%)
LinearT6	KAZB	49.1	49.1	49.1
	BasicSim	59.7	59.7	59.7
	Dolphin	**98.1**	**72.9**	**83.6**
LinearT2	KAZB	37.5	37.5	37.5
	BasicSim	46.3	46.3	46.3
	Dolphin	**97.3**	**68.0**	**80.0**
Linear	BasicSim	32.3	32.3	32.3
	Dolphin	**95.7**	**63.6**	**76.4**
Test set all	BasicSim	29.0	29.0	29.0
	Dolphin	**95.4**	**60.2**	**73.8**

Table 5: Evaluation results

The reason for such a high precision is that, by transforming NL text to DOL trees, the system "*understands*" the problem (or has structured and accurate information about quantity relations). Therefore it is more likely to generate correct results than statistical methods who simply "guess" according to features. By examining the problems in the dev set that we cannot generate answers, we find that most of them are due to empty parsing results.

On the other hand, statistical approaches have the advantage of generating answers without understanding the semantic meaning of problems (as long as there are similar problems in the training data). So they are able to handle (with probably low precision) problems that are complex in terms of language and logic.

Please pay attention that our experimental results reported here are on *number word problems*. General math word problems are much harder to our approach because the entity types, properties, relations, and actions contained in general word problems are much larger in quantity and more complex in quality. We are working on extending our approach to general math word problems. Now our DOL language and CFG grammar already have a good coverage on common entity types, but the coverage on properties, relations, and actions is quite limited. As a result, our parser fails to parse many sentences in general math word problems because they contain properties, relations or actions that are unknown to our system. We also observe that sometimes we are able to parse a problem successfully, but cannot derive math expressions in the reasoning stage. This is often because some relations or actions in the problem are not modeled appropriately. As future work, we plan to extend our DOL lexicon and grammar to improve the coverage of properties, relations, and actions. We also plan to study the mechanism of modeling relations and actions.

5 Conclusion

We proposed a semantic parsing and reasoning approach to automatically solve math number word problems. We have designed a new meaning representation language DOL to bridge NL text and math expressions. A CFG parser is implemented to parse NL text to DOL trees. A reasoning module is implemented to derive math expressions from DOL trees, by applying the semantic interpretation of DOL nodes. We achieve a high precision and a reasonable recall on our test set of over 1,500 problems. We hope to extend our techniques to handling general math word problems and to other domains (like physics and chemistry) in the future.

Acknowledgments

We would like to thank the annotators for their efforts in assigning math equations and answers to the problems in our dataset. Thanks to the anonymous reviewers for their helpful comments and suggestions.

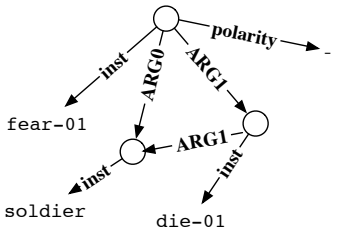
Abstract

We present a parser for Abstract Meaning Representation (AMR). We treat English-to-AMR conversion within the framework of string-to-tree, syntax-based machine translation (SBMT). To make this work, we transform the AMR structure into a form suitable for the mechanics of SBMT and useful for modeling. We introduce an AMR-specific language model and add data and features drawn from semantic resources. Our resulting AMR parser significantly improves upon state-of-the-art results.



The soldier was not afraid of dying.
The soldier was not afraid to die.
The soldier did not fear death.

Figure 1: An Abstract Meaning Representation (AMR) with several English renderings.

1 Introduction

Abstract Meaning Representation (AMR) is a compact, readable, whole-sentence semantic annotation (Banarescu et al., 2013). It includes entity identification and typing, PropBank semantic roles (Kingsbury and Palmer, 2002), individual entities playing multiple roles, as well as treatments of modality, negation, etc. AMR abstracts in numerous ways, e.g., by assigning the same conceptual structure to *fear* (v), *fear* (n), and *afraid* (adj). Figure 1 gives an example.

AMR parsing is a new research problem, with only a few papers published to date (Flanigan et al., 2014; Wang et al., 2015) and a publicly available corpus of more than 10,000 English/AMR pairs.[1] New research problems can be tackled either by developing new algorithms/techniques (Flanigan et al., 2014; Wang et al., 2015) or by adapting existing algorithms/techniques to the problem at hand. In this paper, we investigate the second approach.

The AMR parsing problem bears a strong formal resemblance to syntax-based machine translation (SBMT) of the string-to-tree variety, in that a string is transformed into a nested structure in both cases. Because of this, it is appealing to apply the substantial body of techniques already invented for SBMT[2] to AMR parsing. By re-using an SBMT inference engine instead of creating custom inference procedures, we lose the ability to embed some task-specific decisions into a custom transformation process, as is done by Flanigan et al. (2014) and Wang et al. (2015). However, we reap the efficiency gains that come from working within a tested, established framework. Furthermore, since production-level SBMT systems are widely available, anyone wishing to generate AMR from text need only follow our recipe and retrain an existing framework with relevant data to quickly obtain state-of-the-art results.

Since SBMT and AMR parsing are, in fact, distinct tasks, as outlined in Figure 2, to adapt the SBMT parsing framework to AMR parsing, we develop novel representations and techniques. Some of our key ideas include:

1. Introducing an AMR-equivalent representation that is suitable for string-to-tree SBMT rule extraction and decoding (Section 4.1).

	SBMT	AMR parsing
Target	tree	graph
Nodes	labeled	unlabeled
Edges	unlabeled	labeled
Alignments	words to leaves	words to leaves + words to edges
Children	ordered	unordered
Accuracy Metric	BLEU (Papineni et al., 2002)	Smatch (Cai and Knight, 2013)

Figure 2: Differences between AMR parsing and syntax-based machine translation (SBMT).

2. Proposing a target-side reordering technique that leverages the fact that child nodes in AMR are unordered (Section 4.4).
3. Introducing a hierarchical AMR-specific language model to ensure generation of likely parent-child relationships (Section 5).
4. Integrating several semantic knowledge sources into the task (Section 6).
5. Developing tuning methods that maximize Smatch (Cai and Knight, 2013) (Section 7).

By applying these key ideas, which constitute lightweight changes on a baseline SBMT system, we achieve state-of-the-art AMR parsing results. We next describe our baseline, and then describe how we adapt it to AMR parsing.

2 Syntax-Based Machine Translation

Our baseline SBMT system proceeds as follows. Given a corpus of (source string, target tree, source-target word alignment) sentence translation training tuples and a corpus of (source, target, score) sentence translation tuning tuples:

1. **Rule extraction:** A grammar of string-to-tree rules is induced from training tuples using the GHKM algorithm (Galley et al., 2004; Galley et al., 2006).
2. **Local feature calculation:** Statistical and indicator features, as described by Chiang et al. (2009), are calculated over the rule grammar.
3. **Language model calculation:** A Kneser-Ney-interpolated 5-gram language model (Chen and Goodman, 1996) is learned from the yield of the target training trees.
4. **Decoding:** A beamed bottom-up chart decoder (Pust and Knight, 2009; Hopkins and Langmead, 2010) calculates the optimal derivations given a source string and feature parameter set.
5. **Tuning:** Feature parameters are optimized using the MIRA learning approach (Chiang et al., 2009) to maximize the objective, typically BLEU (Papineni et al., 2002), associated with a tuning corpus.

We initially use this system with no modifications and pretend that English–AMR is a language pair indistinct from any other.

Corpus	Sentences	Tokens
Training	10,313	218,021
Development	1,368	29,484
Test	1,371	30,263

Table 1: Data splits of AMR 1.0, used in this work. Tokens are English, after tokenization.

3 Data and Comparisons

We use English–AMR data from the AMR 1.0 corpus, LDC Catalog number 2014T12. In contrast to narrow-domain data sources that are often used in work related to semantic parsing (Price, 1990; Zelle, 1995; Kuhlmann et al., 2004), the AMR corpus covers a broad range of news and web forum data. We use the training, development, and test splits specified in the AMR corpus (Table 1). The training set is used for rule extraction, language modeling, and statistical rule feature calculation. The development set is used both for parameter optimization and qualitatively for hill-climbing. The test set is held out blind for evaluation. We preprocess the English with a simple rule-based tokenizer and, except where noted, lowercase all data. We obtain English–AMR alignments by using the unsupervised alignment approach of Pourdamghani et al. (2014), which linearizes the AMR and then applies the models of Brown et al. (1993) with an additional symmetrization constraint.

All parsing results reported in this work are obtained with the Smatch 1.0 software (Cai and Knight, 2013). We compare our results to those of Flanigan et al. (2014) on the AMR 1.0 data splits; we run that work's JAMR software according to the provided instructions.[3] We also compare our results to published scores in the recent work of Wang et al. (2015). Their work uses slightly different data than that used here [4] but in practice we have not seen significant variation in results.

4 AMR Transformations

In this section we discuss various transformations to our AMR data. Initially, we concern ourselves with converting AMR into a form that is amenable to GHKM rule extraction and string to tree decoding. We then turn to structural transformations designed to improve system performance. Figure 3 progressively shows all the transformations described in this section; the example we follow is shown in its original form in Figure 3a. We note that all transformations are done internally; the input to the final system is a sentence and the output is an AMR. We further observe that all transformations are data-driven and language agnostic.

4.1 Massaging AMRs into Syntax-Style Trees

The relationships in AMR form a directed acyclic graph (DAG), but GHKM requires a tree, so we must begin our transformations by discarding some information. We arbitrarily disconnect all but a single parent from each node (see Figure 3b). This is the only lossy modification we make to our AMR data. As multi-parent relationships occur 1.05 times per training sentence and at least once in 48% of training sentences, this is indeed a regrettable loss. We nevertheless make this modification, since it allows us to use the rest of our string-to-tree tools.

AMR also contains labeled edges, unlike the constituent parse trees we are used to working with in SBMT. These labeled edges have informative content and we would like to use the alignment procedure of Pourdamghani et al. (2014), which aligns words to edges as well as to terminal nodes. So that our AMR trees are compatible with both our desired alignment approach and our desired rule extraction approach, we propagate edge labels to terminals via the following procedure:

1. For each node n in the AMR tree we create a corresponding node m with the all-purpose symbol 'X' in the SBMT-like tree. Outgoing edges from n come in two flavors: *concept*

edges, labeled 'inst,' which connect n to a terminal *concept* such as `fear-01`, and *role edges*, which have a variety of labels such as **ARG0** and **name**, and connect n to another instance or to a *string*.[5] A node has one instance edge and zero or more role edges. We consider each type of edge separately.

2. For each outgoing role edge we insert two unlabeled edges into the corresponding transformation; the first is an edge from m to a terminal bearing the original edge's role label (a so-called *role label edge*), and the second (a *role filler edge*) connects m to the transformation of the original edge's target node, which we process recursively. String targets of a role receive an 'X' preterminal to be consistent with the form of role filler edges.
3. For the outgoing concept edge we insert an unlabeled edge connecting m and the concept. It is unambiguous to determine which of m's edges is the concept edge and which edges constitute role label edges and their corresponding role filler edges, as long as paired label and filler edges are adjacent.
4. Since SBMT expects trees with preterminals, we simply replicate the label identities of concepts and role labels, adding a marker ('P' in Figure 3) to distinguish preterminals.

The complete transformation can be seen in Figure 3c. Apart from multiple parent ancestry, the original AMR can be reconstructed deterministically from this SBMT-compliant rewrite.

4.2 Tree Restructuring

While the transformation in Figure 3c is acceptable to GHKM, and hence an entire end-to-end AMR parser may now be built with SBMT tools, the resulting parser does not exhibit very good performance (Table 3, first line). The trees we are learning on are exceedingly flat, and thus yield rules that do not generalize sufficiently. Rules produced from the top of the tree in Figure 3c, such as that in Figure 4a, are only appropriate for cases where `fear-01` has exactly three roles: **ARG0** (agent), **ARG1** (patient), and **polarity**.

We follow the lead of Wang et al. (2010), who in turn were influenced by similar approaches in monolingual parsing (Collins, 1997; Charniak, 2000), and re-structure trees at nodes with more than three children (i.e. instances with more than one role), to allow generalization of flat structures.

However, our trees are unlike syntactic constituent trees in that they do not have labeled nonterminal nodes, so we have no natural choice of an intermediate ("bar") label. We must choose a meaningful label to characterize an instance and its roles. We initially choose the concept label, resulting in trees like that in Figure 3d, in which a chain of fear-01 nodes is used to unflatten the root, which has instance `fear-01`.

This attempt at re-structuring yields rules like that in Figure 4b, which are general in form but are tied to the concept context in which they were extracted. This leads to many redundant rules and blows up the nonterminal vocabulary size to approximately 8,000, the size of the concept vocabulary. Furthermore, the rules elicited by this procedure encourage undesirable behavior such as the immediate juxtaposition of two rules generating **ARG1**.

We next consider restructuring with the immediately dominant role labels, resulting in trees like that in Figure 3e and rules like that in Figure 4c. The shape of the structure added is the same as in Figure 3d but the bar nodes now take their labels from their second children. This approach leads to more useful rules with fewer undesirable properties.

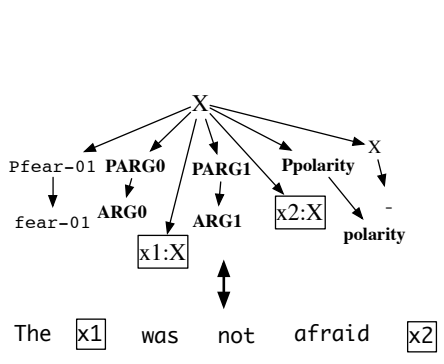
4.3 Tree Relabeling

AMR strings have an effective preterminal label of 'X,' which allows them to compete with full AMR instances at decode time. However, whether or not a role is filled by a string or an instance is highly dependent on the kind of role being filled. The **polarity** and **mode** roles, for instance, are nearly always filled by strings, but **ARG0** and **ARG1** are always filled by instances. The **quant** role, which is used for representation of numerical quantities, can be filled by an instance (e.g. for approximate quantities such as 'about 3') or a string. To capture this behavior we relabel string preterminals of the tree with labels indicating role identity and string subsumption. This relabeling, replaces, for example, one 'X' preterminal in Figure 3c with "Spolarity," as shown in Figure 3f.

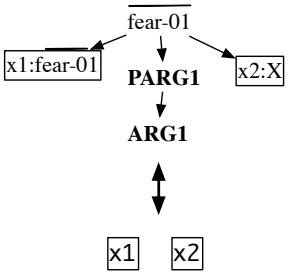
4.4 Tree Reordering

Finally, let us consider the alignments between English and AMR. As is known in SBMT, nonmonotone alignments can lead to large, unwieldy

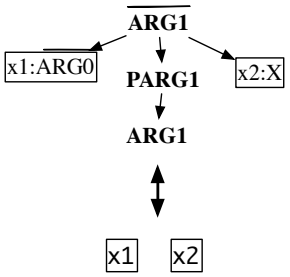
[5] In Figure 3 the negative polarity marker '-' is a string. Disconnected referents labeled '*' are treated as AMR instances with no roles.



(a) A rule extracted from the AMR tree of Figure 3c. All roles seen in training must be used.



(b) A rule from the AMR tree of Figure 3d. Many nearly identical rules of this type are extracted, and this rule can be used multiple times in a single derivation.



(c) A rule from the AMR tree of Figure 3e. This rule can be used independent of the concept context it was extracted from and multiple reuse is discouraged.

Figure 4: Impact of restructuring on rule extraction.

rules and in general make decoding more difficult (May and Knight, 2007). While this is often an unavoidable fact of life when trying to translate between two natural languages with different syntactic behavior, it is an entirely artificial phenomenon in this case. AMR is an *unordered* representation, yet in order to use an SBMT infrastructure we must declare an order of the AMR tree. This means we are free to choose whatever order is most convenient to us, as long as we keep role label edges immediately adjacent to their corresponding role filler edges to preserve conversion back to the edge-labeled AMR form. We thus choose the order that is as close as possible to that of the source yet still preserves these constraints. We use a simple greedy bottom-up approach that permutes the children of each internal node of the unrestructured tree so as to minimize crossings. This leads to a 79% overall reduction in crossings and is exemplified in Figure 3g (before) and Figure 3h (after). We may then restructure our trees, as described above, in an instance-outward manner. The final restructured, relabeled, and reordered tree is shown in Figure 3i.

5 AMR Language Models

We now turn to language models of AMRs, which help us prefer reasonable target structures over unreasonable ones.

Our first language model is unintuitively simple—we pretend there is a language called *AMRese* that consists of yields of our restructured AMRs. An example AMRese string from Figure 3i is '**ARG0** `soldier polarity -` `fear-01` **ARG1** `die-01` **ARG1** *.' We then build a standard n-gram model for AMRese.

It also seems sensible to judge the correctness of an AMR by calculating the empirical probability of the concepts and their relations to each other. This is the motivation behind the following model of an AMR:[6]

We define an AMR instance $i = (c, R)$, where c is a *concept* and R is a set of *roles*. We define an AMR role $r = (l, i)$, where l is a role label, and i is an AMR instance labeled l. For an AMR instance i let $\hat{c}_i$ be the concept of i's parent instance, and $\hat{l}_i$ be the label of the role that i fills with respect to its parent. We also define the special instance and role labels ROOT and STOP. Then, we define $P_{\text{AMR}}(i|\hat{l}_i, \hat{c}_i)$, the conditional probability of AMR instance i given its ancestry as $P_{\text{AMR}}(i = (c, R)|\hat{l}_i, \hat{c}_i) = P(c|\hat{l}_i, \hat{c}_i) \prod_{r \in R} P_{\text{Role}}(r|c) \times P(\text{STOP}|c)$, where $P_{\text{Role}}(r = (l, i)|c) = P(l|c)P_{\text{AMR}}(i|l, c)$.

We define $P(c|\hat{l}_i, \hat{c}_i)$, $P(l|c)$, and $P(\text{STOP}|c)$ as empirical conditional probabilities, Witten-Bell interpolated (Witten and Bell, 1991) to lower-order models by progressively discarding context from the right.[7] We model exactly one STOP event per instance. We define the probability of a full-sentence AMR i as $P_{\text{AMR}}(i|\text{ROOT})$ where ROOT in this case serves as both parent concept and role label.

[6] This model is only defined over AMRs that can be represented as trees, and not over all AMRs. Since tree AMRs are a prerequisite of our system we did not yet investigate whether this model could be sufficiently generalized.

[7] That is, $P(c|\hat{l}_i, \hat{c}_i)$ is interpolated with $P(c|\hat{l}_i)$ and then $P(c)$.

System	Tune	Test
AMRese n-gram LM	61.7	59.7
AMR LM	59.1	57.1
both LMs	62.3	60.6

Table 2: The effect of AMRese n-gram and AMR LMs on Smatch quality.

As an example, the instance associated with concept `die-01` in Figure 3b has $\hat{l}_i$ = **ARG1** and $\hat{c}_i$ = `fear-01`, so we may score it as $P(\texttt{die-01}|\textbf{ARG1}, \texttt{fear-01}) \times P(\textbf{ARG1}|\texttt{die-01}) \times P(\text{STOP}|\texttt{die-01}) \times P(*|\textbf{ARG1}, \texttt{die-01})$

In Table 2 we compare the effect of varying LMs on Smatch quality. The AMR LM by itself is inferior to the AMRese n-gram LM, but combining the two yields superior quality.

6 Adding External Semantic Resources

Although we are engaged in the task of semantic parsing, we have not yet discussed the use of any semantic resources. In this section we rectify that omission.

6.1 Rules from Numerical Quantities and Named Entities

While the majority of string-to-tree rules in SBMT systems are extracted from aligned parallel data, it is common practice to dynamically generate additional rules to handle the translation of dates and numerical quantities, as these follow common patterns and are easily detected at decode-time. We follow this practice here, and additionally detect person names at decode-time using the Stanford Named Entity Recognizer (Finkel et al., 2005). We use cased, tokenized source data to build the decode-time rules. We add indicator features to these rules so that our tuning methods can decide how favorable the resources are. We leave as future work the incorporation of named-entity rules for other classes, since most available named-entity recognition beyond person names is at a granularity level that is incompatible with AMR (e.g. we can recognize 'Location' but not distinguish between 'City' and 'Country').

6.2 Hierarchical Semantic Categories

In order to further generalize our rules, we modify our training data AMRs once more, this time replacing the identity preterminals over concepts

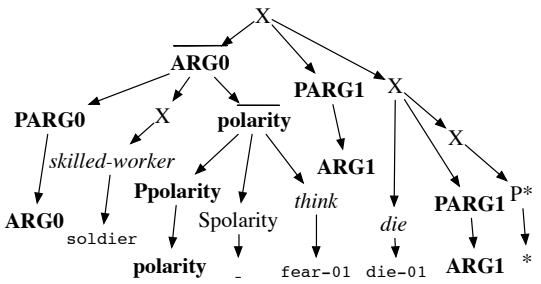


Figure 5: Final modification of the AMR data; semantically clustered preterminal labels are added to concepts.

with preterminals designed to enhance the applicability of our rules in semantically similar contexts. For each concept c expressed in AMR, we consult WordNet (Fellbaum, 1998) and a curated set of gazetteers and vocabulary lists to identify a hierarchy of increasingly general semantic categories that describe the concept. So as not to be overwhelmed by the many fine-grained distinctions present in WordNet, we pre-select around 100 salient semantic categories from the WordNet ontology. When traversing the WordNet hierarchy, we propagate a smoothed count[8] of the number of examples seen per concept sense,[9] combining counts when paths meet. For each selected semantic category s encountered in the traversal, we calculate a weight by dividing the propagated example count for c at s by the frequency s was proposed over all AMR concepts. We then assign c to the highest scoring semantic category s. An example calculation for the concept `computer` is shown in Figure 7.

We apply semantic categories to our data as replacements for identity preterminals of concepts. This leads to more general, more widely-applicable rules. For example, with this transformation, we can parse correctly not only contexts in which "soldiers die," but also contexts in which other kinds of "skilled workers die." Figure 5 shows the addition of semantic preterminals to the tree from Figure 3i. We also incorporate semantic categories into the AMR LM. For concept c, let s_c be the semantic category of c. Then we reformu-

[8] We use very simple smoothing, and add 0.1 to the provided example counts.

[9] Since WordNet senses do not correspond directly to PropBank or AMR senses, we simply use a lexical match and must consider all observed senses for that match.

late $P_{\text{AMR}}(i|\hat{l}_i, \hat{c}_i)$ as $P_{\text{AMR}}(i = (c, R)|\hat{l}_i, \hat{c}_i) = P(s_c|\hat{l}_i, s_{\hat{c}_i}, \hat{c}_i)P(c|s_c, \hat{l}_i, s_{\hat{c}_i}, \hat{c}_i) \prod_{r \in R} P_{\text{Role}}(r|c) \times P(\text{STOP}|s_c, c)$, where $P_{\text{Role}}(r = (l, i)|c) = P(l|s_c, c) \times P_{\text{AMR}}(i|l, c)$.

6.3 Morphological Normalization

While we rely heavily on the relationships between words in-text and concept nodes expressed in parallel training data, we find this is not sufficient for complete coverage. Thus we also include a run-time module that generates AMRese base forms at the lexical level, expressing relationships such as those depicted in Table 4. We build these dictionary rules using three resources:

1. An inflectional morphological normalizing table, comprising a lexicon with 84,558 entries, hand-written rules for regular inflectional morphology, and hand-written lists of irregular verbs, nouns, and adjectives.
2. Lists of derivational mappings (e.g. 'quietly' → 'quiet', 'naval' → 'navy').
3. PropBank framesets, which we use, e.g., to map the morphologically normalized 'break up' (from 'broke up') into a sense match, such as `break-up-08`.

6.4 Semantically informed Rule-based Alignments

For our final incorporation of semantic resources we revisit the English-to-AMR alignments used to extract rules. As an alternative to the unsupervised approach of Pourdamghani et al. (2014), we build alignments by taking a linguistically-aware, supervised heuristic approach to alignment:

First, we generate a large number of potential links between English and AMR. We attempt to link English and AMR tokens after conversion through resources such as a morphological analyzer, a list of 3,235 pertainym pairs (e.g. adj-'gubernatorial' → noun-'governor'), a list of 2,444 adverb/adjective pairs (e.g. 'humbly' → 'humble'), a list of 2,076 negative polarity pairs (e.g. 'illegal' → 'legal'), and a list of 2,794 known English-AMR transformational relationships (e.g. 'asleep' → `sleep-01`, 'advertiser' → `person` **ARG0-of** `advertise-01`, 'Greenwich Mean Time' → `GMT`). These links are then culled based on context and AMR structure. For example, in the sentence "The big fish ate the little fish," ini-

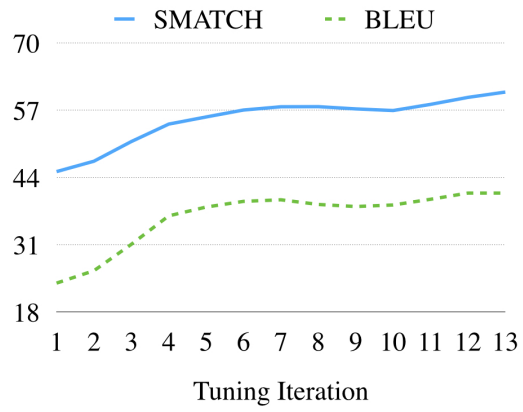

Figure 6: BLEU of AMRese and Smatch correlate closely when tuning.

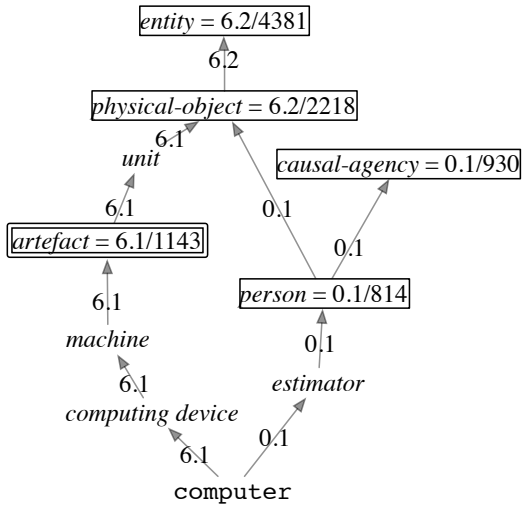

Figure 7: WordNet hierarchy for `computer`. Pre-selected salient WordNet categories are boxed. Smoothed sense counts are propagated up the hierarchy and re-combined at join points. Scores are calculated by dividing propagated sense count by count of the category's prevalence over the set of AMR concepts. The double box indicates the selection of *artefact* as the category label for `computer`.

tially both English 'fish' are aligned to both AMR `fish`. However, based on the context of 'big' and 'little' the spurious links are removed.

In our experiments we explore both replacing the unsupervised alignments of Pourdamghani et al. (2014) with these alignments and concatenating the two alignment sets together, essentially doubling the size of the training corpus. Because the different alignments yield different target-side tree reorderings, it is necessary to build separate 5-gram AMRese language models.[10] When using both alignment sets together, we also use both AMRese language models simultaneously.

7 Tuning

We would like to tune our feature weights to maximize Smatch directly. However, a very convenient alternative is to compare the AMRese yields of candidate AMR parses to those of reference AMRese strings, using a BLEU objective and forest-based MIRA (Chiang et al., 2009). Figure 6 shows that MIRA tuning with BLEU over AMRese tracks closely with Smatch. Note that, for experiments using reordered AMR trees, this requires obtaining similarly permuted reference tuning AMRese and hence requires alignments on the development corpus. When using unsupervised alignments we may simply run inference on the trained alignment model to obtain development alignments. The rule-based aligner runs one sentence at a time and can be employed on the development corpus. When using both sets of alignments, each approach's AMRese is used as a development reference (i.e. each development sentence has two possible reference translations).

[10]The AMR LM is insensitive to reordering so we do not need to vary it when varying alignments.

8 Results and Discussion

Our AMR parser's performance is shown in Table 3. We progressively show the incremental improvements and compare to the systems of Flanigan et al. (2014) and Wang et al. (2015). Purely transforming AMR data into a form that is compatible with the SBMT pipeline yields suboptimal results, but by adding role-based restructuring, relabeling, and reordering, as described in Section 4, we are able to surpass Flanigan et al. (2014). Adding an AMR LM and semantic resources increases scores further, outperforming Wang et al. (2015). Rule-based alignments are an improvement upon unsupervised alignments, but concatenating the two alignments is even better. We compare rule set sizes of the various systems in Table 5; initially we improve the rule set by removing numerous overly brittle rules but then successive changes progressively add useful rules. The parser is available for public download and use at `http://amr.isi.edu`.

System	Rules
flat trees	1,430,124
concept restructuring	678,265
role restructuring (rr)	660,582
rr + preterminal relabeling (rl)	661,127
rr + rl + semantic categories (sc)	765,720
rr + rl + sc + reordering (ro)	790,624
rr + rl + sc + ro + rule-based alignments	908,318
rr + rl + sc + ro + both alignments	1,306,624

Table 5: Comparison of extracted rule set size on the systems evaluated in this work. Note that, as compared to Table 3, only systems that affect the rule size are listed.

9 Related Work

The first work that addressed AMR parsing was that of Flanigan et al. (2014). In that work, multiple discriminatively trained models are used to identify individual concept instances and then a minimum spanning tree algorithm connects the concepts. That work was extended and improved upon by Werling et al. (2015). Recent work by Wang et al. (2015) also uses a two-pass approach; dependency parses are modified by a tree-walking algorithm that adds edge labels and restructures to resolve discrepancies between dependency standards and AMR's specification. In contrast to these works, we use a single-pass approach and re-use existing machine translation architecture, adapting to the AMR parsing task by modifying training data and adding lightweight AMR-specific features.

Several other recent works have used a machine translation approach to semantic parsing, but all have been applied to domain data that is much narrower and an order of magnitude smaller than that of AMR, primarily the Geoquery corpus (Zelle and Mooney, 1996). The WASP system of Wong and Mooney (2006) uses hierarchical SMT techniques and does not apply semantic-specific improvements; its extension (Wong and Mooney, 2007) incorporates a target-side reordering component much like the one presented in Section 4.4. Jones et al. (2012a) cast semantic parsing as an instance of hyperedge replacement grammar transduction; like this work they use an IBM model-influenced alignment algorithm and a GHKM-based extraction algorithm. Andreas et al. (2013) use phrase-based and hierarchical SMT techniques on Geoquery. Like this work, they perform a transformation of the input semantic representation so that it is amenable to use in an existing machine translation system. However, they are unable to reach the state of the art in performance. Li et al. (2013) directly address GHKM's word-to-terminal alignment requirement by extending that algorithm to handle word-to-node alignment.

Our SBMT system is grounded in the theory of tree transducers, which were applied to the task of semantic parsing by Jones et al. (2011; 2012b).

Semantic parsing in general and AMR parsing specifically can be considered a subsumption of many semantic resolution sub-tasks, e.g. named entity recognition (Nadeau and Sekine, 2007), semantic role labeling (Gildea and Jurafsky, 2002), word sense disambiguation (Navigli, 2009) and relation finding (Bach and Badaskar, 2007).

10 Conclusion

By restructuring our AMRs we are able to convert a sophisticated SBMT engine into a baseline semantic parser with little additional effort. By further restructuring our data to appropriately model the behavior we want to capture, we are able to rapidly achieve state-of-the-art results. Finally, by incorporating novel language models and external semantic resources, we are able to increase quality even more. This is not the last word on AMR parsing, as fortunately, machine translation technology provides more low-hanging fruit to pursue.

The Forest Convolutional Network: Compositional Distributional Semantics with a Neural Chart and without Binarization

Phong Le and **Willem Zuidema**
Institute for Logic, Language and Computation
University of Amsterdam, the Netherlands
{p.le,zuidema}@uva.nl

Abstract

According to the principle of compositionality, the meaning of a sentence is computed from the meaning of its parts and the way they are syntactically combined. In practice, however, the syntactic structure is computed by automatic parsers which are far-from-perfect and not tuned to the specifics of the task. Current recursive neural network (RNN) approaches for computing sentence meaning therefore run into a number of practical difficulties, including the need to carefully select a parser appropriate for the task, deciding how and to what extent syntactic context modifies the semantic composition function, as well as on how to transform parse trees to conform to the branching settings (typically, binary branching) of the RNN. This paper introduces a new model, the Forest Convolutional Network, that avoids all of these challenges, by taking a parse forest as input, rather than a single tree, and by allowing arbitrary branching factors. We report improvements over the state-of-the-art in sentiment analysis and question classification.

1 Introduction

For many natural language processing tasks we need to compute meaning representations for sentences from meaning representations of words. In a recent line of research on 'recursive neural networks' (e.g., Socher et al. (2010)), both the word and sentence representations are vectors, and the word vectors ("embeddings") are borrowed from work in distributional semantics or neural language modelling. Sentence representations, in this approach, are computed by recursively applying a neural network that combines two vectors into one (typically according to the syntactic structure provided by an external parser). The network, which thus implements a 'composition function', is optimized for delivering sentence representations that support a given semantic task: sentiment analysis (Irsoy and Cardie, 2014; Le and Zuidema, 2015), paraphrase detection (Socher et al., 2011), semantic relatedness (Tai et al., 2015) etc. Studies with recursive neural networks have yielded promising results on a variety of such tasks.

In this paper, we represent a new recursive neural network architecture that fits squarely in this tradition, but aims to solve a number of difficulties that have arisen in existing work. In particular, the model we propose addresses three issues:

1. how to make the composition functions adaptive, in the sense that they operate adequately for the many different types of combinations (e.g., adjective-noun combinations are of a very different type than VP-PP combinations);

2. how to deal with different branching factors of nodes in the relevant syntactic trees (i.e., we want to avoid having to binarize syntactic trees,[1] but also do not want ternary productions to be completely independent from binary productions);

3. how to deal with uncertainty about the correct parse inside the neural architecture (i.e., we don't want to work with just the best or k-best parses for a sentence according to an external model, but receive an entire distribution over possible parsers).

[1] Eisner (2001, Chapter 2) shows that using flat rules is linguistically beneficial, "most crucially, a flat lexical entry corresponds to the local domain of a headword-the word together with all its semantic arguments and modifiers". From the computational perspective, flat rules make trees less deep, thus avoiding the vanishing gradient problem and capturing long range dependencies.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1155–1164,
Lisbon, Portugal, 17-21 September 2015.

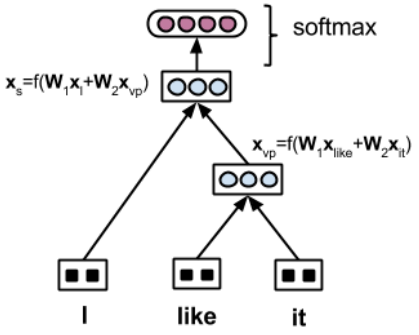

Figure 1: Recursive Neural Network. For simplicity, bias vectors are removed.

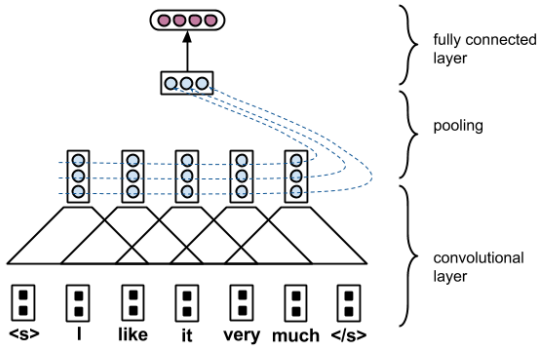

Figure 2: Convolutional Neural Network (one convolutional layer and one fully connected layer) with a window-size-3 kernel.

To solve these challenges we take inspiration from two other traditions: the convolutional neural networks and classic parsing algorithms based on dynamic programming. Including convolution in our network provides a direct solution for issue (2), and turns out, somewhat unexpectedly, to also provide a solution for issue (1). Introducing the chart representation from classic parsing into our architecture then allows us to tackle issue (3). The resulting model, the Forest Convolutional Network, outperforms all other models on a sentiment analysis and question classification task.

2 Background

This section is to introduce the recursive neural network (RNN) and convolutional neural network (CNN) models, on which our work is based.

2.1 Recursive Neural Network

A recursive neural network (RNN) (Goller and Küchler, 1996) is a feed-forward neural network where, given a tree structure, we recursively apply the same weight matrices at each inner node in a bottom-up manner. In order to see how an RNN works, consider the following example. Assume that there is a constituent with parse tree $(S\ \ I\ \ (VP\ \ like\ \ it))$ (Figure 1), and that $\mathbf{x}_I, \mathbf{x}_{like}, \mathbf{x}_{it} \in \mathbb{R}^d$ are the vectorial representations of the three words I, $like$ and it, respectively. We use a neural network which consists of a weight matrix $\mathbf{W}_1 \in \mathbb{R}^{d\times d}$ for left children and a weight matrix $\mathbf{W}_2 \in \mathbb{R}^{d\times d}$ for right children to compute the vector for a parent node in a bottom up manner. Thus, we compute $\mathbf{x}_{VP}$

$$\mathbf{x}_{VP} = f(\mathbf{W}_1\mathbf{x}_{like} + \mathbf{W}_2\mathbf{x}_{it} + \mathbf{b}) \qquad (1)$$

where $\mathbf{b}$ is a bias vector and f is an (non-linear) activation function. Having computed $\mathbf{x}_{VP}$, we can then move one level up in the hierarchy and compute $\mathbf{x}_S$

$$\mathbf{x}_S = f(\mathbf{W}_1\mathbf{x}_I + \mathbf{W}_2\mathbf{x}_{VP} + \mathbf{b})$$

This process is continued until we reach the root node.

For classification tasks, we put a *softmax* layer on the top of the root node, and compute the probability of assigning a class c to an input $\mathbf{x}$ by

$$Pr(c|\mathbf{x}) = \text{softmax}(c) = \frac{e^{u(c,\mathbf{y}_{\text{top}})}}{\sum_{c'\in C} e^{u(c',\mathbf{y}_{\text{top}})}} \qquad (2)$$

where $\left[u(c_1, \mathbf{y}_{top}), ..., u(c_{|C|}, \mathbf{y}_{top})\right]^T = \mathbf{W}_u\mathbf{y}_{top} + \mathbf{b}_u$; C is the set of all possible classes; $\mathbf{W}_u \in \mathbb{R}^{|C|\times d}, \mathbf{b}_u \in \mathbb{R}^{|C|}$ are a weight matrix and a bias vector.

Training an RNN uses the gradient descent method to minimize an objective function $J(\theta)$. The gradient $\partial J/\partial\theta$ is efficiently computed thanks to the back-propagation through structure algorithm (Goller and Küchler, 1996).

Departing from the original RNN model, many extensions have been proposed to enhance its compositionality (Socher et al., 2013; Irsoy and Cardie, 2014; Le and Zuidema, 2015) and applicability (Le and Zuidema, 2014b). The model we are going to propose can be considered as an extension of RNN with an ability to solve the three issues introduced in Section 1.

2.2 Convolutional Neural Network

A convolutional neural network (CNN) (LeCun et al., 1998) is also a feed-forward neural network; it consists of one or more convolutional layers (often with a pooling operation) followed by one or more fully connected layers. This architecture was

invented for computer vision. It then has been widely applied to solve natural language processing tasks (Collobert et al., 2011; Kalchbrenner et al., 2014; Kim, 2014).

To illustrate how a CNN works, the following example uses a simplified model proposed by Collobert et al. (2011) which consists of one convolutional layer with the max pooling operation, followed by one fully connected layer (Figure 2). This CNN uses a *kernel* with window size 3; when we slide this kernel along the sentence "⟨s⟩ I like it very much ⟨/s⟩", we get five vectors:

$$\mathbf{u}^{(1)} = \mathbf{W}_1\mathbf{x}_{<s>} + \mathbf{W}_2\mathbf{x}_I + \mathbf{W}_3\mathbf{x}_{like} + \mathbf{b}_c$$
$$\mathbf{u}^{(2)} = \mathbf{W}_1\mathbf{x}_I + \mathbf{W}_2\mathbf{x}_{like} + \mathbf{W}_3\mathbf{x}_{it} + \mathbf{b}_c$$
$$...$$
$$\mathbf{u}^{(5)} = \mathbf{W}_1\mathbf{x}_{very} + \mathbf{W}_2\mathbf{x}_{much} + \mathbf{W}_3\mathbf{x}_{</s>} + \mathbf{b}_c$$

where $\mathbf{W}_1, \mathbf{W}_2, \mathbf{W}_3 \in \mathbb{R}^{d\times m}$ are weight matrices, $\mathbf{b}_c \in \mathbb{R}^m$ is a bias vector. The max pooling operation is then applied to those resulted vectors in an element-wise manner:

$$\mathbf{x} = \big[\max_{1\le i\le 5} \mathbf{u}_1^{(i)}, ..., \max_{1\le i\le 5} \mathbf{u}_j^{(i)}, ...\big]^T$$

Finally, a fully connected layer is employed

$$\mathbf{y} = f(\mathbf{W}\mathbf{x} + \mathbf{b})$$

where $\mathbf{W}$, $\mathbf{b}$ are a real weight matrix and bias vector, respectively; f is an activation function.

Intuitively, a window-size-k kernel extracts (local) features from k-grams, and is thus able to capture k-gram composition. The max pooling operation is for reducing dimension, forcing the network to discriminate important features from others by assigning high values to them. For instance, if the network is used for sentiment analysis, local features corresponding to k-grams containing the word "like" should receive high values in order to be propagated to the top layer.

3 Forest Convolutional Network

We now first propose a solution to the issues (1) and (2) (i.e., making the composition functions adaptive and dealing with different branching factors), called Recursive convolutional neural network (RCNN), and then a solution to the third issue (i.e., dealing with uncertainty about the correct parse), called Chart Neural Network (ChNN). A combination of them, Forest Convolutional Network (FCN), will be introduced lastly.

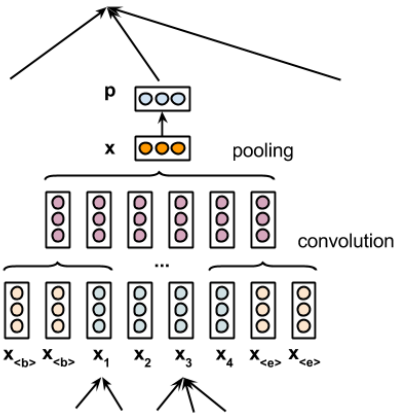

Figure 3: Recursive Convolutional Neural Network with a nonlinear window-size-3 kernel.

3.1 Recursive Convolutional Neural Network[2]

Given a subtree $p \rightarrow x_1 \ ... \ x_l$, an RCNN (Figure 3), like a CNN, slides a window-size-k kernel along the sequence of children $(x_1, ..., x_l)$ to compute a pool of vectors. The max pooling operation followed by a fully connected layer is then applied to this pool to compute a vector for the parent p.

This RCNN differs from the CNN introduced in Section 2.2 at two points. First, we use a non-linear kernel: after linearly transforming input vectors, an activation function is applied. Second, we put $k-1$ padding tokens <b> at the beginning of the children sequence and $k-1$ padding tokens <e> at the end. This thus guarantees that all the children contribute equally to the resulted vector pool, which now has $l+k-1$ vectors.

It is obvious that this RCNN can solve the second issue (i.e., dealing with different branching factors), we now show how it can make the composition functions adaptive. We first see what happens if the window size k is larger than the number of children l, for instance $k=3$ and $l=2$. There are four vectors in the pool

$$\mathbf{u}^{(1)} = f(\mathbf{W}_1\mathbf{x}_{<b>} + \mathbf{W}_2\mathbf{x}_{<b>} + \mathbf{W}_3\mathbf{x}_1 + \mathbf{b}_c)$$
$$\mathbf{u}^{(2)} = f(\mathbf{W}_1\mathbf{x}_{<b>} + \mathbf{W}_2\mathbf{x}_1 + \mathbf{W}_3\mathbf{x}_2 + \mathbf{b}_c)$$
$$\mathbf{u}^{(3)} = f(\mathbf{W}_1\mathbf{x}_1 + \mathbf{W}_2\mathbf{x}_2 + \mathbf{W}_3\mathbf{x}_{<e>} + \mathbf{b}_c)$$
$$\mathbf{u}^{(4)} = f(\mathbf{W}_1\mathbf{x}_2 + \mathbf{W}_2\mathbf{x}_{<e>} + \mathbf{W}_3\mathbf{x}_{<e>} + \mathbf{b}_c)$$

where $\mathbf{W}_1, \mathbf{W}_2, \mathbf{W}_3$ are weight matrices, $\mathbf{b}_c$ is a

[2]While finalizing the current paper we discovered a paper by Zhu et al. (2015) proposing a similar model which is evaluated on syntactic parsing. Our work goes substantially beyond theirs, however, as it takes a parse forest rather than a single tree as input.

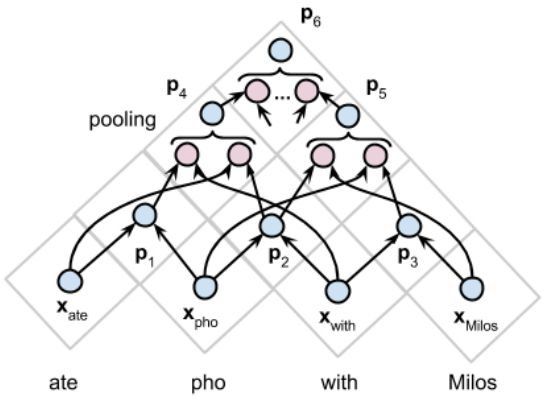

Figure 4: Chart Neural Network.

bias vector, f is an activation function. These four resulted vectors correspond to four ways of composing the two children:

(1) the first child stands alone (e.g., when the information of the second child is not important, it is better to ignore it),

(2,3) the two children are composed with two different weight matrix sets,

(4) the second child stands alone.

Now, imagine that we must handle binary syntactic rules with different head positions such as $S \rightarrow NP\ VP$ (e.g. "Jones runs") where the second child is the head and $VP \rightarrow VBD\ NP$ (e.g., "ate spaghetti") where the first child is the head. We can set those weight matrices such that when multiplying $\mathbf{W}_2$ by the vector of a head, we have a vector with high-value entries. And when multiplying $\mathbf{W}_2$ by the vector of a non-head, or when multiplying $\mathbf{W}_1$ or $\mathbf{W}_3$ by a vector, the resulted vector has low-value entries. This is possible thanks to the max pooling operation and that heads are often more informative than non-heads.

If the window size k is smaller than the number of children l, the argument above is still valid in some cases such as head position. However, there is no longer a direct interaction between any two children whose distance is larger than k.[3] In practice, this problem is not serious because rules with a large number of children are very rare.

3.2 Chart Neural Network

Unseen sentences are always parsed by an automatic parser, which is far from perfect and task-independent. Therefore, a good solution is to give the system a set of parses and let it decide which parse is the best or to combine some of them. The RNN model handles one extreme where this set contains only one parse. We now consider the other extreme where the set contains all possible parses. Because the number of all possible binary parse trees of a length-n sentence is the n-th Catalan number, processing individual parses is not practical. We thus propose a new model working on charts in the CKY style (Younger, 1967), called Chart Neural Network (ChNN).

We describe this model by the following example. Given a phrase "ate pho with Milos", a ChNN will process its parse chart as in Figure 4. Because any 2-word constituent has only one parse, the computation for p_1, p_2, p_3 is identical to Equation 1. For 3-word constituent p_4, because there are two possible productions $p_4 \rightarrow ate\ p_2$ and $p_4 \rightarrow p_1\ with$, we compute one vector for each production

$$\begin{aligned} \mathbf{u}^{(1)} &= f(\mathbf{W}_1\mathbf{x}_{ate} + \mathbf{W}_2\mathbf{p}_2 + \mathbf{b}) \\ \mathbf{u}^{(2)} &= f(\mathbf{W}_1\mathbf{p}_1 + \mathbf{W}_2\mathbf{x}_{with} + \mathbf{b}) \end{aligned} \quad (3)$$

and then apply the max pooling operation to these two vectors to compute $\mathbf{p}_4$. We do the same to compute $\mathbf{p}_5$. Finally, at the top, there are three productions $p_6 \rightarrow ate\ p_5$, $p_6 \rightarrow p_1\ p_3$ and $p_6 \rightarrow p_4\ Milos$. Similarly, we compute one vector for each production and employ the max pooling operation to compute $\mathbf{p}_6$.

Because this ChNN processes a chart like the CKY algorithm, its time complexity is $O(n^2d^2 + n^3d)$ where n and d are the sentence length and the dimension of vectors, respectively.[4] A ChNN is thus notably more complex than an RNN, whose complexity is $O(nd^2)$. Like chart parsing, the complexity can be reduced significantly by pruning the chart before applying the ChNN. This will be discussed right below.

3.3 Forest Convolutional Network

We now introduce the Forest Convolutional Network (FCN) model, which is a combination of the RCNN and the ChNN. The idea is to use an automatic parser to prune a chart[5], debinarize productions (if applicable), and then apply a ChNN

[3] An indirect interaction can be set up through pooling.

[4] In each cell, we apply the matrix-vector multiplication two times and (if the cell is not a leaf) apply the max pooling to a pool of maximally n d-D vectors.

[5] Pruning a chart by an automatic parser is also not perfect. However, the quality of a pruned chart can get very close to human annotation. For instance, the chart pruner proposed by Huang (2008) has a forest oracle of 97.8% F-

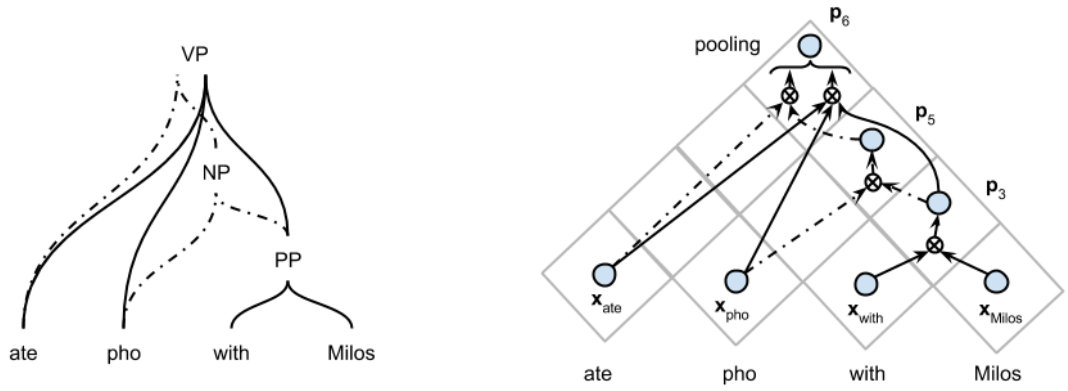

Figure 5: Forest of parses (left) and Forest Convolutional Network (right). $\otimes$ denotes a convolutional layer followed by the max pooling operation and a fully connected layer as in Figure 3.

where the computation in Equation 3 is replaced by a convolutional layer followed by the max pooling operation and a fully connected layer as in the RCNN.

Figure 5 shows an illustration how the FCN works on the phrase "ate pho with Milos". A forest of parses, given by an external parser, comprises two parses $(VP\ ate\ pho\ (PP\ with\ Milos))$ (solid lines) and $(VP\ ate\ (NP\ pho\ (PP\ with\ Milos)))$ (dash-dotted lines). The first parse is the preferred reading if Milos is a person, but the second one is a possible reading (for instance, if Milos is the name of a sauce). Instead of forcing the external parser to decide which one is correct, we let the FCN network do that because it has more information about the context and domain, which are embedded in training data. What the network should do is depicted in Figure 5-right.

Training Training an FCN is similar to training an RNN. We use the mini-batch gradient descent method to minimize an objective function J, which depends on which task this network is applied to. For instance, if the task is sentiment analysis, J is the cross-entropy over the training sentence set $\mathcal{D}$ plus an L2-norm regularization term

$$J(\theta) = -\frac{1}{|\mathcal{D}|}\sum_{s\in\mathcal{D}}\sum_{p\in s}\log Pr(c_p|\mathbf{p}) + \frac{\lambda}{2}||\theta||^2$$

where θ is the parameter set, c_p is the sentiment class of phrase p, $\mathbf{p}$ is the vector representation at the node covering p, $Pr(c_p|\mathbf{p})$ is computed by the softmax function, and λ is the regularization parameter.

The gradient $\partial J/\partial\theta$ is computed efficiently thanks to the back-propagation through structure (Goller and Küchler, 1996). We use the AdaGrad method (Duchi et al., 2011) to automatically update the learning rate for each parameter.

4 Experiments

We evaluate the FCN model with two tasks: question classification and sentiment analysis. The evaluation metric is the classification accuracy.

Our networks were initialized with the 300-D GloVe word embeddings trained on a corpus of 840B words[6] (Pennington et al., 2014). The initial values for a weight matrix were uniformly sampled from the symmetric interval $\left[-\frac{1}{\sqrt{n}}, \frac{1}{\sqrt{n}}\right]$ where n is the number of total input units. In each experiment, a development set was used to tune the model. We run the model ten times and chose the run with the highest performance on the development set. We employed early stopping: training is halted if performance on the development set does not improve after three consecutive epochs.

4.1 Sentiment Analysis

The Stanford Sentiment Treebank (SST)[7] (Socher et al., 2013) which consists of 5-way fine-grained sentiment labels (very negative, negative, neutral, positive, very positive) for 215,154 phrases of 11,855 sentences. We used the standard splitting: 8544 sentences for training, 1101 for development, and 2210 for testing. The average sentence length is 19.1. In addition, the treebank

score on section 23 of the Penn Treebank whereas resulted forests are very compact: the average number of hyperedges per forest is 123.1.

[6] http://nlp.stanford.edu/projects/GloVe/

[7] http://nlp.stanford.edu/sentiment/treebank.html

Model	Fine-grained	Binary
RNTN	45.7	85.4
CNN	48.0	88.1
DCNN	48.5	86.8
PV	48.7	87.8
DRNN	49.8	86.6
LSTM-RNN	49.9	88.0
CT-LSTM	**51.0**	88.0
FCN (dep.)	50.4	88.2
FCN (const.)	**51.0**	**89.1**

Table 1: Accuracies at sentence level on the SST dataset. FCN (dep.) and FCN (const.) denote the FCN with dependency forests and with constituent forests, respectively. The accuracies of RNTN, CNN, DCNN, PV, DRNN, LSTM-RNN and CT-LSTM are copied from the corresponding papers (see text).

also supports binary sentiment (positive, negative) classification by removing neutral labels, leading to: 6920 sentences for training, 872 for development, and 1821 for testing.

All sentences were parsed by Liang Huang's dependency parser[8] (Huang and Sagae, 2010). We used this parser because it generates parse forests and that dependency trees are less deep than constituent trees. In addition, because the SST was annotated in a constituency manner, we also employed the Charniak's constituent parser (Charniak and Johnson, 2005) with Huang (2008)'s forest pruner. We found that the beam width 16 for the dependency parser and the log probability beam 10 for the other worked best. Lower values harmed the system's performance and higher values were not beneficial.

Our FCN has the dimension of vectors at inner nodes 200, a window size for the convolutional kernel of 7, and the activation function $tanh$. It was trained with the learning rate 0.01, the regularization parameter 10^{-4}, and the mini batch size 5. To reduce the average depth of the network, the fully connected layer following the convolutional layer was removed (i.e., $\mathbf{p} = \mathbf{x}$, see Figure 3).

We compare the FCN against other models: the Recursive neural tensor network (RNTN) (Socher et al., 2013), the Convolutional neural network (CNN) (Kim, 2014), the Dynamic convolutional neural network (DCNN) (Kalchbrenner et al., 2014), the Paragraph vectors (PV) (Le and Mikolov, 2014), the Deep recursive neural network (DRNN) (Irsoy and Cardie, 2014), the Recursive neural network with Long short term memory (LSTM-RNN) (Le and Zuidema, 2015) and the Constituent Tree LSTM (CT-LSTM) (Tai et al., 2015).[9]

Table 1 shows the results. Our FCN using constituent forests achieved the highest accuracies in both fine-grained task and binary task, 51% and 89.1%. Comparing to CT-LSTM, although there is no difference in the fine-grained task, the difference in the binary task is significant (1.1%). Comparing to LSTM-RNN, the differences in both tasks are all remarkable (1.1% and 1.1%).

Constituent parsing is clearly more helpful than dependency parsing: the improvements that the FCN got are 0.6% in the fine-grained task and 0.9% in the binary task. We conjecture that, because sentences in the treebank were parsed by a constituent parser (here is the Stanford parser), training with constituent forests is easier.

4.2 Question Classification

In this task we used the TREC question dataset[10] (Li and Roth, 2002) which contains 5952 questions (5452 questions for training and 500 questions for testing). The task is to assign a question to one in six types: ABBREVIATION, ENTITY, DESCRIPTION, HUMAN, LOCATION, NUMERIC. The average length of the questions in the training set is 10.2 whereas in the test set is 7.5. This difference is due to the fact that those questions are from different sources. All questions were parsed by Liang Huang's dependency parser with the beam width 16.

We randomly picked 5% of the training set (272 questions) for validation. Our FCN has the dimension of vectors at inner nodes 200, a window size for the convolutional kernel of 5, and the activation function $tanh$. It was trained with the learning rate 0.01, the regularization parameter 10^{-4}, and the mini batch size 1. The vectors representing the two padding tokens <b>, <e> were fixed to $\mathbf{0}$.

We compare the FCN against the Convolutional neural network (CNN) (Kim, 2014), the Dynamic convolutional neural network (DCNN) (Kalch-

[8] http://acl.cs.qc.edu/~lhuang/software

[9] LSTM-RNN and CT-LSTM are very similar: they are RNNs using LSTMs for composition. Their difference is that LSTM-RNN uses one input gate for each child where as CT-LSTM uses only one input gate for all children.

[10] http://cogcomp.cs.illinois.edu/Data/QA/QC

Model	Acc. (%)
DCNN	93.0
MaxEnt$_H$	93.6
CNN-non-static	93.6
SVM$_S$	**95.0**
LSTM-RNN	93.4
FCN	<u>94.8</u>

Table 2: Accuracies on the TREC question type classification dataset. The accuracies of DCNN, MaxEnt$_H$, CNN-non-static, and SVM$_S$ are copied from the corresponding papers (see text).

brenner et al., 2014), MaxEnt$_H$ (Huang et al., 2008) (which uses MaxEnt with uni-bi-trigrams, POS, wh-word, head word, word shape, parser, hypernyms, WordNet) and the SVM$_S$ (Silva et al., 2011) (which uses SVM with, in addition to features used by MaxEnt$_H$, 60 hand-coded rules). We also include the LSTM-RNN (Le and Zuidema, 2015) whose accuracy was computed by running their published source code[11] on binary trees from the Stanford Parser[12] (Klein and Manning, 2003). This network was also initialized by the 300-D GloVe word embeddings.

Table 2 shows the results.[13] The FCN achieved the second best accuracy, only lightly lower than SVM$_S$ (0.2%). This is a promising result because our network used only parse forests, unsupervisedly pre-trained word embeddings whereas SVM$_S$ used heavily engineered resources. The difference between FCN and the third best is remarkable (1.2%). Interestingly, LSTM-RNN did not perform well on this dataset. This is likely because the questions are short and the parse trees quite shallow, such that the two problems that the LSTM was invented for (long range dependency and vanishing gradient) do not play much of a role.

4.3 Visualization

We visualize the charts we obtained in the sentiment analysis task as in Figure 6. To identify how important each cell is for determining the final vector at the root, we compute the number of features of each that are actually propagated all the way to the root in the successive max pooling operations. The circles in a graph are proportional to this number. Here, to make the contribution of each individual cell clearer, we have set the window size to 1 to avoid direct interactions between cells.

At the lexical level, we can see that the FCN can discriminate important words from the others. Two words "most" and "incoherent" are the key of the sentiment of this sentence: if one of them is replaced by another word (e.g. replacing "most" by "few" or "incoherent" by "coherent"), the sentiment will flip. The punctuation "." however also has a high contribution to the root. This happens to other charts as well. We conjecture that the network uses the vector of "." to store neutral features and propagate them to the root whenever it can not find more useful features in other vectors. Our future work is to examine this.

At the phrasal level, the network tends to group words in grammatical constituents, such as "most of the action setups", "are incoherent". Ill-formed constituents such as "of the action" and "incoherent ." receive little attention from the network.

Interestingly, we can see that the circle of "incoherent" is larger than the circles of any inner cells, suggesting that the network is able to make use of parses containing direct links from that word to the root. This is evidence that the network has an ability of selecting (or combining) parses that are beneficial to this sentiment analysis task.

5 Related Work

The idea that a composition function must be able to change its behaviour on the fly according to input vectors is explored by Socher et al. (2013), Le and Zuidema (2015), among others. The tensor in the former is multiplied with the vector representations of the phrases it is going to combine to define a composition function (a matrix) on the fly, and then multiplies again with these vectors to yield a compound representation. In the LSTM architecture of the latter, there is one input gate for each child in order to control how the vector of the child affects the composition at the parent node. Because the input gate is a function of the vector of the child, the composition function has an *infinite* number of behaviours. In this paper, we instead slide a kernel function along the sequence of children to generate different ways of composition. Although the number of behaviours is limited (and depends on the window size), it simultane-

[13] While finalizing the current paper we discovered a paper by Ma et al. (2015) proposing a convolutional network model for dependency trees. They report a new state-of-the-art accuracy of 95.6%.

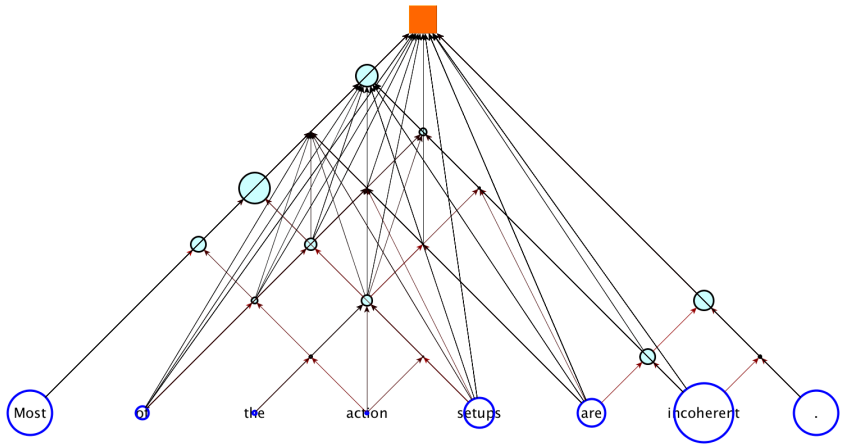

Figure 6: Chart of sentence "Most of the action setups are incoherent ." The size of a circle is propositional to the number of the cell's features that are propagated to the root.

ously provides us with a solution to handle rules with different branching sizes.

Some approaches try to overcome the problem of varying branching sizes. Le and Zuidema (2014b) use different sets of weight matrices for different branching sizes, thus requiring a large number of parameters. Because large branching-size rules are rare, many parameters are infrequently updated during training. Socher et al. (2014), for dependency trees, use a weight matrix for each relative position to the head word (e.g., first-left, second-right). Le and Zuidema (2014a) replace relative positions by dependency relations (e.g., OBJ, SUBJ). These approaches strongly depend on input parse trees and are very sensitive to parsing errors. The approach presented in this paper, on the other hand, does not need the information about the head word position and is less sensitive to parsing errors. Moreover, its number of parameters is independent from the maximal branching size.

Convolutional networks have been widely applied to solve natural language processing tasks. Collobert et al. (2011), Kalchbrenner et al. (2014), and Kim (2014) use convolutional networks to deal with varying length sequences. Recently, Zhu et al. (2015) and Ma et al. (2015) try to intergrate syntactic information by employing parse trees. Ma et al. (2015) extend the work of Kim (2014) by taking into acount dependency relations so that long range dependencies could be captured. The model proposed by Zhu et al. (2015), which is very similar to our Recursive convolutional neural network model, is to use a convolutional network for the composition purpose. Our work, although also employing a convolutional network and syntactic information, goes beyond them: we address the issue of how to deal with uncertainty about the correct parse inside the neural architecture. Therefore, instead of using a single parse, our proposed FCN model takes as input a forest of parses.

Related to our FCN is the Gated recursive convolutional neural network model proposed by Cho et al. (2014) which is stacking $n-1$ convolutional neural layers using a window-size-2 gated kernel (where n is the sentence length). Mapping their network into a chart, each cell is only connected to the two cells right below it. What makes this network special is the gated kernel which is a 3-gate switcher for choosing one of three options: directly transmit the left/right child's vector to the parent node, or compose the vectors of the two children. Thanks to this, the network can capture any binary parse trees by setting those gates properly. However, because only one gate is allowed to open in a cell, the network is not able to capture an arbitrary forest. Our FCN is thus more expressive and flexible than their model.

6 Conclusions

We proposed the Forest Convolutional Network (FCN) model that addresses the three issues: (1) how to make the composition functions adaptive, (2) how to deal with different branching factors of nodes in the relevant syntactic trees, (3) how to deal with uncertainty about the correct parse inside the neural architecture. The key principle is to carry out many different ways of computation

and then choose or combine some of them. For more details, the two first issues are solved by employing a convolutional net for composition. To the third issue, the network takes input as a forest of parses instead of a single parse as in traditional approaches.

Our future work is to focus on how to choose/combine different ways of computation. For instance, we might replace the max pooling by different pooling operations such as mean pooling, k-max pooling (Kalchbrenner et al., 2014), and stochastic pooling (Zeiler and Fergus, 2013). We can even bias the selection/combination toward grammatical constituents by weighing cells by their inside probabilities.

Alignment-Based Compositional Semantics for Instruction Following

Jacob Andreas and **Dan Klein**
Computer Science Division
University of California, Berkeley
{jda,klein}@cs.berkeley.edu

Abstract

This paper describes an alignment-based model for interpreting natural language instructions in context. We approach instruction following as a search over plans, scoring sequences of actions conditioned on structured observations of text and the environment. By explicitly modeling both the low-level compositional structure of individual actions and the high-level structure of full plans, we are able to learn both grounded representations of sentence meaning and pragmatic constraints on interpretation. To demonstrate the model's flexibility, we apply it to a diverse set of benchmark tasks. On every task, we outperform strong task-specific baselines, and achieve several new state-of-the-art results.

1 Introduction

In instruction-following tasks, an agent executes a sequence of actions in a real or simulated environment, in response to a sequence of natural language commands. Examples include giving navigational directions to robots and providing hints to automated game-playing agents. Plans specified with natural language exhibit compositionality both at the level of individual actions and at the overall sequence level. This paper describes a framework for learning to follow instructions by leveraging structure at both levels.

Our primary contribution is a new, alignment-based approach to grounded compositional semantics. Building on related logical approaches (Reddy et al., 2014; Pourdamghani et al., 2014), we recast instruction following as a pair of nested, structured alignment problems. Given instructions and a candidate plan, the model infers a *sequence-to-sequence* alignment between sentences and atomic actions. Within each sentence–action pair, the model infers a *structure-to-structure* alignment between the syntax of the sentence and a graph-based representation of the action.

At a high level, our agent is a block-structured, graph-valued conditional random field, with alignment potentials to relate instructions to actions and transition potentials to encode the environment model (Figure 3). Explicitly modeling sequence-to-sequence alignments between text and actions allows flexible reasoning about action sequences, enabling the agent to determine which actions are specified (perhaps redundantly) by text, and which actions must be performed automatically (in order to satisfy pragmatic constraints on interpretation). Treating instruction following as a sequence prediction problem, rather than a series of independent decisions (Branavan et al., 2009; Artzi and Zettlemoyer, 2013), makes it possible to use general-purpose planning machinery, greatly increasing inferential power.

The fragment of semantics necessary to complete most instruction-following tasks is essentially predicate–argument structure, with limited influence from quantification and scoping. Thus the problem of sentence interpretation can reasonably be modeled as one of finding an alignment between language and the environment it describes. We allow this structure-to-structure alignment—an "overlay" of language onto the world—to be mediated by linguistic structure (in the form of dependency parses) and structured perception (in what we term *grounding graphs*). Our model thereby reasons directly about the relationship between language and observations of the environment, without the need for an intermediate logical representation of sentence meaning. This, in turn, makes it possible to incorporate flexible feature representations that have been difficult to integrate with previous work in semantic parsing.

We apply our approach to three established

instruction-following benchmarks: the map reading task of Vogel and Jurafsky (2010), the maze navigation task of MacMahon et al. (2006), and the puzzle solving task of Branavan et al. (2009). An example from each is shown in Figure 1. These benchmarks exhibit a range of qualitative properties—both in the length and complexity of their plans, and in the quantity and quality of accompanying language. Each task has been studied in isolation, but we are unaware of any published approaches capable of robustly handling all three. Our general model outperforms strong, task-specific baselines in each case, achieving relative error reductions of 15–20% over several state-of-the-art results. Experiments demonstrate the importance of our contributions in both compositional semantics and search over plans. We have released all code for this project at `github.com/jacobandreas/instructions`.

2 Related work

Existing work on instruction following can be roughly divided into two families: semantic parsers and linear policy estimators.

Semantic parsers Parser-based approaches (Chen and Mooney, 2011; Artzi and Zettlemoyer, 2013; Kim and Mooney, 2013) map from text into a formal language representing commands. These take familiar structured prediction models for semantic parsing (Zettlemoyer and Collins, 2005; Wong and Mooney, 2006), and train them with task-provided supervision. Instead of attempting to match the structure of a manually-annotated semantic parse, semantic parsers for instruction following are trained to maximize a reward signal provided by black-box execution of the predicted command in the environment. (It is possible to think of response-based learning for question answering (Liang et al., 2013) as a special case.)

This approach uses a well-studied mechanism for compositional interpretation of language, but is subject to certain limitations. Because the environment is manipulated only through black-box execution of the completed semantic parse, there is no way to incorporate current or future environment state into the scoring function. It is also in general necessary to hand-engineer a task-specific formal language for describing agent behavior. Thus it is extremely difficult to work with environments that cannot be modeled with a fixed inventory of predicates (e.g. those involving novel strings or arbitrary real quantities).

Much of contemporary work in this family is evaluated on the maze navigation task introduced by MacMahon et al. (2006). Dukes (2013) also introduced a "blocks world" task for situated parsing of spatial robot commands.

Linear policy estimators An alternative family of approaches is based on learning a policy over primitive actions directly (Branavan et al., 2009; Vogel and Jurafsky, 2010).[1] Policy-based approaches instantiate a Markov decision process representing the action domain, and apply standard supervised or reinforcement-learning approaches to learn a function for greedily selecting among actions. In linear policy approximators, natural language instructions are incorporated directly into state observations, and reading order

[1]This is distinct from semantic parsers in which greedy inference happens to have an interpretation as a policy (Vlachos and Clark, 2014).

becomes part of the action selection process.

Almost all existing policy-learning approaches make use of an unstructured parameterization, with a single (flat) feature vector representing all text and observations. Such approaches are thus restricted to problems that are simple enough (and have small enough action spaces) to be effectively characterized in this fashion. While there is a great deal of flexibility in the choice of feature function (which is free to inspect the current and future state of the environment, the whole instruction sequence, etc.), standard linear policy estimators have no way to model compositionality in language or actions.

Agents in this family have been evaluated on a variety of tasks, including map reading (Anderson et al., 1991) and gameplay (Branavan et al., 2009).

Though both families address the same class of instruction-following problems, they have been applied to a totally disjoint set of tasks. It should be emphasized that there is nothing inherent to policy learning that prevents the use of compositional structure, and nothing inherent to general compositional models that prevents more complicated dependence on environment state. Indeed, previous work (Branavan et al., 2011; Narasimhan et al., 2015) uses aspects of both to solve a different class of gameplay problems. In some sense, our goal in this paper is simply to combine the strengths of semantic parsers and linear policy estimators for fully general instruction following. As we shall see, however, this requires changes to many aspects of representation, learning and inference.

3 Representations

We wish to train a model capable of following commands in a simulated environment. We do so by presenting the model with a sequence of training pairs $(\mathbf{x}, \mathbf{y})$, where each $\mathbf{x}$ is a sequence of *natural language instructions* $(x_1, x_2, \ldots, x_m)$, e.g.:

(*Go down the yellow hall.*, *Turn left.*, ...)

and each $\mathbf{y}$ is a demonstrated *action sequence* $(y_1, y_2, \ldots, y_n)$, e.g.:

(`rotate(90)`, `move(2)`, ...)

Given a start state, $\mathbf{y}$ can equivalently be characterized by a sequence of (state, action, state) triples resulting from execution of the environment model. An example instruction is shown in Figure 2a. An example action, situated in the environment where it occurs, is shown in Figure 2e.

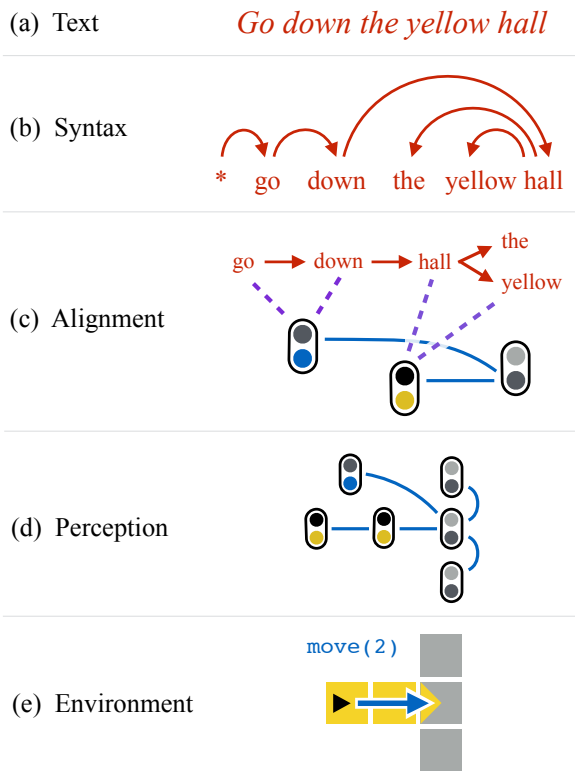

Figure 2: Structure-to-structure alignment connecting a single sentence (via its syntactic analysis) to the environment state (via its grounding graph). The connecting alignments take the place of a traditional semantic parse and allow flexible, feature-driven linking between lexical primitives and perceptual factors.

Our model performs compositional interpretation of instructions by leveraging existing structure inherent in both text and actions. Thus we interpret x_i and y_j not as raw strings and primitive actions, but rather as structured objects.

Linguistic structure We assume access to a pretrained parser, and in particular that each of the instructions x_i is represented by a tree-structured dependency parse. An example is shown in Figure 2b.

Action structure By analogy to the representation of instructions as parse trees, we assume that each (state, action, state) triple (provided by the environment model) can be characterized by a *grounding graph*. The structure and content of this representation is task-specific. An example grounding graph for the maze navigation task is

shown in Figure 2d. The example contains a node corresponding to the primitive action `move(2)` (in the upper left), and several nodes corresponding to locations in the environment that are visible after the action is performed.

Each node in the graph (and, though not depicted, each edge) is decorated with a list of features. These features might be simple indicators (e.g. whether the primitive action performed was `move` or `rotate`), real values (the distance traveled) or even string-valued (English-language names of visible landmarks, if available in the environment description). Formally, a grounding graph consists of a tuple $(V, E, \mathcal{L}, f_V, f_E)$, with

- V a set of vertices
- $E \in V \times V$ a set of (directed) edges
- $\mathcal{L}$ a space of labels (numbers, strings, etc.)
- $f_V : V \to 2^{\mathcal{L}}$ a vertex feature function
- $f_E : E \to 2^{\mathcal{L}}$ an edge feature function

In this paper we have tried to remain agnostic to details of graph construction. Our goal with the grounding graph framework is simply to accommodate a wider range of modeling decisions than allowed by existing formalisms. Graphs might be constructed directly, given access to a structured virtual environment (as in all experiments in this paper), or alternatively from outputs of a perceptual system. For our experiments, we have remained as close as possible to task representations described in the existing literature. Details for each task can be found in the accompanying software package.

Graph-based representations are extremely common in formal semantics (Jones et al., 2012; Reddy et al., 2014), and the version presented here corresponds to a simple generalization of familiar formal methods. Indeed, if $\mathcal{L}$ is the set of all atomic entities and relations, f_V returns a unique label for every $v \in V$, and f_E always returns a vector with one active feature, we recover the existentially-quantified portion of first order logic exactly, and in this form can implement large parts of classical neo-Davidsonian semantics (Parsons, 1990) using grounding graphs.

Crucially, with an appropriate choice of $\mathcal{L}$ this formalism also makes it possible to go beyond set-theoretic relations, and incorporate string-valued features (like names of entities and landmarks) and real-valued features (like colors and positions) as well.

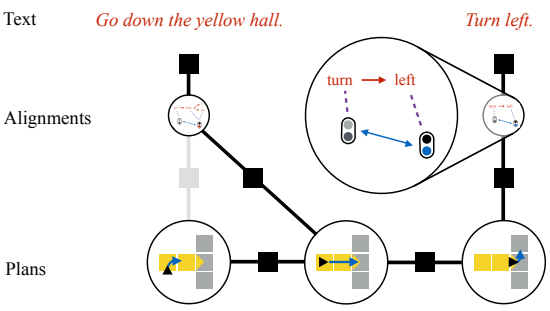

Figure 3: Our model is a conditional random field that describes distributions over state-action sequences conditioned on input text. Each variable's domain is a structured value. Sentences align to a subset of the state–action sequences, with the rest of the states filled in by pragmatic (planning) implication. State-to-state structure represents planning constraints (environment model) while state-to-text structure represents compositional alignment. All potentials are log-linear and feature-driven.

Lexical semantics We must eventually combine features provided by parse trees with features provided by the environment. Examples here might include simple conjunctions (`word=yellow` $\wedge$ `rgb=(0.5, 0.5, 0.0)`) or more complicated computations like edit distance between landmark names and lexical items. Features of the latter kind make it possible to behave correctly in environments containing novel strings or other features unseen during training.

This aspect of the syntax–semantics interface has been troublesome for some logic-based approaches: while past work has used related machinery for selecting lexicon entries (Berant and Liang, 2014) or for rewriting logical forms (Kwiatkowski et al., 2013), the relationship between text and the environment has ultimately been mediated by a discrete (and indeed finite) inventory of predicates. Several recent papers have investigated simple grounded models with real-valued output spaces (Andreas and Klein, 2014; McMahan and Stone, 2015), but we are unaware of any fully compositional system in recent literature that can incorporate observations of these kinds.

Formally, we assume access to a joining feature function $\phi : (2^{\mathcal{L}} \times 2^{\mathcal{L}}) \to \mathbb{R}^d$. As with grounding graphs, our goal is to make the general framework as flexible as possible, and for individual experiments have chosen ϕ to emulate modeling decisions from previous work.

4 Model

As noted in the introduction, we approach instruction following as a sequence prediction problem. Thus we must place a distribution over sequences of actions conditioned on instructions. We decompose the problem into two components, describing interlocking models of "path structure" and "action structure". Path structure captures how sequences of instructions give rise to sequences of actions, while action structure captures the compositional relationship between individual utterances and the actions they specify.

Path structure: aligning utterances to actions

The high-level path structure in the model is depicted in Figure 3. Our goal here is to permit both under- and over-specification of plans, and to expose a planning framework which allows plans to be computed with lookahead (i.e. non-greedily).

These goals are achieved by introducing a sequence of latent alignments between instructions and actions. Consider the multi-step example in Figure 1b. If the first instruction *go down the yellow hall* were interpreted immediately, we would have a presupposition failure—the agent is facing a wall, and cannot move forward at all. Thus an implicit `rotate` action, unspecified by text, must be performed before any explicit instructions can be followed.

To model this, we take the probability of a (text, plan, alignment) triple to be log-proportional to the sum of two quantities:

1. a path-only score $\psi(n;\theta) + \sum_j \psi(y_j;\theta)$
2. a path-and-text score, itself the sum of all pair scores $\psi(x_i, y_j;\theta)$ licensed by the alignment

(1) captures our desire for pragmatic constraints on interpretation, and provides a means of encoding the inherent plausibility of paths. We take $\psi(n;\theta)$ and $\psi(y;\theta)$ to be linear functions of θ. (2) provides context-dependent interpretation of text by means of the structured scoring function $\psi(x, y;\theta)$, described in the next section.

Formally, we associate with each instruction x_i a sequence-to-sequence alignment variable $a_i \in 1 \dots n$ (recalling that n is the number of actions). Then we have[2]

$$p(\mathbf{y},\mathbf{a}|\mathbf{x};\theta) \propto \exp\left\{\psi(n) + \sum_{j=1}^{n}\psi(y_j) + \sum_{i=1}^{m}\sum_{j=1}^{n}\mathbf{1}[a_j = i]\,\psi(x_i, y_j)\right\} \quad (1)$$

We additionally place a monotonicity constraint on the alignment variables. This model is globally normalized, and for a fixed alignment is equivalent to a linear-chain CRF. In this sense it is analogous to IBM Model I (Brown et al., 1993), with the structured potentials $\psi(x_i, y_j)$ taking the place of lexical translation probabilities. While alignment models from machine translation have previously been used to align words to fragments of semantic parses (Wong and Mooney, 2006; Pourdamghani et al., 2014), we are unaware of such models being used to align entire instruction sequences to demonstrations.

Action structure: aligning words to percepts

Intuitively, this scoring function $\psi(x, y)$ should capture how well a given utterance describes an action. If neither the utterances nor the actions had structure (i.e. both could be represented with simple bags of features), we would recover something analogous to the conventional policy-learning approach. As structure is essential for some of our tasks, $\psi(x, y)$ must instead fill the role of a semantic parser in a conventional compositional model.

Our choice of $\psi(x, y)$ is driven by the following fundamental assumptions: *Syntactic relations approximately represent semantic relations. Syntactic proximity implies relational proximity.* In this view, there is an additional hidden structure-to-structure alignment between the grounding graph and the parsed text describing it. [3] Words line up with nodes, and dependencies line up with relations. Visualizations are shown in Figure 2c and the zoomed-in portion of Figure 3.

As with the top-level alignment variables, this approach can viewed as a simple relaxation of a familiar model. CCG-based parsers assume that syntactic type strictly determines semantic type,

[2] Here and the remainder of this paper, we suppress the dependence of the various potentials on θ in the interest of readability.

[3] It is formally possible to regard the sequence-to-sequence and structure-to-structure alignments as a single (structured) random variable. However, the two kinds of alignments are treated differently for purposes of inference, so it is useful to maintain a notational distinction.

and that each lexical item is associated with a small set of functional forms. Here we simply allow all words to license all predicates, multiple words to specify the same predicate, and some edges to be skipped. We instead rely on a scoring function to impose soft versions of the hard constraints typically provided by a grammar. Related models have previously been used for question answering (Reddy et al., 2014; Pasupat and Liang, 2015).

For the moment let us introduce variables b to denote these structure-to-structure alignments. (As will be seen in the following section, it is straightforward to marginalize over all choices of b. Thus the structure-to-structure alignments are never explicitly instantiated during inference, and do not appear in the final form of $\psi(x, y)$.) For a fixed alignment, we define $\psi(x, y, b)$ according to a recurrence relation. Let x^i be the ith word of the sentence, and let y^j be the jth node in the action graph (under some topological ordering). Let $c(i)$ and $c(j)$ give the indices of the dependents of x^i and children of y^j respectively. Finally, let x^{ik} and y^{jl} denote the associated dependency type or relation. Define a "descendant" function:

$$d(i, j) = \big\{(k, l) : \; k \in c(i), \; l \in c(j), \; (k, l) \in b\big\}$$

Then,

$$\psi(x^i, y^j, b) = \exp\Bigg\{\theta^\top \phi(x^i, y^j) + \sum_{(k,l)\in d(x,y)} \Big[\theta^\top \phi\big(x^{ik}, y^{jl}\big) \cdot \; \psi(x^k, y^l, b)\Big]\Bigg\}$$

This is just an unnormalized synchronous derivation between x and y—at any aligned (node, word) pair, the score for the entire derivation is the score produced by combining that word and node, times the scores at all the aligned descendants. Observe that as long as there are no cycles in the dependency parse, it is perfectly acceptable for the relation graph to contain cycles and even self-loops—the recurrence still bottoms out appropriately.

5 Learning and inference

Given a sequence of training pairs $(\mathbf{x}, \mathbf{y})$, we wish to find a parameter setting that maximizes $p(\mathbf{y}|\mathbf{x}; \theta)$. If there were no latent alignments a or b, this would simply involve minimization of a convex objective. The presence of latent variables complicates things. Ideally, we would like to sum over the latent variables, but that sum is intractable. Instead we make a series of variational approximations: first we replace the sum with a maximization, then perform iterated conditional modes, alternating between maximization of the conditional probability of $\mathbf{a}$ and θ. We begin by initializing θ randomly.

Algorithm 1 Computing structure-to-structure alignments

x^i are words in reverse topological order
y^j are grounding graph nodes (root last)
chart is an $m \times n$ array
for $i = 1$ to $|x|$ **do**
  for $j = 1$ to $|y|$ **do**
    score $\leftarrow \exp\{\theta^\top \phi(x^i, y^j)\}$
    for $(k, l) \in d(i, j)$ **do**
      $s \leftarrow \sum_{l \in c(j)} \Big[\exp\{\theta^\top \phi(x^{ik}, y^{jl})\} \cdot$ *chart*$[k, l]\Big]$
      score $\leftarrow$ *score* $\cdot\, s$
    end for
    chart$[i, j] \leftarrow score$
  end for
end for
return *chart*$[n, m]$

As noted in the preceding section, the variable b does not appear in these equations. Conditioned on $\mathbf{a}$, the sum over structure-to-structure $\psi(x, y) = \sum_b \psi(x, y, b)$ can be performed exactly using a simple dynamic program which runs in time $\mathcal{O}(|x||y|)$ (assuming out-degree bounded by a constant, and with $|x|$ and $|y|$ the number of words and graph nodes respectively). This is Algorithm 1.

In our experiments, θ is optimized using L-BFGS (Liu and Nocedal, 1989). Calculation of the gradient with respect to θ requires computation of a normalizing constant involving the sum over $p(\mathbf{x}, \mathbf{y}', \mathbf{a})$ for *all* $\mathbf{y}'$. While in principle the normalizing constant can be computed using the forward algorithm, in practice the state spaces under consideration are so large that even this is intractable. Thus we make an additional approximation, constructing a set $\tilde{Y}$ of alternative actions and taking

$$p(\mathbf{y}, \mathbf{a}|\mathbf{x}) \approx \sum_{j=1}^{n} \frac{\exp\left\{\psi(y_j) + \sum_{i=1}^{m} \mathbf{1}[a_i = j]\psi(x_i, y_i)\right\}}{\sum_{\tilde{y} \in \tilde{Y}} \exp\left\{\psi(\tilde{y}) + \sum_{i=1}^{m} \mathbf{1}[a_i = j]\psi(x_i, \tilde{y})\right\}}$$

$\tilde{Y}$ is constructed by sampling alternative actions from the environment model. Meanwhile, maximization of $\mathbf{a}$ can be performed exactly using the Viterbi algorithm, without computation of normalizers.

Inference at test time involves a slightly different pair of optimization problems. We again perform iterated conditional modes, here on the alignments $\mathbf{a}$ and the unknown output path $\mathbf{y}$. Maximization of $\mathbf{a}$ is accomplished with the Viterbi algorithm, exactly as before; maximization of $\mathbf{y}$ also uses the Viterbi algorithm, or a beam search when this is computationally infeasible. If bounds on path length are known, it is straightforward to adapt these dynamic programs to efficiently consider paths of all lengths.

6 Evaluation

As one of the main advantages of this approach is its generality, we evaluate on several different benchmark tasks for instruction following. These exhibit great diversity in both environment structure and language use. We compare our full system to recent state-of-the-art approaches to each task. In the introduction, we highlighted two core aspects of our approach to semantics: compositionality (by way of grounding graphs and structure-to-structure alignments) and planning (by way of inference with lookahead and sequence-to-sequence alignments). To evaluate these, we additionally present a pair of ablation experiments: *no grounding graphs* (an agent with an unstructured representation of environment state), and *no planning* (a reflex agent with no lookahead).

Map reading Our first application is the map navigation task established by Vogel and Jurafsky (2010), based on data collected for a psychological experiment by Anderson et al. (1991) (Figure 1a). Each training datum consists of a map with a designated starting position, and a collection of landmarks, each labeled with a spatial coordinate and a string name. Names are not always unique, and landmarks in the test set are never observed during training. This map is accompanied by a set of instructions specifying a path from the starting position to some (unlabeled) destination point. These instruction sets are informal and redundant, involving as many as a hundred utterances. They are transcribed from spoken text, so grammatical errors, disfluencies, etc. are common. This is a prime example of a domain that does not lend itself to logical representation—grammars may be too rigid, and previously-unseen landmarks and real-valued positions are handled more easily with feature machinery than predicate logic.

	P	R	F_1
Vogel and Jurafsky (2010)	0.46	0.51	**0.48**
Andreas and Klein (2014)	0.43	0.51	0.45
Model [no planning]	0.44	0.46	0.45
Model [no grounding graphs]	0.52	0.52	0.52
Model [full]	0.51	0.60	**0.55**

Table 1: Evaluation results for the map-reading task. P is precision, R is recall and F_1 is F-measure. Scores are calculated with respect to transitions between landmarks appearing in the reference path (for details see Vogel and Jurafsky (2010)). We use the same train / test split. Some variant of our model achieves the best published results on all three metrics.

Feature	Weight
`word=top ∧ side=North`	1.31
`word=top ∧ side=South`	0.61
`word=top ∧ side=East`	−0.93
`dist=0`	4.51
`dist=1`	2.78
`dist=4`	1.54

Table 2: Learned feature values. The model learns that the word *top* often instructs the navigator to position itself above a landmark, occasionally to position itself below a landmark, but rarely to the side. The bottom portion of the table shows learned *text-independent* constraints: given a choice, near destinations are preferred to far ones (so shorter paths are preferred overall).

The map task was previously studied by Vogel and Jurafsky (2010), who implemented SARSA with a simple set of features. By combining these features with our alignment model and search procedure, we achieve state-of-the-art results on this task by a substantial margin (Table 1).

Some learned feature values are shown in Table 2. The model correctly infers cardinal directions (the example shows the preferred side of a destination landmark modified by the word *top*). Like Vogel et al., we see support for both allocentric references (*you are on top of the hill*) and egocentric references (*the hill is on top of you*). We can also see pragmatics at work: the model learns useful text-independent constraints—in this case, that near destinations should be preferred to far ones.

Maze navigation The next application we consider is the maze navigation task of MacMahon et al. (2006) (Figure 1b). Here, a virtual agent is sit-

	Success (%)
Kim and Mooney (2012)	57.2
Chen (2012)	**57.3**
Model [no planning]	58.9
Model [no grounding graphs]	51.7
Model [full]	**59.6**
Kim and Mooney (2013) [reranked]	62.8
Artzi et al. (2014) [semi-supervised]	**65.3**

Table 3: Evaluation results for the maze navigation task. "Success" shows the percentage of actions resulting in a correct position and orientation after observing a single instruction. We use the leave-one-map-out evaluation employed by previous work.[4] All systems are trained on full action sequences. Our model outperforms several task-specific baselines, as well as a baseline with path structure but no action structure.

uated in a maze (whose hallways are distinguished with various wallpapers, carpets, and the presence of a small set of standard objects), and again given instructions for getting from one point to another. This task has been the subject of focused attention in semantic parsing for several years, resulting in a variety of sophisticated approaches.

Despite superficial similarity to the previous navigation task, the language and plans required for this task are quite different. The proportion of instructions to actions is much higher (so redundancy much lower), and the interpretation of language is highly compositional.

As can be seen in Table 3, we outperform a number of systems purpose-built for this navigation task. We also outperform both variants of our system, most conspicuously the variant without grounding graphs. This highlights the importance of compositional structure. Recent work by Kim and Mooney (2013) and Artzi et al. (2014) has achieved better results; these systems make use of techniques and resources (respectively, discriminative reranking and a seed lexicon of hand-annotated logical forms) that are largely orthogonal to the ones used here, and might be applied to improve our own results as well.

Puzzle solving The last task we consider is the Crossblock task studied by Branavan et al. (2009) (Figure 1c). Here, again, natural language is used to specify a sequence of actions, in this case the solution to a simple game. The environment is simple enough to be captured with a flat feature representation, so there is no distinction between the full model and the variant without grounding graphs.

[4]We specifically targeted the single-sentence version of this evaluation, as an alternative full-sequence evaluation does not align precisely with our data condition.

	Match (%)	Success (%)
No text	54	78
Branavan '09	**63**	–
Model [no planning]	64	66
Model [full]	**70**	**86**

Table 4: Results for the puzzle solving task. "Match" shows the percentage of predicted action sequences that exactly match the annotation. "Success" shows the percentage of predicted action sequences that result in a winning game configuration, regardless of the action sequence performed. Following Branavan et al. (2009), we average across five random train / test folds. Our model achieves state-of-the-art results on this task.

Unlike the other tasks we consider, Crossblock is distinguished by a challenging associated search problem. Here it is nontrivial to find *any* sequence that eliminates all the blocks (the goal of the puzzle). Thus this example allows us measure the effectiveness of our search procedure.

Results are shown in Table 4. As can be seen, our model achieves state-of-the-art performance on this task when attempting to match the human-specified plan exactly. If we are purely concerned with task completion (i.e. solving the puzzle, perhaps not with the exact set of moves specified in the instructions) we can measure this directly. Here, too, we substantially outperform a no-text baseline. Thus it can be seen that text induces a useful heuristic, allowing the model to solve a considerable fraction of problem instances not solved by naïve beam search.

The problem of inducing planning heuristics from side information like text is an important one in its own right, and future work might focus specifically on coupling our system with a more sophisticated planner. Even at present, the results in this section demonstrate the importance of lookahead and high-level reasoning in instruction following.

7 Conclusion

We have described a new alignment-based compositional model for following sequences of natural language instructions, and demonstrated the effectiveness of this model on a variety of tasks. A fully general solution to the problem of contextual interpretation must address a wide range of well-studied problems, but the work we have described

here provides modular interfaces for the study of a number of fundamental linguistic issues from a machine learning perspective. These include:

Pragmatics How do we respond to presupposition failures, and choose among possible interpretations of an instruction disambiguated only by context? The mechanism provided by the sequence-prediction architecture we have described provides a simple answer to this question, and our experimental results demonstrate that the learned pragmatics aid interpretation of instructions in a number of concrete ways: ambiguous references are resolved by proximity in the map reading task, missing steps are inferred from an environment model in the maze navigation task, and vague hints are turned into real plans by knowledge of the rules in Crossblock. A more comprehensive solution might explicitly describe the process by which instruction-givers' own beliefs (expressed as distributions over sequences) give rise to instructions.

Compositional semantics The graph alignment model of semantics presented here is an expressive and computationally efficient generalization of classical logical techniques to accommodate environments like the map task, or those explored in our previous work (Andreas and Klein, 2014). More broadly, our model provides a compositional approach to semantics that does not require an explicit formal language for encoding sentence meaning. Future work might extend this approach to tasks like question answering, where logic-based approaches have been successful.

Our primary goal in this paper has been to explore methods for integrating compositional semantics and the pragmatic context provided by sequential structures. While there is a great deal of work left to do, we find it encouraging that this general approach results in substantial gains across multiple tasks and contexts.

Acknowledgments

The authors would like to thank S.R.K. Branavan for assistance with the Crossblock evaluation. The first author is supported by a National Science Foundation Graduate Fellowship.

Do we need bigram alignment models? On the effect of alignment quality on transduction accuracy in G2P

Steffen Eger

steeger@em.uni-frankfurt.de

Abstract

We investigate the need for *bigram* alignment models and the benefit of *supervised* alignment techniques in grapheme-to-phoneme (G2P) conversion. Moreover, we quantitatively estimate the relationship between alignment quality and overall G2P system performance. We find that, in English, bigram alignment models do perform better than unigram alignment models on the G2P task. Moreover, we find that supervised alignment techniques may perform considerably better than their unsupervised brethren and that few manually aligned training pairs suffice for them to do so. Finally, we estimate a highly significant impact of alignment quality on overall G2P transcription performance and that this relationship is linear in nature.

1 Introduction

Grapheme-to-phoneme (G2P) conversion is the problem of converting a string of letters into a string of phonetic symbols. Closely related to G2P are other string transduction problems in natural language processing (NLP) such as transliteration (Sherif and Kondrak, 2007), lemmatization (Dreyer et al., 2008), and spelling error correction (Brill and Moore, 2000). The classical learning paradigm in each of these settings is to train a model on pairs of strings $\{(\mathbf{x}, \mathbf{y})\}$ and then to evaluate model performance on test data. While there are exceptions (e.g., (Rao et al., 2015)), most state-of-the-art modelings (e.g., (Jiampojamarn et al., 2007; Bisani and Ney, 2008; Jiampojamarn et al., 2008; Jiampojamarn et al., 2010; Novak et al., 2012)) view string transduction as a two-stage process in which string pairs $(\mathbf{x}, \mathbf{y})$ in the training data are first *aligned*, and then a subsequent (e.g., sequence labeling) module is learned on the aligned data.

ph	oe	n	i	x
f	i	n	ɪ	ks

Table 1: Sample monotone many-to-many alignment between $\mathbf{x} =$ phoenix and $\mathbf{y} =$ fɪnɪks.

State-of-the-art alignments in G2P are characterized by the following properties:

(i) Alignments are *monotone* in that the ordering of characters in input and output sequences is preserved by the alignments. Furthermore, they are *many-to-many* in the sense that several $\mathbf{x}$ sequence characters may be matched up with several $\mathbf{y}$ sequence characters as illustrated in Table 1.

(ii) The alignment is a *latent variable* and learnt in an *unsupervised* manner from pairs of strings in the training data.

(iii) The unsupervised alignment models are *unigram alignment* models insofar as the overall score that the alignment model assigns an alignment is the same for all orderings of the matched-up subsequences (context independence).

To illustrate point (iii), consider, in the field of lemmatization, the case of aligning an inflected word form with the extended infinitive in German, such as *absagt* ('rejects') with *abzusagen* ('to reject'). Critically, the insertion *-zu-* appears in infixal position and a plausible alignment might be as in Table 2. Then, correctly aligning certain

a	b	ϵ	s	a	g	t
a	b	zu	s	a	g	en

Table 2: Alignment between *absagen* and *abzusagen*. Empty string denoted by ϵ.

analogous forms such as *zusagt* ('accepts') with

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1175–1185,
Lisbon, Portugal, 17-21 September 2015.

their corresponding extended infinitive *zuzusagen* ('to accept') is beyond the scope of a unigram alignment model since this cannot distinguish the linguistically correct alignment from the following linguistically incorrect alignment

ϵ	z	u	s	a	g	t
zu	z	u	s	a	g	en

precisely because it has no notion of context.

In this work, we **firstly** address bigram alignment models in G2P. We investigate whether there are phenomena in G2P that require bigram alignment models and, more generally, whether bigram alignment models produce better alignments — with respect to a human gold standard — than unigram alignment models within the G2P setting. We do so, **secondly**, in a *supervised* setting where the model learns from gold-standard alignments. While this may seem an odd scenario at first sight, modern alignment toolkits in the related field of machine translation typically include the possibility to learn both in a supervised and unsupervised manner (Liu et al., 2010; Liu and Sun, 2015). The rationale behind supervised learning models may be that they perform better than unsupervised models, and if alignment quality has a large impact upon subsequent string translation performance, then a supervised model may be a suitable alternative. **Thirdly**, we investigate how alignment quality affects overall G2P performance. This allows us to address whether it is worthwhile to work on better alignment models, which bigram and supervised alignment models promise to be. To our knowledge, all three outlined aspects of alignments — bigram models, supervised learning, and *systematically* estimating the relationship between alignment quality and overall string transduction performance — are novel in the G2P setting and its related fields as outlined; however, see also the related work section.

This work is structured as follows. Section 2 presents definitions and algorithms for uni- and bigram alignment models. Section 3 surveys related work. Section 4 presents our data and Section 5 our experiments. We conclude in Section 6.

2 Uni- and bigram alignment models

We first formally define the problem of aligning two strings $\mathbf{x}$ and $\mathbf{y}$ over arbitrary alphabets in a *monotone and many-to-many* manner. Let $\ell_x = |\mathbf{x}|$ and $\ell_y = |\mathbf{y}|$ denote the lengths of $\mathbf{x}$ and $\mathbf{y}$, respectively. Let $\mathbb{N} = \{0, 1, 2, \ldots\}$, and let $S \subseteq \mathbb{N}^2 \backslash \{(0,0)\}$ be a set defining the valid match-up operations between $\mathbf{x}$ characters and $\mathbf{y}$ characters. In other words, when $(s,t) \in S$, then this means we allow matches of subsequences of $\mathbf{x}$ of length s and subsequences of $\mathbf{y}$ of length t.[1]

It is convenient to define a monotone many-to-many alignment of $\mathbf{x}$ and $\mathbf{y}$ as a $2 \times k$ (for $k \geq 1$ arbitrary) nonnegative integer matrix $\mathbf{A}_{\mathbf{x},\mathbf{y}} \in \mathbb{N}^{2 \times k}$ satisfying $\mathbf{A}_{\mathbf{x},\mathbf{y}} \mathbb{1}_k = \begin{pmatrix} \ell_x \\ \ell_y \end{pmatrix}$, i.e., the two rows of $\mathbf{A}_{\mathbf{x},\mathbf{y}}$ sum up to the lengths of the respective strings,[2] and where each column of $\mathbf{A}_{\mathbf{x},\mathbf{y}}$ lies in S. For any such alignment, we let $(\mathbf{x}_1, \ldots, \mathbf{x}_k)$ be the corresponding induced segmentation of $\mathbf{x}$ and $(\mathbf{y}_1, \ldots, \mathbf{y}_k)$ be the corresponding induced segmentation of $\mathbf{y}$.

Example. For any $S \supseteq \{(1,1), (1,2), (2,1)\}$, the alignment of $\mathbf{x}$ = phoenix and $\mathbf{y}$ = finɪks shown in Table 1 may be represented by the matrix $\mathbf{A}_{\mathbf{x},\mathbf{y}} = \begin{pmatrix} 2 & 2 & 1 & 1 & 1 \\ 1 & 1 & 1 & 1 & 2 \end{pmatrix}$. The corresponding induced segmentations are (ph,oe,n,i,x) and (f,i,n,ɪ,ks).

Let $\mathcal{A}_S(\mathbf{x}, \mathbf{y})$ denote the class of all alignments of $\mathbf{x}$ and $\mathbf{y}$. We call a function $f : \mathcal{A}_S(\mathbf{x}, \mathbf{y}) \to \mathbb{R}$ an *alignment model*. We call an alignment model f a *unigram alignment model* if f takes the form, for any $\mathbf{A}_{\mathbf{x},\mathbf{y}} \in \mathcal{A}_S(\mathbf{x}, \mathbf{y})$,

$$f(\mathbf{A}_{\mathbf{x},\mathbf{y}}) = \sum_{i=1}^{k} \mathsf{sim}_1(\mathbf{x}_i, \mathbf{y}_i) \tag{1}$$

where sim_1 is an arbitrary (real-valued) similarity function measuring similarity of two subsequences. We call an alignment model f a *bigram alignment model* if f takes the form

$$f(\mathbf{A}_{\mathbf{x},\mathbf{y}}) = \sum_{i=1}^{k} \mathsf{sim}_2\Big((\mathbf{x}_i, \mathbf{y}_i), (\mathbf{x}_{i-1}, \mathbf{y}_{i-1})\Big) \tag{2}$$

where sim_2 is an arbitrary (real-valued) similarity function measuring similarity of successive pairs of subsequences.

Example. Let $\mathsf{sim}_1(\mathbf{u}, \mathbf{v})$ be equal to $|\mathbf{u}| \cdot |\mathbf{v}|$ and let $f_{\text{uni}}(\mathbf{A}_{\mathbf{x},\mathbf{y}})$ be as in Eq. (1). Then, f_{uni} is a unigram alignment model that assigns the score

[1] This is sometimes denoted in the manner M-N (e.g., 3-2, 1-0), indicating that M characters of one string may be matched up with N characters of the other string. Analogously, we could write here s-t rather than (s,t).

[2] Here, $\mathbb{1}_k$ denotes the unit vector of dimension k.

$1+1+0+1+1+1+2=7$ to the alignment given in Table 2.

Example. Let $\mathsf{sim}_2\big((\mathbf{u},\mathbf{v}),(\mathbf{u}',\mathbf{v}')\big) = (|\mathbf{u}| \cdot |\mathbf{v}|)^{|\mathbf{v}'|}$ if $|\mathbf{u}| = |\mathbf{u}'|-1$ or $\mathbf{u}=\mathbf{v}$ and -2 otherwise. Let $f_{\text{bi}}(\mathbf{A}_{\mathbf{x},\mathbf{y}})$ be as in Eq. (2). Then, f_{bi} is a bigram alignment model assigning the score $(1\cdot 1)^0+(1\cdot 1)^1+(0\cdot 2)^1+(1\cdot 1)^2+(1\cdot 1)^1+(1\cdot 1)^1-2=3$ to the alignment in Table 2.

In statistical alignment modeling, the task is to find an *optimal* alignment (i.e., one with maximal score) given strings $\mathbf{x}$ and $\mathbf{y}$ and given the alignment model f. When f is a unigram model, this can be solved efficiently via dynamic programming (DP). When f is a bigram alignment model, then finding the optimal alignment can still be solved via DP, by introducing a variable M_{ijqw} denoting the score of the best alignment of $\mathbf{x}(1:i)$ and $\mathbf{y}(1:j)$ that ends in the match-up of $\mathbf{x}(q:i)$ with $\mathbf{y}(w:j)$.[3] The variable M_{ijqw} satisfies a recurrence leading to a DP algorithm, shown in Algorithm 1. The actual alignment can be found by storing pointers to the maximizing steps taken. Running time of the algorithm is $\mathcal{O}(\ell_{\mathbf{x}}^2\ell_{\mathbf{y}}^2|S|)$. Note also that the sketched algorithm is supervised insofar as it assumes that the similarity values $\mathsf{sim}_2(\cdot,\cdot)$ are known. Typically, such alignment algorithms can be converted into unsupervised algorithms in which similarity measures sim are learnt iteratively, e.g., in an EM-like fashion (cf., e.g., Eger (2012), Eger (2013)); however, in this paper, we only investigate the supervised base version as indicated.

3 Related work

Monotone alignments have a long tradition in NLP. The classical Needleman-Wunsch algorithm (Needleman and Wunsch, 1970) computes the optimal alignment between two sequences when only single character matches, mismatches, and skips are allowed. It is a special case of the unigram model (1) for which $S=\{(1,0),(0,1),(1,1)\}$ and sim_1 takes on values from $\{0,-1\}$, depending on whether compared subsequences match or not. As is well-known, this alignment specification is equivalent to the edit distance problem (Levenshtein, 1966) in which the minimal number of insertions, deletions and substitutions is sought that transforms one string into another. *Substring-to-substring edit operations* — or equivalently, (monotone) many-to-many alignments — have appeared in the NLP context, e.g., in Deligne et al. (1995), Brill and Moore (2000), Jiampojamarn et al. (2007), Bisani and Ney (2008), Jiampojamarn et al. (2010), or, significantly earlier, in Ukkonen (1985), Véronis (1988). *Learning* edit distance/monotone alignments in an *unsupervised* manner has been the topic of, e.g., Ristad and Yianilos (1998), Cotterell et al. (2014), besides the works already mentioned. All of these approaches are special cases of our unigram model — i.e., they consider particular S (most prominently, $S=\{(1,0),(0,1),(1,1)\}$) and sim_1.[4] Eger (2015b), Yao and Kondrak (2015), and Eger (2015a) generalize to alignments of multiple strings, but likewise only consider unigram alignment models in their experiments.

Probably the most closely related work to ours is Jiampojamarn and Kondrak (2010). There, older and specialized alignment techniques such as ALINE (Kondrak, 2000) (as well as partly heuristic/semi-automatic alignment methods) are compared with variants of the M2M alignment algorithm, which we also survey. This work does not consider supervised alignments or bigram alignments, as we do. Moreover, Jiampojamarn and Kondrak (2010) also evaluate the impact of alignment quality on overall G2P system accuracy by running a few experiments, finding that better alignment quality does not always translate into better G2P accuracy, but that there is a "strong correlation" between the two. We more thorougly investigate this question, using, arguably, more heterogeneous aligners, and many more experiments. We also quantitatively estimate how alignment quality influences G2P system accuracy on two different languages via linear regression.

Goldwater et al. (2006) study the effect of context in (unsupervised) word/sequence segmentation, which may be considered the one-dimensional specialization of sequence alignment, using a Bayesian method. They find that bigram models greatly outperform unigram models for their task.

Of course, our study is also related to the field of machine translation and its studies on the rela-

[3] We denote by $\mathbf{x}(a:b)$ the substring $x_a x_{a+1}\cdots x_b$ of the string $x_1x_2\cdots x_t$.

[4] In Cotterell et al. (2014), context influences alignments, so that the approach goes beyond the unigram model sketched in (1) (but does not allow for many-to-many match-ups). The contextual dependencies in this model are set up differently from the bigram dependencies in our paper.

Algorithm 1

procedure BIGRAM-ALIGN($\mathbf{x} = x_1 \dots x_n, \mathbf{y} = y_1 \dots y_m$; S, sim_2)

  $M_{0000} \leftarrow 0$
  for $i = 0 \dots n$ **do**
    for $j = 0 \dots m$ **do**
      for $q = 0 \dots i + 1$ **do**
        for $w = 0 \dots j + 1$ **do**
          if $(i, j, q, w) \neq (0, 0, 0, 0)$ **then**
            if $(i - q + 1, j - w + 1) \in S$ **then**
              $M_{ijqw} = \max_{(a,b)\in S} M_{q-1,w-1,q-a,w-b} + \mathsf{sim}_2\Big(\big(\mathbf{x}(q{:}i), \mathbf{y}(w{:}j)\big), \big(\mathbf{x}(q-a{:}q-1), \mathbf{y}(w-b{:}w-1)\big)\Big)$

tionship between alignment quality and translation performance (Ganchev et al., 2008). In machine translation, the monotonicity assumption of string transduction does typically not hold, however, rendering alignment and translation techniques different and more heuristic in nature.

4 Data and systems

4.1 Data

For English, we conduct experiments on the General American (GA) variant of the Combilex data set (Richmond et al., 2009). This contains about 128 000 grapheme-phoneme pairs as exemplified in Table 3. Importantly, Combilex provides gold-standard alignments, which we will make use of for the supervised alignment models as well as for measuring alignment quality. For German, we randomly extract 3 000 G2P string pairs from CELEX (Baayen et al., 1995). We had a native speaker manually align them so that gold standard alignments are available here, too. Both data sets contain quite complex match-ups of character subsequences such as (2,3) as in English *s-oi-r-ee-s*/s-wOA-r-P-z or (4,1) as in *w-eigh-t*/w-P-t but the majority of match-ups are of type (1,1), (2,1), and, to a lesser degree, (1,2) and (3,1).

Grapheme string	Phoneme string
g-e-n-e-r-a-l	dZ-E-n-@-r-@-l
p-r-o-b-a-t-ion-a-r-y	p-r-@U-b-eI-S-n=-E-r-i
w-oo-d-e-d	w-U-d-@-d
M-u-r-m-a-n-s-k	m-U@-r-m-A-n-s-k

Table 3: Sample grapheme-phoneme string pairs in Combilex, using Combilex notation for the phoneme strings. Gold-standard alignments indicated in an intuitive manner.

4.2 Alignment toolkits/models

The **M2M aligner** (Jiampojamarn et al., 2007), which is based on EM maximum likelihood estimation of alignment parameters, is the classical unsupervised unigram many-to-many aligner in G2P. As has been pointed out (Kubo et al., 2011), M2M greatly overfits the data.[5] This means that when the M2M aligner is given the freedom to align two sequences without restrictions, it matches them up as a whole. The reason is that a (probabilistic) unigram alignment model adds log-probabilities of matched-up subsequences, which, if not appropriately corrected for, makes alignments with few match-ups a priori more likely than alignments with many match-ups, when probabilities of individual match-ups are uniformly or randomly initialized (as is typically the case for EM maximum likelihood estimation in unsupervised models). To address this, M2M must artifically restrain, in our language, the set S to be $\{(1,1),(1,2),(2,1)\}$. In contrast, the **Mpaligner** (Kubo et al., 2011) introduces a prior (or penalty) in the alignment model which favors 'short' matches (s, t) over 'long' ones. Finally, the **Phonetisaurus** aligner (Novak et al., 2012) modifies the M2M aligner by adding additional soft constraints.

Our own alignment model is, as indicated, supervised. We implement a **unigram** alignment model where we specify $\mathsf{sim}_1(\mathbf{u}, \mathbf{v})$ as

$$\alpha \cdot \text{logp}((\mathbf{u}, \mathbf{v})) + \beta \cdot \text{logp}((|\mathbf{u}|, |\mathbf{v}|)) + \gamma \cdot \text{logp}(\mathbf{u}) + \delta \cdot \text{logp}(\mathbf{v}).$$

Here, $\text{logp}(\mathbf{z})$ denotes the log-probability — estimated from the training data — of observing the

[5] See also the discussion in (Goldwater et al., 2006) for the related word segmentation problem.

object $\mathbf{z}$, and α, β, γ and δ are parameters. This specification says that the subsequences $\mathbf{u}$ and $\mathbf{v}$ are similar insofar as (i) $\mathbf{u}$ and $\mathbf{v}$ have been paired frequently in the training data, (ii) the length of $\mathbf{u}$ and the length of $\mathbf{v}$ have been paired frequently, (iii)/(iv) $\mathbf{u}$/$\mathbf{v}$ by itself is likely. We refer to this unigram alignment model as $\mathsf{uni}_{\alpha,\beta,\gamma,\delta}$. We also implement a **bigram** alignment model where we specify $\mathsf{sim}_2\big((\mathbf{u},\mathbf{v}),(\mathbf{u}',\mathbf{v}')\big)$ as

$$\begin{aligned}&\alpha\cdot\mathrm{logp}\big((\mathbf{u},\mathbf{v})\,|\,(\mathbf{u}',\mathbf{v}')\big)\\+&\beta\cdot\mathrm{logp}\big((|\mathbf{u}|,|\mathbf{v}|)\,|\,(|\mathbf{u}'|,|\mathbf{v}'|)\big)\\+&\gamma\cdot\mathrm{logp}\big(\mathbf{u}|\mathbf{u}'\big)+\delta\cdot\mathrm{logp}\big(\mathbf{v}|\mathbf{v}'\big).\end{aligned}$$

Here, $\mathrm{logp}(\mathbf{z}\,|\,\mathbf{z}')$ denotes the logarithm of the conditional probability of observing the object $\mathbf{z}$ following the object $\mathbf{z}'$. We refer to this bigram alignment model as $\mathsf{bi}_{\alpha,\beta,\gamma,\delta}$.

4.3 Transduction systems

We use two string transduction systems for our experiments. The first one is **DirecTL+** (Jiampojamarn et al., 2010), a discriminative string-to-string translation system incorporating joint n-gram features. DirecTL+ is an extension of the model presented in Jiampojamarn et al. (2008) which treats string transduction as a source sequence segmentation and subsequent sequence labeling task. In addition, we use **Phonetisaurus** (Novak et al., 2012), a weighted finite state-based joint n-gram model employing recurrent neural network language model N-best rescoring in decoding. Both systems take aligned pairs of strings as input and from this construct a monotone translation model.[6]

4.4 Measuring alignment quality

We employ two measures of alignment quality. First, we use **word accuracy**, defined as the fraction of correctly aligned sequence pairs in a test sample. This is a very strict measure that penalizes even tiny deviations from the gold standard. Additionally, we measure the **edit distance** between the true alignment $\mathbf{A}_{\mathbf{x},\mathbf{y}}$ and the predicted alignment $\hat{\mathbf{A}}_{\mathbf{x},\mathbf{y}}$. To implement this, we view the two induced segmentations that constitute an alignment — e.g., (ph,oe,n,i,x) and (f,i,n,ɪ,ks) — as strings including splitting signs. Thus, we can compute the edit distance between the gold-standard segmented $\mathbf{x}$ string and the predicted segmentation, and analogously for the $\mathbf{y}$ sequence. Then, we define the edit distance between $\mathbf{A}_{\mathbf{x},\mathbf{y}}$ and $\hat{\mathbf{A}}_{\mathbf{x},\mathbf{y}}$ as the *sum* of these two string edit distances. For a test sample, we indicate so-defined *average* edit distance, averaged over all pairs in the sample.

5 Experiments

5.1 Alignment quality

To measure alignment quality for the different systems, for English, we run experiments on sets of size x+5 000, where x = 1 000, 2 000, 5 000, 10 000, and 20 000. For the supervised models, we consider x as the training data and the 5 000 additional string pairs as test data.[7] To quantify effects when training data is very little, we let x also range over 100 and 500 string pairs for the supervised models. For the unsupervised models, we simply take all x+5 000 string pairs as data to learn from (but evaluate performance only on the 5 000 string pairs, for comparability).

Results are shown in Tables 4, 5, and 6. We first note (Table 4) that the *unsupervised* models perform decently, obtaining accuracy rates of 80% and beyond under appropriate parametrizations. We also observe the M2M aligner's deterioration in performance as we increase its degrees of freedom (allowing it to match subsequences of larger length), confirming our previous remarks. The Mpaligner does not suffer from this problem as it penalizes large matches. Phonetisaurus suffers from the same problems as M2M, but to a lesser degree. Overall, we find that, under optimal parametrizations, Phonetisaurus produces best alignments, followed by Mpalign and M2M. However, peak performances of all three unsupervised aligners are close. Unsurprisingly, the *supervised* alignment models perform better than the unsupervised ones (Tables 5 and 6). Surprisingly, however, they do so with very little training data; fewer than 100 aligned string pairs suffice to outperform the unsupervised models under good calibrations. When there is sufficient training data, the supervised models perform splendidly, with a peak accuracy of 99.43% for the bigram alignment model that includes appropriate features (scoring lengths of aligned subsequences,

[6] We run both systems with parameters determined by some manual tuning, without trying to systematically optimize their individual performances, however.

[7] For all our below experiments involving the supervised aligners, we set S to a ('pessimistically' large) value of $\{(a,b)\,|\,1\leq a\leq 6, 1\leq b\leq 6\}$. Also, for the bigram models, we add special sequence boundary markers.

etc.). We also note that the bigram alignment model is almost consistently better than the unigram alignment model, with a surplus of about 1% point, depending on specific parametrizations.

We performed an analogous analysis for the German data. Results are quite similar except that unigram and bigram alignment model have indistinguishable performance on the German data, indicating (the known fact) that G2P is a more complex task in English, apparently not requiring bigram alignment models.

20000	97.21	98.73	**99.43**

Table 6: Bigram model and its alignment accuracies in % for various training sizes.

Error analysis Concerning errors that the unigram model commits and the bigram model does not, the majority of errors (roughly 80%) involve match-ups of *ed/d* and d. For example, the unigram model aligns as in

t	w	i	n	k	le	d
t	w	I	N	k	@l	d

while the gold-standard alignment is

t	w	i	n	k	l	ed
t	w	I	N	k	@l	d

While all match-ups in both alignments are plausible, the bigram model assigns here higher probability to the correct *ed/d* match-up in terminal position (consistently favored in the data set), which has a particular meaning there, namely, that of a suffix marker for past tense.[8,9] In the German data, there is a single instance where the unigram and bigram alignment model disagree, namely, in the alignment of *s-t-o-ff-f-l-a-sch-e*/S-t-O-f-f-l-&-S-@, which the unigram model falsely aligns as *s-t-o-f-ff-l-a-sch-e*/S-t-O-f-f-l-&-S-@; note that in the correct alignment *f* must follow *ff*, not vice versa, which depends on context information, e.g., that o/O signifies a short vowel which is followed by a double consonant, not a single consonant.

All remaining errors that the bigram alignment models commits are, for the best considered parametrization and training set size, typically due to match-up types not seen in the training data, and thus mostly concern foreign names or writings (e.g., *Bh-u-tt-o*/b-u-t-F, falsely aligned as *B-hu-tt-o*/b-u-t-F). A few other errors might be corrected when the feature coefficients $\alpha, \beta, \gamma, \delta$ were optimized on a development set rather than set manually. We find no indication that our G2P data, either for English or German, would further benefit from n-gram alignment models of order $n > 2$.

5.2 Alignment quality vs. overall G2P performance

Next, we estimate the relationship between alignment quality and overall G2P performance (transcription accuracy). To this end, for the English data, we use the 5 000 aligned string pairs from the previous experiment on alignment quality and feed them in — as training data — to either DirecTL+ or Phonetisaurus as outlined in Section 4. We then evaluate G2P performance — in terms of **word accuracy** (fraction of correctly transcribed strings) — on a distinct test set of size 10 000. Figure 1 shows a plot of overall G2P accuracy vs. *training set size for the aligner* (ranging over the x values in the last section); and a second plot that sketches G2P accuracy as a function of corresponding alignment accuracy. We first note that, as the supervised aligner receives more training

[8] Similar cases are, e.g., alignments of the type *f-ee-d-b-a-ck*/f-i-d-b-a-k, which the unigram model falsely aligns as *f-e-ed-b-a-ck*/f-i-d-b-a-k. Here, too, the unigram is unable to account for the almost exclusive terminal position of the *ed/d* match-up in the data.

[9] Other errors involve 'unusual/foreign' spelling/pronunciation pairs such as *Ph-oe-n-i-c-ia*/f-@-n-i-S-@ (wrongly aligned as *Ph-o-en-i-c-ia*/f-@-n-i-S-@ by the unigram model) or *m-a-d-e-m-oi-s-e-ll-e-'s*/m-a-d-@-m-w@-z-E-l-0-z (*m-a-d-e-m-o-i-s-e-ll-e-'s*/m-a-d-@-m-w-@-z-E-l-0-z), where the bigram alignment model has apparently gathered the more appropriate statistics.

x	Mpalign	$M2M_{2,2}$	$M2M_{3,3}$	$M2M_{6,6}$	$Phon_{2,2}$	$Phon_{3,3}$	$Phon_{6,6}$
1000	76.48	77.87	34.59	18.96	**78.27**	78.15	11.70

5000	76.68	77.93	35.09	19.72	79.77	**80.47**	17.63
10000	78.86	77.97	35.03	21.35	79.60	**81.30**	23.57
20000	79.87	78.60	37.09	22.90	80.09	**83.37**	34.61

Table 4: Unsupervised aligners and their alignment accuracies in % for various data sizes as described in the text. Subscripts a, b denote restrictions on maximal lengths of subsequences allowed in match-ups (a/b corresponds to **x**/**y** subsequences).

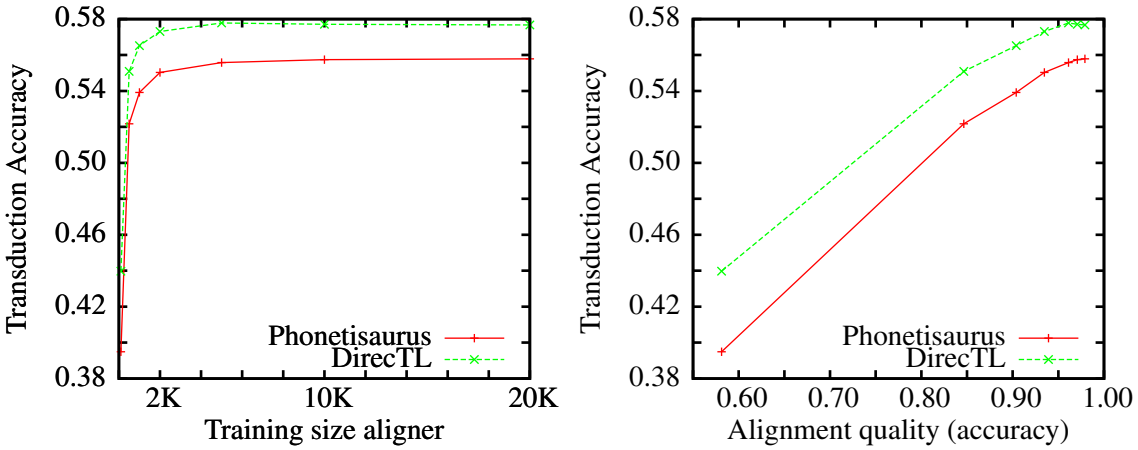

Figure 1: Left: Overall G2P accuracy as a function of training set size of supervised aligner $uni_{1,0,0,0}$. Right: G2P accuracy as a function of alignment quality (measured in accuracy).

data from which to align the 5 000 string pairs, the overall G2P accuracy of both DirecTL+ and Phonetisaurus increase substantially (and as a convex function of training set size). Apparently, the better alignments produced by more training data for the particular supervised aligner considered directly translate into better overall G2P accuracy. The other plot in the figure shows that, indeed, there seems to be a *linear* trend coupling alignment quality with overall G2P performance. Table 7 pairs G2P accuracy with alignment accuracy of selected systems, all run in the $x = 20\,000$ setting. While, in the table, better alignments do not necessarily imply better overall G2P performance, the two best alignments also lead to the two best overall G2P performances (although, in this case, the second best alignment is paired with the best overall G2P performance); conversely, the worst alignment quality is coupled with the worst overall G2P performance.

Overall, we ran 249 experiments (including the German data) in which we trained DirecTL+ or Phonetisaurus with alignments of specific qualities obtained from particularly parametrized aligners. In each of these cases, we obtained an alignment quality score and a subsequent overall G2P system performance. The English part of this data is sketched in Figure 2. This figure seems to corroborate the linear relationship (apparently present in Figure 1) between alignment quality and overall G2P system accuracy, particularly, when alignment quality is measured in the more fine-grained metric of edit distance. To formally test

	Alignment acc.	Phon.	DirecTL+
Mpalign	79.87	55.48	57.54

this, we regress overall G2P system performance (measured in word accuracy) on edit distance and other variables.[10] This yielded the coefficients as given in Table 8; in each case, the goodness-of-fit of the linear model was quite large, with R^2 values above 90% for the English data and about 84% for the German data. Also, the coefficients on alignment quality were highly significantly different from zero. The table shows that the coefficients are on the order of about -3.80% to -4.70%, meaning that, all else being equal, increasing alignment quality by 1 edit distance to the gold-standard alignment increases overall G2P by about 3.80 to 4.70%.

	DirecTL+	Phonetisaurus
English	-3.80^{***}	-4.14^{***}
German	-	-4.68^{***}

Table 8: Coefficients on edit distance in the regression of G2P accuracy on edit distance and further variables. For German, DirecTL+ is omitted due to its long run times.

So far, we have estimated the effects of alignment quality on overall G2P system performance for a **fixed** size of training data, namely, 5 000 aligned string pairs. To see whether this relationship changes when we vary the amount of training data, we run several more experiments. In these, we align training sets of sizes 100, 500, 1 000, 2 000, 10 000, 20 000, 40 000 and 60 000 via our several alignment systems. Then we feed the aligned data to the Phonetisaurus system (we omit DirecTL+ here because of its long run times) and compute overall G2P accuracy on a disjoint test set of size 28 000 approximately. This time, we only use the unsupervised aligners and the gold-standard alignments directly, omitting results for our various supervised aligners. Note, however, that these aligners could, in principle, imitate the gold-standard alignments with a very high degree of precision, as previously seen. Table 9

	$M2M_{3,3}$	Mpalign	$Phon_{3,3}$	Gold
100	5.38	6.43	0.19	**9.60**
500	16.80	22.43	5.08	**23.93**
1K	25.79	31.46	18.70	**33.37**

20K	67.70	71.70	71.51	**72.21**
40K	74.69	78.45	78.13	**78.65**
60K	78.00	81.07	80.92	**81.17**

Table 9: Overall G2P accuracy in % as a function training size of aligned data and alignment system.

shows that training G2P systems from the human gold standard alignments in each case yields better overall G2P transcriptions than training them from either of the three unsupervised alignments considered here. However, we note that the surplus over the unsupervised alignments decreases as training set size increases. This may be due to the fact that the unsupervised aligners themselves create better alignments once they are boot-

[10] These include binary dummy variables for the specific systems as well as alignment consistency and its square — measured in conditional entropy $H(Y|X)$ (Pervouchine et al., 2009) — in the regression.

strapped from larger data sets (cf. Table 4). Additionally, the effect of alignment quality on overall G2P system performance may simply vanish as training set sizes become large enough because the translation modules can better accomodate 'noisy' data as long as its size is sufficiently large. Figure

3 sketches the decreasing influence of alignment system on overall G2P system performance as size of the aligned data increases.

6 Conclusion

We have investigated the need for *bigram* alignment models and the benefit of *supervised* alignment techniques in G2P. We have also quantitatively estimated the relationship between alignment quality and overall G2P system performance. We have found that, in English, bigram alignment models do perform better than unigram alignment models on the G2P task (we find almost no differences between unigram and bigram models for the German sample of G2P data we considered). Moreover, we have found that supervised alignment techniques may perform considerably better than their unsupervised brethren and that few manually aligned training pairs suffice for them to do so. Finally, we have estimated a highly significant impact of alignment quality on overall G2P transcription performance and that this relationship is linear in nature. At a particular training size, a linear regression model has estimated that improving alignment quality by 1 edit distance toward the gold standard alignments leads to an 3.80-4.70% increase in G2P transcription accuracy. However, we have also found that the importance of good alignments on G2P accuracy appears to dimish as data set size increases, possibly because the translation modules can accomodate more 'noisy' data in this scenario.

As a 'policy' implication, we recommend the use of supervised alignment techniques particularly when the size of the G2P corpus is small or when high quality alignments, as an end in themselves, are required. In this case, constructing a few dozen or few hundred alignments in an unsupervised manner and correcting them by hand (to serve as an input for a supervised technique) may be highly beneficial.

In future work, it may be worthwhile to study the impact of alignment techniques on overall system performance in other string transduction problems such as transliteration, lemmatization, and spelling error correction.

Our supervised uni- and bigram aligners are available via `https://github.com/SteffenEger/`.

Abstract

In this paper we propose a framework to improve word segmentation accuracy using input method logs. An input method is software used to type sentences in languages which have far more characters than the number of keys on a keyboard. The main contributions of this paper are: 1) an input method server that proposes word candidates which are not included in the vocabulary, 2) a publicly usable input method that logs user behavior (like typing and selection of word candidates), and 3) a method for improving word segmentation by using these logs. We conducted word segmentation experiments on tweets from Twitter, and showed that our method improves accuracy in this domain. Our method itself is domain-independent and only needs logs from the target domain.

1 Introduction

The first step of almost all natural language processing (NLP) for languages with ambiguous word boundaries (such as Japanese and Chinese) is solving the problem of word identification ambiguity. This task is called word segmentation (WS) and the accuracy of state-of-the-art methods based on machine learning techniques is more than 98% for Japanese and 95% for Chinese (Neubig et al., 2011; Yang and Vozila, 2014). Compared to languages like English with clear word boundaries, this ambiguity poses an additional problem for NLP tasks in these languages. To make matters worse, the domains of the available training data often differ from domains where there is a high demand for NLP, which causes a severe degradation in WS performance. Examples include machine translation of patents, text mining of medical texts, and marketing on the micro-blog site Twitter[1]. Some papers have reported low accuracy on WS or the joint task of WS and part-of-speech (POS) tagging of Japanese or Chinese in these domains (Mori and Neubig, 2014; Kaji and Kitsuregawa, 2014; Liu et al., 2014)

To cope with this problem, we propose a way to collect information from people as they type Japanese or Chinese on computers. These languages use far more characters than the number of keys on a keyboard, so users use software called an input method (IM) to type text in these languages. Unlike written texts in these languages, which lack word boundary information, text entered with an IM can provide word boundary information that can used by NLP systems. As we show in this paper, logs collected from IMs are a valuable source of word boundary information.

An IM consists of a client (front-end) and a server (back-end). The client receives a key sequence typed by the user and sends a phoneme sequence (*kana* in Japanese or *pinyin* in Chinese) or some predefined commands to the server. The server converts the phoneme sequence into normal written text as a word sequence or proposes word candidates for the phoneme sequence in the region specified by the user. We noticed that the actions performed by people using the IM (such as typing and selecting word candidates) provide information about word boundaries, including context information.

In this paper, we first describe an IM for Japanese which allows us to collect this information. We then propose an automatic word segmenter that uses IM logs as a language resource to improve its performance. Finally, we report experimental results showing that our method increases the accuracy of a word segmenter on Twitter texts by using logs collected from a browser add-on ver-

sion of our IM.

The three main contributions of this paper are:

- an IM server that proposes word candidates which are not included in the vocabulary (Section 3),
- a publicly usable IM that logs user behavior (such as typing and selection of word candidates) (Section 4),
- a method for improving word segmentation by using these logs (Section 5).

To the best of our knowledge, this is the first paper proposing a method for using IM logs to successfully improve WS.

2 Related Work

The main focus of this paper is WS. Corpus-based, or empirical, methods were proposed in the early 90's (Nagata, 1994). Then (Mori and Kurata, 2005) extended it by lexicalizing the states like many researches in that era, grouping the word-POS pairs into clusters inspired by the class-based n-gram model (Brown et al., 1992), and making the history length variable like a POS tagger in English (Ron et al., 1996). In parallel, there were attempts at solving Chinese WS in a similar way (Sproat and Chang, 1996). WS or the joint task of WS and POS tagging can be seen as a sequence labeling problem. So conditional random fields (CRFs) (Peng et al., 2004; Lafferty et al., 2001) have been applied to this task and showed better performance than POS-based Markov models (Kudo et al., 2004). The training time of sequence-based methods tends to be long, especially when we use partially annotated data. Thus a simple method based on pointwise classification has been shown to be as accurate as sequence-based methods and fast enough to make active learning practically possible (Neubig et al., 2011). Since the pointwise method decides whether there is a word boundary or not between two characters without referring to other word boundary decisions in the same sentence, it is straightforward to train the model from partially annotated sentences. We adopt this WS system for our experiments.

Along with the evolution of models, the NLP community has become increasingly aware of the importance of language resources (Neubig and Mori, 2010; Mori and Neubig, 2014). So Mori and Oda (2009) proposed to incorpolate dictionaries for human into a WS system with a different word definition. CRFs were also extended to enable training from partially annotated sentences (Tsuboi et al., 2008). When using partially annotated sentences for WS training data, word boundary information exists only between some character pairs and is absent for others. This extension was adopted in Chinese WS to make use of so-called natural annotations (Yang and Vozila, 2014; Jiang et al., 2013). In that work, tags in hyper-texts were regarded as annotations and used to improve WS performance. The IM logs used in this paper are also classified as natural annotations, but contain much more noise. In addition, we need an IM that is specifically designed to collect logs as natural annotations.

Server design is the most important factor in capturing information from IM logs. The most popular IM servers are based on statistical language modeling (Mori et al., 1999; Chen and Lee, 2000; Maeta and Mori, 2012). Their parameters are trained from manually segmented sentences whose words are annotated with phoneme sequences, and from sentences automatically annotated with NLP tools which are also based on machine learning models trained on the annotated sentences. Thus normal IM servers are not capable of presenting out-of-vocabulary (OOV) words (which provide large amounts of information on word boundaries) as conversion candidates. To make our IM server capable of presenting OOV words, we extend a statistical IM server based on (Mori et al., 2006), and ensure that it is computationally efficient enough for practical use by the public.

The target domain in our experiments is Twitter, a site where users post short messages called tweets. Since tweets are an immediate and powerful reflection of public attitudes and social trends, there have been numerous attempts at extracting information from them. Examples include information analysis of disasters (Sakai et al., 2010), estimation of depressive tendencies (Tsugawa et al., 2013), speech diarization (Higashinaka et al., 2011), and many others. These works require preprocessing of tweets with NLP tools, and WS is the first step. So it is clear that there is strong demand for improving WS accuracy. Another reason why we have chosen Twitter for the test domain is that the tweets typed using our server are open and

we can avoid privacy problems. Our method does not utilize any other characteristics of tweets. So it also works in other domains such as blogs.

3 Input Method Suggesting OOV Words

In this section we propose a practical statistical IM server that suggests OOV word candidates in addition to words in its vocabulary.

3.1 Statistical Input Method

An input method (IM) is software which converts a phoneme sequence into a word sequence. This is useful for languages which contain far more characters than keys on a keyboard. Since there are some ambiguities in conversion, a conversion engine based on a word n-gram model has been proposed (Chen and Lee, 2000). Today, almost all IM engines are based on statistical methods.

For the LM unit, instead of words we propose to adopt word-pronunciation pairs $u = \langle \boldsymbol{y}, w \rangle$. Thus given a phoneme sequence $\boldsymbol{y}_1^l = y_1 y_2 \cdots y_l$ as the input, the goal of our IM engine is to output a word sequence $\hat{\boldsymbol{w}}_1^m$ that maximizes the probability $P(\boldsymbol{w}, \boldsymbol{y}_1^l)$ as follows:

$$\begin{aligned} \hat{\boldsymbol{w}}_1^m &= \operatorname*{\mathbf{argmax}}_{\boldsymbol{w}} P(\boldsymbol{w}, \boldsymbol{y}_1^l), \\ P(\boldsymbol{w}, \boldsymbol{y}_1^l) &= \prod_{i=1}^{m+1} P(u_i | \boldsymbol{u}_{i-n+1}^{i-1}), \end{aligned}$$

where the concatenation of $\boldsymbol{y}_i$ in each u_i is equal to the input: $\boldsymbol{y}_1^l = \boldsymbol{y}_1 \boldsymbol{y}_2 \cdots \boldsymbol{y}_m$. In addition u_j ($j \leq 0$) are special symbols introduced to simplify the notation and u_{m+1} is a special symbol indicating a sentence boundary.

As in existing statistical IM engines, parameters are estimated from a corpus whose sentences are segmented into words annotated with their pronunciations as follows:

$$P(u_i | \boldsymbol{u}_{i-n+1}^{i-1}) = \frac{F(\boldsymbol{u}_{i-n+1}^{i})}{F(\boldsymbol{u}_{i-n+1}^{i-1})}, \qquad (1)$$

where $F(\cdot)$ denotes the frequency of a pair sequence in the corpus. In contrast to IM engines based on a word n-gram model, ours does not require an additional model describing relationships between words and pronunciations, and thus it is much simpler and more practical.

Existing statistical IM engines only need an accurate automatic word segmenter to estimate the parameters of the word n-gram model. As the equation above shows, our pair-based engine also needs an accurate way of automatically estimating pronunciation (phoneme sequences). However, recently an automatic pronunciation estimator (Mori and Neubig, 2011) that delivers as accurate as state-of-the-art word segmenters has been proposed. As we explain in Section 6, in our experiments both our IM engine and existing ones delivered accuracy of 91%.

3.2 Enumerating Substrings as Candidate Words

Essentially, the IM engine which we have explained above does not have the ability to enumerate words which are unknown to the word segmenter and the pronunciation estimator used to build the training data. The aim of our research is to gather language information from user behavior as they use an IM. So we extend the basic IM engine to enumerate all the substrings in a corpus with all possible pronunciations. For that purpose, we adopt the notion of a stochastically segmented corpus (SSC) (Mori and Takuma, 2004) and extend it to the pronunciation annotation to words.

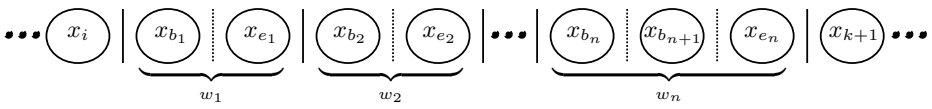
3.2.1 Stochastically Segmented Corpora

An SSC is defined as a combination of a raw corpus C_r (hereafter referred to as the character sequence $\boldsymbol{x}_1^{n_r}$) and word boundary probabilities of the form P_i, which is the probability that a word boundary exists between two characters x_i and x_{i+1}. These probabilities are estimated by a model based on logistic regression (LR)(Fan et al., 2008) trained on a manually segmented corpus referring to the same features as those used in (Neubig et al., 2011). Since there are word boundaries before the first character and after the last character of the corpus, $P_0 = P_{n_r} = 1$. Then word n-gram frequencies on an SSC are calculated as follows:

Word 0-gram frequency: This is defined as the expected number of words in the SSC:

$$f(\cdot) = 1 + \sum_{i=1}^{n_r - 1} P_i.$$

Word n-gram frequency ($n \geq 1$): Consider the situation in which a word sequence $\boldsymbol{w}_1^n$ occurs in the SSC as a subsequence beginning at the $(i+1)$-th character and ending at the k-th character and each word w_m in the word sequence is equal to the character sequence beginning at the



$$f_r(w_1^n) = P_i(1-P_{b_1})P_{e_1}(1-P_{b_2})P_{e_2}\cdots(1-P_{b_n})(1-P_{b_{n+1}})P_{e_n}$$

Figure 1: Word n-gram frequency in a stochastically segmented corpus.

b_m-th character and ending at the e_m-th character ($\boldsymbol{x}_{b_m}^{e_m} = w_m,\ 1 \leq \forall m \leq n;\ e_m + 1 = b_{m+1},\ 1 \leq \forall m \leq n-1;\ b_1 = i+1;\ e_n = k$) (See Figure 1 for an example). The word n-gram frequency of a word sequence $f_r(\boldsymbol{w}_1^n)$ in the SSC is defined by the summation of the stochastic frequency at each occurrence of the character sequence of the word sequence $\boldsymbol{w}_1^n$ over all of the occurrences in the SSC:

$$f_r(\boldsymbol{w}_1^n) = \sum_{(i,\boldsymbol{e}_1^n)\in O_n} P_i \left[\prod_{m=1}^{n} \left\{ \prod_{j=b_m}^{e_m-1} (1-P_j) \right\} P_{e_m} \right],$$

where $\boldsymbol{e}_1^n = (e_1, e_2, \cdots, e_n)$ and $O_n = \{(i, e_1^n) | \boldsymbol{x}_{b_m}^{e_m} = w_m, 1 \leq m \leq n\}$.

We calculate word n-gram probabilities by dividing word n-gram frequencies by word $(n-1)$-gram frequencies. For a detailed explanation and a mathematical proof of this method, please refer to (Mori and Takuma, 2004).

3.2.2 Pseudo-Stochastically Segmented Corpora

The computational costs (in terms of both time and space) for calculating an n-gram model from an SSC are very high[2], so it is not a practical technique for implementing an IM engine. In order to reduce the computational costs we approximate an SSC using a deterministically tagged corpus, which is called a pseudo-stochastically segmented corpus (pSSC) (Kameko et al., 2015). The following is the method for producing a pSSC from an SSC.

- For i = 1 to $n_r - 1$
  1. output a character x_i,
  2. generate a random number $0 \leq p < 1$,
  3. output a word boundary if $p < P_i$ or output nothing otherwise.

Now we have a corpus in the same format as a standard segmented corpus with variable (non-constant) segmentation.

[2]This is because an SSC has many words and word fragments. Additionally, word n-gram frequencies must be calculated using floating point numbers instead of integers.

3.2.3 Pseudo-Stochastically Tagged Corpora

We can annotate a word with its all possible pronunciations and their probabilities, as is done in an SSC. We call a corpus containing sequences of words ($w_1 w_2 \cdots w_i \cdots$) annotated with a sequence of pairs of a pronunciation and its probability ($\langle \boldsymbol{y}_{i,1}, p_{i,1} \rangle, \langle \boldsymbol{y}_{i,2}, p_{i,2} \rangle, \cdots$, where $\sum_j p_{i,j} = 1$, for $\forall i$) a stochastically tagged corpus (STC)[3]. We can estimate these probabilities using an LR model built from sentences annotated with pronunciations (Mori and Neubig, 2011).

Similar to pSSC we then produce a pseudo-stochastically tagged sentence (pSTC) from an STC as follows:

- For each w_i in the sentence
  1. generate a random number $0 \leq p < 1$,
  2. annotate w_i with its j-th phoneme sequence $\boldsymbol{y}_{i,j}$, where $\sum_1^{j-1} p_{i,j} \leq p < \sum_1^{j} p_{i,j}$

Now we have a corpus in the same format as a standard corpus annotated with variable pronunciation.

By estimating the parameters in Equation (1) from a pSTC derived from a pSSC, our IM engine can also suggest OOV word candidates with various possible segmentation and pronunciations without incurring high computational costs.

3.2.4 Suggestion of OOV Words

Here we give an intuitive explanation why our IM engine can suggest OOV words for a certain phoneme sequence. Let us take an OOV word example: "横アリ/yo-ko-a-ri," an abbreviation of "横浜アリーナ" (Yokohama city arena). A WS system tends to segment it into "横" (side) and "アリ" (ant) because they are frequent nouns. In a pSSC, however, some occurrences of the string "横アリ" are remain concatenated as the correct word. For pronunciation, the first character has two possible pronunciations "yo-ko" and "o-u."

[3]Because the existence or non-existence of a word boundary information can also be expressed as a tag, a stochastically tagged corpus includes stochastic segmentation.

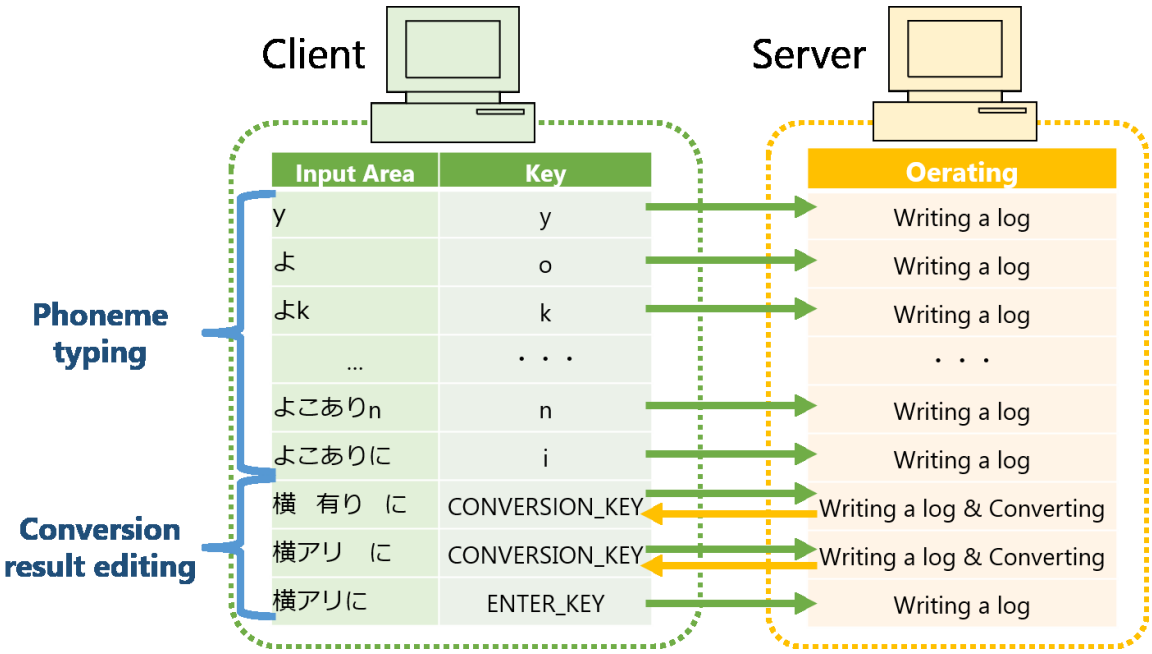


Figure 2: Input method for collecting logs.

So deterministic pronunciation estimation of this new word has the risk of outputting the erroneous result "o-u-a-ri." This prevents our engine from presenting "横アリ" as a conversion candidate for the input "yo-ko-a-ri." The pSTC, however, contains two possible pronunciations for this word and allows our engine to present the OOV word "横アリ" for the input "yo-ko-a-ri."

Thus when the user of our IM engine types "yo-ko-a-ri-ni-i-ku" and selects "横アリ に (to) 行く (go)," the engine can learn an OOV word "横アリ/yo-ko-a-ri" with context "に/ni 行く/i-ku".

4 Input Method Logs

In this section we first propose an IM which allows us to collect user logs. We then examine the characteristics of these logs and some difficulties in using them as language resources.

4.1 Collecting Logs from an Input Method

As Figure 2 shows, the client of our IM, running on the user's PC, is used to input characters and to modify conversion results. The server logs both input from the client and the results of conversions performed in response to requests from the client.

Our IM has two phases: phoneme typing and conversion result editing. In each phase, the client sends the typed keys to the server with a timestamp and its IP address.

Phoneme typing: First the user inputs ASCII characters for a phoneme sequence. If the phoneme sequence itself is what the user wants to write, the user may not go to the next phase. The server records the keys typed to enter the phoneme sequence, cursor movements, and the phoneme sequence if the user selects it as-is.

Conversion result editing: Then the user presses a space key to make the IM engine convert the phoneme sequence to the most likely word sequence based on Equation (1). Sometimes the user changes some word boundaries, makes the IM engine enumerate candidate words covering the region, and selects the intended one from the list of candidates. The server records a space key and the final word sequence.

4.2 Characteristics of Input Method Logs

Table 1 shows an example of interesting log messages from the same IP address[4]. In many cases, users type sentence fragments but not a complete sentence. So in the example there are six fragments within a short period indicated by the timestamps. If the user selects the phoneme sequence as-is without going to the conversion result editing phase, we can expect that there are word boundaries on both sides of the phoneme sequence. In-

[4]In reality, logs from different IPs are stored in the order that they were received.

Table 1: Input method logs of a tweet '横アリに比べると安めかと' (It is cheap compared with Yokohama arena).

Timestamp	Phoneme sequence	Edit result	Note
18:37:11.21	よこありに/yo-ko-a-ri-ni	横アリ/yo-ko-a-ri に/ni	(with Yokohama arena)
18:37:12.60	くらっべる/ku-ra-b-be-ru	くらっ/ku-ra-b ベル/be-ru	Mistyping
18:37:14.94	くらべる/ku-ra-be-ru	比べ/ku-ra-be る/ru	Revised input (compare)
18:37:15.32	と/to	N/A	(*inflectional ending*)
18:37:19.82	ものの/mo-no-no	N/A	Discarded in the twitter
18:37:22.42	やすめかと/ya-su-me-ka-to	安め/ya-su-me か/ka と/to	(cheap)

side the phoneme sequence, however, there is no information. If the user goes to the conversion result editing phase, we can expect that the final word sequence has correct word boundary information.

There are two main problems that make it difficult to directly use IM logs as a training corpus for word segmentation. The first problem is fragmentation. IM users send the phoneme sequences for sentence fragments to the engine to avoid editing long conversion results that require many cursor movements. Thus the phoneme sequence and the final word sequence tend to be sentence fragments (as we noted above) and as a result they lose context information. The second problem is noise. Word boundary information is unreliable even when it is present because of mistakenly selected conversions or words entered separately. From these observations, the IM logs are treated as partially segmented sentence fragments that include noise.

5 Word Segmentation Using Input Method Logs

In this section we first explain various ways to generate language resources for a word segmenter from IM logs. We then describe an automatic word segmenter which utilizes these resources. In the examples below we use the three-valued notation (Mori and Oda, 2009) to denote partial segmentation as follows:

- | : there is a word boundary,
- – : there is not a word boundary,
- ␣ : there is no information.

5.1 Input Method Logs as Language Resources

The phoneme sequences and edit results in the final selection themselves are considered to be partially segmented sentences. We call the corpus generated directly from the logs "**Log-as-is**." Examples in Table 1 are converted as following.

Example of Log-as-is (12 annotations)

横–ア–リ | に
く–ら–っ | べ–ル
比–べ | る
と
も␣の␣の
安–め | か | と

Here the number of annotations is the sum of "–" and "|". In this example, one entry corresponds to one entry of the training data for the word segmenter. As you can easily imagine, Log-as-is may contain mistaken results (noise) and short entries (fragmentation). Both are harmful for a word segmenter.

To cope with the fragmentation problem, we propose to connect some logs based on their timestamps. If the difference between the timestamps of two sequential logs is short, both logs are probably from the same sentence. So we connect two sequential logs if the time difference between the last key of the first log and the first key of the second log is smaller than a certain threshold s. In the experiment we set $s = 500[\mathtt{ms}]$ based on observations of our behavior[5]. This method is referred to as "**Log-chunk**." Using this method, we obtain the following from the examples in Table 1.

Example of Log-chunk (15 annotations)

横–ア–リ | に | く–ら–っ | べ–ル
比–べ | る | と | も␣の␣の
安–め | か | と

We see that Log-chunk contains more context information than Log-as-is.

For preventing the noise problem, we propose to filter out logs with a small number of conversions. We expect that an edited sentence will have many OOV words and not much noise. Therefore we use logs which were converted more than n_c times. In the experiment we set $n_c = 2$ based on

[5]The results were stable for s in preliminary experiments.

Table 2: Corpus specifications.

	#sent.	#words	#char.
Training			
BCCWJ	56,753	1,324,951	1,911,660
Newspaper	8,164	240,097	361,843
Conversation	11,700	147,809	197,941
Test			
BCCWJ-test	6,025	148,929	212,261
TWI-test	2,976	37,010	58,316

observations of our behavior[6]. This method is referred to as "**Log-mconv**." Using this method, the examples in Table 1 becomes the following.

Example of Log-mconv (3 annotations)
横–ア–リ | に

As this example shows, Log-mconv contains short entries (fragmentation) like Log-as-is. However, we expect that the annotated tweets do not include mistaken boundaries or conversions that were discarded.

Obviously we can combine Log-chunk and Log-mconv to avoid both the fragmentation and noise problems. This combination is referred to as "**Log-chunk-mconv**."

5.2 Training a Word Segmenter on Logs

The IM logs give us partially segmented sentence fragments, so we need a word segmenter capable of learning from them. We can use a word segmenter based on a sequence classifier (Tsuboi et al., 2008; Yang and Vozila, 2014; Jiang et al., 2013) or one based on a pointwise classifier (Neubig et al., 2011). Although both types are viable, we adopt the latter in the experiments because it requires much less training time while delivering comparable accuracy.

Here is a brief explanation of the word segmenter based on the pointwise method. For more detail the reader may refer to (Neubig et al., 2011). The input is an unsegmented character sequence $\boldsymbol{x} = x_1 x_2 \cdots x_k$. The word segmenter decides if there is a word boundary $t_i = 1$ or not $t_i = 0$ by using support vector machines (SVMs) (Fan et al., 2008)[7]. The features are character n-grams and character type n-grams ($n = 1, 2, 3$) around the decision points in a window with a width of 6 characters. Additional features are triggered if character n-grams in the window match with character sequences in the dictionary. This approach is called pointwise because the word boundary decision is made without referring to the other decisions on the points $j \neq i$. As you can see from the explanation given above, we can also use partially segmented sentences from IM logs for training in the standard way.

Table 3: Language resources derived from logs.

	#sentence fragments	#annotations
Log-as-is	32,119	39,708
Log-chunk	8,685	63,144
Log-mconv	4,610	10,852
Log-chunk-mconv	1,218	14,242

6 Evaluation

As an evaluation of our methods, we measured the accuracy of WS without using logs (the baseline) and using logs converted by several methods. There are two test corpora: one is the general domain corpus from which we built the baseline WS, and the other is the same domain that the IM logs were collected from, Twitter.

6.1 Corpora

The annotated corpus we used to build the baseline word segmenter is the manually annotated part (core data) of the Balanced Corpus of Contemporary Written Japanese (BCCWJ) (Maekawa, 2008), plus newspaper articles and daily conversation sentences. We also used a 234,652-word dictionary (UniDic) provided with the BCCWJ. A small portion of the BCCWJ core data is reserved for testing. In addition, we manually segmented sentences randomly obtained from Twitter[8] during the same period as the log collection for the test corpus. Table 2 shows the details of these corpora.

[6]The results were stable for n_c in the preliminary experiments.

[7]The reason why we use SVM for word segmentation is that the accuracy is generally higher than that based on LR. It was so in the experiments of this paper. The F-measure of LR on TWI-test was 91.30 (Recall = 89.50, Precision = 93.17), which is lower than that of SVM (see Table 4). To make an SSC, however, we use an LR model because we need word boundary probabilities.

[8]We extracted body text from 1,592 tweets excluding mentions, hash tags, URLs, and ticker symbols. Then we divided the body text into sentences by separating on newline characters, resulting in 2,976 sentences.

Table 4: WS accuracy on the tweets.

	Recall [%]	Precision [%]	F-measure
Baseline	90.31	94.05	92.14
+ Log-as-is	90.33	93.77	92.02
+ Log-chunk	91.04	94.29	92.64
+ Log-mconv	90.62	94.09	92.32
+ Log-chunk-mconv	91.40	94.45	92.90

Table 5: WS accuracy on BCCWJ.

	Recall [%]	Precision [%]	F-measure
Baseline	99.01	98.97	98.99
+ Log-as-is	99.02	98.87	98.94
+ Log-chunk	99.05	98.88	98.96
+ Log-mconv	98.98	98.91	98.95
+ Log-chunk-mconv	98.98	98.92	98.95

6.2 Models using Input Method Logs

To make the training data for our IM server, we first chose randomly selected tweets (786,331 sentences) in addition to the unannotated part of the BCCWJ (358,078 sentences). We then trained LR models which estimate word boundary probabilities and pronunciation probabilities for words (and word candidates) from the training data shown in Table 2 and UniDic. We made a pSTC for our IM engine from 1,207,182 sentences randomly obtained from Twitter by following the procedure which we explained in Subsection 3.2.3[9].

We launched our IM as a browser add-on for Twitter and collected 19,770 IM logs from 7 users between April 24 and December 31, 2014. Following the procedures in Section 5.1, we obtained the language resources shown in Table 3. We combined them with the training corpus and dictionaries to build four WSs, which we compared with the baseline.

6.3 Results and Discussion

Following the standard in WS experiments, the evaluation criteria are recall, precision, and F-measure (their harmonic mean). Recall is the number of correctly segmented words divided by the number of words in the test corpus. Precision is the number of correctly segmented words divided by the number of words in the system output.

Table 4 and 5 show WS accuracy on TWI-test and BCCWJ-test, respectively. The difference in accuracy of the baseline method on BCCWJ-test and TWI-test shows that WS of tweets is very difficult. The fact that the precision on TWI-test is much higher than the recall indicates that the baseline model suffers from over-segmentation. This over-segmentation problem is mainly caused by OOV words being divided into known words. For example, “横アリ” (Yokohama arena) is divided into the two know words “横” (side) and “アリ” (ant).

When we compare the F-measures on TWI-test, all the models referring to the IM logs outperform the baseline model trained only from the BCCWJ. The highest is the Log-chunk-mconv model and the improvement over the baseline is statistically significant (significance level: 1%). In addition the accuracies of the five methods on the BCCWJ (Table 5) are almost the same and there is no statistical significance (significance level: 1%) between any two of them.

We analyzed the words misrecognized by the WSs, which we call error words. Table 6 shows the number of error words, the number of OOV words, and the ratio of OOV words to error words. Here the vocabulary is the set of the words appearing in the training data or in UniDic (see Table 2). Although the result of the WS trained on Log-as-is contains more error words than the baseline, the OOV ratio is less than the baseline. This means that the IM logs have a potential to reduce errors caused by OOV words.

Table 6 also indicates that the best method Log-chunk-mconv had the greatest success in reducing

[9]There is no overlap with the test data.

Table 6: Ratio of OOV words in error words.

	#Error words	#OOV words	(ratio[%])
Baseline	446	103	(23.09)
+ Log-as-is	467	89	(19.06)
+ Log-chunk	428	81	(18.93)
+ Log-mconv	443	88	(19.86)
+ Log-chunk-mconv	413	74	(17.79)

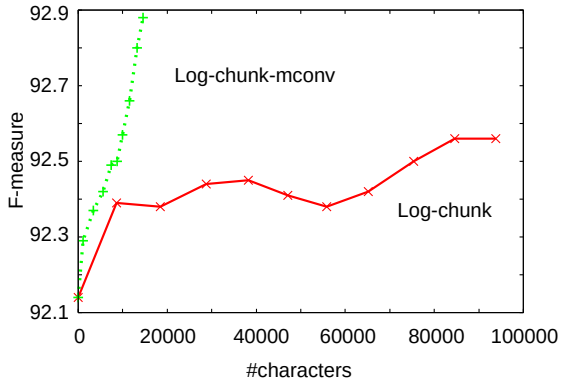

Figure 3: Relationship between WS accuracy on the tweets and log size.

errors caused by OOV words. However, the majority of error words are in-vocabulary words. It can be said that our log chunking method (Log-chunk or Log-chunk-mconv) enabled the WSs to eliminate many known word errors by using context information.

To investigate the impact of the log size, we measured WS accuracy on TWI-test when varying the log size during training. Figure 3 shows the results. Table 4 says that Log-chunk-mconv and Log-chunk increase the accuracy nicely. The graph, however, clarifies that Log-chunk-mconv achieves high accuracy with fewer training data converted from logs. In other words, the method Log-chunk-mconv is good at distilling the informative parts and filtering out the noisy parts. These characteristics are very important properties to have as we consider deploying our IM to a wider audience. An IM is needed to type Japanese and the number of Japanese speakers is more than 100 million. If we can use input logs of even 1% of them for the same or longer period[10], the idea we propose in this paper can improve WS accuracy on various domains efficiently and automatically.

As a final remark, this paper describes a successful example of how to build a useful tool for the NLP community. This process has three steps: 1) design a useful NLP application that can collect user logs, 2) deploy it for public use, and 3) devise a method for mining data from the logs.

[10]The number of users using our system in this paper is 7 for 8 months.

7 Conclusion

This paper described the design of a publicly usable IM which collects natural annotations for use as training data for another system. Specifically, we (1) described how to construct an IM server that suggests OOV word candidates, (2) designed a publicly usable IM that collects logs of user behavior, and (3) proposed a method for using this data to improve word segmenters. Tweets from Twitter are a promising source of data with great potential for NLP, which is one reason why we used them as the target domain for our experiments. The experimental results showed that our methods improve accuracy in this domain. Our method itself is domain-independent and only needs logs from the target domain, so it is worth testing on other domains and with much longer periods of data collection.

Abstract

Currently most of state-of-the-art methods for Chinese word segmentation are based on supervised learning, whose features are mostly extracted from a local context. These methods cannot utilize the long distance information which is also crucial for word segmentation. In this paper, we propose a novel neural network model for Chinese word segmentation, which adopts the long short-term memory (LSTM) neural network to keep the previous important information in memory cell and avoids the limit of window size of local context. Experiments on PKU, MSRA and CTB6 benchmark datasets show that our model outperforms the previous neural network models and state-of-the-art methods.

1 Introduction

Word segmentation is a fundamental task for Chinese language processing. In recent years, Chinese word segmentation (CWS) has undergone great development. The popular method is to regard word segmentation task as a sequence labeling problem (Xue, 2003; Peng et al., 2004). The goal of sequence labeling is to assign labels to all elements in a sequence, which can be handled with supervised learning algorithms such as Maximum Entropy (ME) (Berger et al., 1996) and Conditional Random Fields (CRF) (Lafferty et al., 2001). However, the ability of these models is restricted by the design of features, and the number of features could be so large that the result models are too large for practical use and prone to overfit on training corpus.

Recently, neural network models have increasingly used for NLP tasks for their ability to minimize the effort in feature engineering (Collobert et al., 2011; Socher et al., 2013; Turian et al., 2010; Mikolov et al., 2013b; Bengio et al., 2003). Collobert et al. (2011) developed the SENNA system that approaches or surpasses the state-of-the-art systems on a variety of sequence labeling tasks for English. Zheng et al. (2013) applied the architecture of Collobert et al. (2011) to Chinese word segmentation and POS tagging, also he proposed a perceptron style algorithm to speed up the training process with negligible loss in performance. Pei et al. (2014) models tag-tag interactions, tag-character interactions and character-character interactions based on Zheng et al. (2013). Chen et al. (2015) proposed a gated recursive neural network (GRNN) to explicitly model the combinations of the characters for Chinese word segmentation task. Each neuron in GRNN can be regarded as a different combination of the input characters. Thus, the whole GRNN has an ability to simulate the design of the sophisticated features in traditional methods.

Despite of their success, a limitation of them is that their performances are easily affected by the size of the context window. Intuitively, many words are difficult to segment based on the local information only. For example, the segmentation of the following sentence needs the information of the long distance collocation.

冬天 (winter)，能 (can) 穿 (wear) 多少 (amount) 穿 (wear) 多少 (amount)；夏天 (summer)，能 (can) 穿 (wear) 多 (more) 少 (little) 穿 (wear) 多 (more) 少 (little)。

Without the word “夏天 (summer)” or “冬天 (winter)”, it is difficult to segment the phrase “能穿多少穿多少”. Therefore, we usually need utilize the non-local information for more accurate word segmentation. However, it does not work by simply increasing the context window size. As reported in (Zheng et al., 2013), the performance drops smoothly when the window size is larger than 3. The reason is that the number of its parameters is so large that the trained network has

Lisbon, Portugal, 17-21 September 2015.

overfitted on training data. Therefore, it is necessary to capture the potential long-distance dependencies without increasing the size of the context window.

In order to address this problem, we propose a neural model based on Long Short-Term Memory Neural Network (LSTM) (Hochreiter and Schmidhuber, 1997) that explicitly model the previous information by exploiting input, output and forget gates to decide how to utilize and update the memory of pervious information. Intuitively, if the LSTM unit detects an important feature from an input sequence at early stage, it easily carries this information (the existence of the feature) over a long distance, hence, capturing the potential useful long-distance information. We evaluate our model on three popular benchmark datasets (PKU, MSRA and CTB6), and the experimental results show that our model achieves the state-of-the-art performance with the smaller context window size (0,2).

The contributions of this paper can be summarized as follows.

- We first introduce the LSTM neural network for Chinese word segmentation. The LSTM can capture potential long-distance dependencies and keep the previous useful information in memory, which avoids the limit of the size of context window.
- Although there are relatively few researches of applying dropout method to the LSTM, we investigate several dropout strategies and find that dropout is also effective to avoid the overfitting of the LSTM.
- Despite Chinese word segmentation being a specific case, our model can be easily generalized and applied to the other sequence labeling tasks.

2 Neural Model for Chinese Word Segmentation

Chinese word segmentation is usually regarded as character-based sequence labeling. Each character is labeled as one of {B, M, E, S} to indicate the segmentation. {B, M, E} represent *Begin*, *Middle*, *End* of a multi-character segmentation respectively, and S represents a *Single* character segmentation.

The neural model is usually characterized by three specialized layers: (1) a character embedding layer; (2) a series of classical neural network layers and (3) tag inference layer. An illustration is shown in Figure 1.

The most common tagging approach is based on a local window. The window approach assumes that the tag of a character largely depends on its neighboring characters. Given an input sentence $c^{(1:n)}$, a window of size k slides over the sentence from character $c^{(1)}$ to $c^{(n)}$, where n is the length of the sentence. As shown in Figure 1, for each character $c^{(t)}(1 \leq t \leq n)$, the context characters ($c^{(t-2)}$,$c^{(t-1)}$,$c^{(t)}$,$c^{(t+1)}$,$c^{(t+2)}$) are fed into the lookup table layer when the window size k is 5. The characters exceeding the sentence boundaries are mapped to one of two special symbols, namely "start" and "end" symbols. The character embeddings extracted by the lookup table layer are then concatenated into a single vector $\mathbf{x}^{(t)} \in \mathbb{R}^{H_1}$, where $H_1 = k \times d$ is the size of layer 1. Then $\mathbf{x}^{(t)}$ is fed into the next layer which performs linear transformation followed by an element-wise activation function g such as sigmoid function $\sigma(x) = (1+e^{-x})^{-1}$ and hyperbolic tangent function $\phi(x) = \frac{e^x - e^{-x}}{e^x + e^{-x}}$here.

$$\mathbf{h}^{(t)} = g(\mathbf{W}_1\mathbf{x}^{(t)} + \mathbf{b}_1), \quad (1)$$

where $\mathbf{W}_1 \in \mathbb{R}^{H_2 \times H_1}$, $\mathbf{b}_1 \in \mathbb{R}^{H_2}$, $\mathbf{h}^{(t)} \in \mathbb{R}^{H_2}$. H_2 is a hyper-parameter which indicates the number of hidden units in layer 2. Given a set of tags $\mathcal{T}$ of size $|\mathcal{T}|$, a similar linear transformation is performed except that no non-linear function is followed:

$$\mathbf{y}^{(t)} = \mathbf{W}_2\mathbf{h}^{(t)} + \mathbf{b}_2, \quad (2)$$

where $\mathbf{W}_2 \in \mathbb{R}^{|\mathcal{T}| \times H_2}$, $\mathbf{b}_2 \in \mathbb{R}^{|\mathcal{T}|}$. $\mathbf{y}^{(t)} \in \mathbb{R}^{|\mathcal{T}|}$ is the score vector for each possible tag. In Chinese word segmentation, the most prevalent tag set $T \subseteqq \mathcal{T}$ is {B, M, E, S} as mentioned above.

To model the tag dependency, a transition score $\mathbf{A}_{ij}$ is introduced to measure the probability of jumping from tag $i \in T$ to tag $j \in T$ (Collobert et al., 2011). Although this model works well for Chinese word segmentation and other sequence labeling tasks, it just utilizes the information of context of a limited-length window. Some useful long distance information is neglected.

3 Long Short-Term Memory Neural Network for Chinese Word Segmentation

In this section, we introduce the LSTM neural network for Chinese word segmentation.

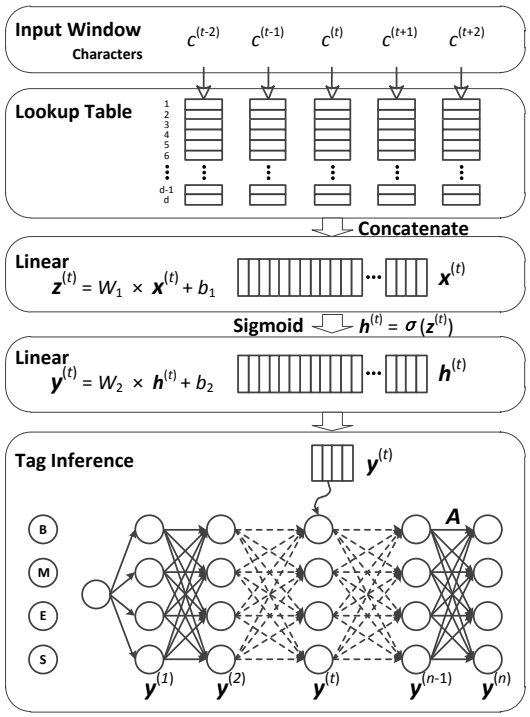

Figure 1: General architecture of neural model for Chinese word segmentation.

3.1 Character Embeddings

The first step of using neural network to process symbolic data is to represent them into distributed vectors, also called embeddings (Bengio et al., 2003; Collobert and Weston, 2008).

Formally, in Chinese word segmentation task, we have a character dictionary $\mathcal{C}$ of size $|\mathcal{C}|$. Unless otherwise specified, the character dictionary is extracted from the training set and unknown characters are mapped to a special symbol that is not used elsewhere. Each character $c \in \mathcal{C}$ is represented as a real-valued vector (character embedding) $\mathbf{v}_c \in \mathbb{R}^d$ where d is the dimensionality of the vector space. The character embeddings are then stacked into an embedding matrix $\mathbf{M} \in \mathbb{R}^{d \times |\mathcal{C}|}$. For a character $c \in \mathcal{C}$, the corresponding character embedding $\mathbf{v}_c \in \mathbb{R}^d$ is retrieved by the lookup table layer. And the lookup table layer can be regarded as a simple projection layer where the character embedding for each context character is achieved by table lookup operation according to its index.

3.2 LSTM

The long short term memory neural network (LSTM) (Hochreiter and Schmidhuber, 1997) is an extension of the recurrent neural network (RNN).

The RNN has recurrent hidden states whose output at each time is dependent on that of the previous time. More formally, given a sequence $\mathbf{x}^{(1:n)} = (\mathbf{x}^{(1)}, \mathbf{x}^{(2)}, \ldots, \mathbf{x}^{(t)}, \ldots, \mathbf{x}^{(n)})$, the RNN updates its recurrent hidden state $\mathbf{h}^{(t)}$ by

$$\mathbf{h}^{(t)} = g(\mathbf{U}\mathbf{h}^{(t-1)} + \mathbf{W}\mathbf{x}^{(t)} + \mathbf{b}), \quad (3)$$

where g is a nonlinear function as mentioned above.

Though RNN has been proven successful on many tasks such as speech recognition (Vinyals et al., 2012), language modeling (Mikolov et al., 2010) and text generation (Sutskever et al., 2011), it can be difficult to train them to learn long-term dynamics, likely due in part to the vanishing and exploding gradient problem (Hochreiter and Schmidhuber, 1997).

The LSTM provides a solution by incorporating memory units that allow the network to learn when to forget previous information and when to update the memory cells given new information. Thus, it is a natural choice to apply LSTM neural network to word segmentation task since the LSTM neural network can learn from data with long range temporal dependencies (memory) due to the considerable time lag between the inputs and their corresponding outputs. In addition, the LSTM has been applied successfully in many NLP tasks, such as text classification (Liu et al., 2015) and machine translation (Sutskever et al., 2014).

The core of the LSTM model is a memory cell $\mathbf{c}$ encoding memory at every time step of what inputs have been observed up to this step (see Figure 2) . The behavior of the cell is controlled by three "gates", namely input gate $\mathbf{i}$, forget gate $\mathbf{f}$ and output gate $\mathbf{o}$. The operations on gates are defined as element-wise multiplications, thus gate can either scale the input value if the gate is non-zero vector or omit input if the gate is zero vector. The output of output gate will be fed into the next time step $t+1$ as previous hidden state and input of upper layer of neural network at current time step t. The definitions of the gates, cell update and output are as follows:

$$\mathbf{i}^{(t)} = \sigma(\mathbf{W}_{ix}\mathbf{x}^{(t)} + \mathbf{W}_{ih}\mathbf{h}^{(t-1)} + \mathbf{W}_{ic}\mathbf{c}^{(t-1)}), \quad (4)$$

$$\mathbf{f}^{(t)} = \sigma(\mathbf{W}_{fx}\mathbf{x}^{(t)} + \mathbf{W}_{fh}\mathbf{h}^{(t-1)} + \mathbf{W}_{fc}\mathbf{c}^{(t-1)}), \quad (5)$$

$$\mathbf{c}^{(t)} = \mathbf{f}^{(t)} \odot \mathbf{c}^{(t-1)} + \mathbf{i}^{(t)} \odot \phi(\mathbf{W}_{cx}\mathbf{x}^{(t)} + \mathbf{W}_{ch}\mathbf{h}^{(t-1)}), \quad (6)$$

$$\mathbf{o}^{(t)} = \sigma(\mathbf{W}_{ox}\mathbf{x}^{(t)} + \mathbf{W}_{oh}\mathbf{h}^{(t-1)} + \mathbf{W}_{oc}\mathbf{c}^{(t)}), \quad (7)$$

$$\mathbf{h}^{(t)} = \mathbf{o}^{(t)} \odot \phi(\mathbf{c}^{(t)}), \quad (8)$$

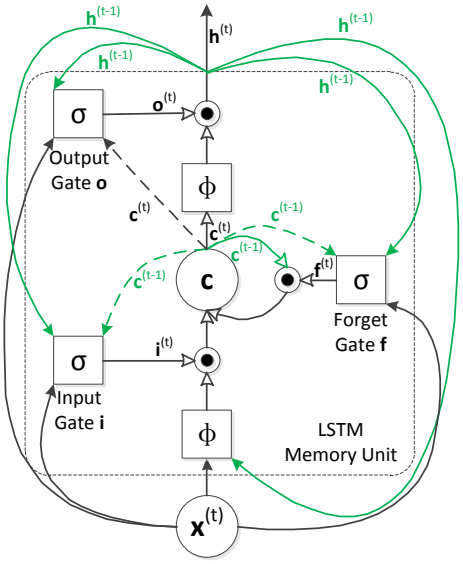

Figure 2: LSTM Memory Unit. The memory unit contains a cell **c** which is controlled by three gates. The green links show the signals at time $t-1$, while the black links show the current signals. The dashed links represent the weight matrices from beginning to end are diagonal. Moreover, the solid pointers mean there are weight matrices on the connections, and hollow pointers mean none. The current output signal, $\mathbf{h}^{(t)}$, will fed back to the next time $t+1$ via three gates, and is the input of the higher layer of the neural network as well.

where σ and ϕ are the logistic sigmoid function and hyperbolic tangent function respectively; $\mathbf{i}^{(t)}$, $\mathbf{f}^{(t)}$, $\mathbf{o}^{(t)}$ and $\mathbf{c}^{(t)}$ are respectively the input gate, forget gate, output gate, and memory cell activation vector at time step t, all of which have the same size as the hidden vector $\mathbf{h}^{(t)} \in \mathbb{R}^{H_2}$; the parameter matrices Ws with different subscripts are all square matrices; $\odot$ denotes the element-wise product of the vectors. Note that $\mathbf{W}_{ic}$, $\mathbf{W}_{fc}$ and $\mathbf{W}_{oc}$ are diagonal matrices.

3.3 LSTM Architectures for Chinese Word Segmentation

To fully utilize the LSTM, we propose four different structures of neural network to select the effective features via memory units. Figure 3 illustrates our proposed architectures.

LSTM-1 The LSTM-1 simply replace the hidden neurons in Eq. (1) with LSTM units (See Figure 3a).

The input of the LSTM unit is from a window of context characters. For each character, $c^{(t)}, (1 \leq t \leq n)$, the input of the LSTM unit $\mathbf{x}^{(t)}$,

$$\mathbf{x}^{(t)} = \mathbf{v}_c^{(t-k_1)} \oplus \cdots \oplus \mathbf{v}_c^{(t+k_2)}, \quad (9)$$

is concatenated from character embeddings of $c^{(t-k_1):(t+k_2)}$, where k_1 and k_2 represent the numbers of characters from left and right contexts respectively. The output of the LSTM unit is used in final inference function (Eq. (11)) after a linear transformation.

LSTM-2 The LSTM-2 can be created by stacking multiple LSTM hidden layers on top of each other, with the output sequence of one layer forming the input sequence for the next (See Figure 3b). Here we use two LSTM layers. Specifically, input of the upper LSTM layer takes $\mathbf{h}^{(t)}$ from the lower LSTM layer without any transformation. The input of the first layer is same to LSTM-1, and the output of the second layer is as same operation as LSTM-1.

LSTM-3 The LSTM-3 is a extension of LSTM-1, which adopts a local context of LSTM layer as input of the last layer (See Figure 3c). For each time step t, we concatenate the outputs of a window of the LSTM layer into a vector $\hat{\mathbf{h}}^{(t)}$,

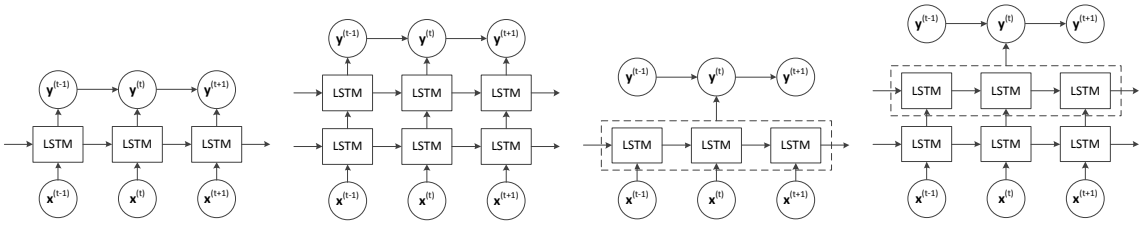
$$\hat{\mathbf{h}}^{(t)} = \mathbf{h}^{(t-m_1)} \oplus \cdots \oplus \mathbf{h}^{(t+m_2)}, \quad (10)$$

where m_1 and m_2 represent the lengths of time lags before and after current time step.Finally, $\hat{\mathbf{h}}^{(t)}$ is used in final inference function (Eq. (11)) after a linear transformation.

LSTM-4 The LSTM-4 (see Figure 3d) is a mixture of the LSTM-2 and LSTM-3, which consists of two LSTM layers. The output sequence of the lower LSTM layer forms the input sequence of the upper LSTM layer. The final layer adopts a local context of upper LSTM layer as input.

3.4 Inference at Sentence Level

To model the tag dependency, previous neural network models (Collobert et al., 2011; Zheng et al., 2013; Pei et al., 2014) introduced the transition score $\mathbf{A}_{ij}$ for measuring the probability of jumping from tag $i \in T$ to tag $j \in T$. For a input sentence $c^{(1:n)}$ with a tag sequence $y^{(1:n)}$, a sentence-level score is then given by the sum of tag transition scores and network tagging scores:



(a) LSTM-1 (b) LSTM-2 (c) LSTM-3 (d) LSTM-4

Figure 3: Our proposed LSTM architectures for Chinese word segmentation.

$$s(c^{(1:n)}, y^{(1:n)}, \theta) = \sum_{t=1}^{n} \left(\mathbf{A}_{y^{(t-1)}y^{(t)}} + \mathbf{y}^{(t)}_{y^{(t)}} \right), \quad (11)$$

where $\mathbf{y}^{(t)}_{y^{(t)}}$ indicates the score of tag $y^{(t)}$, and $\mathbf{y}^{(t)}$ is computed by the network as in Eq. (2). The parameter set of our model $\theta = \{\mathbf{M}, \mathbf{A}, \mathbf{W}_{ic}, \mathbf{W}_{fc}, \mathbf{W}_{oc}, \mathbf{W}_{ix}, \mathbf{W}_{fx}, \mathbf{W}_{ox}, \mathbf{W}_{ih}, \mathbf{W}_{fh}, \mathbf{W}_{oh}, \mathbf{W}_{cx}, \mathbf{W}_{ch}\}$.

4 Training

4.1 Max-Margin criterion

We use the Max-Margin criterion to train our model. Intuitively, the Max-Margin criterion provides an alternative to probabilistic, likelihood based estimation methods by concentrating directly on the robustness of the decision boundary of a model (Taskar et al., 2005). We use $Y(x_i)$ to denote the set of all possible tag sequences for a given sentence x_i and the correct tag sequence for x_i is y_i. The parameter set of our model is θ. We first define a structured margin loss $\Delta(y_i, \hat{y})$ for predicted tag sequence $\hat{y}$:

$$\Delta(y_i, \hat{y}) = \sum_{t}^{n} \eta \mathbf{1}\{y_i^{(t)} \neq \hat{y}^{(t)}\}, \quad (12)$$

where n is the length of sentence x_i and η is a discount parameter. The loss is proportional to the number of characters with incorrect tags in the proposed tag sequence. For a given training instance (x_i, y_i),the predicted tag sequence $\hat{y}_i \in Y(x_i)$ is the one with the highest score:

$$\hat{y}_i = \underset{y \in Y(x_i)}{\arg\max}\, s(x_i, y, \theta), \quad (13)$$

where the function $s(\cdot)$ is sentence-level score and defined in equation (11).

Given a set of training set $\mathcal{D}$, the regularized objective function is the loss function $J(\theta)$ including a l_2-norm term:

$$J(\theta) = \frac{1}{|\mathcal{D}|} \sum_{(x_i, y_i) \in \mathcal{D}} l_i(\theta) + \frac{\lambda}{2} \|\theta\|_2^2, \quad (14)$$

where $l_i(\theta) = \max(0, s(x_i, \hat{y}_i, \theta) + \Delta(y_i, \hat{y}_i) - s(x_i, y_i, \theta))$.

To minimize $J(\theta)$, we use a generalization of gradient descent called subgradient method (Ratliff et al., 2007) which computes a gradient-like direction.

Following (Socher et al., 2013), we also use the diagonal variant of AdaGrad (Duchi et al., 2011) with minibatchs to minimize the objective. The parameter update for the i-th parameter $\theta_{t,i}$ at time step t is as follows:

$$\theta_{t,i} = \theta_{t-1,i} - \frac{\alpha}{\sqrt{\sum_{\tau=1}^{t} g_{\tau,i}^2}} g_{t,i}, \quad (15)$$

where α is the initial learning rate and $g_\tau \in \mathbb{R}^{|\theta_i|}$ is the subgradient at time step τ for parameter θ_i. In addition, the process of back propagation is followd Hochreiter and Schmidhuber (1997).

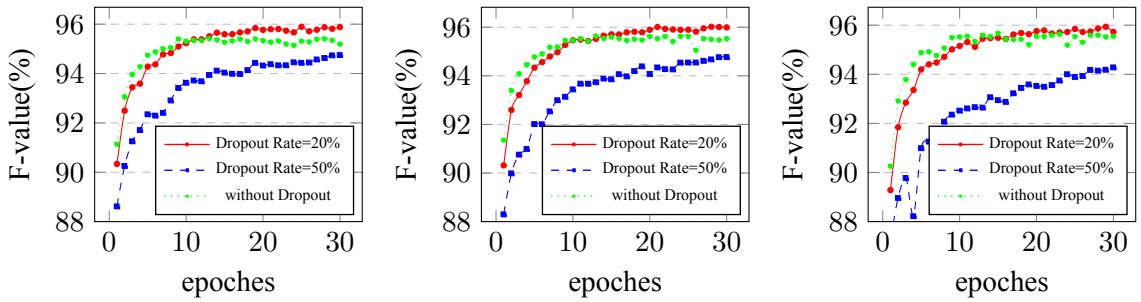
4.2 Dropout

Dropout is one of prevalent methods to avoid overfitting in neural networks (Srivastava et al., 2014). When dropping a unit out, we temporarily remove it from the network, along with all its incoming and outgoing connections. In the simplest case, each unit is omitted with a fixed probability p independent of other units, namely dropout rate, where p is also chosen on development set.

5 Experiments

5.1 Datasets

We use three popular datasets, PKU, MSRA and CTB6, to evaluate our model. The PKU



(a) LSTM-1(2,2) (b) LSTM-1 (1,2) (c) LSTM-1(0,2)

Figure 4: Performances of LSTM-1 with the different context lengths and dropout rates on PKU development set.

Context length	$(k_1, k_2) = (0, 2)$
Character embedding size	$d = 100$
Hidden unit number	$H_2 = 150$
Initial learning rate	$\alpha = 0.2$
Margin loss discount	$\eta = 0.2$
Regularization	$\lambda = 10^{-4}$
Dropout rate on input layer	$p = 0.2$

Table 1: Settings of the hyper-parameters.

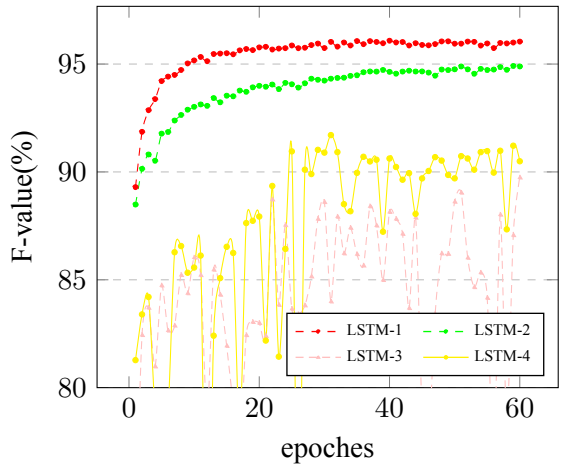


Figure 5: Performances of LSTM-1 (0,2) with 20% dropout on PKU development set.

and MSRA data are provided by the second International Chinese Word Segmentation Bakeoff (Emerson, 2005), and CTB6 is from Chinese TreeBank 6.0 (LDC2007T36) (Xue et al., 2005), which is a segmented, part-of-speech tagged and fully bracketed corpus in the constituency formalism. These datasets are commonly used by previous state-of-the-art models and neural network models. In addition, we use the first 90% sentences of the training data as training set and the rest 10% sentences as development set for PKU and MSRA datasets. For CTB6 dataset, we divide the training, development and test sets according to (Yang and Xue, 2012)

All datasets are preprocessed by replacing the Chinese idioms and the continuous English characters and digits with a unique flag.

For evaluation, we use the standard bake-off scoring program to calculate precision, recall, F1-score and out-of-vocabulary (OOV) word recall.

5.2 Hyper-parameters

Hyper-parameters of neural model impact the performance of the algorithm significantly. According to experiment results, we choose the hyper-parameters of our model as showing in Figure 1. The minibatch size is set to 20. Generally, the number of hidden units has a limited impact on the performance as long as it is large enough. We found that 150 is a good trade-off between speed and model performance. The dimensionality of character embedding is set to 100 which achieved the best performance. All these hyper-parameters are chosen according to their average performances on three development sets.

For the context lengths (k_1, k_2) and dropout strategy, we give detailed analysis in next section.

5.3 Dropout and Context Length

We first investigate the different dropout strategies, including dropout at different layers and with different dropout rate p. As a result, we found that it is a good trade-off between speed and model performance to drop the input layer only with dropout rate $p_{input} = 0.2$. However, it does not show any significant improvement to dropout on hidden LSTM layers.

Context Length	Dropout rate=20%			Dropout rate=50%			without Dropout		
	P	R	F	P	R	F	P	R	F
LSTM-1 (2,2)	95.8	95.3	95.6	94.8	94.4	94.6	95.2	94.9	95.1
LSTM-1 (1,2)	95.7	95.3	95.5	94.8	94.4	94.6	95.4	94.9	95.2
LSTM-1 (0,2)	**95.8**	**95.5**	**95.7**	94.6	94.2	94.4	95.4	95.0	95.2

Table 2: Performances of LSTM-1 with the different context lengths and dropout rates on PKU test set.

models	Contextr Length = (0,2)		
	P	R	F
LSTM-1	**95.8**	**95.5**	**95.7**
LSTM-2	95.1	94.5	94.8
LSTM-3	89.1	90.4	89.8
LSTM-4	92.1	91.7	91.9

Table 3: Performance on our four proposed models on PKU test set.

Due to space constraints, we just give the performances of LSTM-1 model on PKU dataset with different context lengths (k_1, k_2) and dropout rates in Figure 4 and Table 2. From Figure 4, we can see that 20% dropout converges slightly slower than the one without dropout, but avoids overfitting. 50% or higher dropout rate seems to be underfitting since its training error is also high.

Table 2 shows that the LSTM-1 model performs consistently well with the different context length, but the LSTM-1 model with short context length saves computational resource, and gets more efficiency. At the meanwhile, the LSTM-1 model with context length (0,2) can receive the same or better performance than that with context length (2,2), which shows that the LSTM model can well model the pervious information, and it is more robust for its insensitivity of window size variation.

We employ context length (0,2) with the 20% dropout rate in the following experiments to balance the tradeoff between accuracy and efficiency.

5.4 Model Selection

We also evaluate the our four proposed models with the hyper-parameter settings in Table 1. For LSTM-3 and LSTM-4 models, the context window length of top LSTM layer is set to (2,0). For LSTM-2 and LSTM-4,the number of upper hidden LSTM layer is set to 100. We use PKU dataset to select the best model. Figure 5 shows the results of the four models on PKU development set from first epoch to 60-th epoch. We see that the LSTM-1 is the fastest one to converge and achieves the best performance. The LSTM-2 (two LSTM layers) get worse, which shows the performance seems not to benefit from deep model. The LSTM-3 and LSTM-4 models do not converge, which could be caused by the complexity of models.

The results on PKU test set are also shown in Table 3, which again show that the LSTM-1 achieves the best performance. Therefore, in the rest of the paper we will give more analysis based on the LSTM-1 with hyper-parameter settings as showing in Table 1.

5.5 Experiment Results

In this section, we give comparisons of the LSTM-1 with pervious neural models and state-of-the-art methods on the PKU, MSRA and CTB6 datasets.

We first compare our model with two neural models (Zheng et al., 2013; Pei et al., 2014) on Chinese word segmentation task with random initialized character embeddings. As showing in Table 4, the performance is boosted significantly by utilizing LSTM unit. And more notably, our window size of the context characters is set to (0,2), while the size of the other models is (2,2).

Previous works found that the performance can be improved by pre-training the character embeddings on large unlabeled data. We use word2vec [1] (Mikolov et al., 2013a) toolkit to pre-train the character embeddings on the Chinese Wikipedia corpus. The obtained embeddings are used to initialize the character lookup table instead of random initialization. Inspired by (Pei et al., 2014), we also utilize bigram character embeddings which is simply initialized as the average of embeddings of two consecutive characters.

Table 5 shows the performances with additional pre-trained and bigram character embeddings. Again, the performances boost significantly as a result. Moreover, when we use bigram embeddings only, which means we do close test without pre-training the embeddings on other extra corpus, our model still perform competitively compared

Table 6: Comparison of our model with state-of-the-art methods on three test sets.

with previous neural models with pre-trained embedding and bigram embeddings.

Table 6 lists the performances of our model as well as previous state-of-the-art systems. (Zhang and Clark, 2007) is a word-based segmentation algorithm, which exploit features of complete words, while the rest of the list are character-based word segmenters, whose features are mostly extracted from a window of characters. Moreover, some systems (such as Sun and Xu (2011) and Zhang et al. (2013)) also exploit kinds of extra information such as unlabeled data or other knowledge. Despite our model only uses simple bigram features, it outperforms previous state-of-the-art models which use more complex features.

Since that we do not focus on the speed of the algorithm in this paper, we do not optimize the speed a lot. On PKU dataset, it takes about 3 days to train the model (last row of Table 5) using CPU (Intel(R) Xeon(R) CPU E5-2665 @ 2.40GHz) only. All implementation is based on Python.

6 Related Work

Chinese word segmentation has been studied with considerable efforts in the NLP community. The most popular word segmentation methods is based on sequence labeling (Xue, 2003). Recently, researchers have tended to explore neural network based approaches (Collobert et al., 2011) to reduce efforts of feature engineering (Zheng et al., 2013; Pei et al., 2014; Qi et al., 2014; Chen et al., 2015). The features of all these methods are extracted from a local context and neglect the long distance information. However, previous information is also crucial for word segmentation. Our model adopts the LSTM to keep the previous important information in memory and avoids the limitation of ambiguity caused by limit of the size of context window.

7 Conclusion

In this paper, we use LSTM to explicitly model the previous information for Chinese word segmentation, which can well model the potential long-

distance features. Though our model use smaller context window size (0,2), it still outperforms the previous neural models with context window size (2,2). Besides, our model can also be easily generalized and applied to other sequence labeling tasks.

Although our model achieves state-of-the-art performance, it only makes use of previous context. The future context is also useful for Chinese word segmentation. In future work, we would like to adopt the bidirectional recurrent neural network (Schuster and Paliwal, 1997) to process the sequence in both directions.

Abstract

This paper presents a bilingual semi-supervised Chinese word segmentation (CWS) method that leverages the natural segmenting information of English sentences. The proposed method involves learning three levels of features, namely, character-level, phrase-level and sentence-level, provided by multiple sub-models. We use a sub-model of conditional random fields (CRF) to learn monolingual grammars, a sub-model based on character-based alignment to obtain explicit segmenting knowledge, and another sub-model based on transliteration similarity to detect out-of-vocabulary (OOV) words. Moreover, we propose a sub-model leveraging neural network to ensure the proper treatment of the semantic gap and a phrase-based translation sub-model to score the translation probability of the Chinese segmentation and its corresponding English sentences. A cascaded log-linear model is employed to combine these features to segment bilingual unlabeled data, the results of which are used to justify the original supervised CWS model. The evaluation shows that our method results in superior results compared with those of the state-of-the-art monolingual and bilingual semi-supervised models that have been reported in the literature.

1 Introduction

Chinese word segmentation (CWS) is generally accepted to be a necessary first step in most Chinese NLP tasks because Chinese sentences are written in continuous sequences of characters with no explicit delimiters (e.g., the spaces in English). Many studies have been conducted in this area, resulting in extensive investigation of the problem of CWS using machine learning techniques in recent years. However, the reliability of CWS that can be achieved using machine learning techniques relies heavily on the availability of a large amount of high-quality, manually segmented data. Because hand-labeling individual words and word boundaries is very difficult (Jiao et al., 2006), producing segmented Chinese texts is very time-consuming and expensive. Although a number of manually segmented datasets have been constructed by various organizations, it is not feasible to combine them into a single complete dataset because of their incompatibility due to the use of various segmenting standards. Thus, it is difficult to build a large-scale manually segmented corpus, and the resulting lack of such a corpus is detrimental to further enhancement of the accuracy of CWS.

To address the scarcity of manually segmented corpora, a number of semi-supervised CWS approaches have been intensively investigated in recent years. These approaches attempt to either learn the predicted label distribution (Jiao et al., 2006) or extract mutual information ((Liang et al., 2005); (Sun and Xu, 2011); (Zeng et al., 2013a)) from large-scale monolingual unlabeled data to update the baseline model (from manually segmented corpora). In addition to these techniques, several co-training approaches (Zeng et al., 2013b) using character-based and word-based models have also been employed. However, because monolingual unlabeled data contain limited natural segmenting information, in most semi-supervised methods, the objective function tends to be optimized based on the personal experience and knowledge of the researchers. This practice means that these methods can typically yield high performance in certain specialized domains, but they lack generalizability. In contrast with these methods, we propose to leverage bilingual unlabeled data, i.e., a Chinese-English corpus with sentence alignment. Because English sentences

Lisbon, Portugal, 17-21 September 2015.

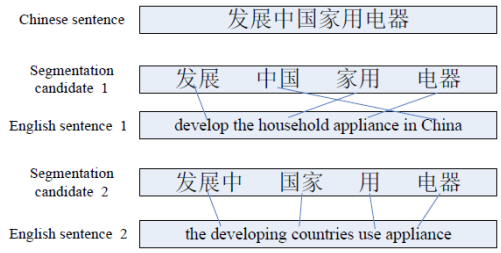

Figure 1: The examples of different segmentation on the same Chinese sentences guided by the English sentences

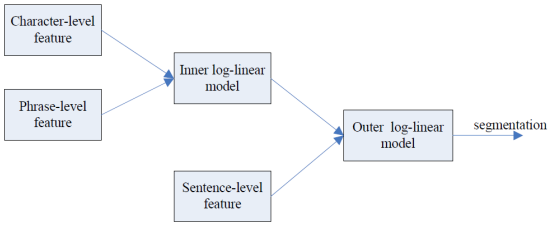

Figure 2: The structure of cascaded log-linear model with multilevel features

are naturally segmented, extracting information from a bilingual corpus is a much more objective task. As the example presented in Fig 1 shows, the English sentences that correspond to Chinese text can easily help guide better segmentation, and thus, the learning of segmenting information from bilingual data is a very promising approach.

In this paper, to obtain high-quality segmenting information from bilingual unlabeled data, we leverage multilevel features using the following steps: first, we integrate character-level features calculated using a conditional random field (CRF) model, which is used to capture the monolingual grammars. Then, we employ a statistical aligner to perform character-based alignment. Given the results of this character-based alignment, we apply several phrase-level features to extract explicit and implicit segmenting information: (1) we use two types of English-Chinese co-occurrence features (one-to-many and many-to-many) to learn the explicit segmenting information of the English sentences, (2) we use the transliteration similarity feature to detect out-of-vocabulary (OOV) words using a phrase-based translation model, and (3) we employ a neural network to calculate the semantic gap between the Chinese and English words to ensure that the Chinese segmentation follows the semantic meanings of the corresponding English sentences as closely as possible. Finally, we employ another phrase-based translation model to perform a sentence-level calculation of the translation probability of the Chinese segmentation and its corresponding English sentences. After obtaining these multilevel features, we normalize them and combine them into two log-linear models in a cascaded structure, which is illustrated in Fig 2. Finally, we segment the bilingual unlabeled data using the proposed model and use the segmentation of those data to justify the original supervised CWS model, which was trained on a standard manually segmented corpus.

In fact, several semi-supervised CWS methods have previously been proposed that leverage bilingual unlabeled data ((Xu et al., 2008); (Chang et al., 2008); (Ma and Way, 2009);(Chung et al., 2009); (Xi et al., 2012)). However, most were developed for statistical machine translation (SMT), causing them to focus on decreasing the perplexity of the bilingual data and the word alignment process rather than on achieving more accurate segmentation. These methods achieve significant improvement in SMT performance but are not very suitable for common NLP tasks because in many situations, they ignore the standard grammars to satisfy the needs of SMT. By contrast, we employ various types of features to capture both monolingual standard grammars and bilingual segmenting information, which allows our semi-supervised CWS model to be very efficient at other NLP tasks and endows it with higher generalizability.

Our evaluation also shows that our method significantly outperforms the state-of-the-art monolingual and bilingual semi-supervised approaches.

2 Related Work

First, we review related work on monolingual supervised and semi-supervised CWS methods. Then, we review bilingual semi-supervised CWS.

2.1 Monolingual Supervised and Semi-supervised CWS Methods

Considerable efforts have been made in the NLP community in the study of Chinese word segmentation. The most popular supervised approach treats word segmentation as a sequence labeling problem, as first proposed by (Xue et al., 2003). Most previous systems have addressed this task using linear statistical models with carefully designed features ((Peng et al., 2004); (Asahara et

al., 2005); (Zhang and Clark, 2007); (Zhao et al., 2010)). However, the primary shortcoming of these approaches is that they rely heavily on a large amount of labeled data, which is very time-consuming and expensive to produce. Thus, the scale of available manually labeled data has placed considerable limitations on the further enhancement of supervised CWS methods.

To address this problem, a number of semi-supervised CWS approaches have been intensively investigated in recent years. For example, (Sun and Xu, 2011) enhanced their segmentation results by interpolating statistics-based features derived from unlabeled data into a CRF model. (Zeng et al., 2013a) introduced a graph-based semi-supervised joint model of Chinese word segmentation and part-of-speech tagging and regularized the learning of a linear CRF model based on the label distributions derived from unlabeled data. However, because monolingual unlabeled data lack natural segmenting information, most previous semi-supervised CWS methods have required certain assumptions to be made regarding their objective functions based on the researchers' personal experiences. By contrast, we leverage bilingual unlabeled data that contain the natural segmentation that is present in English sentences and can therefore extract linguistic knowledge without any manual assumptions or bias.

2.2 Bilingual Semi-supervised CWS Methods

Some previous work ((Xu et al., 2008); (Chang et al., 2008); (Ma and Way, 2009);(Chung et al., 2009); (Xi et al., 2012)) has been performed on leveraging bilingual unlabeled data to achieve better segmentation, although most such studies have focused on statistical machine translation (SMT). These approaches leverage the mappings of individual English words to one or more consecutive Chinese characters either to construct a Chinese word dictionary for maximum-matching segmentation (Xu et al., 2004) or to form a labeled dataset for training a sequence labeling model (Peng et al., 2004). (Zeng et al., 2014) also used such mappings to bias a supervised segmentation model toward a better solution for SMT. However, because most of these approaches focus on SMT performance, they emphasize decreasing the perplexity of the bilingual data and word alignment rather than improving the CWS accuracy. Thus, they sometimes ignore the standard grammars during segmentation in favor of satisfying the needs of SMT, thereby causing these methods to be rather unsuitable for other NLP tasks. By contrast, we propose to use various types of features to capture syntactic and semantic information and a cascaded log-linear model to maintain balance between the monolingual grammars and the bilingual knowledge.

3 Multilevel Features

In this section, we describe the three levels of features used in our approach. We propose to use character-level features to capture monolingual grammars and phrase-level and sentence-level features to obtain bilingual segmenting information. Moreover, we describe a cascaded log-linear model by proposing both inner and outer log-linear models.

3.1 Character-level Feature

The conditional random field (CRF) (Lafferty et al., 2001) model was first used for CWS tasks by (Xue et al., 2003) who treated the CWS task as a sequence tagging problem and demonstrated this model's effectiveness in detecting OOV words.

In this paper, we score the character-level feature in the same manner defined by (Xue et al., 2003). For the jth character c_j in the sentence $c_1^J = c_1...c_J$, the score can be calculated as follows:

$$f_{CRF}(j) = \sum_k \lambda_k f_k(y_{j-1}, y_j, c_1^J, j) \quad (1)$$

where $f_k(y_{j-1}, y_j, c_1^J, j)$ is a feature function and λ_k is a learned weight that corresponds to the feature f_k. j represents the index of the character in the sentence. y_{j-1} and y_j represent the tags of the previous and current characters, respectively.

We do not introduce the CRF-based CWS model in detail here, but more information can be obtained from (Lafferty et al., 2001) and (Xue et al., 2003).

3.2 Phrase-level Features

In this section, we first describe English-Chinese character-based alignment. Then, we propose several phrase-level features to obtain explicit and implicit segmenting information from the character-based alignment. Finally, we describe the inner log-linear model that is used to combine the character-level and phrase-level features.

3.2.1 English-Chinese Character-based Alignment

To avoid introducing omissions and mistakes into the linguistic information in the initial segmentations of the bilingual data, we perform a statistical character-based alignment: First, every Chinese character in the bitexts is separated by white spaces so that individual characters are recognized as unique "words" or alignment targets. Then, they are associated with English words using a statistical word aligner.

By representing the English and Chinese sentences as $e_1^I = e_1 e_2 ... e_I$ and $c_1^J = c_1 c_2 ... c_J$, respectively, where e_i and c_j represent single elements of the sentences, we define their alignment as a_1^K, of which each element is a span $a_k =< s, t >$ and represents the alignment of the English word e_s with the Chinese character c_t. Then, the corpus of unlabeled bilingual data can be represented as the set of sentence tuples $<e_1^I, c_1^J, a_1^K>$

To obtain the character-based alignment, we employ an open-source toolkit Pialign[1] ((Neubig et al., 2011); (Neubig et al., 2012)) which uses Bayesian learning and inversion transduction grammars.

3.2.2 Features Obtained from the Character-based Alignment

Given the English-Chinese character-based alignment a_1^K, we extract several phrase-level features to optimize the segmentation. For the jth character in c_1^J, we assume that one of the segmentations of the substring c_1^j can be represented as $w_1^{N+1} = w_1 w_2 w_3 ... w_{N+1} = c_1^{j_1} c_{j_1+1}^{j_2} ... c_{j_N+1}^{j}$. Then, we calculate the scores of each Chinese word $w_n = c_{j_m}^{j_n}$ $(j_m = j_{n-1} + 1)$ in w_1^{N+1} using the following features.

English-Chinese One-to-Many Alignment

To evaluate the probability that a sequence of Chinese characters $c_{j_m}^{j_n} = c_{j_m} c_{j_m+1} ... c_{j_n}$ should be combined into a word w_n based on the corresponding English sentence, we integrate the feature of English-Chinese one-to-many alignment (one English word is aligned with multiple Chinese characters). First, for any English word e_i in e_1^I, the phrase tuple $< e_i, c_{j_m}^{j_n} >$ can be defined as an aligned One-to-Many phrase tuple if it satisfies the following conditions:

(1) $< i, j_m > \in a_1^K, < i, j_n > \in a_1^K$

(2) $\forall j' \notin [j_m, j_n], < i, j' > \notin a_1^K$

(3) $\forall i' \neq i,\ \forall j' \in [j_m, j_n], < i', j' > \notin a_1^K$

Then, for any phrase tuple $< \overline{e_i}, c_{j_m}^{j_n} >$ that satisfies these conditions, the span $< \overline{i}, j_m, j_n >$ is defined as a One-to-Many span and as a member of the set A_{One}.

Thus, for each span $< i, j_m, j_n >$, the One-to-Many score can be calculated as follows:

$$s(< i, j_m, j_n >) = \begin{cases} t(c_{j_m}^{j_n} | e_i) & if < i, j_m, j_n > \in A_{One} \\ 0 & else \end{cases} \quad (2)$$

where $t(c_{j_m}^{j_n} | e_i)$ represents the translation probability of the phrase tuple $c_{j_m}^{j_n} | e_i$.

Finally, the score for the feature of English-Chinese One-to-Many alignment for $w_n = c_{j_m}^{j_n}$ is derived as follows:

$$f_{One-to-Many}(n) = \underset{i \in [1,I]}{\operatorname{argmax}}\, s(< i, j_m, j_n >) \quad (3)$$

English-Chinese Many-to-Many Alignment

The second phrase-level feature, called English-Chinese Many-to-Many Alignment (multiple English words are aligned with multiple Chinese characters), is used to evaluate the probability that a space should be inserted between c_n and c_{n+1}. Similar to One-to-Many alignment, for any sequence of English words $e_{i_1}^{i_2}$ and the Chinese word $w_n = c_{j_m}^{j_n}$, the phrase tuple $< e_{i_1}^{i_2}, c_{j_1}^{j_n} >$ is defined as an aligned Many-to-Many phrase tuple if it satisfies the following conditions:

(1) $j_1 \leq j_m$, and j_1 is the beginning character of a word in w_1^n

(1) $< i_1, j_1 > \in a_1^K, < i_2, j_m > \in a_1^K$

(2) $\forall j' \notin [j_1, j_m], \forall i' \in [i_1, i_2], < i', j' > \notin a_1^K$

(3) $\forall j' \in [j_1, j_m], \forall i' \notin [i_1, i_2], < i', j' > \notin a_1^K$

Then, for any phrase tuple $< \overline{e_{i_1}^{i_2}}, c_{j_m}^{j_n} >$ that satisfies these conditions, the span $< \overline{i_1, i_2}, j_1, j_n >$ is defined as a Many-to-Many span and as a member of the set A_{Many}.

Thus, for each span $< i_1, i_2, j_1, j_n >$, the Many-to-Many score can be calculated as follows:

$$s(< i_1, i_2, j_1, j_n >) = \begin{cases} t(c_{j_1}^{j_n} | e_{i_1}^{i_2}) \\ \quad if < i_1, i_2, j_1, j_n > \in A_{Many} \\ 0 \quad else \end{cases} \quad (4)$$

where $t(c_{j_1}^{j_n} | e_{i_1}^{i_2})$ represents the translation probability of the phrase tuple $< e_{i_1}^{i_2}, c_{j_1}^{j_n} >$.

[1] http://www.phontron.com/pialign/

Finally, the score for the feature of English-Chinese Many-to-Many alignment for $w_n = c_{j_m}^{j_n}$ is derived as follows:

$$f_{Many-to-Many}(n) = \underset{i_1 \in [1,I] i_2 \in [i_1,I] j_1 \leq j_m}{\operatorname{argmax}} s(i_1, i_2, j_1, j_n) \tag{5}$$

Transliteration Feature

To account for named entities (NEs), which suffer from sparsity and thus make it difficult to calculate the probabilities discussed above, we introduce a transliteration feature to evaluate the similarities between the pronunciations of Chinese and English words because many NEs are translated via transliteration. To perform this task, we first introduce an initial NE dictionary and convert each dictionary item—for example, we convert "爱丽斯/Alice" into "ai l i s i/a l i c e" —by transforming the Chinese word into its pronunciation (represented by the function $F_{py}(\cdot)$) and splitting the English word into its constituent letters (represented by the function $F_{let}(\cdot)$). Then, we train two phrase-based translation models (Chinese-English and English-Chinese) on the data obtained from the converted NE dictionary.

Specifically, we apply two standard log-linear phrase-based SMT models. The GIZA++ aligner is adopted to obtain word alignments (Och and Ney, 2000) from the converted NE dictionary. The heuristic strategy of grow-diag-final-and (Koehn et al., 2003) is used to combine the bidirectional alignments to extract phrase translations and to reorder tables. A 5-gram language model with Kneser-Ney smoothing is trained using SRILM (Stolcke et al., 2002) on the target language. Moses (Koehn et al., 2007) is used as a decoder. Minimum error rate training (MERT) (Och et al., 2003) is applied to tune the feature parameters on the development dataset.

Given these two phrase-based translation models, we calculate each span $< i, j_m, j_n >$ in A_{One} for the Chinese word w_n using the following formula:

$$\begin{aligned} S_{tr}(< i, j_m, j_n >) = S_{ch-en}(< i, j_m, j_n >) \\ + S_{en-ch}(< i, j_m, j_n >) \end{aligned} \tag{6}$$

where $S_{ch-en}(<i, j_m, j_n>) = D_{Lev}(F_{let}e_i, PT_{ch-en}(F_{py}(c_{j_m}^{j_n})))$ means that the pronunciation conversion in the Chinese-English direction is performed as follows: First, the English word e_i is split into its constituent letters; Second, the sequence of Chinese characters $c_{j_m}^{j_n}$ is converted into its pronunciation; Third, this pronunciation is input into the Chinese-English phrase-based translation model, and the corresponding translation result is obtained; And finally, the Levenshtein distance between the English letters and the translation result is returned.

$S_{en-ch}(<i, j_m, j_n>)$ can be calculated in exactly the same way.

We set any span that does not belong to A_{One} to zero, and the transliteration feature score of a word $w_n = c_{j_m}^{j_n}$ is derived as follows:

$$f_{transliteration}(n) = \underset{i \in [1,I]}{\operatorname{argmax}} S_{tr}(< i, j_m, j_n >) \tag{7}$$

English-Chinese semantic gap feature

To guarantee that the semantic meanings of the Chinese segmentation match those of the corresponding English sentences as closely as possible, we propose to use a feature based on the English-Chinese semantic gap to ensure the retention of semantic meaning during the segmentation process.

First, we pre-train word embeddings using the open-source toolkit Word2Vec (Mikolov et al., 2013) on the Chinese (segmented using character-level features only) and English sentences separately, thereby obtaining the vocabularies V_{ch} and V_{en} and their corresponding embedding matrixes $L_{ch} \in R^{n \times |V_{ch}|}$ and $L_{en} \in R^{n \times |V_{en}|}$. Given a Chinese word w_n with an index i in the vocabulary, it is then straightforward to retrieve the word's vector representation via simple multiplication with a binary vector d that is equal to zero at all positions except that with index i:

$$X_i = L_{ch} d_i \in R^n \tag{8}$$

Because the word embeddings for the two languages (L_{ch} and L_{en}) are learned separately and located in different vector spaces, we suppose that a transformation exists between these two semantic embedding spaces. Thus, we collect all the One-to-Many phrase tuples $< e_1, c_{j_1}^{j_2} >$ that satisfy $e_1 \in V_{en}$ and $c_{j_1}^{j_2} \in V_{ch}$ from the entire corpus of bilingual data. Then, we insert the word embedding tuple of each One-to-Many phrase tuple into the set A_{embed}. Let us consider a word embedding tuple $< p_s, p_t >$ in A_{embed} as an example. We define a bidirectional semantic distance using the parameter θ as follows:

$$E_{sem}(p_s, p_t; \theta) = E_{sem}(p_s|p_t, \theta) + E_{sem}(p_t|p_s, \theta) \quad (9)$$

Here, $E_{sem}(p_s|p_t, \theta) = E_{sem}(p_t, f(W_{en}^{ch} p_s + b_{en}^{ch}))$ represents the transformation of p_s and is performed as follows: We first multiply a parameter matrix W_{en}^{ch} by p_s, and after adding a bias term b_{en}^{ch}, we apply an element-wise activation function $f = tanh(\cdot)$. Finally, we calculate their Euclidean distance:

$$E_{sem}(p_s|p_t, \theta) = \frac{1}{2}||p_t - f(W_{en}^{ch} p_s + b_{en}^{ch})||^2 \quad (10)$$

$E_{sem}(p_t|p_s, \theta)$ can be calculated in exactly the same way.

Given the definition of the semantic distance of each word-embedding tuple in A_{embed}, we wish to minimize the following objective function:

$$J = \sum_{<p_s, p_t> \in A_{embed}} E_{sem}(p_s, p_t; \theta) \quad (11)$$

We apply the Stochastic Gradient Descent (SGD) algorithm to optimize each parameter and ultimately obtain the optimized parameters θ^*.

Using θ^*, we can calculate the semantic gap for any possible span for w_n, such as $< i, j_m, j_n >$, as follows:

$$S_{gap}(< i, j_m, j_n >) = \begin{cases} \frac{1}{E_{sem}(p'_s|p'_t, \theta^*)} \\ \quad if \quad e_i \in V_{en} \quad c_{j_m}^{j_n} \in V_{ch} \\ \quad\quad\quad < i, j_m, j_n > \in A_{One} \\ 0 \quad else \end{cases} \quad (12)$$

where p'_s and p'_t are the word vector representation of e_i and $c_{j_m}^{j_n}$, respectively. Thus, the semantic gap feature score of the word $w_n = c_{j_m}^{j_n}$ is derived as follows:

$$f_{sem}(w_n) = \underset{i \in [1,I]}{\operatorname{argmax}} S_{gap}(< i, j_m, j_n >) \quad (13)$$

3.2.3 Normalization and the Inner Log-Linear Model

Because the output scores of each sub-model described above are not probabilistic and they vary by orders of magnitude, we must first normalize the output scores of each sub-model. After normalization, the scores have means and standard deviations of zero. We represent the normalization function by $Norm(\cdot)$.

Thus, for the substring c_1^j ($j \in [1, J)$) in c_1^J of the sentence tuple $<e_1^I, c_1^J, a_1^K>$, assuming that one of its candidate segmentations is $w_1^{N+1} = w_1 w_2 w_3 ... w_{N+1} = c_1^{j_1} c_{j_1+1}^{j_2} ... c_{j_N+1}^{j}$, the feature score of the inner log-linear model is derived as follows:

$$f_{inner} = \sum_{j' \in [1,j]} Norm(f_{CRF}(j')) + \lambda_1 \sum_{n \in [1, N+1]} (\sum_k Norm(f_k(n))) \quad (14)$$

where $f_k(n)$ represents the phrase-level features.

Then, we tune the weight λ_1 from 0 to 1 in equal increments of 0.1 to optimize its value.

3.3 Sentence-level Features

In this section, we describe the sentence-level features calculated using the phrase-based translation model and the outer log-linear model that is used to combine the sentence-level features with the features in the inner log-linear model.

3.3.1 Features Obtained from the Phrase-based Translation Model

Let us consider the last character c_J in c_1^J and assume that its candidate segmentation (according to the inner log-linear model only) is $w_1^{N+1} = w_1 w_2 w_3 ... w_{N+1}$. We now add a sentence-level feature to incorporate into the inner log-linear model. This sentence-level feature is obtained using a phrase-based translation model. We segment the Chinese sentences from the bilingual unlabeled data using character-level features only and train a phrase-based translation model on the bilingual data that is similar to the phrase-based translation model used for the transliteration features.

Unlike the usage of the phrase-based translation model in the case of the transliteration features, here, we input both the source and target sentences and achieve the output of translation probability. Thus, we perform a force decoding for the sentence tuple $<w_1^{N+1}, e_1^I>$ and obtain the set of decoding paths P(w_1^{N+1}), where each element acts as a decoding path that can translate w_1^{N+1} into e_1^I. Finally, we define the sentence-level feature score of $<w_1^{N+1}, e_1^I>$ as follows:

$$f_{sent}(w_1^{N+1}) = \underset{p(w_1^{N+1}) \in P(w_1^{N+1})}{\operatorname{argmax}} F_{trans}(p(w_1^{N+1})) \quad (15)$$

where $F_{trans}(\cdot)$ returns the translation score of the given decoding path based on the phrase-based translation model.

3.3.2 The Outer Log-Linear Model

Finally, we normalize the sentence-level features in a manner similar to that described previously and construct the outer log-linear model by combining the inner log-linear model and the sentence-level features as follows:

$$f_{outer} = f_{inner} + \lambda_2 Norm(f_{sent}(w_1^{N+1})) \quad (16)$$

Then, we also tune the weight λ_2 from 0 to 1 in equal increments of 0.1 to optimize its value.

3.3.3 Decoder

A traditional viterbi beam search procedure is applied in the decoder to seek the segmented sequence with the highest score. Given a sentence tuple $< e_1^I, c_1^J, a_1^K >$, the decoding procedure will proceed in a left-right fashion using a dynamic programming approach. At each position j in the sequence c_1^J, we maintain a vector of size N to store the top N candidate segmentations of subsequence c_1^j which are scored using the inner log-linear model ($j \in [1, J)$) or the outer log-linear model ($j = J$). Finally, we return the best segmentation.

4 Justifying the Original CWS Model

We justify the original CWS model (the CRF-based model trained on manually segmented data) using the new CRF model trained on the segmentation of unlabeled bilingual data. To avoid over-weakening the influence of the small-scale manually segmented data, we again utilized a log-linear model to balance their weights. The formula can be described as follows:

$$\begin{aligned} f_{new\_mono} = & \sum_{k_1} \lambda_{k_1} f_{k_1}(y_{j-1}, y_j, c_1^J, j) \\ & + \theta_3 \sum_{k_2} \lambda_{k_2} f_{k_2}(y_{j-1}, y_j, c_1^J, j) \end{aligned} \quad (17)$$

where θ_3 represents the weights of the second CRF model, which are set via minimum error rate training using the developing dataset, and λ_{k_i} (i =1, 2) represents the learned weights of the features of the CRF models.

5 The Datasets

In this paper, we conduct our experiments on the corpus of People's daily of 1998 (from January to June) as the standard (manually segmented) training corpus, the corpus of Bakeoff-2 CWS evaluation as the developing and testing dataset. As the corpus of Bakeoff-2 is made up of several sets provided by different organizations, we only select two sets whose segmenting standards are similar to the training corpus. For each set, we take 3000 sentences as the developing dataset and the others as the testing dataset. The statistics of every set and the standard training corpus are shown in Table 1.

Data Set	of sent.	of words
Training	120K	7.28M
AS	708K	5.45M
PKU	19K	1.1M

Table 1: Statistics of training and testing datasets

Moreover, the bilingual unlabeled data is formed by a large in-house Chinese-English parallel corpus (Tian et al., 2014). There are in total 2,215,000 Chinese-English sentence pairs crawled from online resources, concentrated in 5 different domains including laws, novels, spoken, news and miscellaneous.

6 Experiments

In our evaluation, the F-score was used as the accuracy measure. The precision p is defined as the percentage of words in the decoder output that are segmented correctly, and the recall r is the percentage of gold-standard output words that are correctly segmented by the decoder. The balanced F- score is calculated as 2pr/(p + r). We also report the recall of OOV words in our experiments. In the following, we refer to our methods as "SLBD" (segmenter leveraging bilingual data).

Initially, we evaluated state-of-the-art supervised CWS methods, i.e., those of (Peng et al., 2004) (Peng); (Asahara et al., 2005) (Asahara); (Zhang and Clark, 2007) ($Z\&C$); (Zhao et al., 2010) (Zhao), whose models are trained only on manually segmented data. Moreover, we also evaluated the performance of our sub-models by

methods	AS		PKU	
	F	OOV	F	OOV
Peng	91.6	52.5	91.1	59
Asahara	92.2	63.1	91.4	61.6
$Z\&C$	92.9	69.9	91.6	67.9
Zhao	93.1	72	92.3	60.6
character-level	92.3	58.6	92.9	60.8
Inner log-linear	95.9	78.8	96.1	81
Outer log-linear	96.7	80.8	97.1	85

Table 2: Word segmentation performance of SLBD and supervised CWS methods[%]

segmenting the bilingual unlabeled dataset using character-level features only, the inner log-linear model (which includes character-level and phrase-level features) and the outer log-linear model (the full SLBD approach). After applying these three segmentations using the different sub-models, we trained the new CRF models on the results of the three segmentations to justify the original CWS model. The evaluation results for the supervised CWS methods and the sub-models are presented in Table 2.

It can be seen that we achieved significant improvement in performance when we combined the character-level and phrase-level features in the inner log-linear model, demonstrating that the proposed phrase-level features can be used to efficiently obtain bilingual segmenting information. Moreover, the outer log-linear model achieves a further enhancement, thereby demonstrating that the sentence-level features can be used to effectively re-rank the candidate segmentations produced by the inner log-linear model.

Next, we compared the SLBD method with several state-of-the-art monolingual semi-supervised methods, including those of (Sun et al., 2012) (Sun); (Sun and Xu, 2011) ($S\&X$); (Zeng et al., 2013b) (Zeng). To ensure a fair comparison, we performed the evaluation in two steps. First, we input the entire bilingual unlabeled dataset into the SLBD method and input only the Chinese sentences from the bilingual unlabeled dataset into the other semi-supervised methods. Then, because the available monolingual unlabeled dataset was much larger than the bilingual unlabeled dataset in natural, we used the XIN_CMN portion of Chinese Gigaword 2.0 as an additional unlabeled dataset for the monolingual semi-supervised methods. which contains 204 million words, more than ten times

methods	Bilingual data		Monolingual data	
	F	OOV	F	OOV
Sun	93.9	63.1	94.6	67.9
$S\&X$	94.1	66	94.4	71
Zeng	94.0	64.5	94.8	63.2
SLBD	96.7	80.8	-	-

Table 3: Word segmentation performance of SLBD and other monolingual semi-supervised CWS methods[%]

methods	AS		PKU	
	F	OOV	F	OOV
Xu	92.8	70.5	92.1	66
Ma	93.1	73	92.6	71.1
Xi	90.2	63	90.9	67.2
Zeng2014	93.5	76	93.2	73.3
SLBD	96.7	80.8	97.1	85

Table 4: Word segmentation performance of SLBD and other bilingual semi-supervised CWS methods[%]

the number of words in the bilingual unlabeled dataset. The testing data was the set of AS only. The evaluation is summarized in Table 3.

The results demonstrate that either leveraging the same unlabeled data or providing a much larger unlabeled dataset for the monolingual semi-supervised methods, the SLBD method can significantly outperform the evaluated monolingual semi-supervised methods, which indicates that the segmenting information obtained using SLBD is much more efficient at optimizing segmentation.

Finally, we evaluated SLBD in comparison with other bilingual semi-supervised methods, including (Xu et al., 2008) (Xu); (Ma and Way, 2009) (Ma); (Xi et al., 2012) (Xi);(Zeng et al., 2014) (Zeng2014). The results presented in Table 4 indicate that SLBD demonstrates much stronger performance, primarily because these other methods were developed with a focus on SMT, which causes them to preferentially decrease the perplexity of the subsequent SMT steps rather than producing a highly accurate segmentation. In contrast to these methods, the SLBD method exhibits greater generalizability.

7 Conclusion

In this paper, we propose a cascaded log-linear model to involve learning three levels of bilingual linguistic features to semi-supervisedly learn a new CWS model. Different from other monolingual and bilingual semi-supervised approaches, we employ various types of features to capture both monolingual grammars and bilingual segmenting information, which allows our model to be very efficient at other NLP tasks and endows it with higher generalizability. The evaluation shows that our method significantly outperforms the state-of-the-art monolingual and bilingual semi-supervised approaches.

Abstract

In hierarchical phrase-based machine translation, a rule table is automatically learned by heuristically extracting synchronous rules from a parallel corpus. As a result, spuriously many rules are extracted which may be composed of various incorrect rules. The larger rule table incurs more run time for decoding and may result in lower translation quality. To resolve the problems, we propose a hierarchical back-off model for Hiero grammar, an instance of a synchronous context free grammar (SCFG), on the basis of the hierarchical Pitman-Yor process. The model can extract a compact rule and phrase table without resorting to any heuristics by hierarchically backing off to smaller phrases under SCFG. Inference is efficiently carried out using two-step synchronous parsing of Xiao et al., (2012) combined with slice sampling. In our experiments, the proposed model achieved higher or at least comparable translation quality against a previous Bayesian model on various language pairs; German/French/Spanish/Japanese-English. When compared against heuristic models, our model achieved comparable translation quality on a full size German-English language pair in Europarl v7 corpus with significantly smaller grammar size; less than 10% of that for heuristic model.

1 Introduction

Hierarchical phrase-based statistical machine translation (HPBSMT) (Chiang, 2007) is a popular alternative to phrase-based SMT (PBSMT), in which synchronous context free grammar (SCFG) is used as the basis of the machine translation model. With HPBSMT, a restricted form of an SCFG, i.e., Hiero grammar, is usually used and is especially suited for linguistically divergent language pairs, such as Japanese and English. However, a rule table, i.e., a synchronous grammar, may be composed of spuriously many rules with potential errors especially when it was automatically acquired from a parallel corpus. As a result, the increase in the rule table incurs a large amount of time for decoding and may result in lower translation quality.

Pruning a rule table either on the basis of significance test (Johnson et al., 2007) or entropy (Ling et al., 2012; Zens et al., 2012) used in PBSMT can be easily applied for HPBSMT. However, these methods still rely on a heuristically determined threshold parameter. Bayesian SCFG methods (Blunsom et al., 2009) solve the spurious rule extraction problem by directly inducing a compact rule table from a parallel corpus on the basis of a non-parametric Bayesian model without any heuristics. Training for Bayesian SCFG models infers a derivation tree for each training instance, which demands the time complexity of $O(|\mathbf{f}|^3|\mathbf{e}|^3)$ when we use dynamic programming SCFG biparsing (Wu, 1997). Gibbs sampling without biparsing (Levenberg et al., 2012) can avoid this problem, though the induced derivation trees may strongly depend on initial derivation trees. Even though we may learn a statistically sound model on the basis of non-parametric Bayesian methods, current approaches for an SCFG still rely on exhaustive heuristic rule extraction from the word-alignment decided by derivation trees since the learned models cannot handle rules and phrases of various granularities.

We propose a model on the basis of the previous work on the non-parametric Inversion Transduction Grammar (ITG) model (Neubig et al., 2011) wherein phrases of various granularities are

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1217–1227,
Lisbon, Portugal, 17-21 September 2015.

learned in a hierarchical back-off process. We extend it by incorporating arbitrary Hiero rules when backing off to smaller spans. For efficient inference, we use a fast two-step bi-parsing approach (Xiao et al., 2012) which basically runs in a time complexity of $O(|\mathbf{f}|^3)$. Slice sampling for an SCFG (Blunsom and Cohn, 2010) is used for efficiently sampling a derivation tree from a reduced space of possible derivations.

Our model achieved higher or at least comparable BLEU scores against the previous Bayesian SCFG model on language pairs; German/French/Spanish-English in the News-Commentary corpus, and Japanese-English in the NTCIR10 corpus. When compared against heuristically extracted model through the GIZA++ pipeline, our model achieved comparable score on a full size Germany-English language pair in Europarl v7 corpus with significantly less grammar size.

2 Related Work

Various criteria have been proposed to prune a phrase table without decreasing translation quality, e.g., Fisher's exact test (Johnson et al., 2007) or relative entropy (Ling et al., 2012; Zens et al., 2012). Although those methods are easily applied for pruning a rule table, they heavily rely on the heuristically determined threshold parameter to trade off the translation quality and decoding speed of an MT system.

Previously, EM-algorithm based generative models were exploited for generating compact phrase and rule tables. Joint phrase alignment model (Marcu and Wong, 2002) can directly express many-to-many word aligments without heuristic phrase extraction. DeNero et al. (2006) proposed IBM Model 3 based many-to-many alignment model. Rule arithmetic method (Cmejrek and Zhou, 2010) can generate SCFG rules by combining other rule pairs through an inside-outside algorithm. However, those previous attempts were restricted in that the rules and phrases were induced by heuristic combination.

Bayesian SCFG models can induce a compact model by incorporating sophisticated non-parametric Bayesian models for an SCFG, such as a dirichlet process (DeNero et al., 2008; Blunsom et al., 2009; Chung et al., 2014) or Pitman-Yor process (Levenberg et al., 2012; Peng and Gildea, 2014). A model is learned by sampling derivation trees in a parallel corpus and by accumulating the rules in the sampled trees into the model. Due to the $O(|\mathbf{f}|^3|\mathbf{e}|^3)$ time complexity for bi-parsing a bilingual sentence, previous studies relied on bi-parsing at the initialization step, and conducted Gibbs sampling by local operators (Blunsom et al., 2009; Levenberg et al., 2012) or sampling on fixed word alignments (Chung et al., 2014; Peng and Gildea, 2014). As a result, the inference can easily result in local optimum, wherein induced derivation trees may strongly depend on the initial trees.

Xiao et al. (2012) proposed a two-step approach for bi-parsing a bilingual sentence in $O(|\mathbf{f}|^3)$ in the context of inducing SCFG rules discriminatively; however, their approach violates the detailed balance due to its heuristic k-best pruning. Blunsom and Cohn (2010) proposed a slice sampling for an SCFG, in the same manner as that for Infinite Hiden Markov Model (iHMM) (Van Gael et al., 2008), which can efficiently prune a space of possible derivations on the basis of dynamic programming. Although slice sampling can prune spans without violating the detailed balance, its time complexity of $O(|\mathbf{f}|^3|\mathbf{e}|^3)$ is still impractical for a large-scale experiment. We efficiently carried out large-scale experiments on the basis of the two-step bi-parsing of Xiao et al. combined with slice sampling of Blunsom and Cohn.

After learning a Bayesian model, it is not directly used in a decoder since it is composed of only minimum rules without considering phrases of various granularities. As a consequence, it is a standard practice to obtain word alignment from derivation trees and to extract SCFG rules heuristically from the word-aligned data (Cohn and Haffari, 2013). The work by Neubig et al. (2011) was the first attempt to directly use the learned model on the basis of a Bayesian ITG in which phrases of many granularities were encoded in the model by employing a hierarchical back-off procedure. Our work is strongly motivated by their work, but greatly differs in that our model can incorporate many arbitrary Hiero rules, not limited to ITG-style binary branching rules.

3 Model

We use Hiero grammar (Chiang, 2007), an instance of an SCFG, which is defined as a context-free grammar for two languages. Let Σ denote a set of terminal symbols in the source language, Δ a set of terminal symbols in the target language,

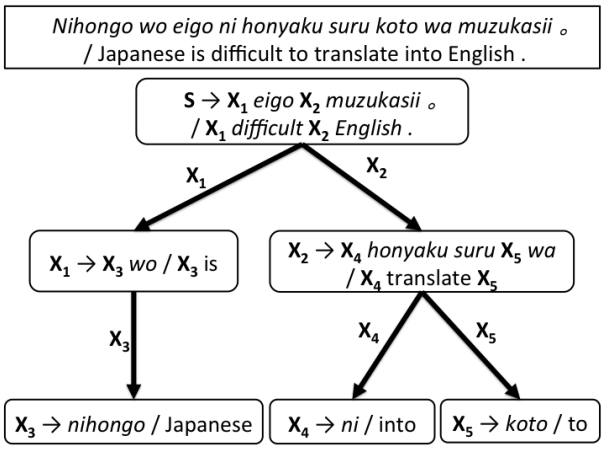

Figure 1: Derivation tree generated from Bayesian SCFG model

V a set of non-terminal symbols, S a start symbol and R a set of rewrite rules. An SCFG is denoted as a tuple of $\langle \Sigma, \Delta, V, S, R \rangle$. Each rewrite rule in R is represented as $X \rightarrow \langle \alpha / \beta \rangle$ in which α is a string of non-terminals and source side terminals $(V \cup \Sigma)^*$ and β is a string of non-terminals and target side terminals $(V \cup \Delta)^*$. An example derivation in an SCFG for the sentence pair "*nihongo wo eigo ni honyaku suru koto wa muzukasii* 。 / Japanese is difficult to translate into English ." is represented as follows:
$S \rightarrow X_1$ *eigo* X_2 *muzukasii* 。 / X_1 difficult X_2 English .
$X_1 \rightarrow X_3$ *wo* / X_3 is
$X_2 \rightarrow X_4$ *honyaku suru* X_5 *wa* / X_4 translate X_5
$X_3 \rightarrow$ *nihongo* / Japanese
$X_4 \rightarrow$ *ni* / into
$X_5 \rightarrow$ *koto* / to .

A Hiero grammar has additional constraints over a general SCFG; the number of terminal symbols in each rule for both source and target sides is limited to 5. Each rule may contain at most two non-terminal symbols; adjacent non-terminal symbols in the source side are prohibited. For details, refer to (Chiang, 2007).

3.1 Bayesian SCFG Models

Previous Bayesian SCFG Models, for instance a model proposed by Levenberg et al. (2012), are based on the Pitman-Yor process (Pitman and Yor, 1997) and learn SCFG rules by sampling a derivation tree for each bilingual sentence. Figure 1 shows an example derivation tree for our running example sentence pair under the model. The generative process is represented as follows:

$$\begin{aligned} G_X &\sim P_{rule}(d_r, \theta_r, G_{r_0}), \\ X \rightarrow \langle \alpha / \beta \rangle &\sim G_X, \end{aligned} \tag{1}$$

where G_X is a derivation tree and $P_{rule}(d_r, \theta_r, G_{r_0})$ is a Pitman-Yor process (Pitman and Yor, 1997), which is a generalization of a Dirichlet process parametrized by a discount parameter d_r, a strength parameter θ_r and a base measure G_{r_0}. The output probability of a Pitman-Yor process obeys the power-law distribution with the discount parameter, which is very common in standard NLP tasks.

The probability that a rule r_k is drawn from a model $P_{rule}(d_r, \theta_r, G_{r_0})$ is determined by a Chinese restaurant process which is decomposed into two probability distributions. If r_k already exists in a table, we draw r_k with probability

$$\frac{c_k - d_r \cdot |\varphi_{r_k}|}{\theta_r + n_r}, \tag{2}$$

where c_k is the number of customers of r_k, n_r is the number of all customers and φ_{r_k} is a number of r_k's tables. On the other hand, if r_k is a new rule, we draw r_k with probability

$$\frac{\theta_r + d_r \cdot |\varphi_r|}{\theta_r + n_r} \cdot G_{r_0}, \tag{3}$$

where $|\varphi_r|$ is the number of tables in the model.

3.2 Hierarchical Back-off Model

In the previous models, the generative process is represented as a rewrite process starting from the symbol S, which can incorporate only minimal rules. Following Neubig et al. (2011), our model reverses the process by recursively backing off to smaller phrase pairs as shown in Figure 2. First, our model attempts to generate a phrase pair, i.e., a sentence pair, as a derivation tree. If the model successfully generates the phrase pair, we will finish the generation process. Otherwise, a Hiero rule is generated to fallback to smaller spans represented in each non-terminal symbol X in the rule. Then, each phrase pair corresponding to each smaller span is recursively generated through our model. In Figure 2, a phrase pair with "nil" indicates those not in our model; therefore the phrase pair is forced to back-off either by generating a new phrase pair from a base measure (base) or by falling back to smaller phrases using a Hiero rule (back-off). The recursive procedure is done until

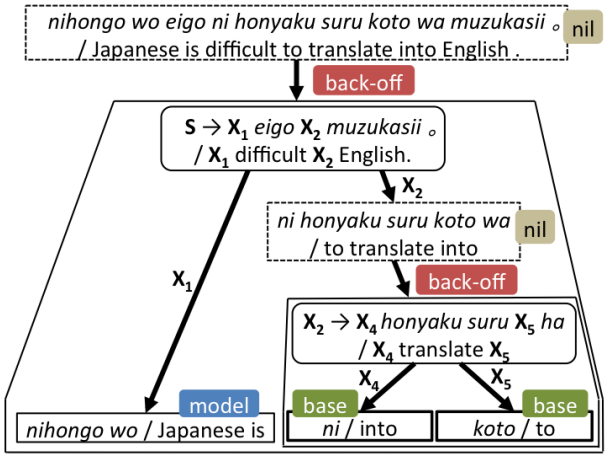

Figure 2: Derivation tree generated from the hierarchical back-off model

we reach phrase pairs which are generated without any back-offs. Let a discount parameter be d_p, a strength parameter be θ_p, and a base measure be G_{p_0}. More formally, the generative process is represented as follows:

$$\begin{aligned} G_X &\sim P_{rule}(d_r, \theta_r, G_{phrase}), \\ G_{phrase} &\sim P_{phrase}(d_p, \theta_p, G_X), \\ X \rightarrow \langle \mathbf{s}/\mathbf{t} \rangle &\sim G_{phrase}, \\ X \rightarrow \langle \alpha/\beta \rangle &\sim G_X, \end{aligned} \quad (4)$$

where $\mathbf{s}$ is source side terminals and $\mathbf{t}$ is target side terminals in phrase pair $\langle \mathbf{s}/\mathbf{t} \rangle$. P_{phrase} is composed of three states, i.e., model, back-off, and base, and follows a hierarchical Pitman-Yor process (Teh, 2006).

model: We draw a phrase pair $\langle \mathbf{s}/\mathbf{t} \rangle$ with the probability similar to Equation (2):

$$\frac{c_k - d_p \cdot |\varphi_{p_k}|}{\theta_p + n_p}, \quad (5)$$

where c_k is the numbers of customers of a phrase pair p_k and n_p is the number of all customers Note that this state is reachable when the phrase pair $\langle \mathbf{s}/\mathbf{t} \rangle$ exists in the model in the same manner as Equation (2).

back-off: We will back off to smaller phrases using a rule generated by P_{rule} as follows:

$$\begin{aligned} &\frac{\theta_p + d_p \cdot |\varphi_p|}{\theta_p + n_p} \cdot \frac{c_{back} + \gamma_b \cdot G_b}{c_{back} + c_{base} + \gamma_b} \\ &\cdot P_{rule}(d_r, \theta_r, G_{phrase}) \\ &\cdot \prod_{X \in \langle \alpha/\beta \rangle} P_{phrase}(d_p, \theta_p, G_X), \end{aligned} \quad (6)$$

where c_{back} and c_{base} are the number of customers sampled from the back-off and base phrases, respectively, with a base measure G_b and hyper-parameter γ_b. We use a uniform distribution for $G_b = 0.5$ since we consider only two states, back-off and base. Unlike the model state, P_{phrase} may reach this state even when a phrase pair is not in the model. The phrase pair is backed-off to smaller phrase pairs using P_{phrase} through the non-terminals in the generated rule $X \in \langle \alpha/\beta \rangle$.

base: As an alternative to the back-off state, we may reach the base state which follows the probability distribution on the basis of the base measure G_{p_0},

$$\frac{\theta_p + d_p \cdot |\varphi_p|}{\theta_p + n_p} \cdot \frac{c_{base} + \gamma_b \cdot G_b}{c_{back} + c_{base} + \gamma_b} \cdot G_{p_0}. \quad (7)$$

In summary, $P_{phrase}(d_p, \theta_p, G_X)$ is defined as a joint probability of Equations (5) through (7).

3.3 Base Measure

Similar to Levenberg et al. (2012), the base measure for rule probability G_{r_0} is composed of four generative processes. First, a number of symbols in a source side of a rule $|\alpha|$ is generated from a Poisson distribution, i.e., $|\alpha| \sim Poisson(0.1)$. Let $t(x)$ denote a function that returns terminals from a string x. The number of target side terminal symbols $|t(\beta)|$ is also generated from a Poisson distribution and represented as $|t(\beta)| \sim Poisson(\alpha + \lambda_0)$[1]. The type of symbol α_i in the source side, $type_i$, either terminal or non-terminal symbol, is determined by $type_i \sim Bernoulli(\phi^{|\alpha|})$ where ϕ is a hyper-parameter taking $0 < \phi < 1$. $\phi^{|\alpha|}$ is based on an intuition that shorter rules should be relatively more likely to contain terminal symbols than longer rules. Source and target terminal symbol pair $\langle t(\alpha), t(\beta) \rangle$ are generated from the geometric means of two directional IBM Model 1 word alignment probabilities and monolingual unigram probabilities for two languages, and represented as:

$$\begin{aligned} \langle t(\alpha), t(\beta) \rangle \sim (&P_{uni}(t(\alpha)) P_{\overrightarrow{M1}}(t(\alpha), t(\beta)) \cdot \\ &P_{uni}(t(\beta)) P_{\overleftarrow{M1}}(t(\alpha), t(\beta)))^{\frac{1}{2}}. \end{aligned} \quad (8)$$

When the $t(\alpha)$ or $t(\beta)$ is empty, we use the constant 0.01 instead of the Model1 probabilities.

[1]Note that λ_0 is a small constant for the input distribution greater than zero.

The base measure for phrases G_{p_0} is composed of three generative processes, in a similar manner as Levenberg et al. (2012), the number of terminal symbols in a phrase pair in the source side, $|\mathbf{s}|$, is generated from a Poisson distribution $|\mathbf{s}| \sim Poisson(0.1)$. The length for the target side $|\mathbf{t}|$ is generated in the same manner as the source side of the phrase pair. The alignments between $\mathbf{s}$ and $\mathbf{t}$ are also generated in the same manner as those for the base measure in a rule.

4 Inference

In inference, we use a sentence-wise block sampling of Blunsom and Cohn (2010), which has a better convergence property when compared with a step-wise Gibbs sampling. We repeat the following steps given a sentence pair.

1. Decrement customers of the rules and phrase pairs used in the current derivation for the sentence pair.
2. Bi-parse the sentence pair in a bottom up manner.
3. Sample a new derivation tree in a top-down manner.
4. Increment customers of the rules and phrase pairs in the sampled derivation tree.

The most time-consuming step during the inference procedure is bi-parsing of a sentence pair which essentially takes $O(|\mathbf{f}|^3|\mathbf{e}|^3)$ time using a bottom up dynamic programming algorithm (Wu, 1997). When a span is very large, it can easily suffer combinatorial explosion. To avoid this problem, we use a two-step slice sampling by performing the two-step bi-parsing of Xiao et al. (2012) and by pruning possible derivation space (Blunsom and Cohn, 2010) in each step (Algorithm 1). From lines 1 to 7, a set of word alignment is enumerated and put into $cube_a$. In addition to the arbitrary word alignment of $source_i$ to $target_j$, null word alignment is also merged into $cube_a$ (line 5). Note that word alignment considered in the algorithm is restricted to one-to-many. The set of word alignments in $cube_a$ is pruned and added to the $chart_a$ by SliceSampling. From lines 8 to 15, all possible phrases and rules for each span constrained by the pruned word alignment are enumerated and temporally stored into $cube$. The phrases and rules in $cube$ are pruned by SliceSampling and the remainders are added to $chart$. The

Algorithm 1 Two-step slice sampling

```
1:  for i ← 1, ··· , |source| do
2:    for j ← 1, ··· , |target| do
3:      cube_a ← {souce_i, target_j}
4:    end for
5:    cube_a ← {souce_i, null}
6:    chart_a ← SliceSampling(cube_a)
7:    clear cube_a
8:  end for
9:  for h ← 1, ··· , |source| do
10:   for all the i, j s.t j − i = h do
11:     for inferable rule, phrase from the sub-
        spans of [i, j] of all charts do
12:       cube ← rule, phrase
13:     end for
14:     chart ← SliceSampling(cube)
15:     clear cube
16:   end for
17: end for
```

time complexity for the word alignment enumeration from lines 1 to 7 is $O(|f||e|)$ and that for the phrase and rule enumeration from lines 8 to 15 is $O(|f|^3)$.

The key difference to the slice sampling of Blunsom and Cohn (2010) lies in lines 6 and 3 of Algorithm 1. Let $\mathbf{d}$ denote a set of derivation trees d and $\mathbf{u}$ be a set of slice variables u. In slice sampling, we prune the rules $\mathbf{r_{sp}}$ in each source span sp based on a slice variable u_{sp} corresponding to that sp. After pruning, we sample trees from the pruned space of $\mathbf{r}$. The above process is formally represented as:

$$\begin{aligned} \mathbf{u} &\sim P(\mathbf{u}|\mathbf{d}), \\ \mathbf{d} &\sim P(\mathbf{d}|\mathbf{u}), \end{aligned} \tag{9}$$

where $P(\mathbf{d}|\mathbf{u})$ is computed through sampling in a top-down manner after parsing in a bottom-up manner with Algorithm 1, and is equal to $\prod_d P(d|\mathbf{u})$. The probability $P(\mathbf{u}|\mathbf{d})$ is equal to $\prod_{sp} P(u_{sp}|\mathbf{d})$. Let r^*_{sp} denote a currently adopted rule in the span sp and $P(u_{sp}|d)$ be defined using a pruning score $Score(r^*_{sp})$ as follows:

$$Score(r_{sp_i}) = Inside(r_{sp_i}) \cdot Future(r_{sp_i}), \tag{10}$$

where $Inside(r_{sp})$ and $Future(r_{sp})$ are inside and outside probabilities for sp, respectively. Let $\mathbf{s}_{r_{sp}}$ denote a set of source side words in r_{sp}, $\mathbf{t}_{r_{sp}}$ a set of target side words in r_{sp}, $\overline{\mathbf{s}_{sp}}$ a set of words in a source sentence without $\mathbf{s}_{r_{sp}}$ and $\overline{\mathbf{t}_{sp}}$, a set of

words in a target sentence without $\mathbf{t}_{r_{sp}}$. By using IBM Model 1 probabilities in two directions, $Inside(r_{sp})$ is calculated by

$$(P_{\overrightarrow{M1}}(\mathbf{s}_{sp}, \mathbf{t}_{sp}) \cdot P_{\overleftarrow{M1}}(\mathbf{s}_{sp}, \mathbf{t}_{sp}))^{\frac{1}{2}}. \quad (11)$$

We use IBM Model1 outside probability for future score $Future(r_{sp})$. Similarly, the future score $Future(r_{sp})$ is computed using the two directional models:

$$(P_{\overrightarrow{M1}}(\overline{\mathbf{s}_{sp}}, \overline{\mathbf{t}_{sp}}) \cdot P_{\overleftarrow{M1}}(\overline{\mathbf{s}_{sp}}.\overline{\mathbf{t}_{sp}}))^{\frac{1}{2}}. \quad (12)$$

When sp is used in the current derivation $\mathbf{d}$, slice variable u_{sp} is sampled from a uniform distribution[2]:

$$P(u_{sp}|d) = \frac{\mathbb{I}(u_{sp} < Score(r^*_{sp}))}{Score(r^*_{sp})}, \quad (13)$$

otherwise, u_{sp} is sampled from a beta distribution if sp is not in the current derivation $\mathbf{d}$:

$$P(u_{sp}|d) = Beta(u_{sp}; a, 1.0), \quad (14)$$

where $a < 1$ is a parameter for the beta distribution. If the $Score(r_{sp_i})$ is less than u_{sp}, we prune the r_{sp_i} from $cube$. Similar to Blunsom and Cohn (2010), if the span sp is not in the current derivation, the rules with low probability are pruned according to Equation (14). Let r^d_{sp} denotes a rule in d with span sp, $P(d|\mathbf{u})$ is calculated by:

$$\prod_{sp \in d} \frac{P(r^d_{sp})}{\sum_{r_j \in \mathbf{r_{sp}}} P(r_j)\mathbb{I}(u_{sp} < Score(r_j))}. \quad (15)$$

In our experiments discussed in Section 6, slice sampling parameter a was set to 0.02 when incorporating the future score of Equation (12). In contrast, we used $a = 0.1$ when performing slice sampling without the future score. We empirically found that setting a lower value for a led to slower progress in learning due to a combinatorial explosion when inferencing a derivation for each sentence pair.

In the beginning of training, we do not have any derivation trees for given training data, although the derivation trees are required for estimating parameters for Bayesian models. We use the two-step parsing for generating initial derivation trees from only base measures. The k-best pruning is conducted against the score denoted by the equation 10 , which is very similar to Xiao et al. (2012).[3]

For faster bi-parsing, we run sampling in parallel in the same way as Zhao and Huang (2013), in which bi-parsing is performed in parallel among the bilingual sentences in a mini-batch. The updates to the model are synchronized by incrementing and decrementing customers for the bilingual sentences in the mini-batch. Note that the bi-parsing for each mini-batch is conducted on the fixed model parameters after the synchronised parameter updates.

In addition to the model parameters, hyperparameters are re-sampled after each training iteration following the discount and strength hyperparameter resampling in a hierarchical Pitman-Yor process (Teh, 2006). In particular, we resample $\langle d_p, \theta_p \rangle$, the pair of discount and strength parameters for phrases from a distribution:

$$\frac{[\theta_p]^{|\varphi_p|}_{d_p}}{[\theta_p]^{n_p}_1} \prod_{\langle \mathbf{s},\mathbf{t} \rangle} \prod_{k=1}^{|\varphi_p|} [1 - d_p]^{(c_{\langle \mathbf{s},\mathbf{t} \rangle} - 1)}_1 \quad (16)$$

where $[\,]$ denotes a generalized Pochhammer symbol, and $c_{\langle \mathbf{s},\mathbf{t} \rangle}$ the number of customers of phrase pair $\langle \mathbf{s}, \mathbf{t} \rangle$. We resample the pair $\langle d_r, \theta_r \rangle$ in the same way as $\langle d_p, \theta_p \rangle$. The hyperparameter γ_b is resampled from distribution:

$$\frac{(c_{back} + \gamma_b \cdot G_b)(c_{base} + \gamma_b \cdot G_b)}{(c_{back} + c_{base} + \gamma_b)^2}, \quad (17)$$

where ϕ, used in the generative process for either terminal or non-terminal symbol $type_i \sim Bernoulli(\phi^\alpha)$, is resampled from a distribution:

$$\prod_{\langle \alpha/\beta \rangle \in Base} Bernoulli(\phi^{|\alpha|})^{c_{\langle \alpha/\beta \rangle}}, \quad (18)$$

where $c_{\langle \alpha/\beta \rangle}$ denotes the number of customers of rule $\langle \alpha/\beta \rangle$, and $Base$ denotes a set of rules generated from the base measure. All the hyperparameters are inferred by slice sampling (Neal, 2003).

5 Extraction of Translation Model

In the previous work on Bayesian approaches (Blunsom and Cohn, 2010; Levenberg et al., 2012), it is a standard practice to heuristically extract rules and phrase pairs from the word alignment derived from the derivation trees sampled

[2] $\mathbb{I}(\cdot)$ is a function returns 1 if the condition is satisfied and 0 otherwise

[3] Note that we use $k = 30$ for k-best pruning.

from the Bayesian models. Instead of the heuristic method, we directly extract rules and phrase pairs from the learned models which are represented as Chinese restaurant tables. To limit grammar size, we include only phrase pairs that are selected at least once in the sample. During this extraction process, we limit the source or target terminal symbol size of phrase pairs to 5.

For each extracted rule or phase pair, we compute a set of feature scores used for a HPBSMT decoder; a weighted combination of multiple features is necessary in SMT since the model learned from training data may not fit well to translate an unseen test data (Och, 2003). We use the following six features; the joint model probability P_{model} is calculated by Equation (2) for rules and by Equation (5) for phrase pairs. The joint posterior probability $P_{posterior}(f, e)$ is estimated from the posterior probabilities for every rule and phrase pair in derivation trees through relative count estimation, motivated by Neubig et al. (2011) [4]. The joint posterior probability is considered as an approximation for those back-off scores. The conditional model probabilities in two directions, $P_{model}(f|e)$ and $P_{model}(e|f)$, are estimated by marginalizing the joint probability $P_{model}(f, e)$:

$$P_{model}(f|e) = \frac{P_{model}(f, e)}{\sum_{f'} P_{model}(f', e)}. \quad (19)$$

The inverse direction $P_{model}(e|f)$ is estimated, similarly. The lexical probabilities in two directions, $P_{lex}(f|e)$ and $P_{lex}(e|f)$, are scored by IBM Model probabilities between the source and target terminal symbols in rules and phrase pairs. In addition to the above features, we use Word penalty for each rule and phrase pair used in the cdec decoder (Dyer et al., 2010).

As indicated in previous studies (Koehn et al., 2003; DeNero et al., 2006), the translation quality of generative models is lower than that of models with heuristically extracted rules and phrase pairs. DeNero et al. (2006) reported that considering multiple phrase boundaries is important for improving translation quality. The generative models, in particular Bayesian models, are strict in determining phrase boundaries since their models are usually estimated from sampled derivations. As a result, translation quality is poorer when compared with a model estimated using a heuristic method. The Hiero grammar severely suffers from the phrase granularity problem and can overfit to the training data due to the flexibility of the rules.

To alleviate this problem, Neubig et al. (2011) combined the derivation trees across training iterations by averaging the features for each rule and phrase pair. During the sampling process, each training iteration draws a different derivation tree for each sentence pair, and the combination of those different derivation trees can provide multiple possible phrase boundaries to the model. Inspired by the averaging over the models from different iterations, we combine them as a part of a sampling process; we treat the derivation trees acquired from different iterations as additional training data, and increment the corresponding customers into our model. Hyperparameters are resampled after the merging process. The new features are directly computed from the merged model.

6 Experiments

6.1 Comparison with Previous Bayesian Model

First, we compared the previous Bayesian model (Gen) with our hierarchical back-off model (Back). We used the first 100K sentence pairs of the WMT10 News-Commentary corpus for German/Spanish/French-to-English pairs (Callison-Burch et al., 2010) and NTCIR10 corpus for Japanese-English (Goto et al., 2013) for the translation model. All sentences are lowercased and filtered to preserve at most 40 words on both source and target sides. We sampled 20 iterations for Gen and Back and combined the last 10 iterations for extracting the translation model.[5] The batch size was set to 64. The language models were estimated from the all-English side of the WMT News-Commentary and europarl-v7. In NTCIR10, we simply used the all-English side of the training data. All the 5-gram language models were estimated using SRILM (Stolcke and others, 2002) with interpolated Kneser-Ney smoothing. The details of the corpus are presented in Table 2. For detailed analysis, we also evaluate Hiero grammars extracted from GIZA++ (Och and Ney, 2003) grow-diag-final bidirectional alignments using Moses (Koehn et al., 2007) with Hiero options.

[4] Note that the correct way to decode from our model is to score every phrase pair created during decoding with back-off states, which is computationally intractable

[5] Gen and Back took 1 day, Back+future took 1.5 days for inference.

Table 3: The number of words in training data

We use GIZA++ and Moses default parameters for training. Decoding was carried out using the cdec decoder (**?**). Feature weights were tuned on the development data by running MIRA (Chiang, 2012) for 20 iterations with 16 parallel. For other parameters, we used cdec's default values. The numbers reported here are the average of three tuning runs (Hopkins and May, 2011).

Table 1 lists the results measured using BLEU (Papineni et al., 2002).The term Sample denotes the combination size for each model. The term SIZE in the table denotes the number of the extracted grammar types composed of Hiero rules and phrase pairs. The numbers in italic denotes the score of Back, significantly improved from the score of 1 sampled combinated Gen. The numbers in bold denotes the score of Back + future, significantly improved from the score of 1 sampled combinated Back. All significance test are performed using Clark et al. (2011) under p-value of 0.05. Back performed better than Gen on Spanish-English and French-English language pairs. Note that the gains were achieved with the comparable grammar size. When comparing German-English and Japanese-English language pairs, there are no significant differences between Back and Gen. The combination of our Back with future score during slice sampling (+future) achieved further gains over the slice sampling without future scores, and slightly decrese the grammar size, compared to Back. However, there are still no significant difference between Back+future and Gen on German-English and Japanese-English language pairs. Sample combination has no or slight gain on BLEU score, in spite of the increase in grammar size. From the results, using last one sample as a grammar is sufficient for translation quality. The performance of the Bayesian model did not match with that for the GIZA++ pipeline heuristic approach. In general, complex model, such as Gen and Back, demands larger corpus size for training, and the evaluation on such smaller corpus may not be a fair comparison, since the sampling approach can rely on only sampled derivations. Thus, we evaluate these methods on large size corpus in the next section.

6.2 Comparison with Heuristic Extraction

As reported in (Koehn et al., 2003; DeNero et al., 2006), the comparison against heuristic extraction is a challenging task. We compare the Back+future and a baseline extracted from grow-diag-final alignments of GIZA++ using Moses with Hiero options. We use GIZA++ and Moses default parameters for training. In addition, we present heuristic extraction from the last 1 sample of Back+future in +Exhaustive.

We used the full europarl-v7 German-English corpus as presented in Table 3. The experimental set up was similar to that in Section 6.1 with the following exceptions; Slice sampling parameter a was set to 0.05. Mini-batch size was set to 1024 and sampling was performed 5 iterations.[6] The translation model was extracted by last 1 iterations.

Table 4 lists the results[7]. Our Back+future can

[6]Inference took 5 days.

decrease the grammar size against GIZA++ with comparable BLEU score. Surprisingly, exhaustive extraction had no gains, probably because of the word alignment in each Hiero rules relied on the IBM Model 1.

7 Analysis

Intuitively, the use of the hierarchical back-off increases the Hiero grammar size, since the phrases of all the granularities in the derivation trees are incorporated in the grammar. In contrast, our hierarchical back-off model achieved gains in translation quality without increasing the size of the extracted grammar when compared to the previous generative model. The major differences were the use of the minimal phrase pairs used in the previous work in which only minimal phrase pairs in the leaves of derivation trees were included in the model. As a result, larger phrase pairs were forced to be constructed from those minimal rules. On the other hand, our back-off model could directly express phrase pairs of multiple granularities. In particular, a complex noun may be composed of several Hiero rules in the previous model, but it can be directly expressed by a single phrase pair in our model. Table 5 gives an example of a Japanese-English phrase pair which is represented by two Hiero rules in the previous model; it is directly expressed by a single phrase pair in our model.

The BLEU score of Back+future was higher than the generative baseline with comparable grammar size. We observed that a very different word alignment was sampled in every training iteration; the tendency was very frequent for function words. Our future score for inferring the slice variables may take into account the context in a sentence better than those without the future score. As a result, Back+future infers better models by avoiding over pruning spans.

The BLEU score of our back-off model did not achieve gains over the heuristic baselines. The detail analysis of the learned Hiero grammar's CRP tables reveals that the grammar is very sparse and may have little generalization capacity. The expansion of back-off process and the use of word classes will solve the sparsity and increase the translation quality.

class informations. Model 3 and our Back-off model dose not use any word class informations.

8 Conclusion

We proposed a hierarchical back-off model for Hiero grammar. Our back-off model achieved higher or equal translation quality against a previous Bayesian model under BLEU score on various language pairs;German/French/Spanish/Japanese-English. In addition to the hierarchical back-off model, we also proposed a two-step slice sampling approach. We showed that the two-step slice sampling approach can avoid over-pruning by incorporating a future score for estimating slice variables, which led to increase in translation quality through the experiments. The joint use of hierarchical back-off model and two step slice sampling approach achieved comparable translation quality on a full size Germany-English language pair in Europarl v7 corpus with with significantly smaller grammar size; 10% less than that for he heuristic baseline.

For future work, we plan to embed a back-off feature to decoder which is computed for all the phrase pairs constructed in a derivation during the decoding process. We will reflect the change of a probability as a statefull feature for decoding step.

Abstract

As conventional word alignment search algorithms usually ignore the consistency constraint in translation rule extraction, improving alignment accuracy does not necessarily increase translation quality. We propose to use *coverage*, which reflects how well extracted phrases can recover the training data, to enable word alignment to model consistency and correlate better with machine translation. This can be done by introducing an objective that maximizes both alignment model score and coverage. We introduce an efficient algorithm to calculate coverage on the fly during search. Experiments show that our consistency-aware search algorithm significantly outperforms both generative and discriminative alignment approaches across various languages and translation models.

1 Introduction

Word alignment, which aims to identify the correspondence between words in two languages, plays an important role in statistical machine translation (Brown et al., 1993). Word alignment and translation rule extraction often constitute two consecutive steps in the training pipeline. Word-aligned bilingual corpora serve as a fundamental resource for translation rule extraction, not only for phrase-based models (Koehn et al., 2003; Och and Ney, 2004), but also for syntax-based models (Chiang, 2005; Galley et al., 2006). Dividing alignment and extraction into two separate steps significantly improves the efficiency and scalability of parameter estimation as compared with directly learning translation models from bilingual corpora (Marcu and Wong, 2002; DeNero and Klein, 2008; Cohn and Blunsom, 2009).

However, separating word alignment from translation rule extraction suffers from a major problem: maximizing the accuracy of word alignment does not necessarily lead to the improvement of translation quality. A number of studies show that alignment error rate (AER) only has a loose correlation with BLEU (Callison-Burch et al., 2004; Goutte et al., 2004; Ittycheriah and Roukos, 2005). Ayan and Dorr (2006) find that precision-oriented alignments result in better translation performance than recall-oriented alignments. Fraser and Marcu (2007) show that using AER and balanced F-measure can only partially explain the effect of alignment quality on BLEU for several language pairs.

We believe that the correlation problem arises from the discrepancy between word alignment and translation rule extraction. On one hand, aligners seek to find the alignment with the highest alignment model score, without regard to structural constraints. Consequently, sensible translation rules may not be extracted because they violate consistency constraints required by translation rule extraction (Och and Ney, 2004). Wang et al. (2010) find that the standard alignment tools are not optimal for training syntax-based models. As a result, they have to resort to re-aligning. On the other hand, the consistency constraint used in most translation rule extraction algorithms tolerate wrong links within consistent phrase pairs. Chiang (2007) uses the union of two unidirectional alignments, which usually has a low precision, for extracting hierarchical phrases. Therefore, it is important to include both alignment model score and the consistency constraint in the optimization objective of word alignment.

In this work, we propose to use *coverage*, which measures how well extracted phrases can

Lisbon, Portugal, 17-21 September 2015.

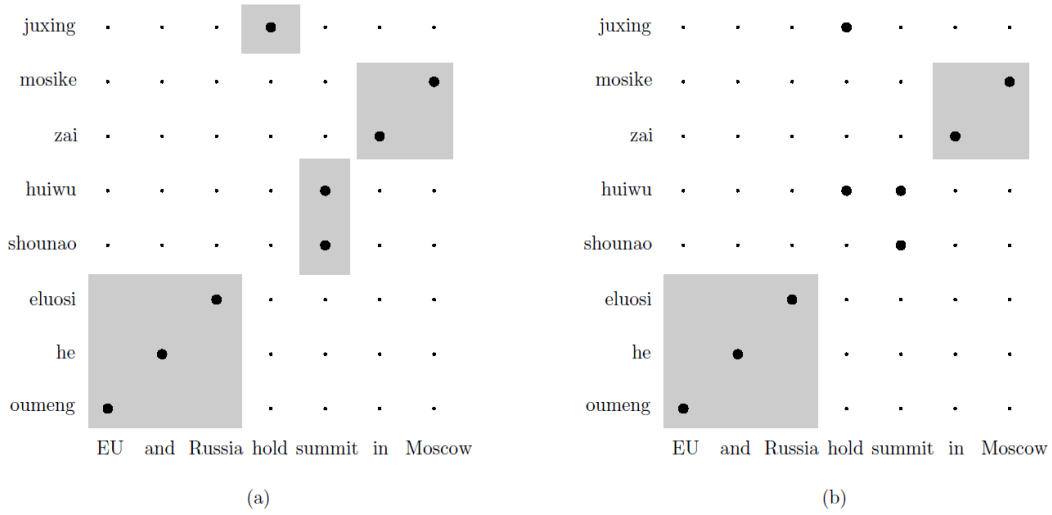

Figure 1: (a) An alignment resulting in a set of bilingual phrases (highlighted by shading) that can recover the training example, and (b) an alignment resulting in a set of bilingual phrases that fails to fully recover the training example. We assume the maximum phrase length $w = 3$. Our approach aims to avoid adding links that both have low posterior probabilities and hurt the recovery (e.g., the link between "huiwu" and "hold").

recover the training data, to bridge word alignment and (hierarchical) phrase-based translation. We introduce a new alignment search algorithm with an objective that maximizes both alignment model score and coverage while keeping the training algorithm unchanged. The coverage of an alignment is calculated on the fly during search using a local phrase extraction algorithm. Experiments show that our approach achieves significant improvements over state-of-the-art baselines across various languages and translation models.

2 Background

We begin by introducing the preliminaries of word alignment and phrase-based translation.

Definition 1 Given a source-language sentence $\mathbf{f} = f_1^J = f_1 \dots f_J$ and a target-language sentence $\mathbf{e} = e_1^I = e_1 \dots e_I$, an **alignment** $\mathbf{a}$ is a subset of the Cartesian product of the word positions of two sentences: $\mathbf{a} \subseteq \{(j, i) : j = 1, \dots, J; i = 1, \dots, I\}$.

Figure 1(a) shows an alignment for a Chinese sentence "oumeng he eluosi shounao huiwu zai mosike juxing" and an English sentence "EU and Russia hold summit in Moscow". We use black circles to denote links. The link $(1, 1)$ indicates that the first Chinese word "oumeng" and the first English word "EU" are translations of each other.

Definition 2 Given a training example $\langle \mathbf{f}, \mathbf{e}, \mathbf{a} \rangle$, a **bilingual phrase** B is a pair of source and target phrases: $B = (f_{j_1}^{j_2}, e_{i_1}^{i_2})$ such that $1 \le j_1 \le j_2 \le J \wedge 1 \le i_1 \le i_2 \le I$.

For example, ("zai mosike", "in Moscow") in Figure 1 can be denoted as a bilingual phrase $B = (f_6^7, e_6^7)$. For convenience, We use $B.j_1$ and $B.j_2$ to denote the beginning and ending positions of the source phrase in B, respectively. $B.i_1$ and $B.i_2$ are defined likewise for the target side.

Definition 3 A bilingual phrase $B = (f_{j_1}^{j_2}, e_{i_1}^{i_2})$ is said to be **tight** if and only if all boundary words (i.e., f_{j_1}, f_{j_2}, e_{i_1}, and e_{i_2}) are aligned. Otherwise, it is a **loose** bilingual phrase.

For example, in Figure 1, while (f_1^3, e_1^3) is a tight bilingual phrase, (f_1^4, e_1^4) is a loose bilingual phrase.

Definition 4 (Och and Ney, 2004) Given a training example $\langle \mathbf{f}, \mathbf{e}, \mathbf{a} \rangle$, a bilingual phrase $B = (f_{j_1}^{j_2}, e_{i_1}^{i_2})$ is said to be **consistent** with the word alignment $\mathbf{a}$ if and only if:

1. No words in the source phrase are aligned with words outside the target phrase and vice versa: $\forall (j, i) \in \mathbf{a} : j_1 \le j \le j_2 \leftrightarrow i_1 \le i \le i_2$,
2. At least one word in the source phrase is aligned with at least one word in the target

phrase: $\exists(j,i) \in \mathbf{a} : j_1 \leq j \leq j_2 \wedge i_1 \leq i \leq i_2$.

Alignment consistency forms the basis of translation rule extraction in modern SMT systems (Koehn and Hoang, 2007; Chiang, 2007; Galley et al., 2006; Liu et al., 2006). In Figure 1, (f_1^3, e_1^3) is consistent with the alignment because all words in "oumeng he eluosi" are aligned with all words in "EU and Russia". In contrast, in Figure 1(b), "huiwu shounao" and "hold summit" are not consistent with the alignment because "hold" is also aligned to a word "juxing" outside.

However, alignment consistency only defines a loose relationship between alignment and translation. A phrase pair consistent with alignment tolerates wrong inside links. For example, even if "oumeng" is aligned with "Russia", (f_1^3, e_1^3) is still consistent. This is one possible reason that maximizing alignment accuracy does not necessarily lead to improved translation performance.

3 Modeling Consistency in Word Alignment

Our intuition is that including the consistency constraint in word alignment can hopefully reduce the discrepancy between alignment and translation. While this idea has been suggested by a number of authors (e.g., (Deng and Zhou, 2009; DeNero and Klein, 2010)), our goal is to optimize arbitrary alignment models with respect to end-to-end translation in the search phase without labeled data (see Related Work for detailed comparison).

A natural way is to include consistency in the optimization objective as a regularization term. However, as consistency is only defined at the phrase level (see **Definition 4**), we need a sentence-level measure to reflect how well an alignment conforms to the consistency constraint. A straightforward measure is the number of bilingual phrases consistent with the alignment (*phrase count* for short), which is easy and efficient to calculate during search (Deng and Zhou, 2009). Unfortunately, optimizing with respect to *phrase count* is prone to yield alignments with very few links in a biased way, which result in a large number of bilingual phrases extracted from a small fraction of the training data. Another alternative is *reachability* (Liang et al., 2006a; Yu et al., 2013) that indicates whether there exists a full derivation to recover the training data. However, calculating reachability faces a major problem: a large portion of training data cannot be fully recovered due to noisy alignments and the distortion limit (Yu et al., 2013).

In this work, we propose *coverage*, which reflects how well extracted phrases can recover the training data, to measure the sentence-level consistency. In the following, we will introduce a number of definitions to facilitate the exposition.

Definition 5 A source word f_j is said to be **covered** by a bilingual phrase $B = (f_{j_1}^{j_2}, e_{i_1}^{i_2})$ if and only if $j_1 \leq j \leq j_2 : cov(f_j, B) = [\![j_1 \leq j \leq j_2]\!]$. Similarly, a target word e_i is covered by B if and only if $i_1 \leq i \leq i_2$.

The indicator function $[\![expr]\!]$ returns 1 if the boolean expression $expr$ is true and returns 0 otherwise. For example, in Figure 1(a), "oumeng" and "EU" are covered by the bilingual phrase $B = (f_1^3, e_1^3)$.

Definition 6 Given a set of bilingual phrases $\mathbf{B} = \{B^{(k)}\}_{k=1}^{K}$, a source word f_j is said to be **covered** by the bilingual phrase set $\mathbf{B}$ if and only if it is covered by at least one phrase in $B : cov(f_j, \mathbf{B}) = [\![\sum_{k=1}^{K} cov(f_j, B^{(k)}) > 0]\!]$. The definition for a target word is similar.

For example, in Figure 1(a), all source and target words are covered by the bilingual phrase set. In Figure 1(b), the source words "shounao", "huiwu", "juxing" and the target words "hold" and "summit" are not covered.

Definition 7 Given a sentence pair $\langle \mathbf{f}, \mathbf{e} \rangle$ and a phrase length limit w [1], the **hard coverage** of an alignment $\mathbf{a}$ is defined as a boolean value:

$$C_h(\mathbf{f}, \mathbf{e}, \mathbf{a}, w) = \Big[\!\Big[\delta\Big(\sum_{j=1}^{J} cov(f_j, \mathbf{B}), J \Big) \wedge \delta\Big(\sum_{i=1}^{I} cov(e_i, \mathbf{B}), I \Big) \Big]\!\Big] \quad (1)$$

where $\mathbf{B} = \textsc{Extract}(\mathbf{f}, \mathbf{e}, \mathbf{a}, 1, J, 1, I, w)$ is the set of consistent bilingual phrases extracted from the sentence pair using a standard phrase extraction algorithm (Och and Ney, 2004). The function δ returns true if the two parameters are same and returns false otherwise.

[1] The phrase length limit w is essential in defining coverage, restricting that the sentence pair must be covered by bilingual phrases no longer than w words. Otherwise, a very long bilingual phrase (e.g., the entire sentence pair) can achieve full coverage in a biased way.

Algorithm 1 A consistency-aware search algorithm for word alignment.

1: **procedure** ALIGN($\mathbf{f}, \mathbf{e}, \boldsymbol{\theta}, w, \beta, b, n$)
2: $open \leftarrow \emptyset$
3: $\mathcal{N} \leftarrow \emptyset$
4: $\langle \mathbf{a}, \mathbf{B} \rangle \leftarrow \langle \emptyset, \emptyset \rangle$
5: ADD($open, \langle \mathbf{a}, \mathbf{B} \rangle, \beta, b$)
6: **while** $open \neq \emptyset$ **do**
7: $closed \leftarrow \emptyset$
8: **for all** $\langle \mathbf{a}, \mathbf{B} \rangle \in open$ **do**
9: **for all** $l \in J \times I - \mathbf{a}$ **do**
10: $\mathbf{a}' \leftarrow \mathbf{a} \cup \{l\}$
11: $\mathbf{B}' \leftarrow$ UPDATE($\mathbf{f}, \mathbf{e}, \mathbf{a}, l, \mathbf{B}, w$)
12: **if** GAIN($\mathbf{f}, \mathbf{e}, \mathbf{a}, \mathbf{a}', w, \boldsymbol{\theta}$) > 0 **then**
13: ADD($closed, \langle \mathbf{a}', \mathbf{B}' \rangle, \beta, b$)
14: **end if**
15: ADD($\mathcal{N}, \langle \mathbf{a}', \mathbf{B}' \rangle, \beta, n$)
16: **end for**
17: **end for**
18: $open \leftarrow closed$
19: **end while**
20: **return** $\mathcal{N}$
21: **end procedure**

Depending on the tightness of extracted phrases (see **Definition 3**), we further distinguish between $C_{h+t}(\mathbf{f}, \mathbf{e}, \mathbf{a}, w)$ and $C_{h+l}(\mathbf{f}, \mathbf{e}, \mathbf{a}, w)$, which denote hard coverage calculated with tight and loose phrases, respectively.

Hard coverage denotes whether extracted phrases can fully recover the training data. For example, the values of hard coverage for Figures 1(a) and 1(b) are 1 and 0, respectively. As most training examples can hardly be fully recovered, we introduce *soft coverage* to better account for partially recoverable training data.

Definition 8 Given a sentence pair $\langle \mathbf{f}, \mathbf{e} \rangle$ and a phrase length limit w, the **soft coverage** of an alignment $\mathbf{a}$ is defined as

$$C_s(\mathbf{f}, \mathbf{e}, \mathbf{a}, w) = \frac{\sum_{j=1}^{J} cov(f_j, \mathbf{B}) + \sum_{i=1}^{I} cov(e_i, \mathbf{B})}{J + I} \quad (2)$$

Similarly, we also distinguish between C_{s+t} and C_{s+l} depending on the tightness of extracted phrases.

Definition 9 Given a word-aligned bilingual corpus $D = \{\langle \mathbf{f}^{(s)}, \mathbf{e}^{(s)}, \mathbf{a}^{(s)} \rangle\}_{s=1}^{S}$ and a phrase length limit w, the **corpus-level soft coverage** is defined as

$$C_s(D, w) = \frac{\sum_{j=1}^{|\mathbf{f}^{(s)}|} cov(f_j^{(s)}, \mathbf{B}^{(s)})}{\sum_{s=1}^{S} |\mathbf{f}^{(s)}| + |\mathbf{e}^{(s)}|} + \frac{\sum_{i=1}^{|\mathbf{e}^{(s)}|} cov(e_i^{(s)}, \mathbf{B}^{(s)})}{\sum_{s=1}^{S} |\mathbf{f}^{(s)}| + |\mathbf{e}^{(s)}|} \quad (3)$$

Algorithm 2 Updating the set of extracted bilingual phrases after adding a link.

1: **procedure** UPDATE($\mathbf{f}, \mathbf{e}, \mathbf{a}, l, \mathbf{B}, w$)
2: $\mathbf{B}' \leftarrow \mathbf{B}$
3: **for all** $B \in \mathbf{B}'$ **do**
4: **if** $B.j_1 \leq l.j \leq B.j_2 \vee B.i_1 \leq l.i \leq B.i_2$ **then**
5: $\mathbf{B}' \leftarrow \mathbf{B}' - \{B\}$
6: **end if**
7: **end for**
8: $j_1 \leftarrow l.j - w + 1$
9: $j_2 \leftarrow l.j + w - 1$
10: $i_1 \leftarrow l.i - w + 1$
11: $i_2 \leftarrow l.i + w - 1$
12: $\mathbf{a}' \leftarrow \mathbf{a} \cup \{l\}$
13: $\mathbf{B}'' \leftarrow$ EXTRACT($\mathbf{f}, \mathbf{e}, \mathbf{a}', j_1, j_2, i_1, i_2, w$)
14: $\mathbf{B}' \leftarrow \mathbf{B}' \cup \mathbf{B}''$
15: **return** $\mathbf{B}'$
16: **end procedure**

The corpus-level hard coverage is defined likewise.

4 Consistency-Aware Search

While Deng and Zhou (2009) focus on introducing an effectiveness function such as phrase count into alignment symmetrization, we are interested in guiding the search algorithms of arbitrary alignment models using coverage. Therefore, the objective of our search algorithm is defined as

$$score(\mathbf{f}, \mathbf{e}, \mathbf{a}, w, \boldsymbol{\theta}) = M(\mathbf{f}, \mathbf{e}, \mathbf{a}, \boldsymbol{\theta}) + \lambda C(\mathbf{f}, \mathbf{e}, \mathbf{a}, w) \quad (4)$$

where $M(\mathbf{f}, \mathbf{e}, \mathbf{a}, \boldsymbol{\theta})$ is alignment model score, $\boldsymbol{\theta}$ is a set of model parameters, $C(\mathbf{f}, \mathbf{e}, \mathbf{a}, w)$ is coverage (either hard or soft), and λ is a hyper-parameter that controls the preference between alignment model score and coverage. [2]

Therefore, the decision rule is given by

$$\hat{\mathbf{a}} = \underset{\mathbf{a} \in \mathcal{A}(\mathbf{f}, \mathbf{e})}{\operatorname{argmax}} \left\{ score(\mathbf{f}, \mathbf{e}, \mathbf{a}, w, \boldsymbol{\theta}) \right\} \quad (5)$$

where $\mathcal{A}(\mathbf{f}, \mathbf{e})$ is a set of all possible alignments for the sentence pair.

Algorithm 1 shows the consistency-aware search algorithm for word alignment. The input of the algorithm includes a source sentence $\mathbf{f}$, a target sentence $\mathbf{e}$, a set of model parameters $\boldsymbol{\theta}$, phrase length limit w, pruning parameters β and b, and the number of most likely alignments to be retaind n (line 1). Inspired by Liu et al. (2010),

[2] Note that training algorithms are unchanged. We only introduce a new search algorithm that takes coverage into consideration. We leave consistency-aware training algorithms for arbitrary alignment models for future work.

the algorithm starts with an empty alignment $\mathbf{a}$ together with an empty phrase set $\mathbf{B}$. We use $open$ to store active alignments during search and $\mathcal{N}$ to store top-n alignments after search (lines 2-4). The procedure ADD($open, \langle \mathbf{a}, \mathbf{B} \rangle, \beta, b$) adds $\langle \mathbf{a}, \mathbf{B} \rangle$ to $open$ and discards any alignment that has a score worse than β multiplied by the best score in the list or the score of the b-th best alignment (line 5). For each iteration (line 6), we use a list $closed$ to store promising alignments that have higher scores than the current alignment (line 8). For every possible link l (line 9), the algorithm produces a new alignment $\mathbf{a}'$ and updates the phrase set by calling a procedure UPDATE($\mathbf{f}, \mathbf{e}, \mathbf{a}, l, \mathbf{B}, w$) (lines 10-11). Then, the algorithm calls a procedure GAIN($\mathbf{f}, \mathbf{e}, \mathbf{a}, \mathbf{a}', w, \boldsymbol{\theta}$) to calculate the difference of model score after adding the link l:

$$score(\mathbf{f}, \mathbf{e}, \mathbf{a}', w, \boldsymbol{\theta}) - score(\mathbf{f}, \mathbf{e}, \mathbf{a}, w, \boldsymbol{\theta})$$

If $\mathbf{a}'$ has a higher score, it is added to $closed$ (line 13). We also update $\mathcal{N}$ to retain the top n alignment explored during the search (line 15). This process iterates until the model score does not increase.

Algorithm 2 describes how to update the set of extracted bilingual phrases after adding a link. Our idea is to only update the phrases near the added link l and keep other phrases unchanged. This strategy improves the efficiency by avoiding extracting phrases from the entire sentence pair. The algorithm first removes bilingual phrases that are either in the same row or in the same column with l (lines 2-7). For example, in Figure 1, the following bilingual phrases are removed after adding the link between "huiwu" and "hold" because the link breaks the consistency:

("shounao huiwu", "summit")
("juxing", "hold")

Other phrases out of the reach of the added link remain unchanged.

Then, the algorithm extracts bilingual phrases near l by calling the procedure EXTRACT. Note that the phrase extraction is restricted to a local region (j_1, j_2, i_1, i_2) by the phrase length limit w. We use $l.i$ and $l.j$ to denote the source and target positions of the link, respectively.

coverage	BLEU
C_{h+l}	24.89
C_{h+t}	23.16
C_{s+l}	24.69
C_{s+t}	25.41

Table 1: Comparison of different settings of coverage on the Chinese-English dataset using Moses. "h" denotes "hard", "s" denotes "soft", "l" denotes "loose", and "t" denotes "tight". The BLEU scores were calculated on the development set. For quick validation, we used a small fraction of the training data to train the phrase-based model.

5 Experiments

5.1 Setup

5.1.1 Languages and Datasets

We evaluated our approach in terms of alignment and translation quality on five language pairs: Chinese-English (ZH-EN), Czech-English (CS-EN), German-English (DE-EN), Spanish-English (ES-EN), and French-English (FR-EN). The evaluation metrics for alignment and translation are alignment error rate (AER) (Och and Ney, 2003) and case-insensitive BLEU (Papineni et al., 2002), respectively.

For Chinese-English, the training data consists of 1.2M pairs of sentences with 30.9M Chinese words and 35.5M English words. We used the SRILM toolkit (Stolcke, 2002) to train a 4-gram language model on the Xinhua portion of the English GIGAWORD corpus, which contains 398.6M words. For alignment evaluation, we used the Tsinghua Chinese-English word alignment evaluation data set (Liu and Sun, 2015). [3] For translation evaluation, we used the NIST 2006 dataset as the development set and the NIST 2002, 2003, 2004, 2005 and 2008 datasets as the test sets.

For other languages, the training data is Europarl v7. The English language model trained on the Xinhua portion of the English GIGAWORD corpus was also used for translation from European languages to English. For translation evaluation, we used the "news-test2012" dataset that contains 3,003 sentences as the development set and the "news-test2013" dataset that contains 3,000 sentences as the test set.

Table 2: Comparison of different alignment methods on the Chinese-English dataset. "GDF" denotes the grow-diag-final heuristic. "phrase count" denotes optimizing with respect to maximizing the number of extracted tight phrases. We used Moses to extract loose phrases from word-aligned training data for all methods. "# bp" denotes the number of extracted bilingual phrases, "# sp" denotes the number of source phrases, "# tp" denotes the number of target phrases, "# sw" denotes the source vocabulary size, "# tw" denotes the target vocabulary size. We report BLEU scores on the NIST 2005 test set.

alignment	NIST06	NIST02	NIST03	NIST04	NIST05	NIST08
generative	29.60	31.84	31.68	31.80	30.40	24.53
+*coverage*	30.63**	32.89**	32.77**	32.96**	31.33**	25.25**
discriminative	28.98	32.31	31.69	31.89	30.65	23.20
+*coverage*	29.98**	32.93**	32.45**	32.45**	31.10**	24.67**

Table 3: Translation evaluation on different alignment models. We apply our approach to both generative and discriminative alignment models. "generative" denotes applying the grow-diag-final heuristic to the alignments produced by IBM Model 4 in two directions. "discriminative" denotes the log-linear alignment model (Liu et al., 2010). Adding coverage leads to significant improvements. We use "**" to denote that the difference is statistically significant at $p < 0.01$ level.

5.1.2 Alignment Models

We apply our approach to both generative and discriminative alignment models. For generative models, we used GIZA++ (Och and Ney, 2003) to train IBM Model 4 in two directions. To calculate a model score for symmetrized alignments, we follow Liang et al. (2006b) to leverage link posterior marginal probabilities. For discriminative models, we used the open-source toolkit TsinghuaAligner (Liu and Sun, 2015) that implements the log-linear alignment model as described in (Liu et al., 2010). The model score for the log-linear model is also defined using link posteriors.

5.1.3 Translation Models

Two kinds of translation models, phrase-based (Koehn et al., 2003) and hierarchical phrase-based (Chiang, 2007), are used to evaluate whether our approach improves the correlation between alignment and translation. For the phrase-based model, we used the open-source toolkit Moses (Koehn and Hoang, 2007). For the hierarchical phrase-based model, we used an in-house re-implementation on par with state-of-the-art open-source decoders.

5.2 Comparison of Different Settings

We first investigate the optimal setting for coverage (hard vs. soft, tight vs. loose) on the Chinese-English dataset. For quick validation, we used a subset of the training data to train the phrase-based model using Moses. We used the development set to optimize the scaling factor λ (see Eq. (4)) and set it to 0.3 in our experiments.

Table 1 compares C_{h+l}, C_{h+t}, C_{s+l}, and C_{s+t}. We find that the "*soft + tight*" combination (i.e., C_{s+t}) yields the highest BLEU score on the development set. One possible reason is that tight phrases are usually of high quality and soft coverage allows for taking full advantage of the training data. On the contrary, C_{h+t} yields the lowest BLEU score because hard coverage fails to distinguish between partially recoverable training examples as it assigns zero to all partially recoverable data.

Then, we investigate the effect of the phrase length limit w in Algorithm 1 on translation quality. We find $w = 7$ achieves the best result,

which is consistent with the default setting in Moses. As a result, we used C_{s+t} and set $w = 7$ in the following experiments.

5.3 Comparison of Different Alignment Methods

We compare our approach with a number of alignment methods in terms of AER and BLEU, including IBM Model 4 in two directions (C $\rightarrow$ E and E $\rightarrow$ C), symmetrization heuristics (Intersection, Union, grow-diag-final), and consistency-aware models (tight phrase count and coverage). We used Moses to extract loose bilingual phrases from word-aligned bilingual corpora from all methods. Note that our approach uses C_{s+t} for finding alignments, from which Moses extracts loose phrases.

Table 2 lists the numbers of extracted bilingual phrases ("# bp"), source phrases ("# sp"), target phrases ("# tp"), source vocabulary size ("# sw"), and target vocabulary size ("# tw"). We find that a very large number of loose phrases can be extracted from the Intersection alignments, which also have the highest vocabulary sizes. However, a large portion of words in these phrases are actually unaligned, resulting in low translation quality.

We observe that adding consistency, either in terms of phrase count or coverage, significantly improves alignment accuracy by a large margin, suggesting that imposing structural constraint helps to reduce alignment errors. Our approach outperforms all methods in terms of BLEU significantly. Note that the coverage itself does not correlate well with BLEU. It is important to achieve a balance between model score and coverage. As mentioned in Section 5.2, we set $\lambda = 0.3$ in our experiments.

5.4 Translation Evaluation on Different Alignment Models

We apply our approach to both generative (Brown et al., 1993) and discriminative (Liu et al., 2010) alignment models. As shown in Table 3, we find that adding coverage to the optimization objective significantly improves the BLEU scores. All differences are statistically significant at $p < 0.01$ level. This finding suggests that our approach generalizes well to various alignment models.

5.5 Translation Evaluation on Different Translation Models

We also evaluated our approach on both phrase-based and hierarchical phrase-based models. As shown in Table 4, adding coverage to generative models leads to significant improvements for both models. All the differences are statistically significant at $p < 0.01$ level.

Although coverage is designed for extracting phrases, using coverage is still beneficial to hierarchical phrase-based models because hierarchical phrases are derived from phrases consistent with word alignment. [4]

5.6 Translation Evaluation on Different Language Pairs

Finally, we report BLEU scores across five language pairs in Table 5: Chinese-English (ZH-EN), Czech-English (CS-EN), German-English (DE-EN), Spanish-English (ES-EN), and French-English (FR-EN). ZH-EN uses four references and other language pairs only use single references.

We find that our approach outperforms the baseline statistically significantly at $p < 0.01$ for four language pairs and $p < 0.05$ for one language pair. Therefore, using coverage to bridge word alignment and machine translation can hopefully benefit more languages.

6 Related Work

Our work is inspired by three lines of research: (1) reachability in discriminative training of translation models, (2) structural constraints for alignment, and (3) learning with constraints.

6.1 Reachability in Discriminative Training of Translation Models

Discriminative training algorithms for statistical machine translation often need *reachable* training examples to find full derivations for updating model parameters (Liang et al., 2006a; Yu et al., 2013). Yu et al. (2013) report that only 32.1% sentences in the Chinese-English training data that contain 12.7% words are fully reachable

[4] We also tested our approach on syntax-based models (Galley et al., 2006; Liu et al., 2006) but failed to achieve significant improvements. The reason is that extracting syntactic translation rules often imposes an additional constraint: a phrase must be a constituent that is subsumed by a subtree. We believe that appending such constraint to the optimization objective will hopefully benefit syntax-based translation models. We leave this for future work.

translation	alignment	NIST06	NIST02	NIST03	NIST04	NIST05	NIST08
phrase	generative	29.60	31.84	31.68	31.80	30.40	24.53
	+*coverage*	30.63**	32.89**	32.77**	32.96**	31.33**	25.25**
hierarchical	generative	30.43	33.36	32.58	32.72	31.57	24.21
	+*coverage*	31.60**	34.67**	34.14**	34.24**	32.73**	24.89**

Table 4: Translation evaluation on different translation models. For translation, We used both phrase-based and hierarchical phrase-based models. For alignment, we used the generative model. "generative" denotes applying the grow-diag-final heuristic to the alignments produced by IBM Model 4 in two directions. Adding coverage leads to significant improvements. We use "**" to denote that the difference is statistically significant at $p < 0.01$ level.

alignment	ZH-EN	CS-EN	DE-EN	ES-EN	FR-EN
generative	30.40	19.89	21.13	26.39	26.22
+*coverage*	31.33**	20.04*	21.63**	26.79**	26.76**

Table 5: Translation evaluation on five language pairs. "generative" denotes applying the grow-diag-final heuristic to the alignments produced by IBM Model 4 in two directions. We use "*" and"**" to denote that the difference is statistically significant at $p < 0.05$ and $p < 0.01$, respectively. Note that ZH-EN uses four references and other language pairs only use single references.

due to noisy alignments and distortion limit. They find that most reachable sentences are short and generally literal.

We borrow the idea of measuring the degree of recovering training data from reachability but ignore the dependency between bilingual phrases for efficiency. To calculate reachability, one needs to figure out a full derivation, in which the bilingual phrases cover the training data and do not intersect with each other. Yu et al. (2013) indicate that using forced decoding to select reachable sentences with an unlimited distortion limit runs in $O(2^n n^3)$ time. In contrast, calculating coverage is much easier and more efficient by ignoring the dependency between phrases but still retains the spirit of measuring recovery.

6.2 Structural Constraints for Alignment

Modeling structural constraints in alignment has received intensive attention in the community, either directly modeling phrase-to-phrase alignment (Marcu and Wong, 2002; DeNero and Klein, 2008; Cohn and Blunsom, 2009) or intersecting synchronous grammars with alignment (Wu, 1997; Zhang and Gildea, 2005; Haghighi et al., 2009).

Our work is in spirit most close to (Deng and Zhou, 2009) and (DeNero and Klein, 2010). Deng and Bowen (2009) cast combining IBM Model 4 alignments in two directions as an optimization problem driven by an effectiveness function. They evaluate the impact of adding or removing a link with respect to phrase extraction using the effectiveness function of phrase count. The major difference is that we generalize their idea to arbitrary alignment models in the search phase rather than bidirectional alignment combination in the post-processing phase. In addition, we find that using coverage instead of phrase count results in better translation performance (see Table 2).

DeNero and Klein (2010) develop a discriminative model of extraction sets and optimize an extraction-based loss function with respect to translation. Their model is capable of predicting the extracted phrase set. While their approach relies on annotated data for training the discriminative model, our method only needs to tune the scaling factor λ on the development set. In addition, our approach is very general and can easily apply to arbitrary alignment models by appending a term to the optimization objective.

6.3 Learning with Constraints

Our work is also related to learning with constraints such as constraint-driven learning (Chang et al., 2007) and posterior regularization (Ganchev et al., 2010). The basic idea is to inject prior knowledge to the model as a regularization term. The major difference is that our coverage regularizer is independent of model parameters. As a result, alignment models can still be trained independently.

7 Conclusion

In this work, we have presented a general framework for optimizing word alignment with respect to machine translation. We introduce coverage to measure how well extracted bilingual phrases can recover the training data. We develop a consistency-aware search algorithm that calculates coverage on the fly during search efficiently. Experiments show the our approach is effective in both alignment and translation tasks across various alignment models, translation models, and language pairs.

In the future, we plan to apply our approach to syntax-based models (Galley et al., 2006; Liu et al., 2006; Shen et al., 2008) and include the constituency constraint in the optimization objective. It is also interesting to develop consistency-aware training algorithms for word alignment.

Abstract

Lexical selection is of great importance to statistical machine translation. In this paper, we propose a graph-based framework for collective lexical selection. The framework is established on a *translation graph* that captures not only local associations between source-side content words and their target translations but also target-side global dependencies in terms of relatedness among target items. We also introduce a random walk style algorithm to collectively identify translations of source-side content words that are strongly related in translation graph. We validate the effectiveness of our lexical selection framework on Chinese-English translation. Experiment results with large-scale training data show that our approach significantly improves lexical selection.

1 Introduction

Lexical selection, which selects appropriate translations for lexical items on the source side, is a crucial task in statistical machine translation (SMT). The task is closely related to two factors: 1) associations of selected translations with lexical items on the source side, including corresponding source items and their neighboring words, and 2) dependencies[1] between selected target translations and other items on the target side.

As translation rules and widely-used n-gram language models can only capture local associations and dependencies, we have witnessed increasing efforts that attempt to incorporate non-local associations/dependencies into lexical selection. Efforts using source-side associations mainly focus on the exploitation of either sentence-level context (Chan et al., 2007; Carpuat and Wu, 2007; Hasan et al., 2008; Mauser et al., 2009; He et al., 2008; Shen et al., 2009) or the utilization of document-level context (Xiao et al., 2011; Ture et al., 2012; Xiao et al., 2012; Xiong et al., 2013). In contrast, target-side dependencies attract little attention, although they have an important impact on the accuracy of lexical selection. The most common practice is to use language models to estimate the strength of target-side dependencies (Koehn et al., 2003; Shen et al., 2008; Xiong et al., 2011). However, conventional n-gram language models are not good at capturing long-distance dependencies. Consider the example shown in Figure 1. As the translations of polysemous words "*wèntí*", "*chíyǒu*" and "*lìchǎng*" are far from each other, our baseline can only correctly translate "*lìchǎng*" as "*stance*". It inappropriately translates the other two words as "*problem*" and *null*, respectively, even with the support of an n-gram language model. If we could model long-distance dependencies among target translations of source words "*wèntí*"(*issue*), "*chíyǒu*"(*hold*) and "*lìchǎng*"(*stance*), these translation errors could be avoided.

In order to model target-side global dependencies, we propose a novel graph-based collective lexical selection framework for SMT. Specifically,

- First, we propose a translation graph to model not only local associations between source-side content words and their target translations but also global relatedness among target-side items.

*Corresponding author.

[1]Please note that dependencies in this paper are not necessarily syntactic dependencies.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1238–1247,
Lisbon, Portugal, 17-21 September 2015.

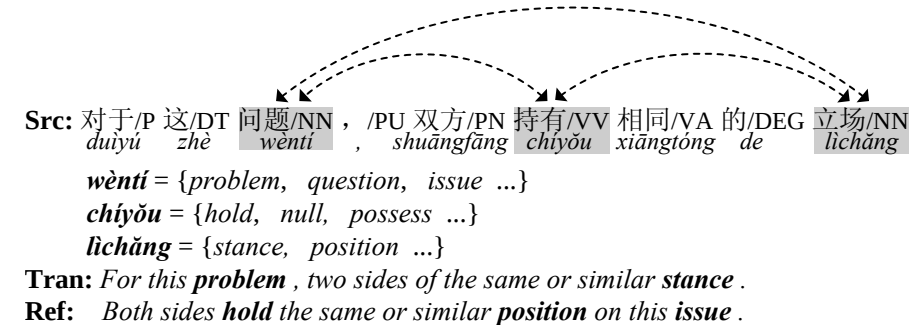

Figure 1: A Chinese-English translation example to illustrate the importance of target-side long-distance dependencies for lexical selection. Dotted lines show long-distance dependencies of source content words. Three content words "*wèntí*", "*chíyǒu*", "*lìchǎng*", and their candidate translations with high translation probabilities are also presented. **Src**: A Chinese sentence with part-of-speech tags. **Tran**: system output. **Ref**: reference translation.

- Second, we introduce a collective lexical selection algorithm, which can jointly identify translations of all source-side content words in the translation graph.

- Finally, we incorporate confidence scores of candidate translations in the translation graph, which are derived by the collective selection algorithm, into SMT to improve lexical selection.

We validate the effectiveness of our graph-based lexical selection framework on a hierarchical phrase-based system (Chiang, 2007). Experiment results on the NIST Chinese-English test sets show that our approach significantly improves translation quality.

We begin in Section 2 with the construction of translation graph for each translated sentence. Then, we propose a graph-based collective lexical selection framework for SMT in Section 3. Experiment results are reported in Section 4. We summarize and compare related work in Section 5. Finally, Section 6 presents conclusions and directions for future research.

2 Translation Graph

Formally, a translation graph is a weighted graph G=(N, E). In the node set N, each node represents either a source word or a target translation that contains one or multiple target words. In the edge set E, an edge linking a source word to a target translation is referred to as a *source-target association edge*, and an edge connecting two target translations is called as a *target-target relatedness edge*. In Section 2.1 and 2.2, we will answer the following two questions on the translation graph:

- Which source words and their translations should be included in the translation graph?

- How can we measure the strength of the above two types of relations in the graph with edge weights?

2.1 Graph Nodes

For a source sentence, the most ideal translation graph is a graph that includes all source words and their candidate translations. However, this ideal graph has two problems: intensive computation for graph inference and difficulty in modeling dependencies between function and content words. In order to get around these two issues, we only consider lexical selection for source content words[2].

We first identify source-side content word pairs using statistical metrics, and then keep word pairs with a high relatedness strength in the translation graph. To be specific, we use pointwise mutual information (PMI) (Church and Hanks, 1990) and co-occurrence frequency to measure the relatedness strength of two source-side words s and s' within a window d_s. Content word pairs will be kept when their co-occurrence frequencies are more than ϵ_{cf} times in our training corpus and PMI values are larger than ϵ_{pmi}. In this process, we remove noisy word pairs using the following heuristic rules: (1) As an adjective only has relations with its head nouns or dependent adverbs, we remove all word pairs where an adjective is paired with words other than its head nouns or dependent adverbs; (2) We apply a similar constraint to adverbs too, since the same thing happens to an adverb and its head verb or head ad-

[2]In this work, we consider nouns, verbs, adjectives and adverbs as content words in the source/target language.

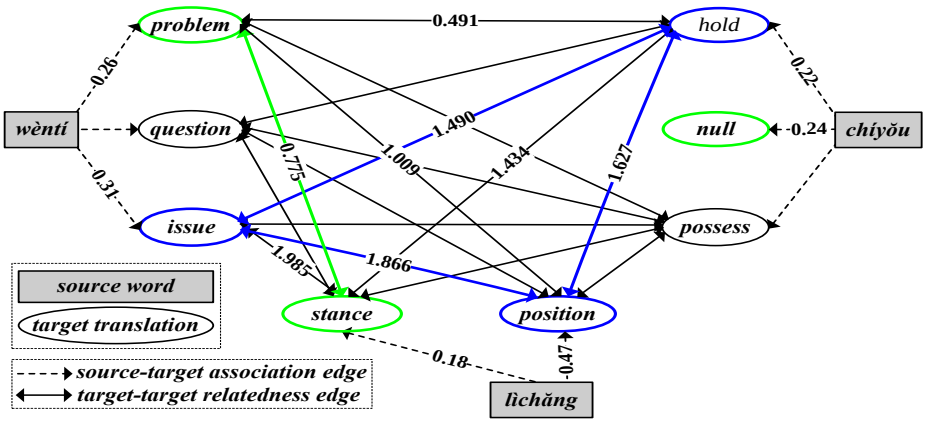

Figure 2: Translation graph of the example shown in Figure 1. Relatedness scores on edges are shown for two group of translations {"*problem*", *null*, "*stance*"} (**green**) and {"*issue*", "*hold*", "*position*"} (**blue**), which are estimated with PMI. Note that the *null* node does not have any relations with other nodes. Besides, two translation combinations {"*problem*", *null*, "*stance*"} (green) and {"*issue*", "*hold*", "*position*"} (blue) have different strengths of relatedness.

jective. For example, in the Chinese sentence in Figure 1, the adjective "*xiāngtóng*" is only related to the noun "*lìchǎng*" although it also frequently co-occur with "*wèntí*".

After identifying source-side content word pairs, we collect all target translations of these content words from extracted bilingual rules according to word alignments. These content words and target translations are used to build a translation graph, where each node represents a source-side content word or a candidate target translation. Note that there may be hundreds of different translations for a source word. For simplicity, we only consider target translations from translation options that are adopted by the decoder after rule filtering. Let's revisit the example in Figure 2, we include the following target translations in the translation graph: "*problem*", "*question*", "*issue*", "*hold*", *null*, "*possess*", "*stance*" and "*position*".

2.2 Edges and Weights

In this section, we introduce how we calculate weights for two kinds of edges in a translation graph.

2.2.1 Source-Target Association Edge

Connecting a source-side content word and its candidate target translations, a source-target association edge provides a way to propagate translation association evidence from a source word to its candidate translations. Obviously, the stronger the association between a source word and its candidate translation, the more evidence the corresponding edge will propagate. For each source-side content word, we obtain its candidate translations via the kept word alignments. Following Xiong et al. (2014), we allow a target translation to be either a phrase of length up to 3 words or *null* when s is not aligned to any word in the corresponding bilingual rule. We define the weight of the edge from a source-side content word s to its target translation $\tilde{t}$ as follows:

$$Weight(s \rightarrow \tilde{t}) = \frac{TP(s,\tilde{t})}{\sum_{\tilde{t}' \in N(s)} TP(s,\tilde{t}')} \quad (1)$$

where $N(s)$ denotes the set of candidate target translations of s kept on the translation graph, and $TP(s,\tilde{t})$ measures the probability of s being translated to $\tilde{t}$. It is very important to note that there is no evidence propagated from a target translation to a source word, as source-target association edges only go from a source-side content word to its translations.

We compute $TP(s,\tilde{t})$ according to the principle of maximal likelihood as follows:

$$TP(s,\tilde{t}) = \frac{count(s,\tilde{t})}{count(s)} \quad (2)$$

where $count(s,\tilde{t})$ indicates how often s is aligned to $\tilde{t}$ in the training corpus. Using this method, we can compute the translation probabilities of the *source-target association edges* in Figure 2 as follows: *TP*("*wèntí*", "*issue*")=0.31, *TP*("*chíyǒu*", "*hold*")=0.22 and *TP*("*lìchǎng*", "*position*")=0.47.

2.2.2 Target-Target Relatedness Edge

Connecting two target translations of different related source content words, a target-target relatedness edge enables translation graph to capture

dependencies between translations of any two different source words.

Computing the weight of a target-target relatedness edge is crucial for our method. Intuitively, the stronger co-occurrence strength two translations have, the more evidence should be propagated between them. Therefore we calculate the weight of a target-target related edge based on the co-occurrence strength of two translations linked by the edge. Formally, given the translation $\tilde{t}$ of source-side content word s and the translation $\tilde{t}'$ of source-side content word s', the weight of the edge from $\tilde{t}$ to $\tilde{t}'$ is defined as follows:

$$Weight(\tilde{t} \rightarrow \tilde{t}') = \frac{RS(\tilde{t}, \tilde{t}')}{\sum_{\tilde{t}'' \in N(\tilde{t})} RS(\tilde{t}, \tilde{t}'')} \quad (3)$$

where $N(\tilde{t})$ denotes the set of candidate translations that link to $\tilde{t}$, and $RS(\tilde{t}, \tilde{t}')$ measures the strength of relatedness between $\tilde{t}$ and $\tilde{t}'$ which is calculated as the average word-level relatedness over all content words in these two translations $\tilde{t}$ and $\tilde{t}'$.

As for the word-level relatedness $RS(t, t')$ for a content word pair (t, t'), we estimate it with the following two approaches over collected co-occurring word pairs within a window of size d_t: (1) $RS(t, t')$ is computed as a bigram conditional probability $p_{lm}(t'|t)$ via the language model; (2) Following (Xiong et al., 2011) and (Liu et al., 2014), we employ PMI to define $RS(t, t')$ as $\ln \frac{p(t,t')}{p(t)p(t')}$.

3 Collective Lexical Selection Algorithm

Based on the translation graph, we propose a collective lexical selection algorithm to jointly identify translations of all source words in the graph.

3.1 Problem Statement and Solution Method

As stated previously, the translation of a source-side content word s should be: 1) associated with s; 2) related to the translations of other source-side content words. Thus, in the translation graph, the translation of s should be a target-side node which has: 1) an association edge with the node of s; 2) many relatedness edges with other target-side nodes that represent translations of other source words.

Let's revisit Figure 2. If we know that the translation of "*wèntí*" is "*issue*", the relatedness between ("*issue*", "*hold*") and between ("*issue*", "*position*") can provide evidences that "*hold*" and "*position*" are the correct translations of "*chíyǒu*" and "*lìchǎng*", respectively. On the other hand, the candidate translation "*problem*" is less related to "*hold*" and "*position*", which may suggest that it is not likely to be the correct translation of "*wèntí*", even if it has a strong source-target association relation with "*wèntí*". However, in the translation graph, the correct target translation of a source word depends on correct translations of other source words in the graph, and vice versa. So how do we find these correct translations?

We propose a *Random Walk* (Gobel and Jagers, 1974) style algorithm to solve this problem, aiming to use both local source-target associations and global target-target relatedness simultaneously during translation. In our algorithm, we assign each node an *evidence score* in the translation graph, which indicates either the importance of a source word (for a source word node) or the confidence of a target translation being a correct translation (for a target word node). Specifically, we perform collective inference on the translation graph as follows:

- First, we set initial evidence scores for nodes in the translation graph.
- Second, evidence scores are simultaneously updated by propagating evidences along edges in the translation graph.

In the following sub-section, we describe the two steps in detail.

3.2 Details of Our Algorithm

Using the algorithm shown in Algorithm 1, we iteratively derive evidence scores for candidate translations.

3.2.1 Notations

For a translation graph with $\boldsymbol{n}$ nodes, we assign each node an index from 1 to $\boldsymbol{n}$ and use this index to represent the node. We also use the following two notations:

- **The evidence vector $\boldsymbol{V}$**: an n-dimensional vector where the ith component $\boldsymbol{V}_i$ is the evidence score contained in this node (if node i corresponds to a source word), or the evidence score from the related translations (if node i corresponds to a target translation). In particular, we use $\boldsymbol{V}^{(0)}$ to denote the initial

Algorithm 1 Collective Inference in Translation Graph.

Input: $\boldsymbol{S}$: the set of source-side content words, and $S(i)$ denotes the source word of node i;
$\boldsymbol{k}$: the number of source-side content words ;
$\boldsymbol{T}$: the set of all candidate target translations, and $T(j)$ denotes the target translation of node j;
$\boldsymbol{l}$: the number of candidate target translations;
λ: the reallocation weight;
maxIter: the maximum iteration number;
ϵ: the difference threshold;

1: **for** $i = 1, 2..., \boldsymbol{k}$
2: **for** $j = 1, 2..., \boldsymbol{l}$
3: **if** $\boldsymbol{S}(i)$ is linked to $\boldsymbol{T}(j)$
4: $\boldsymbol{M}_{\boldsymbol{k}+j,i} \leftarrow \textbf{\textit{Weight}}(\boldsymbol{S}(i) \rightarrow \boldsymbol{T}(j))$
5: **for** $j_1 = 1, 2..., \boldsymbol{l}$
6: **for** $j_2 = 1, 2..., \boldsymbol{l}$
7: **if** $\boldsymbol{T}(j_1)$ is linked to $\boldsymbol{T}(j_2)$
8: $\boldsymbol{M}_{\boldsymbol{k}+j_2,\boldsymbol{k}+j_1} \rightarrow \textbf{\textit{Weight}}(\boldsymbol{T}(j_1) \rightarrow \boldsymbol{T}(j_2))$
9: **for** $i = 1, 2..., \boldsymbol{k}$
10: $\boldsymbol{V}_i^{(0)} \leftarrow \textbf{\textit{Importance}}(\boldsymbol{S}(i))$
11: **for** $j = 1, 2..., \boldsymbol{l}$
12: $\boldsymbol{V}_{\boldsymbol{k}+j}^{(0)} \leftarrow 0$
13: $\delta \leftarrow \infty$
14: $r \leftarrow 1$
15: **while** $r \leq maxIter$ && $\delta > \epsilon$ **do**
16: $\boldsymbol{V}^{(r)} \leftarrow (1-\lambda) \times \boldsymbol{M} \times \boldsymbol{V}^{(r-1)} + \lambda \times \boldsymbol{V}^{(0)}$
17: $\delta \leftarrow \|\boldsymbol{V}^{(r)} - \boldsymbol{V}^{(r-1)}\|_2$
18: $r \leftarrow r + 1$
19: **end while**
20: **for** $i = 1, 2..., \boldsymbol{k}$
21: **for** $j = 1, 2..., \boldsymbol{l}$
22: **if** $\boldsymbol{S}(i)$ is linked to $\boldsymbol{T}(j)$
23: $\textbf{\textit{LexiTable}}(\boldsymbol{S}(i), \boldsymbol{T}(j)) \leftarrow normalize(\boldsymbol{V}_{\boldsymbol{k}+j}^{(r)})$

Return: ***LexiTable***;

evidence vector, and $\boldsymbol{V}^{(r)}$ to represent the evidence vector we obtain at the rth iteration.

- **The evidence propagation matrix $\boldsymbol{M}$**: an $\boldsymbol{n} \times \boldsymbol{n}$ matrix where $\boldsymbol{M}_{ij}$ is the evidence propagation ratio from node j to node i, and its value is the weight of the edge from node j to node i.

3.2.2 Algorithm

In Algorithm 1, we jointly infer the evidence scores of all candidate translations in the following three steps.

In **Step 1**, we calculate the evidence propagation matrix $\boldsymbol{M}$ according to the method described in Section 2.2 (equations (1) and (3)) (**Lines 1-8**).

In **Step 2**, we adopt different methods to set the value of $\boldsymbol{V}^{(0)}$ according to the node type. If the node corresponds to a source word, we set the initial value using its importance score in the translation graph, as implemented in (Han et al. 2011) (**Lines 9-10**). We calculate the importance score of the source word s using *tf.idf* as follows:

$$\textbf{\textit{Importance}}(s) = \frac{tf.idf(s)}{\sum_{s' \in N_{src}} tf.idf(s')} \quad (4)$$

where N_{src} is the set of source words in the translation graph. If the node corresponds to a target translation, its initial evidence score is 0 (**Lines 11-12**).

In **Step 3**, evidences are simultaneously reinforced by propagating them among semantically related translations (**Lines 13-19**). Specific to our algorithm, we update them by propagating evidences according to different types of relations in the evidence propagation matrix $\boldsymbol{M}$. Formally, the recursive update of the evidence vector is defined as follows:

$$\boldsymbol{V}^{(r)} = \boldsymbol{M} \times \boldsymbol{V}^{(r-1)} \quad (5)$$

where r is the number of iterations.

One problem with the above equation is that some nodes in the translation graph do not have evidence outgoing edges, such as translation nodes containing only function words or the *null* node. The evidence will disappear when passing through these nodes. To solve this problem, we propagate evidence in the form of reallocation: we reallocate a fraction of evidence to the initial evidence vector $\boldsymbol{V}^{(0)}$ at each step. The new recursive update of the evidence vector is formulated as follows:

$$\boldsymbol{V}^{(r)} = (1-\lambda) \times \boldsymbol{M} \times \boldsymbol{V}^{(r-1)} + \lambda \times \boldsymbol{V}^{(0)} \quad (6)$$

where $\lambda \in (0, 1)$ is the fraction of the reallocated evidence. We keep updating the evidence vector according to this equation (**Line 16**), until the maximal number of iteration $maxIter$ is reached or the Euclidean distance (**Line 17**) between evidence vectors calculated in two consecutive iterations is less than a pre-defined threshold ϵ (**Line 15**).

In this way, we jointly infer the evidence scores of all candidate target translations in the translation graph. Table 1 gives the evidence scores of the example in Figure 2. We can find that our system enhanced with target translation dependencies is able to select correct translations.

3.2.3 Integration of Derived Evidence Score

For each translated sentence, we may build multiple translation graphs. For each translation graph,

	scores of the source words			scores of the target translations							
	wèntí	***chíyǒu***	***lìchǎng***	***problem***	***question***	***issue***	***hold***	***null***	***possess***	***stance***	***position***
$\boldsymbol{V}^{(0)}$	0.2015	0.3989	0.3996	0	0	0	0	0	0	0	0
$\boldsymbol{V}^{(\tau)}$	0.0302	0.0598	0.0599	0.0533	0.0774	**0.1071**	**0.1218**	0.0244	0.0604	0.1186	**0.1486**

Table 1: The initial and final evidence scores of some source words and their target translations in Figure 2. Here we set the reallocation weight λ as 0.15. Note that the translations "*issue*", "*hold*" and "*position*" are given high evidence scores.

we infer evidence scores of translations represented by graph nodes using the above-mentioned algorithm before decoding. Then, for each candidate translation of a source-side content word, we normalize its evidence score over the corresponding translation graph to form an additional lexical translation probability (**Lines 20-23**). For instance, the normalized evidence score of "*chíyǒu*" translated into "*hold*" is calculated as $0.1218/(0.1218+0.0244+0.0604) \approx 0.5895$. In this way, for each bilingual rule with word alignments, we will obtain a new lexical weight which can be used together with the original translation probabilities and lexical weight to improve lexical selection in SMT.

4 Experiments

4.1 Setup

Our bilingual training corpus is the combination of the FBIS corpus and Hansards part of LDC2004T07 corpus ($1M$ parallel sentences, $54.6K$ documents, with $25.2M$ Chinese words and $29M$ English words). We word-aligned them using *GIZA++* (Och and Ney, 2003) with the option "*grow-diag-final-and*". We chose the NIST evaluation set of 2005 (MT05) as the development set, and the sets of MT06/MT08 as test sets. We used *SRILM* Toolkit (Stolcke, 2002) to train one 5-gram language model on the Xinhua portion of Gigaword corpus.

To construct translation graphs, we first used the *ZPar* toolkit[3] and the Stanford toolkit[4] to preprocess (word segmentation, PoS tagging and so on) Chinese and English sentences, respectively. We used the Chinese part of our bilingual corpus and an additional Chinese LDC Xinhua news corpus ($10.2M$ sentences with $279.9M$ words) as training data to collect Chinese word pairs. We set window size d_s=15, thresholds ϵ_{pmi}=0, ϵ_{cf}=5 to identify Chinese related word pairs in the NIST translated sentences. Averagely, these three sets contain 13.5, 10.3 and 9.5 content words used to build translation graphs per sentence, respectively. Using the English part of our bilingual corpus and the Xinhua portion of Gigaword corpus as training data, we set window size d_t=20, and used the SRILM toolkit with Witten-Bell smoothing and PMI to calculate relatedness strengths for target-side translations. To avoid data sparseness, we build the graph using the surface forms of words while calculating the word relatedness at the lemma level. To achieve this, we converted each word into its corresponding lemma with the exception of adjectives and adverbs. In the procedure of collective lexical selection, the difference threshold ϵ was set as 10^{-10}, and the maximal iteration number *maxIter* 100.

We reimplemented the decoder of Hiero (Chiang, 2007), a famous hierarchical phrase-based (HPB) system. HPB system is a formally syntax-based system and delivers good performance in various translation evaluations. During decoding, we set the *ttable-limit* as 20, the *stack-size* as 100. The translation quality is evaluated by case-insensitive BLEU-4 metric (Papineni et al., 2002). To alleviate the impact of the instability of MERT (Och, 2003), we ran it three times for each experiment and reported the average BLEU scores as suggested in (Clark et al., 2011). Finally, we conducted *paired bootstrap sampling* (Koehn, 2004) to test the significance in BLEU score differences.

4.2 Our Method vs Other Methods

In the first group of experiments, we investigated the effectiveness of our model by comparing it against the baseline as well as two additional models: (1) *lexicalized rule selection model* (He et al., 2008) (**LRSM**), which employs local context to improve rule selection in the HPB system; (2) *topic similarity model* (Xiao et al., 2012)[5] (**TSM**), which explores document-level topic information for translation rule selection in the HPB system. Furthermore, we combined our model with the two models to see if we could obtain further improvements. For this, we integrated the new lexi-

[3]http://people.sutd.edu.sg/∼yue_zhang/doc/index.html

[4]http://nlp.stanford.edu/software

[5]We used 30 topics following (Xiao et al., 2012).

System	MT06	MT08	Avg
Baseline	30.25	21.25	25.75
LRSM	31.12	21.98	26.55
TSM	30.79	21.90	26.35
GM(LM)	30.64	21.78	26.21
GM(PMI)	31.02	21.77	26.40
LRSM +GM(PMI)	31.66	22.23	26.95
TSM +GM(PMI)	31.34	22.26	26.80

Table 2: Experiment results on the test sets with λ=0.15. **Avg** = average BLEU scores, **GM(LM)** and **GM(PMI)** denote our model using the measure based on language model and PMI, respectively.

cal weight learned by our model as a new feature into the **LRSM/TSM** system.

Table 2 reports the results. All models outperform the baseline. Especially, our graph-based lexical selection model GM(PMI) achieves an average BLEU score of **26.40** on the two test sets, which is higher than that of the baseline by **0.65** BLEU points. This improvement is statistically significant at $p<0.01$. The BLEU score of our model is close to those of LRSM and TSM, which achieve an average BLEU score of 26.55 and 26.35 on the two test sets, respectively. As PMI is slightly better than LM in our model, we use PMI in experiments hereafter.

The combination of our model and LRSM is able to further improve translation quality in terms of BLEU. In this case, the average BLEU score of the improved system is 26.95, with 0.4 BLEU points higher than LRSM. When combining our model with TSM, we obtain an average BLEU score of 26.80, which is better than TSM by 0.45 BLEU points. The two improvements over LRSM and TSM are also statistically significant at $p<0.05$. These experiment results suggest that exploring long-distance dependencies among target translations is complementary to the previous lexical selection methods which focus on source-side context information.

In order to know how our approach improves the performance of the HPB system, we compared the best translations of the HPB system using different models. We find that our approach really improves translation quality by utilizing target-side long-distance dependencies which are, on the contrary, ignored in previous methods.

For example, the source sentence "... 穆沙拉夫 去年 9月 和 [巴] 北方 地区... 塔利班 残余 势力..." is translated as follows:

- **Ref**: ... *musharraf and some tribal leaders in the northern region of [pakistan] last september ... the remnant forces of the taliban ...*
- **Baseline**: ... *musharraf last september and [palestine] north of tribal leaders ... the remnants of the taliban ...*
- **LRSM**: ... *musharraf last september and some tribal chiefs of the northern region of [palestine] ... the remnants of the taliban ...*
- **LRSM+GM(PMI)**: ... *last september musharraf and some tribal chiefs of the northern region of [pakistan] ... the remnants of the taliban ...*

Here both the baseline and LRSM fail to obtain the right translation for the word "巴" because "*palestine*" has a higher probability than "*pakistan*" (0.0374 vs 0.0285). However, in our model, the long-distance dependencies between (*"musharraf", "pakistan"*) and (*"taliban", "pakistan"*) help the decoder correctly choose the translation "*pakistan*" for "巴".

In yet another example, the source sentence "美 希望 朝 核 问题 [协议] 得到 全面 执行" is translated as follows:

- **Ref**: *us hopes agreement on north korean nuclear issue be fully implemented*
- **Baseline**: *us hoped that the dprk nuclear issue is the full implementation*
- **TSM**: *us hope that the full implementation of the nuclear issue*
- **TSM+GM(PMI)**: *us hope that the dprk nuclear issue [agreement] to be fully implemented*

Even with TSM, the HPB system did not translate "协议" at all because translation rules "X_1 协议 得到 ||| X_1 is" and "X_1 协议 X_2 执行 ||| X_2 implementation of X_1" are used to translate the source sentence by the baseline and TSM systems respectively. However, in the combined model TSM+GM(PMI), the differences in relatedness scores between (*"nuclear", "agreement"*), (*"issue", "agreement"*) and (*"agreement", "implemented"*) encourage the enhanced system to select right translation for this word.

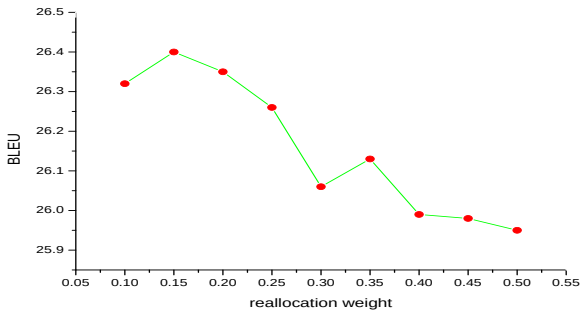

Figure 3: Experiment results on the test sets using different reallocation weights.

4.3 Effect of Reallocation Weight λ.

In Eq. (6), the reallocation weight λ determines which part plays a more important role in our method. In order to investigate the effect of λ on our method, we tried different values for λ: from 0.1 to 0.5 with an increment of 0.05 each time. The experimental setup is the same as the previous experiments. Figure 3 shows the average BLEU scores on the two test sets. Our system performs well when λ ranges from 0.1 to 0.25. The performance drops when λ is larger than 0.25. A small reallocation weight λ reduces the impact of initial evidences and local source-side associations in the collective lexical selection algorithm, but increases the impact of global dependencies of target-side translation, which are normally not considered in previous lexical selection methods. This performance curve on the values of λ suggests that target-side global dependencies are important for lexical selection.

5 Related Work

The collective inference algorithm is partially inspired by Han et al. (2011) who propose a graph-based collective entity linking (EL) method to model global interdependences among different EL decisions. We successfully adapt this algorithm to lexical selection in SMT. Other related work mainly includes the following two strands.

(1) Lexical selection in SMT. In order to capture source-side context for lexical selection, some researchers propose *trigger-based lexicon models* to capture long-distance dependencies (Hasan et al., 2008; Mauser et al., 2009), and many more researchers build classifiers with rich context information to select desirable translations during decoding (Chan et al., 2007; Carpuat and Wu, 2007; He et al., 2008; Liu et al., 2008). Shen et al. (2009) introduce four new linguistic and contextual features for HPB system. We have also witnessed increasing efforts in the exploitation of document-level context information. Xiao et al. (2011) impose a hard constraint to guarantee the translation consistency in document-level translation. Ture et al. (2012) soften this consistency constraint by integrating three counting features into decoder. Hardmeier et al. (2012, 2013) introduce a document-wide phrase-based decoder and integrate a semantic language model that cross sentence boundaries into the decoder. Based on topic models, Xiao et al. (2012) present a topic similarity model for HPB system, where each rule is assigned with a topic distribution. Also relevant is the work of Xiong et al. (2013), who use three different models to capture lexical cohesion for document-level machine translation. Compared with the above-mentioned studies, our method focuses on the exploitation of global dependencies among target translations, which has attracted little attention before.

Different from exploring source-side context, other researchers pay attention to the utilization of target-side context information. The common practice in SMT is to use an n-gram language model to capture local dependencies between translations (Koehn et al., 2003; Xiong et al., 2011). Yet another approach exploring target-side context information is proposed by Shen et al. (2008), who use a dependency language model to capture long-distance relations on the target side. Moreover, Zhang et al. (2014) treat translation as an unconstrained target sentence generation task, using soft features to capture lexical and syntactic correspondences between the source and target language. Recently, many researcher have proposed to use deep neural networks to model long-distance dependencies of arbitrary length for SMT (Auli et al., 2013; Kalchbrenner and Blunsom, 2013; Devlin et al., 2014; Hu et al., 2014; Liu et al., 2014; Sundermeyer et al., 2014). Our work is significantly different from these methods. We use a graph representation to capture local and global context information, which, to the best of our knowledge, is the first attempt to explore graph-based representations for lexical selection. Furthermore, our model do not resort to any syntactic resources such as dependency parsers of the target language.

(2) Random walk for SMT. Because of the advantage of global consistency, random walk al-

gorithm has been applied in SMT. For example, Cui et al. (2013) develop an effective approach to optimize phrase scoring and corpus weighting jointly using graph-based random walk. Zhu et al. (2013) apply a random walk method to discover implicit relations between the phrases of different languages. Aiming to better evaluate translation quality at the document level, Gong and Li (2013) run PageRank algorithm to assign weights to words in translation evaluation. Different from these studies, the key interest of our research lies in the lexical selection with random walk.

6 Conclusion and Future Work

This paper has presented a novel graph-based collective lexical selection method for SMT. We build translation graphs to capture local source-side associations and global target-side dependencies, and propose a purely collective inference algorithm to jointly identify target translations of source-side content words in translation graphs. Our method capitalizes on capabilities of translation graphs to represent both local and global relations on the source/target side. Experiment results demonstrate the effectiveness of our method.

In the future, we plan to further improve our model by capturing semantic relatedness among source words. Additionally, we also want to jointly model different levels of context information in a unified framework for SMT.

Abstract

Learning semantic representations and tree structures of bilingual phrases is beneficial for statistical machine translation. In this paper, we propose a new neural network model called Bilingual Correspondence Recursive Autoencoder (BCorrRAE) to model bilingual phrases in translation. We incorporate word alignments into BCorrRAE to allow it freely access bilingual constraints at different levels. BCorrRAE minimizes a joint objective on the combination of a recursive autoencoder reconstruction error, a structural alignment consistency error and a cross-lingual reconstruction error so as to not only generate alignment-consistent phrase structures, but also capture different levels of semantic relations within bilingual phrases. In order to examine the effectiveness of BCorrRAE, we incorporate both semantic and structural similarity features built on bilingual phrase representations and tree structures learned by BCorrRAE into a state-of-the-art SMT system. Experiments on NIST Chinese-English test sets show that our model achieves a substantial improvement of up to 1.55 BLEU points over the baseline.

1 Introduction

Recently a variety of "deep architecture" approaches, including autoencoders, have been successfully used in statistical machine translation (SMT) (Yang et al., 2013; Liu et al., 2013; Zou et al., 2013; Devlin et al., 2014; Tamura et al., 2014; Sundermeyer et al., 2014; Wang et al., 2014; Kočiský et al., 2014). Typically, these approaches represent words as dense, low-dimensional and real-valued vectors, i.e., word embeddings. However, translation units in machine translation have long since shifted from words to phrases (sequence of words), of which syntactic and semantic information cannot be adequately captured and represented by word embeddings. Therefore, learning compact vector representations for phrases or even longer expressions is more crucial for successful "deep" SMT.

To address this issue, many efforts have been initiated on learning representations for bilingual phrases in the context of SMT, inspired by the success of work on monolingual phrase embeddings (Socher et al., 2010; Socher et al., 2011a; Socher et al., 2013b; Chen and Manning, 2014; Kalchbrenner et al., 2014; Kim, 2014). The learning process of bilingual phrase embeddings in these efforts is normally interacted and mingled with single or multiple essential components of SMT, e.g., with reordering models (Li et al., 2013), translation models (Cui et al., 2014; Zhang et al., 2014; Gao et al., 2014), or both language and translation models (Liu et al., 2014). In spite of their success, these approaches center around capturing relations between entire source and target phrases. They do not take into account internal phrase structures and bilingual correspondences of sub-phrases within source and target phrases. The neglect of these important clues may be due to the big challenge imposed by the integration of them into the learning process of bilingual phrase representations. However, we believe such internal structures and correspondences can help us learn better phrase representations since they provide multi-level syntactic and semantic constraints.

In this paper, we propose a Bilingual Correspondence Recursive Autoencoder (BCorrRAE) to learn bilingual phrase embeddings. BCorrRAE substantially extends the Bilingually-constrained Recursive Auto-encoder (BRAE) (Zhang et al., 2014) to exploit both inner structures and corre-

(a) BRAE

(b) BCorrRAE

Figure 1: BRAE vs BCorrRAE models for generating of a bilingual phrase ("今天 所 通过 决议", "*resolution adopted today*") with word alignments ("0-2 2-1 3-0"). The subscript number of each word indicates its position within phrase. Solid lines depict the generation procedure of phrase structures, while dash lines illustrate the reconstruction procedure from one language to the other. In this paper, the dimensionality of vector d in all figures is set to 3 for better illustration.

spondences within bilingual phrases. The intuitions behind BCorrRAE are twofold: 1) bilingual phrase structure generation should satisfy word alignment constraints as much as possible; and 2) corresponding sub-phrases on the source and target side of bilingual phrases should be able to reconstruct each other as they are semantic equivalents. In order to model the first intuition, BCorrRAE punishes bilingual structures that violate word alignment constraints and rewards those in consistent with word alignments. This enables BCorrRAE to produce desirable bilingual phrase structures from the perspective of word alignments. With regard to the second intuition, BCorrRAE reconstructs structures of sub-phrases of one language according to aligned nodes in the other language and minimizes the gap between original and reconstructed structures. In doing so, BCorrRAE is capable of capturing semantic relations at different levels.

To better illustrate our model, let us consider the example in Figure 1. Similar to the conventional recursive antoencoder (RAE), BRAE neglects bilingual correspondences of sub-phrases. Thus, it may combine "*adopted*" and "*today*" together to generate an undesirable target tree structure which violates word alignments. In contrast, BCorrRAE aligns source-side nodes (e.g. ("通过", "决 议")) to their corresponding target-side nodes (accordingly ("*resolution*", "*adopted*")) according to word alignments. Furthermore, in BCorrRAE, each subtree on the target side can be reconstructed from the corresponding source node that aligns to the target-side node dominating the subtree and vice versa. These advantages allow us to obtain improved bilingual phrase embeddings with better inner correspondences of sub-phrases and word alignment consistency.

We conduct experiments with a state-of-the-art SMT system on large-scale data to evaluate the effectiveness of BCorrRAE model. Results on the NIST 2006 and 2008 datasets show that our system achieves significant improvements over baseline methods. The main contributions of our work lie in the following three aspects:

- We learn both embeddings and tree structures for bilingual phrases using cross-lingual RAE reconstruction that minimizes semantic distances between original and reconstructed subtrees. To the best of our knowledge, this has not been investigated before.
- We incorporate word alignment information to guide phrase structure generation and establish internal semantic associations of sub-phrases within bilingual phrases.
- We integrate two similarity features based on BCorrRAE to enhance translation candidate selection, and achieve an improvement of 1.55 BLEU points on Chinese-English translation.

2 RAE and BRAE

In this section, we briefly introduce the RAE and its bilingual variation BRAE. This will provide background knowledge on our proposed BCorrRAE.

2.1 RAE

The component in the dash box of Figure 2 illustrates an instance of an RAE applied to a three-word phrase. The input to the RAE is $x = (x_1, x_2, x_3)$, which are the d-dimensional vector representations of the ordered words in a phrase. For two children $c_1 = x_1$ and $c_2 = x_2$, the parent vector y_1 can be computed in the following way:

$$p = f(W^{(1)}[c_1; c_2] + b^{(1)}) \quad (1)$$

where $[c_1; c_2] \in \mathbb{R}^{2d \times 1}$ is the concatenation of c_1 and c_2, $W^{(1)} \in \mathbb{R}^{d \times 2d}$ is a parameter matrix, $b^{(1)} \in \mathbb{R}^{d \times 1}$ is a bias term, and f is an element-

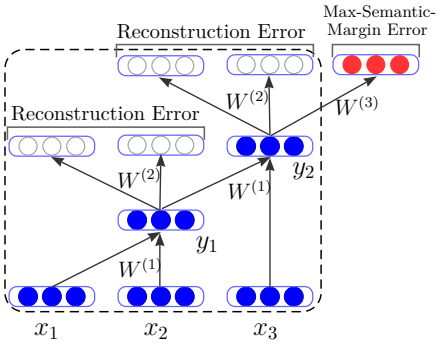

Figure 2: An illustration of the BRAE architecture.

wise activation function such as $tanh(\cdot)$, which is used for all activation functions in BRAE and our model. The learned parent vector p is also a d-dimensional vector. In order to measure how well p represents its children, we reconstruct the original children nodes in a reconstruction layer:

$$[c_1'; c_2'] = f(W^{(2)}p + b^{(2)}) \quad (2)$$

where c_1' and c_2' are reconstructed children vectors, $W^{(2)} \in \mathbb{R}^{2d \times d}$ and $b^{(2)} \in \mathbb{R}^{2d \times 1}$.

We can set $y_1 = p$ and then further use Eq. (1) again to compute y_2 by setting $[c_1; c_2] = [y_1; x_3]$. This combination and reconstruction process of auto-encoder repeats at each node until the vector of the entire phrase is generated. To obtain the optimal binary tree and phrase representation for x, we employ a greedy algorithm (Socher et al., 2011c) to minimize the sum of *reconstruction error* at each node in the binary tree $T(x)$:

$$E_{rec}(x;\theta) = \sum_{n \in T(x)} \frac{1}{2} \parallel [c_1; c_2]_n - [c_1'; c_2']_n \parallel^2 \quad (3)$$

where θ denotes model parameters and n represents a node in $T(x)$.

2.2 BRAE

BRAE jointly learns two RAEs for source and target phrase embeddings as shown in Figure 1(a). The core idea behind BRAE is that a source phrase and its target correct translation should share the same semantic representations, while non-equivalent pairs should have different semantic representations. Zhang et al. (2014) use this intuition to constrain semantic pharse embedding learning.

As shown in Figure 2, in addition to the above-mentioned reconstruction error, BRAE introduces a *max-semantic-margin error* to minimize the semantic distance between translation equivalents and maximize the semantic distance between non-equivalent pairs simultaneously. Formally, the max-semantic-margin error of a bilingual phrase (f, e) is defined as

$$E_{sem}(f, e; \theta) = E^*_{sem}(f|e, \theta) + E^*_{sem}(e|f, \theta) \quad (4)$$

where $E^*_{sem}(f|e, \theta)$ is used to ensure that the semantic error for an equivalent pair is much smaller than that for a non-equivalent pair (the source phrase f and a bad translation e'):

$$E^*_{sem}(f|e, \theta) = max\{0, \; E_{sem}(f|e, \theta) - E_{sem}(f|e', \theta) + 1\} \quad (5)$$

where $E_{sem}(f|e, \theta)$ is defined as the semantic distance between the learned vector representations of f and e, denoted by p_f and p_e, respectively. Since phrase embeddings for the source and target language are learned separately in different vector spaces, a transformation matrix $W^{(3)}_f \in \mathbb{R}^{d \times d}$ is introduced to capture this semantic transformation in the source-to-target direction. Thus, $E_{sem}(f|e, \theta)$ is calculated as

$$E_{sem}(f|e, \theta) = \frac{1}{2} \parallel p_e - f(W^{(3)}_f p_f + b^{(3)}_f) \parallel^2 \quad (6)$$

where $b^{(3)}_f \in \mathbb{R}^{d \times 1}$ is a bias term. $E^*_{sem}(e|f, \theta)$ and $E_{sem}(e|f, \theta)$ can be computed in a similar way. The joint error of (f, e) is therefore defined as follows:

$$E(f, e; \theta) = \alpha(E_{rec}(f, \theta) + E_{rec}(e, \theta)) + (1 - \alpha)(E^*_{sem}(f|e, \theta) + E^*_{sem}(e|f, \theta)) \quad (7)$$

The final BRAE objective function over the training instance set $\mathcal{D}$ becomes:

$$J_{BRAE} = \sum_{(f,e) \in D} E(f, e; \theta) + \frac{\lambda}{2} \|\theta\|^2 \quad (8)$$

Model parameters can be optimized over the total errors on training bilingual phrases in a co-training style algorithm (Zhang et al., 2014).

3 The BCorrRAE Model

As depicted above, the learned embeddings using BRAE may be unreasonable due to the neglect of bilingual constraints at different levels. To address this drawback, we propose the BCorrRAE for bilingual phrase embeddings, which incorporates bilingual correspondence information into the learning process of structures and embeddings via word alignments. In our model, we explore word alignments in two ways: (1) ensuring that a learned bilingual phrase structure is consistent with word alignments as much as possi-

ble; (2) identifying corresponding sub-phrases in the source language for reconstructing sub-phrases in the target language, and vice versa. More specifically, the former is to encourage alignment-consistent generation of sub-structures, while the latter is to minimize semantic distances between bilingual sub-phrases.

In this section, we first formally introduce a concept of structural alignment consistency encoded in bilingual phrase structure learning, which is the basis of our model. Then, we describe the objective function which is composed of three types of errors. Finally, we provide details on the training of our model.

3.1 Structural Alignment Consistency

We adapt word alignment to structural alignment and introduce some related concepts. Given a bilingual phrase (f, e) with its binary tree structures (T_f, T_e), if the source node $n_{\bar{f}} \in T_f$ covers a source-side sub-phrase $\bar{f}$, and there exists a target-side sub-phrase $\bar{e}$ such that $(\bar{f}, \bar{e})$ are consistent with word alignments (Och and Ney, 2003), we say $n_{\bar{f}}$ satisfies the *structural alignment consistency*, and it is referred to as a *structural-alignment-consistent* (SAC) *node*. Further, if $\bar{e}$ is covered by a target node $n_{\bar{e}} \in T_e$, we say $n_{\bar{e}}$ is the *aligned node* of $n_{\bar{f}}$. In this way, several different target nodes may be all aligned to the same source node because of null alignments. For this, we choose the target node with the smallest span as the aligned one for the considered source node. This is because a smaller span reflects a stronger semantic relevance in most situations.

Likewise, we have similar definitions for target nodes. Note that alignment relations between source- and target-side nodes may not be symmetric. For example, in Figure 1(b), node $n_{\bar{e}}$ is the aligned node of node $n_{\bar{f}_1}$, while node $n_{\bar{f}_2}$ rather than $n_{\bar{f}_1}$ is the aligned node of $n_{\bar{e}}$.

3.2 The Objective Function

We elaborate the three types of errors defined for a bilingual phrase (f, e) with its binary tree structures (T_f, T_e) on both sides below.

3.2.1 Reconstruction Error

Similar to RAE, the first error function is used to estimate how well learned phrase embeddings represent corresponding phrases. The *reconstruction error* $E_{rec}(f, e; \theta)$ of (f, e) is defined as follows:

$$E_{rec}(f, e; \theta) = E_{rec}(f; \theta) + E_{rec}(e; \theta) \quad (9)$$

where both $E_{rec}(f; \theta)$ and $E_{rec}(e; \theta)$ can be calculated according to Eq. (3).

3.2.2 Consistency Error

This metric corresponds to the first way in which we exploit word alignments mentioned before, which enables our model to generate as many SAC nodes as possible to respect word alignments.

Formally, the *consistency error* $E_{con}(f, e; \theta)$ of (f, e) is defined in the following way:

$$E_{con}(f, e; \theta) = E_{con}(T_f; \theta) + E_{con}(T_e; \theta) \quad (10)$$

where $E_{con}(T_f; \theta)$ and $E_{con}(T_e; \theta)$ denote the consistency error score for T_f and T_e, given word alignments. Here we only describe the calculation of the former while the latter can be calculated in exactly the same way.

To calculate $E_{con}(T_f; \theta)$, we first judge whether a source node $n_{\bar{f}}$ is an SAC node according to word alignments. Let $p_{n_{\bar{f}}}$ be the vector representation of $n_{\bar{f}}$. Following Socher et al. (2010), who use a simple inner product to measure how well the two words are combined into a phrase, we use inner product to calculate the consistency/inconsistency score for $n_{\bar{f}}$:

$$s(n_{\bar{f}}) = W^{score} p_{n_{\bar{f}}} \quad (11)$$

where $W^{score} \in \mathbb{R}^{1 \times d}$ is the score parameter. We calculate W^{score} by distinguishing SAC from non-SAC nodes defined as follows:

$$W^{score} = \begin{cases} W^{score}_{cns} & \text{if } n_{\bar{f}} \text{ is an SAC node} \\ W^{score}_{inc} & \text{otherwise} \end{cases}$$

where the subscript *cns* and *inc* represent consistency and inconsistency, respectively. For example, in Figure 3, as $n_{\bar{f}_3}$ is a non-SAC node, we calculate the inconsistency score using W^{score}_{inc} for it.

We expect T_f to satisfy structural alignment consistency as much as possible. Therefore we encourage the consistency score for T_f to be larger than its inconsistency score using a max-margin consistency error function:

$$\begin{aligned} E_{con}(T_f; \theta) = & max\{0, 1 - s(T_f)_{cns} \\ & + s(T_f)_{ins}\} \end{aligned} \quad (12)$$

where $s(T_f)_{cns}$ denotes the sum of consistency scores over all SAC nodes and $s(T_f)_{ins}$ the sum of inconsistency scores over all non-SAC nodes in T_f. Minimizing this error function will maximize the sum of consistency scores of SAC nodes and minimize (up to a margin) the sum of inconsis-

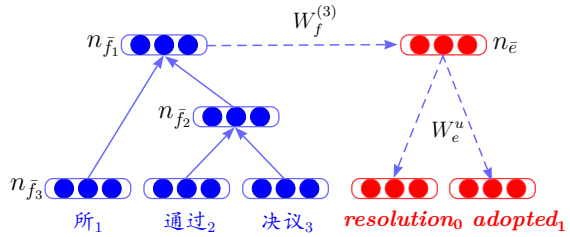

Figure 3: The structure generation procedure of the source sub-phrase "所 通过 决议" and the structure reconstruction procedure of the target sub-phrase "*resolution adopted*". According to word alignments ("2-1 3-0"), the node $n_{\bar{f}_1}$ and $n_{\bar{f}_2}$ are SAC ones while the node $n_{\bar{f}_3}$ is a non-SAC node.

tency scores of non-SAC nodes.

3.2.3 Cross-Lingual Reconstruction Error

This metric corresponds to the second way in which we exploit word alignments. The assumption behind this is that a source/target node should be able to reconstruct the entire subtree rooted at its target/source aligned node as they are semantically equivalent. Based on this, for the considered node, we calculate the cross-lingual reconstruction error along the entire subtree rooted at its aligned node in the other language and use the error to measure how well the learned vector represents this node.

Similarly, the *cross-lingual reconstruction error* $E_{clrec}(f, e; \theta)$ of (f, e) can be decomposed into two parts as follows:

$$E_{clrec}(f, e; \theta) = E_{f2e\cdot rec}(T_f, T_e; \theta) + E_{e2f\cdot rec}(T_f, T_e; \theta) \quad (13)$$

where $E_{f2e\cdot rec}(T_f, T_e; \theta)$ denotes the error score using T_f to reconstruct T_e. Note that in this process, the structure and the original node vector representations of T_e have been already generated. $E_{e2f\cdot rec}(T_f, T_e; \theta)$ denotes the reconstruction error score using T_e to reconstruct T_f. Here we still only describe the method of computing the former, which also applies to the latter.

To calculate $E_{f2e\cdot rec}(T_f, T_e; \theta)$, we first collect all source nodes $(n_{\bar{f}})$ in T_f and their aligned nodes $(n_{\bar{e}})$ in T_e to form a set of aligned node pairs $S = \{\langle n_{\bar{f}}, n_{\bar{e}}\rangle\}$ according to word alignments. We then calculate $E_{f2e\cdot rec}(T_f, T_e; \theta)$ as the sum of error scores over all node pairs in S. Given a source node $n_{\bar{f}}$ with its aligned node $n_{\bar{e}}$ on the target side, we use $n_{\bar{f}}$ to reconstruct the sub-tree structure $T_{\bar{e}}$ rooted at $n_{\bar{e}}$ and compute the error score based on the semantic distance between the original and reconstructed vector representations of nodes in $T_{\bar{e}}$. As source and target phrase embeddings are separately learned, we first introduce a transformation matrix $W_f^{(3)}$ and a bias term $b_f^{(3)}$ to transform source phrase embeddings into the target-side semantic space, following Zhang et al. (2014) and Hermann and Blunsom (2014):

$$p'_{n_{\bar{e}}} = f(W_f^{(3)} p_{n_{\bar{f}}} + b_f^{(3)}) \quad (14)$$

here $p'_{n_{\bar{e}}}$ denotes the reconstructed vector representation of $n_{\bar{e}}$, which is transformed from the vector representation $p_{n_{\bar{f}}}$ of $n_{\bar{f}}$. Then, we repeat the reconstruction procedure in a top-down manner along the corresponding target tree structure until leaf nodes are reached, following Socher et al. (2011a). Specifically, given the vector representation $p'_{n_{\bar{e}}}$, we reconstruct vector representations of its two children nodes:

$$[c_{e1}^u; c_{e2}^u] = f(W_e^u p'_{n_{\bar{e}}} + b_e^u) \quad (15)$$

where c_{e1}^u and c_{e2}^u are the reconstructed vector representations of the children nodes, $W_e^u \in \mathbb{R}^{2d\times d}$, and $b_e^u \in \mathbb{R}^{2d\times 1}$. Eventually, given the original and reconstructed target phrase representations, we calculate $E_{f2e\cdot rec}(T_f, T_e; \theta)$ as follows:

$$E_{f2e\cdot rec}(T_f, T_e; \theta) = \frac{1}{2} \sum_{\langle n_{\bar{f}}, n_{\bar{e}}\rangle \in \mathcal{S}} \sum_{n \in T_{\bar{e}}} \| p_n - p'_n \|^2 \quad (16)$$

where p_n and p'_n are the original and reconstructed vector representations of node n in the sub-tree structure $T_{\bar{e}}$ rooted at $n_{\bar{e}}$. This error function will be minimized so that semantic differences between original and reconstructed structures are minimal.

Figure 3 demonstrates the structure reconstruction from a generated source sub-tree to its target counterpart. In this way, BCorrRAE propagates semantic information along dash lines sequentially until leaf nodes in the generated structure of the target phrase.

3.2.4 The Final Objective

Similar to Eq. (8), we define the final objective function of our model based on the three types of errors described above

$$J_{BCorrRAE} = \sum_{(f,e)\in\mathcal{D}} \{\alpha (E_{rec}(f;\theta) + E_{rec}(e;\theta)) + \beta (E_{con}(T_f;\theta) + E_{con}(T_e;\theta)) + \gamma (E_{f2e\cdot rec}(T_f, T_e;\theta) + E_{e2f\cdot rec}(T_f, T_e;\theta))\} + R(\theta) \quad (17)$$

where weights α, β, γ (s.t. $\alpha+\beta+\gamma=1$) are used to balance the preference among the three errors, and $R(\theta)$ is the regularization term. Parameters θ are divided into four sets[1]:

1. θ_L: the word embedding matrix;
2. θ_{rec}: the RAE parameter matrices $W^{(1)}$, $W^{(2)}$ and bias terms $b^{(1)}$, $b^{(2)}$ (Section 2.1);
3. θ_{con}: the consistency/inconsistency score parameter matrices W_{cns}^{score}, W_{inc}^{score} (Section 3.2.2);
4. θ_{clrec}: the cross-lingual RAE semantic transformation parameter matrices $W^{(3)}$, W^{u} and bias terms $b^{(3)}$, b^{u} (Section 3.2.3).

For regularization, we assign each parameter set a unique weight:

$$\begin{aligned} R(\theta) = &\frac{\lambda_L}{2}\|\theta_L\|^2 + \frac{\lambda_{rec}}{2}\|\theta_{rec}\|^2 \\ &+ \frac{\lambda_{con}}{2}\|\theta_{con}\|^2 + \frac{\lambda_{lcrec}}{2}\|\theta_{lcrec}\|^2 \end{aligned} \tag{18}$$

Additionally, in order to prevent the hidden layer from being very small, we normalize all output vectors of the hidden layer to have length 1, $p = \frac{p}{\|p\|}$, following Socher et al. (2011c).

3.3 Model Training

Similar to Zhang et al. (2014), we adopt a co-training style algorithm to train model parameters in the following two steps:

First, we use a normal distribution ($\mu = 0, \sigma = 0.01$) to randomly initialize all model parameters, and adopt the standard RAE to pre-train source- and target-side phrase embeddings and tree structures (Section 2.1).

Second, for each bilingual phrase, we update its source-side parameters to obtain the fine-tuned vector representation and binary tree of the source phrase, given the target-side phrase structure and node representations, and vice versa. In this process, we apply L-BFGS to tune parameters based on gradients over the joint error, as implemented in (Socher et al., 2011c).

We repeat the procedure of the second step until either the joint error (shown in Eq. (17)) reaches a local minima or the number of iterations is larger than a pre-defined number (25 is used in experiments).

[1]Note that the source and target languages have different four sets of parameters.

4 Decoding with BCorrRAE

Once the model training is completed, we incorporate two different phrasal similarity features built on the trained BCorrRAE into the standard log-linear framework of SMT. Given a bilingual phrase (f, e), we first obtain their semantic phrase representations (p_f, p_e). Then we transform p_f into p'_e in the target semantic space and p_e into p'_f in the source semantic space via transformation matrixes. Finally, we reconstruct sub-trees of p'_f along the source structure T_f learned by BCorrRAE, sub-trees of p'_e along the target structure T_e.

We exploit two kinds of phrasal similarity features based on the learned phrase representations and their tree structures as follows:

- *Semantic Similarity* measures the similarity between original and transformed phrase representations of (f, e):

$$\begin{aligned} Sim_{SM}(p_f, p'_f) &= \frac{1}{2}\|p_f - p'_f\|^2 \\ Sim_{SM}(p_e, p'_e) &= \frac{1}{2}\|p_e - p'_e\|^2 \end{aligned} \tag{19}$$

- *Structural Similarity* calculates the similarity between original and reconstructed tree structures learned by BCorrRAE for (f, e):

$$\begin{aligned} Sim_{ST}(p_f, p'_f) &= \frac{1}{2C_f}\sum_{n\in T_f}\|p_n - p'_n\|^2 \\ Sim_{ST}(p_e, p'_e) &= \frac{1}{2C_e}\sum_{n\in T_e}\|p_n - p'_n\|^2 \end{aligned} \tag{20}$$

where p_n and p'_n represent vector representations of original and reconstructed node n, and C_f and C_e count the number of nodes in the source and target tree structure respectively. Note that if we only compute the similarity for root nodes in the bilingual tree of (f, e), the structural similarity equals to the semantic similarity in Eq. (19).

5 Experiments

We conducted experiments on NIST Chinese-English translation task to validate the effectiveness of BCorrRAE.

5.1 System Overview

Our baseline decoder is a state-of-the-art phrase-based translation system equipped with a maximum entropy based reordering model (MEBTG). It adopts three bracketing transduction grammar rules (Wu, 1997; Xiong et al., 2006): merging

rules $A \rightarrow [A_1, A_2]|\langle A_1, A_2\rangle$ which are used to merge two neighboring blocks[2] A_1 and A_2 in a straight|inverted order, and lexical rule $A \rightarrow f/e$ used to translate a source phrase f into a target phrase e.

The MEBTG system features a maximal entropy classifier based reordering model that predicts orientations of neighboring blocks. During training, we extract bilingual phrases containing up to 7 words on the source side from the training corpus. With the collected reordering examples, we adopt the maximal entropy toolkit[3] developed by Zhang to train the reordering model with the following parameters: iteration number $iter$=200 and gaussian prior g=1.0. Following Xiong et al. (2006), we use only boundary words of blocks to trigger the reordering model.

The whole translation model is organized in a log-linear framework (Och and Ney, 2002). The adopted sub-models mainly include: (1) rule translation probabilities in two directions, (2) lexical weights in two directions, (3) targets-side word number, (4) phrase number, (5) language model score, and (6) the score of maximal entropy based reordering model. We perform *minimum error rate training* (Och, 2003) to tune various feature weights. During decoding, we set $ttable\text{-}limit$=20 for translation candidates kept for each source phrase, $stack\text{-}size$=100 for hypotheses in each span, and $swap\text{-}span$=15 for the length of the maximal reordering span.

5.2 Setup

Our bilingual data is the combination of the FBIS corpus and Hansards part of LDC2004T07 corpus, which contains 1.0M parallel sentences (25.2M Chinese words and 29M English words). Following Zhang et al. (2014), we collected 1.44M bilingual phrases using forced decoding (Wuebker et al., 2010) to train BCorrRAE from the training data. We used a 5-gram language model trained on the Xinhua portion of Gigaword corpus using *SRILM* Toolkits[4]. Translation quality is evaluated by case-insensitive BLEU-4 metric (Papineni et al., 2002). We performed paired bootstrap sampling (Koehn, 2004) to test the significance in BLEU score differences. In our experiments, we used NIST MT05 and MT06/MT08 data set as the development and test set, respectively.

Parameter	BRAE	BCorrRAE
α	0.119	0.121
β	-	0.6331
γ	-	0.2459
λ_L	4.95 $\times 10^{-5}$	3.13 $\times 10^{-5}$
λ_{rec}	2.64 $\times 10^{-7}$	2.05 $\times 10^{-5}$
λ_{con}	-	7.32 $\times 10^{-6}$
λ_{lcrec}	9.31 $\times 10^{-5}$	5.25 $\times 10^{-6}$

Table 1: Hyper-parameters for BCorrRAE and BRAE model.

Method	d	MT06	MT08	AVG
$\mathbf{BCorrRAE}_{SM}$	25	30.81	$22.68^{\Downarrow}$	26.75
	50	$30.58^{\downarrow}$	$22.72^{\Downarrow}$	26.65
	75	30.50	$22.53^{\Downarrow}$	26.52
	100	$30.34^{\Downarrow}$	$22.61^{\Downarrow}$	26.48
$\mathbf{BCorrRAE}_{ST}$	25	30.56	23.28	26.92
	50	30.94	23.33	27.14
	75	30.73	23.40	27.07
	100	30.90	23.50	27.20

Table 2: Experiment results for different dimensions (d). BCorrRAE_{SM} and BCorrRAE_{ST} are our systems that are enhanced with the semantic and structural similarity features learned by BCorrRAE, respectively. $\downarrow/\Downarrow$: significantly worse than the BCorrRAE_{ST} with the same dimensionality ($p < 0.05/p < 0.01$).

In addition to the baseline described below, we also compare our method against the BRAE model, which focuses on modeling relations of source and target phrases as a whole unit. Word embeddings in BRAE are pre-trained with toolkit *Word2Vec*[5] (Mikolov et al., 2013) on large-scale monolingual data that contains 0.83B words for Chinese and 0.11B words for English.

Hyper-parameters in all neural models are optimized by *random search* (Bergstra and Bengio, 2012) based on related joint errors. We randomly extracted $250,000$ bilingual phrases from the above-mentioned training data as training set, $5,000$ as development set and another $5,000$ as test set. We drew α, β, γ uniformly from 0.10 to 0.50, and $\lambda_L, \lambda_{rec}, \lambda_{con}$ and λ_{lcrec} exponentially from 10^{-8} to 10^{-2}. Final parameters are shown in Table 1 for both BRAE and BCorrRAE.

5.3 Dimensionality of Embeddings

To investigate the impact of embedding dimensionality on our BCorrRAE, we tried four different dimensions from 25 to 100 with an increment of 25 each time. The results are displayed in Table 2. We can observe that the performance of our model is not consistently improved with the increment of dimensionality. This may be because a

[2]A block is a bilingual phrase without maximum length limitation.

[3]http://homepages.inf.ed.ac.uk/lzhang10/maxent_toolkit.html

[4]http://www.speech.sri.com/projects/srilm/download.html

[5]https://code.google.com/p/word2vec/

larger dimension brings in much more parameters, and therefore makes parameter tuning more difficult. In practice, setting the dimension d to 50, we can get satisfactory results without much computation effort, which has also been found by Zhang et al. (2014).

5.4 Structural Similarity vs. Semantic Similarity

Table 2 also shows that the performance of BCorrRAE$_{ST}$, the system with the structural similarity feature in Eq. (20), is always superior to that of BCorrRAE$_{SM}$ with the semantic similarity feature in Eq. (19). BCorrRAE$_{ST}$ is better than BCorrRAE$_{SM}$ by 0.483 BLEU points on average. In most cases, differences between BCorrRAE$_{ST}$ and BCorrRAE$_{SM}$ with the same dimensionality are statistically significant. This suggests that digging into structures of bilingual phrases (BCorrRAE$_{ST}$) can obtain further improvements over only modeling bilingual phrases as whole units (BCorrRAE$_{SM}$).

5.5 Overall Performance

Table 3 summarizes the comparison results of different models on the test sets. The BCorrRAE$_{SM}$ outperforms the baseline and BRAE by 1.06 and 0.25 BLEU points on average respectively, while BCorrRAE$_{ST}$ gains 1.55 and 0.74 BLEU points on average over the baseline and BRAE. The improvements of BCorrRAE$_{ST}$ over the baseline, BRAE and BCorrRAE$_{SM}$ are statistically significant at different levels. This demonstrates the advantage of our BCorrRAE over BRAE in that BCorrRAE is able to explore sub-structures of bilingual phrases.

5.6 Analysis

We compute a ratio of aligned nodes (Section 3.1) over all nodes to estimate how well tree structures of bilingual phrases generated by BRAE and BCorrRAE are consistent with word alignments. We consider two factors when computing the ratio: the length of the source side of a bilingual phrase l_s and the length of a span covered by an aligned node l_a. The result is illustrated in Table 4.[6] We find that BCorrRAE significantly outperforms BRAE model by 7.22% on average in terms of the aligned node ratio. This strongly demonstrates that the proposed BCorrRAE is able to generate tree structures that are more consistent with word alignments than those generated by BRAE.

[6]We only give ratios for bilingual phrases with source-side length from 3 to 4 words because 1) ratios of BRAE and BCorrRAE in the case of $l_a < 3$ are very close and 2) phrases with length > 4 are rarely used during decoding (accounting for $< 0.5\%$).

Method	MT06	MT08	AVG
Baseline	$29.66^{\Downarrow}$	$21.52^{\Downarrow}$	25.59
BRAE	$30.27^{\Downarrow}$	$22.53^{\Downarrow}$	26.40
BCorrRAE$_{SM}$	$30.58^{\downarrow}$	$22.72^{\Downarrow}$	26.65
BCorrRAE$_{ST}$	30.94	23.33	27.14

Table 3: Experiment results on the test sets. **AVG** = average BLEU scores for test sets. For both BRAE and BCorrRAE, we set d=50. $\downarrow/\Downarrow$: significantly worse than the BCorrRAE$_{ST}$ with d=50 ($p < 0.05$/$p < 0.01$, respectively).

$[l_s, l_a]$	[3,2]	[4,2]	[4,3]
BRAE	52.70%	39.88%	46.58%
BCorrRAE	60.08%	46.32%	54.43%

Table 4: Aligned node ratio for source phrases of different lengths.

We further show example source phrases in Table 5 with their most semantically similar translations learned by BRAE and BCorrRAE in the training corpus. Both models can select correct translations for content words. However, they are different in dealing with function words. Compared to our model, the BRAE model prefers longer target phrases surrounded with function words. Take the source phrase "严峻 挑战" as an example, the BRAE model learns both "*a serious challenge to*" and "*a serious challenge from*" as its semantically similar target phrases. Although the content words "严峻" and "挑战" are translated correctly into "*serious*" and "*challenge*", the function words "*to*" and "*from*" express exactly the opposite meanings. In contrast, our model, especially the BCorrRAE$_{ST}$ model, tends to choose shorter translations that are consistent with word alignments.

6 Related Work

A variety of efforts have been devoted to learning vector representations for words/phrases with deep neural networks. According to the difference of learning contexts, previous work mainly include the following two strands.

(1) *Monolingual Word/Phrase Embeddings*. The straightforward approach to represent word/phrases is to learn their hidden representations with traditional feature vectors, which requires manual and task-dependent feature engineering (Cui et al., 2014; Wu et al., 2014;

Source Phrase	BRAE	BCorrRAE$_{SM}$	BCorrRAE$_{ST}$
鼓吹 (advocate)	to advocate the in preaching the the promotion of	out to advocate been encouraging an advocate	encouraging claimed advocate
严峻 挑战 (serious challenge)	as well as severe challenges a serious challenge to a serious challenge from	of rigorous challenges as well as severe challenges of severe challenges	rigorous challenge enormous challenge severe challenge

Table 5: Semantically similar target phrases in the training set for example source phrases.

Chen and Manning, 2014). To avoid exploiting manually input features, Bengio et al. (2003) convert words to dense, real-valued vectors by learning probability distributions of n-grams. Mikolov et al. (2013) generate word vectors by predicting their limited context words. Instead of exploiting outside context information, recursive auto-encoder is usually adopted to learn the composition of internal words (Socher et al., 2010; Socher et al., 2011b; Socher et al., 2013b; Socher et al., 2013a). Recently, convolution architecture has drawn more and more attention due to its ability to explicitly capture short and long-range relations (Collobert et al., 2011; Kalchbrenner and Blunsom, 2013; Kalchbrenner et al., 2014; Kim, 2014).

(2) *Bilingual Word/Phrase Embeddings*. In the field of machine translation and cross-lingual information processing, bilingual embedding learning has become an increasingly important study. The bilingual embedding research origins in the word embedding learning, upon which Zou et al. (2013) utilize word alignments to constrain translational equivalence. Kočiský et al. (2014) propose a probability model to capture more semantic information by marginalizing over word alignments. More specifically to SMT, its main components have been exploited to learn better bilingual phrase embeddings in different aspects: language models (Wang et al., 2014; Garmash and Monz, 2014), reordering models (Li et al., 2013) and translation models (Tran et al., 2014; Zhang et al., 2014). Instead of exploiting a single model, Liu et al. (2014) combine the recursive and recurrent neural network to incorporate the language and translation model.

Different from the methods mentioned above, our model considers both the cross-language consistency of phrase structures and internal correspondence relations inside bilingual phrases. The most related works include Zhang et al. (2014) and Socher et al. (2011a). Compared with these works, our model exploits different levels of correspondence relations inside bilingual phrases instead of only the top level of entire phrases, and reconstructs tree structures of sub-phrases in one language according to aligned nodes in the other language, which, to the best of our knowledge, has never been investigated before.

7 Conclusions and Future Work

In this paper, we have presented the BCorrRAE to learn phrase embeddings and tree structures of bilingual phrases for SMT. Punishing structural-alignment-inconsistent sub-structures and minimizing the gap between original and reconstructed structures, our approach is able to not only generate alignment-consistent phrase structures, but also capture different levels of semantic relations within bilingual phrases. Experiment results demonstrate the effectiveness of our model.

In the future, we would like to derive more features from BCorrRAE, e.g., consistency/inconsistency scores of bilingual phrases, to further enhance SMT. Additionally, we also want to apply our model to other bilingual tasks, e.g., learning bilingual terminology or paraphrases.

{sjoty,hsajjad,ndurrani,kmannai,aabdelali,svogel}@qf.org.qa

Abstract

We present novel models for domain adaptation based on the neural network joint model (NNJM). Our models maximize the cross entropy by regularizing the loss function with respect to in-domain model. Domain adaptation is carried out by assigning higher weight to out-domain sequences that are similar to the in-domain data. In our alternative model we take a more restrictive approach by additionally penalizing sequences similar to the out-domain data. Our models achieve better perplexities than the baseline NNJM models and give improvements of up to 0.5 and 0.6 BLEU points in Arabic-to-English and English-to-German language pairs, on a standard task of translating TED talks.

1 Introduction

Rapid influx of digital data has galvanized the use of empirical methods in many fields including Machine Translation (MT). The increasing availability of bilingual corpora has made it possible to automatically learn translation rules that required years of linguistic analysis previously. While additional data is often beneficial for a general purpose Statistical Machine Translation (SMT) system, a problem arises when translating new domains such as lectures (Cettolo et al., 2014), patents (Fujii et al., 2010) or medical text (Bojar et al., 2014), where either the bilingual text does not exist or is available in small quantity. All domains have their own vocabulary and stylistic preferences which cannot be fully encompassed by a system trained on the general domain.

Machine translation systems trained from a simple concatenation of small in-domain and large out-domain data often perform below par because the out-domain data is distant or overwhelmingly larger than the in-domain data. Additional data increases lexical ambiguity by introducing new senses to the existing in-domain vocabulary. For example, an Arabic-to-English SMT system trained by simply concatenating in- and out-domain data translates the Arabic phrase "عن مشكلة الحمل الزائد للاختيار" to "about the problem of unwanted pregnancy". This translation is incorrect in the context of the in-domain data, where it should be translated to "about the problem of choice overload". The sense of the Arabic phrase taken from out-domain data completely changes the meaning of the sentence. In this paper, we tackle this problem by proposing domain adaptation models that make use of all the data while preserving the in-domain preferences.

A significant amount of research has been carried out recently in domain adaptation. The complexity of the SMT pipeline, starting from corpus preparation to word-alignment, and then training a wide range of models opens a wide horizon to carry out domain specific adaptations. This is typically done using either *data selection* (Matsoukas et al., 2009) or *model adaptation* (Foster and Kuhn, 2007). In this paper, we further research in model adaptation using the neural network framework.

In recent years, there has been a growing interest in deep neural networks (NNs) and word embeddings with application to numerous NLP problems. A notably successful attempt on the SMT frontier was recently made by Devlin et al. (2014). They proposed a neural network joint model (NNJM), which augments streams of source with target n-grams and learns a NN model over vector representation of such streams. The model is then integrated into the decoder and used as an additional language model feature.

Our aim in this paper is to advance the state-of-the-art in SMT by extending NNJM for domain adaptation to leverage the huge amount of out-

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1259–1270,
Lisbon, Portugal, 17-21 September 2015.

domain data coming from heterogeneous sources. We hypothesize that the distributed vector representation of NNJM helps to bridge the lexical differences between the in-domain and the out-domain data, and adaptation is necessary to avoid deviation of the model from the in-domain data, which otherwise happens because of the large out-domain data.

To this end, we propose two novel extensions of NNJM for domain adaptation. Our first model minimizes the cross entropy by regularizing the loss function with respect to the in-domain model. The regularizer gives higher weight to the training instances that are similar to the in-domain data. Our second model takes a more conservative approach by additionally penalizing data instances similar to the out-domain data.

We evaluate our models on the standard task of translating Arabic-English and English-German language pairs. Our adapted models achieve better perplexities (Chen and Goodman, 1999) than the models trained on in- and in+out-domain data. Improvements are also reflected in BLEU scores (Papineni et al., 2002) as we compare these models within the SMT pipeline. We obtain gains of up to 0.5 and 0.6 on Arabic-English and English-German pairs over a competitive baseline system.

The remainder of this paper is organized as follows: Section 2 gives an account on related work. Section 3 revisits NNJM model and Section 4 discusses our models. Section 5 presents the experimental setup and the results. Section 6 concludes.

2 Related Work

Previous work on domain adaptation in MT can be broken down broadly into two main categories namely *data selection* and *model adaptation*.

2.1 Data Selection

Data selection has shown to be an effective way to discard poor quality or irrelevant training instances, which when included in an MT system, hurts its performance. The idea is to score the out-domain data using a model trained from the in-domain data and apply a cut-off based on the resulting scores. The MT system can then be trained on a subset of the out-domain data that is closer to in-domain. Selection based methods can be helpful to reduce computational cost when training is expensive and also when memory is constrained. Data selection was done earlier for language modeling using information retrieval techniques (Hildebrand et al., 2005) and perplexity measures (Moore and Lewis, 2010). Axelrod et al. (2011) further extended the work of Moore and Lewis (2010) to translation model adaptation by using both source- and target-side language models. Duh et al. (2013) used a recurrent neural language model instead of an ngram-based language model to do the same. Translation model features were used recently by (Liu et al., 2014; Hoang and Sima'an, 2014) for data selection. Durrani et al. (2015a) performed data selection using operation sequence model (OSM) and NNJM models.

2.2 Model Adaptation

The downside of data selection is that finding an optimal cut-off threshold is a time consuming process. An alternative to completely filtering out less useful data is to minimize its effect by down-weighting it. It is more robust than selection since it takes advantage of the complete out-domain data with intelligent weighting towards the in-domain.

Matsoukas et al. (2009) proposed a classification-based sentence weighting method for adaptation. Foster et al. (2010) extended this by weighting phrases rather than sentence pairs. Other researchers have carried out weighting by merging phrase-tables through linear interpolation (Finch and Sumita, 2008; Nakov and Ng, 2009) or log-linear combination (Foster and Kuhn, 2009; Bisazza et al., 2011; Sennrich, 2012) and through phrase training based adaptation (Mansour and Ney, 2013). Durrani et al. (2015a) applied EM-based mixture modeling to OSM and NNJM models to perform model weighting. Chen et al. (2013b) used a vector space model for adaptation at the phrase level. Every phrase pair is represented as a vector, where every entry in the vector reflects its relatedness with each domain. Chen et al. (2013a) also applied mixture model adaptation for reordering model.

Other work on domain adaptation includes but not limited to studies focusing on topic models (Eidelman et al., 2012; Hasler et al., 2014), dynamic adaptation without in-domain data (Sennrich et al., 2013; Mathur et al., 2014) and sense disambiguation (Carpuat et al., 2013).

In this paper, we do model adaptation using a neural network framework. In contrast to previous work, we perform it at the (bilingual) n-gram level, where n is sufficiently large to capture long-range cross-lingual dependencies. The

generalized vector representation of the neural network model reduces the data sparsity issue of traditional Markov-based models by learning better word classes. Furthermore, our specially designed loss functions for adaptation help the model to avoid deviation from the in-domain data without losing the ability to generalize.

3 Neural Network Joint Model

In recent years, there has been a great deal of effort dedicated to neural networks (NNs) and word embeddings with applications to SMT and other areas in NLP (Bengio et al., 2003; Auli et al., 2013; Kalchbrenner and Blunsom, 2013; Gao et al., 2014; Schwenk, 2012; Collobert et al., 2011; Mikolov et al., 2013a; Socher et al., 2013; Hinton et al., 2012). Recently, Devlin et al. (2014) proposed a neural network joint model (NNJM) and integrated it into the decoder as an additional feature. They showed impressive improvements in Arabic-to-English and Chinese-to-English MT tasks. Let us revisit the NNJM model briefly.

Given a source sentence S and its corresponding target sentence T, the NNJM model computes the conditional probability $P(T|S)$ as follows:

$$P(T|S) \approx \prod_{i}^{|T|} P(t_i|t_{i-1} \dots t_{i-p+1}, \mathbf{s_i}) \quad (1)$$

where, $\mathbf{s_i}$ is a q-word source window for the target word t_i based on the one-to-one (non-NULL) alignment of T to S. As exemplified in Figure 1, this is essentially a $(p+q)$-gram neural network LM (NNLM) originally proposed by Bengio et al. (2003). Each input word i.e. source or target word in the context is represented by a D dimensional vector in the shared look-up layer $L \in \mathbb{R}^{|V_i| \times D}$, where V_i is the input vocabulary.[1] The look-up layer then creates a context vector $\mathbf{x_n}$ representing the context words of the $(p+q)$-gram sequence by concatenating their respective vectors in L. The concatenated vector is then passed through non-linear hidden layers to learn a high-level representation, which is in turn fed to the output layer. The output layer has a `softmax` activation over the output vocabulary V_o of target words. Formally, the probability of getting k-th word in the output given the context $\mathbf{x_n}$ can be written as:

$$P(y_n = k|\mathbf{x_n}, \theta) = \frac{exp\ (\mathbf{w}_k^T \phi(\mathbf{x_n}))}{\sum_{m=1}^{|V_o|} exp\ (\mathbf{w}_m^T \phi(\mathbf{x_n}))} \quad (2)$$

[1]Note that L is a model parameter to be learned.

where $\phi(\mathbf{x_n})$ defines the transformations of $\mathbf{x_n}$ through the hidden layers, and $\mathbf{w}_k$ are the weights from the last hidden layer to the output layer. For notational simplicity, henceforth we will use $(\mathbf{x_n}, y_n)$ to represent a training sequence.

By setting p and q to be sufficiently large, NNJM can capture long-range cross-lingual dependencies between words, while still overcoming the data sparseness issue by virtue of its distributed representations (i.e., word vectors). A major bottleneck, however, is to surmount the computational cost involved in training the model and applying it for MT decoding. Devlin et al. (2014) proposed two tricks to speed up computation in decoding. The first one is to pre-compute the hidden layer computations and fetch them directly as needed during decoding. The second technique is to train a *self-normalized* NNJM to avoid computation of the softmax normalization factor (i.e., the denominator in Equation 2) in decoding. However, self-normalization does not solve the computational cost of training the model. In the following, we describe a method to address this issue.

3.1 Training by Noise Contrastive Estimation

The standard way to train NNLMs is to maximize the log likelihood of the training data:

$$J(\theta) = \sum_{n=1}^{N} \sum_{k=1}^{|V_o|} y_{nk}\ log\ P(y_n = k|\mathbf{x_n}, \theta) \quad (3)$$

where, $y_{nk} = I(y_n = k)$ is an indicator variable (i.e., y_{nk}=1 when y_n=k, otherwise 0). Optimization is performed using first-order online methods, such as stochastic gradient ascent (SGA) with standard *backpropagation* algorithm. Unfortunately, training NNLMs are impractically slow because for each training instance $(\mathbf{x_n}, y_n)$, the softmax output layer (see Equation 2) needs to compute a summation over all words in the output vocabulary.[2] Noise contrastive estimation or NCE (Gutmann and Hyvärinen, 2010) provides an efficient and stable way to avoid this repetitive computation as recently applied to NNLMs (Vaswani et al., 2013; Mnih and Teh, 2012). We can re-write Equation 2 as follows:

$$P(y_n = k|\mathbf{x_n}, \theta) = \frac{\sigma(y_n = k|\mathbf{x_n}, \theta)}{Z(\phi(\mathbf{x_n}), \mathbf{W})} \quad (4)$$

where $\sigma(.)$ is the un-normalized score and $Z(.)$ is the normalization factor. In NCE, we consider

[2]This would take few weeks for a modern CPU machine to train a single NNJM model on the whole data.

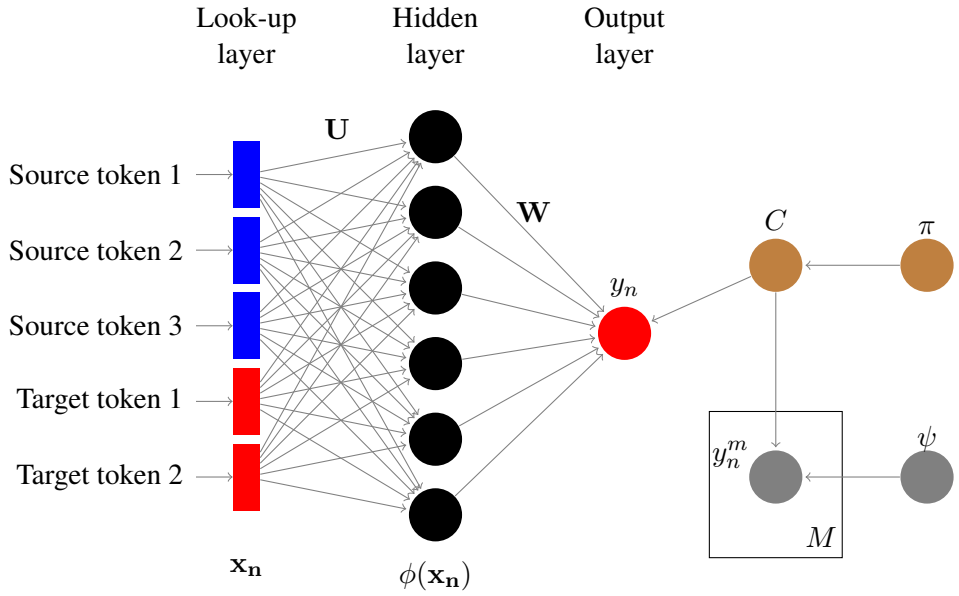

Figure 1: A simplified neural network joint model with noise contrastive loss, where we use 3-gram target words (i.e., 2-words history) and a source context window of size 3. For illustration, the output y_n is shown as a single categorical variable (scalar) as opposed to the traditional one-hot vector representation.

$Z(.)$ as an additional model parameter along with the regular parameters, i.e., weights, look-up vectors. However, it has been shown that fixing $Z(.)$ to 1 instead of learning it in training does not affect the model performance (Mnih and Teh, 2012).

For each training instance $(\mathbf{x_n}, y_n)$, we add M noise samples $(\mathbf{x_n}, y_n^m)$ by sampling y_n^m from a known noise distribution ψ (e.g., `unigram`, `uniform`) M many times (i.e., $m = 1 \ldots M$); see Figure 1. NCE loss is then defined to discriminate a *true* instance from a *noisy* one. Let $C \in \{0, 1\}$ denote the class of an instance with $C = 1$ indicating *true* and $C = 0$ indicating *noise*. NCE maximizes the following conditional log likelihood:

$$J(\theta) = \sum_{n=1}^{N} \Big[log[P(C=1|y_n, \mathbf{x}_n, \theta)] + \sum_{m=1}^{M} log[P(C=0|y_n^m, \mathbf{x}_n, \psi)] \Big] \quad (5)$$

$$= \sum_{n=1}^{N} \Big[log\left[P(y_n|C=1, \mathbf{x}_n, \theta) P(C=1|\pi)\right] + \sum_{m=1}^{M} log\left[\left(P(y_n^m|C=0, \mathbf{x}_n, \psi)\right) P(C=0|\pi)\right] - (M+1)\, log\, Q \Big] \quad (6)$$

where $Q = P(y_n, C=1|\mathbf{x}_n, \theta, \pi) + P(y_n^m, C=0|\mathbf{x}_n, \psi, \pi)$ is a normalization constant. After removing the constant terms, Equation 6 can be further simplified as:

$$J(\theta) = \sum_{n=1}^{N} \sum_{k=1}^{|V_o|} \Big[y_{nk}\, log\, \sigma_{nk} + \sum_{m=1}^{M} y_{nk}^m\, log\, \psi_{nk} \Big] \quad (7)$$

where $\psi_{nk} = P(y_n^m = k|\mathbf{x}_n, \psi)$ is the noise distribution, $\sigma_{nk} = \sigma(y_n = k|\mathbf{x}_n, \theta)$ is the unnormalized score at the output layer (Equation 4), and y_{nk} and y_{nk}^m are indicator variables as defined before. NCE reduces the number of computations needed at the output layer from $|V_o|$ to $M + 1$, where M is a small number in comparison with $|V_o|$. In all our experiments we use NCE loss with $M = 100$ samples as suggested by Mnih and Teh (2012).

4 Neural Domain Adaptation Models

The ability to generalize and learn complex semantic relationships (Mikolov et al., 2013b) and its compelling empirical results gives a strong motivation to use the NNJM model for the problem of domain adaptation in machine translation. However, the vanilla NNJM described above is limited in its ability to effectively learn from a large and diverse out-domain data in the best favor of an in-domain data. To address this, we propose two neural domain adaptation models (NDAM) extending the NNJM model. Our models add regularization to its loss function either with respect to in-domain or both in- and out-domains. In both cases, we first present the regularized loss function for the normalized output layer with the standard softmax,

followed by the corresponding un-normalized one using the noise contrastive estimation.

4.1 NDAM$_{v1}$

To improve the generalization of word embeddings, NNLMs are generally trained on very large datasets (Mikolov et al., 2013a; Vaswani et al., 2013). Therefore, we aim to train our neural domain adaptation models (NDAM) on in- plus out-domain data, while restricting it to drift away from in-domain. In our first model NDAM$_{v1}$, we achieve this by biasing the model towards the in-domain using a regularizer (or prior) based on the in-domain model. Let θ_i be an NNJM model already trained on the in-domain data. We train an adapted model θ_a on the whole data, but regularizing it with respect to θ_i. We redefine the normalized loss function of Equation 3 as follows:

$$J(\theta_a) = \sum_{n=1}^{N}\sum_{k=1}^{|V_o|}\Big[\lambda\, y_{nk}\, logP(y_n = k|\mathbf{x_n}, \theta_a) + (1-\lambda)\, y_{nk}\, P(y_n = k|\mathbf{x_n}, \theta_i)\, logP(y_n = k|\mathbf{x_n}, \theta_a)\Big] \quad (8)$$

$$= \sum_{n=1}^{N}\sum_{k=1}^{|V_o|}\Big[\lambda\, y_{nk}\, log\, \hat{y}_{nk}(\theta_a) + (1-\lambda)\, y_{nk}\, p_{nk}(\theta_i)\, log\, \hat{y}_{nk}(\theta_a)\Big] \quad (9)$$

where $\hat{y}_{nk}(\theta_a)$ is the softmax output and $p_{nk}(\theta_i)$ is the probability of the training instance according to the in-domain model θ_i. Notice that the loss function minimizes the cross entropy of the current model θ_a with respect to the gold labels y_n and the in-domain model θ_i. The mixing parameter $\lambda \in [0, 1]$ determines the relative strength of the two components.[3] Similarly, we can re-define the NCE loss of Equation 7 as:

$$J(\theta_a) = \sum_{n=1}^{N}\sum_{k=1}^{|V_o|}\Big[\lambda\, y_{nk}\, log\, \sigma_{nk} + (1-\lambda)\, y_{nk}\, p_{nk}(\theta_i)\, log\, \sigma_{nk} + \sum_{m=1}^{M} y_{nk}^{m} log\, \psi_{nk}\Big] \quad (10)$$

We use SGA with backpropagation to train this model. The derivatives of $J(\theta_a)$ with respect to the final layer weight vectors $\mathbf{w}_j$ turn out to be:

$$\nabla_{\mathbf{w}_j} J(\theta_a) = \sum_{n=1}^{N}\Big[\lambda\,(y_{nj} - \sigma_{nj}) + (1-\lambda)\,[p_{nj}(\theta_i) - \sum_{k} y_{nk}\, p_{nk}(\theta_i)\, \sigma_{nj}]\Big] \quad (11)$$

[3] We used a balanced value $\lambda = 0.5$ for our experiments.

4.2 NDAM$_{v2}$

The regularizer in NDAM$_{v1}$ is based on an in-domain model θ_i, which puts higher weights to the training instances (i.e., n-gram sequences) that are similar to the in-domain ones. This might work better when the out-domain data is similar to the in-domain data. In cases where the out-domain data is different, we might want to build a more conservative model that penalizes training instances for being similar to the out-domain ones.

Let θ_i and θ_o be the two NNJMs already trained from the in- and out-domains, respectively, and θ_o is trained using the same vocabulary as θ_i. We define the new normalized loss function as follows:

$$J(\theta_a) = \sum_{n=1}^{N}\sum_{k=1}^{|V_o|}\Big[\lambda\, y_{nk}\, log\, \hat{y}_{nk}(\theta_a) + (1-\lambda)\, y_{nk}\, [p_{nk}(\theta_i) - p_{nk}(\theta_o)]\, log\, \hat{y}_{nk}(\theta_a)\Big] \quad (12)$$

where y_{nk}, $\hat{y}_{nk}(\theta_a)$, $p_{nk}(\theta_i)$ and $p_{nk}(\theta_o)$ are similarly defined as before. This loss function minimizes the cross entropy of the current model θ_a with respect to the gold labels y_n and the difference between the in-domain model θ_i and the out-domain model θ_o. Intuitively, the regularizer assigns higher weights to training instances that are not only similar to the in-domain but also dissimilar to the out-domain. The parameter $\lambda \in [0, 1]$ determines the strength of the regularization. The corresponding NCE loss can be defined as follows:

$$J(\theta_a) = \sum_{n=1}^{N}\sum_{k=1}^{|V_o|}\Big[\lambda\, y_{nk}\, log\, \sigma_{nk} + (1-\lambda)\, y_{nk}\, log\, \sigma_{nk}\, (p_{nk}(\theta_i) - p_{nk}(\theta_o)) + \sum_{m=1}^{M} y_{nk}^{m}\, log\, \psi_{nk}\Big] \quad (13)$$

The derivatives of the above cost function with respect to the final layer weight vectors $\mathbf{w}_j$ are:

$$\nabla_{\mathbf{w}_j} J(\theta_a) = \sum_{n=1}^{N}\Big[\lambda\,(y_{nj} - \sigma_{nj}) + (1-\lambda)[p_{nj}(\theta_i) - p_{nj}(\theta_o) - \sum_{k} y_{nk}\, \sigma_{nj}\; (p_{nk}(\theta_i) - p_{nk}(\theta_o))]\Big] \quad (14)$$

In a way, the regularizers in our loss functions are inspired from the data selection methods of Axelrod et al. (2011), where they use cross entropy between the in- and the out-domain LMs to score out-domain sentences. However, our approach is quite different from them in several aspects. First

and most importantly, we take the scoring inside model training and use it to bias the training towards the in-domain model. Both the scoring and the training are performed at the bilingual n-gram level rather than at the sentence level. Integrating scoring inside the model allows us to learn a robust model by training/tuning the relevant parameters, while still using the complete data. Secondly, our models are based on NNs, while theirs utilize the traditional Markov-based generative models.

4.3 Technical Details

In this section, we describe some implementation details of NDAM that we found to be crucial, such as: using *gradient clipping* to handle vanishing/exploding gradient problem in SGA training with backpropagation, selecting appropriate *noise distribution* in NCE, and special handling of out-domain words that are unknown to the in-domain.

4.3.1 Gradient Clipping

Two common issues with training deep NNs on large data-sets are the *vanishing* and the *exploding* gradients problems (Pascanu et al., 2013). The error gradients propagated by the backpropagation may sometimes become very small or very large which can lead to undesired (nan) values in weight matrices, causing the training to fail. We also experienced the same problem in our NDAM quite often. One simple solution to this problem is to truncate the gradients, known as *gradient clipping* (Mikolov, 2012). In our experiments, we limit the gradients to be in the range $[-5; +5]$.

4.3.2 Noise Distribution in NCE

Training with NCE relies on sampling from a noise distribution (i.e., ψ in Equation 5), and the performance of the NDAM models varies considerably with the choice of the distribution. We explored *uniform* and *unigram* noise distributions in this work. With uniform distribution, every word in the output vocabulary has the same probability to be sampled as noise. The *unigram* noise distribution is a multinomial distribution over words constructed by counting their occurrences in the output (i.e., n-th word in the n-gram sequence). In our experiments, unigram distribution delivered much lower perplexity and better MT results compared to the uniform one. Mnih and Teh (2012) also reported similar findings on perplexity.

4.3.3 Handling of Unknown Words

In order to reduce the training time and to learn better word representations, NNLMs are often trained on most frequent vocabulary words only and low frequency words are represented under a class of unknown words, `unk`. This results in a large number of n-gram sequences containing at least one `unk` word and thereby, makes `unk` a highly probable word in the model.[4]

Our NDAM models rely on scoring out-domain sequences (of word Ids) using models that are trained based on the in-domain vocabulary. To score out-domain sequences using a model, we need to generate the sequences using the same vocabulary based on which the model was trained. In doing so, the out-domain words that are unknown to the in-domain data map to the same `unk` class. As a result, out-domain sequences containing `unks` get higher probability although they are distant from the in-domain data.

A solution to this problem is to have an in-domain model that can differentiate between its own `unk` class, resulted from the reduced in-domain vocabulary, and actual unknown words that come from the out-domain data. We introduce a new class $\texttt{unk}_o$ to represent the latter. We train the in-domain model by adding a few dummy sequences containing $\texttt{unk}_o$ occurring on both source and target sides. This enables the model to learn `unk` and $\texttt{unk}_o$ separately, where $\texttt{unk}_o$ is a less probable class according to the model. Later, the n-gram sequences of the out-domain data contain both `unk` and $\texttt{unk}_o$ classes depending on whether a word is unknown to only pruned in-domain vocabulary (i.e., `unk`) or is unknown to full in-domain vocabulary (i.e., $\texttt{unk}_o$).

5 Evaluation

In this section, we describe the experimental setup (i.e., data, settings for NN models and MT pipeline) and the results. First we evaluate our models intrinsically by comparing the perplexities on a held-out in-domain testset against the baseline NNJM model. Then we carry out an extrinsic evaluation by using the NNJM and NDAM models as features in machine translation and compare the BLEU scores. Initial developmental experiments were done on the Arabic-to-English language pair.

[4]For our Arabic-English in-domain data, 30% of n-gram sequences contain at least one `unk` word.

We carried out further experiments on the English-to-German pair to validate our models.

5.1 Data

We experimented with the data made publicly available for the translation task of the International Workshop on Spoken Language Translation (IWSLT) (Cettolo et al., 2014). We used TED talks as our in-domain corpus. For Arabic-to-English, we used the QCRI Educational Domain (QED) – A bilingual collection of educational lectures[5] (Abdelali et al., 2014), the News, and the multiUN (UN) (Eisele and Chen, 2010) as our out-domain corpora. For English-to-German, we used the News, the Europarl (EP), and the Common Crawl (CC) corpora made available for the 9^{th} Workshop of Statistical Machine Translation.[6] Table 1 shows the size of the data used.

Training NN models is expensive. We, therefore, randomly selected subsets of about 300K sentences from the bigger domains (UN, CC and EP) to train the NN models.[7] The systems were tuned on concatenation of the dev. and test2010 and evaluated on test2011-2013 datasets. The tuning set was also used to measure the perplexities of different models.

5.2 System Settings

NNJM & NDAM: The NNJM models were trained using NPLM[8] toolkit (Vaswani et al., 2013) with the following settings. We used a target context of 5 words and an aligned source window of 9 words, forming a joint stream of 14-grams for training. We restricted source and target side vocabularies to the 20K and 40K most frequent words. The word vector size D and the hidden layer size were set to 150 and 750, respectively. Only one hidden layer is used to allow faster decoding. Training was done by the standard stochastic gradient ascent with NCE using 100 noise samples and a mini-batch size of 1000. All models were trained for 25 epochs. We used identical settings to train the NDAM models, except for the special handling of `unk` tokens.

Machine Translation System: We trained a Moses system (Koehn et al., 2007), with the following settings: a maximum sentence length of 80, Fast-Aligner for word-alignments (Dyer et al., 2013), an interpolated Kneser-Ney smoothed 5-gram language model with KenLM (Heafield, 2011), lexicalized reordering model (Galley and Manning, 2008), a 5-gram operation sequence model (Durrani et al., 2015b) and other default parameters. We also used an NNJM trained with the settings described above as an additional feature in our baseline system. In adapted systems, we replaced the NNJM model with the NDAM models. We used ATB segmentation using the Stanford ATB segmenter (Green and DeNero, 2012) for Arabic-to-English and the default tokenizer provided with the Moses toolkit (Koehn et al., 2007) for the English-to-German pair. Arabic OOVs were translated using an unsupervised transliteration module in Moses (Durrani et al., 2014). We used k-best batch MIRA (Cherry and Foster, 2012) for tuning.

5.3 Intrinsic Evaluation

In this section, we compare the NNJM model and our NDAM models in terms of their perplexity numbers on the in-domain held-out dataset (i.e., dev+test2010). We choose Arabic-English language pair for the development experiments and train domain-wise models to measure the relatedness of each domain with respect to the in-domain. We later replicated selective experiments for the English-German language pair.

The first part of Table 2 summarizes the results for Arabic-English. The perplexity numbers in the second column (NNJM$_b$) show that NEWS is the

[5]Guzmán et al. (2013) showed that the QED corpus is similar to IWSLT and adding it improves translation quality.

[6]http://www.statmt.org/wmt14/translation-task.html

[7]Concatenating all the data results in a corpus of approximately 4.5 million sentences which requires roughly 18 days of wall-clock time (18 hours/epoch on a Linux Ubuntu 12.04.5 LTS running on a 16 Core Intel Xeon E5-2650 2.00Ghz and 64Gb RAM) to train NNJM models on our machines. We ran one baseline experiment with all the data and did not find it better than the system trained on randomly selected subset of the data. In the interest of time, we therefore reduced the NN training to a subset (800K and 1M sentences for AR-EN and EN-DE respectively).

Table 2: Comparing the perplexity of NNJM and NDAM models. NNJM$_b$ represents the model trained on each individual domain separately.

most related domain from the perspective of in-domain data, whereas UN is the farthest having the worst perplexity. The third column (NNJM$_{cat}$) shows results of the models trained from concatenating each domain to the in-domain data. The perplexity numbers improved significantly in each case showing that there is useful information available in each domain which can be utilized to improve the baseline. It also shows the robustness of neural network models. Unlike the n-gram model, the NN-based model improves generalization with the increase in data without completely skewing towards the dominating part of the data.

Concatenating in-domain with the NEWS data gave better perplexities than other domains. Best results were obtained by concatenating all the data together (See row *ALL*). The third and fourth columns show results of our models (NDAM$_{v*}$). Both give better perplexities than NNJM$_{cat}$ in all cases. However, it is unclear which of the two is better. Similar observations were made for the English-to-German pair, where we only did experiments on the concatenation of all domains.

5.4 Extrinsic Evaluation

Arabic-to-English: For most language pairs, the conventional wisdom is to train the system with all available data. However, previously reported MT results on Arabic-to-English (Mansour and Ney, 2013) show that this is not optimal and the results are often worse than only using in-domain data. The reason for this is that the UN domain is found to be distant and overwhelmingly large as compared to the in-domain IWSLT data. We carried out domain-wise experiments and also found this to be true.

We considered three baseline systems: (*i*) B$_{in}$, which is trained on the in-domain data, (*ii*) B$_{cat}$, which is trained on the concatenation of in- and out-domain data, and (*ii*) B$_{cat,in}$, where the MT pipeline was trained on the concatenation but the NNJM model is trained only on the in-domain data. Table 3 reports average BLEU scores across three test sets on all domains. Adding QED and NEWS domains gave improvements on top of the in-domain IWSLT baseline. Concatenation of UN with in-domain made the results worse. Concatenating all out-domain and in-domain data achieves +0.4 BLEU gain on top of the baseline in-domain system. We will use B$_{cat}$ systems as our baseline to compare our adapted systems with.

SYS	IWSLT	QED	NEWS	UN	ALL
B$_{in}$	26.1	-	-	-	-
B$_{cat}$	-	26.2	26.7	25.8	26.5
B$_{cat,in}$	-	26.2	26.3	25.9	26.5

Table 3: Results of the baseline Arabic-to-English MT systems. The numbers are averaged over tst2011-2013.

Table 4 shows results of the MT systems S$_{v1}$ and S$_{v2}$ using our adapted models NDAM$_{v1}$ and NDAM$_{v2}$. We compare them to the baseline system B$_{cat}$, which uses the non-adapted NNJM$_{cat}$ as a feature. S$_{v1}$ achieved an improvement of up to +0.4 and S$_{v2}$ achieved an improvement of up to +0.5 BLEU points. However, S$_{v2}$ performs slightly worse than S$_{v1}$ on individual domains. We speculate this is because of the nature of the NDAM$_{v2}$, which gives high weight to out-domain sequences that are liked by the in-domain model and disliked by the out-domain model. In the case of individual domains, NDAM$_{v2}$ might be over penalizing out-domain since the out-domain model is only built on that particular domain and always prefers it more than the in-domain model. In case of *ALL*, the out-domain model is more diverse and has different level of likeness for each domain.

We analyzed the output of the baseline system (S$_{cat}$) and spotted several cases of lexical ambiguity caused by out-domain data. For example, the Arabic phrase الحمل الزائد للاختيار can be translated to *choice overload* or *unwanted pregnancy*. The latter translation is incorrect in the context of in-domain. The bias created due to the out-domain data caused S$_{cat}$ to choose the contextually incorrect translation *unwanted pregnancy*. However, the adapted systems S$_{v*}$ were able to translate it

Table 6: Comparison with Modified Moore-Lewis

correctly. In another example ماذا عن لياقة البدن؟ (*How about fitness?*), the word لياقة is translated to *proprietary* by S_{cat}, a translation frequently observed in the out-domain data. S_{v*} translated it correctly to *fitness*, as preferred by the in-domain.

English-to-German: Concatenating all training data to train the MT pipeline has been shown to give the best results for English-to-German (Birch et al., 2014). Therefore, we did not do domain-wise experiments, except for training a system on the in-domain IWSLT data for the sake of completeness. We also tried $B_{cat,in}$ variation, i.e. training an MT system on the entire data and using in-domain data to train the baseline NNJM. The baseline system B_{cat} gave better results and was used as our reference for comparison.

Table 5 shows the results of our systems, S_{v1} and S_{v2}, compared to the baselines, B_{in} and B_{cat}. Unlike Arabic-to-English, the baseline system B_{in} is much worse than B_{cat}. Our adapted MT systems S_{v1} and S_{v2} both outperformed the best baseline system (B_{cat}) with an improvement of up to 0.6 points. S_{v2} performed slightly better than S_{v1} on one occasion and slightly worse in others.

Comparison with Data Selection: We also compared our results with the MML-based data selection approach as shown in Table 6. The MML-based baseline systems (B_{mml}) used 20% selected data for training the MT system and the NNJM. On Arabic-English, both MML-based selection and our model (S_{v1}) gave similar gains on top of the baseline system (B_{cat}). Further results showed that both approaches are complementary. We were able to obtain an average gain of +0.3 BLEU points by training an $NDAM_{v1}$ model over the selected data (see S_{v1+mml}).

However, on English-German, the MML-based selection caused a drop in the performance (see Table 6). Training an adapted $NDAM_{v1}$ model over selected data gave improvements over MML in two test sets but could not restore the baseline performance, probably because the useful data has already been filtered by the selection process.

6 Conclusion

We presented two novel models for domain adaptation based on NNJM. Adaptation is performed by regularizing the loss function towards the in-domain model and away from the unrelated out-of-domain data. Our models show better perplexities than the non-adapted baseline NNJM models. When integrated into a machine translation system, gains of up to 0.5 and 0.6 BLEU points were obtained in Arabic-to-English and English-to-German systems over strong baselines.

Detecting Content-Heavy Sentences: A Cross-Language Case Study

Junyi Jessy Li
University of Pennsylvania

Ani Nenkova
University of Pennsylvania
nenkova@seas.upenn.edu

Abstract

The information conveyed by some sentences would be more easily understood by a reader if it were expressed in multiple sentences. We call such sentences content heavy: these are possibly grammatical but difficult to comprehend, cumbersome sentences. In this paper we introduce the task of detecting content-heavy sentences in cross-lingual context. Specifically we develop methods to identify sentences in Chinese for which English speakers would prefer translations consisting of more than one sentence. We base our analysis and definitions on evidence from multiple human translations and reader preferences on flow and understandability. We show that machine translation quality when translating content heavy sentences is markedly worse than overall quality and that this type of sentence are fairly common in Chinese news. We demonstrate that sentence length and punctuation usage in Chinese are not sufficient clues for accurately detecting heavy sentences and present a richer classification model that accurately identifies these sentences.

1 Introduction

To generate text, people and machines need to decide how to package the content they wish to express into clauses and sentences. There are multiple possible renderings of the same information, with varying degrees of ease of comprehension, compactness and naturalness. Some sentences, even though they are grammatical, would be more accessible to a reader if expressed in multiple sentences. We call such sentences *content heavy* sentences, or *heavy sentences* for brevity.

In the established areas of language research, text simplification and sentence planning in dialog and generation systems are clearly tasks in which identification of content-heavy sentences is of great importance. In this paper we introduce a novel flavor of the task in the cross-lingual setting, which in the long term may guide improvements in machine translation. We seek to identify sentences in Chinese that would result in heavy sentences in English if translated to a single sentence.

Example I in Table 1 shows a Chinese sentence and its two English translations A and B. Translator A used three English sentences to express all the information. Translator B, on the other hand, used a single sentence, which most readers would find more difficult to read. Example II illustrates a case where a translator would be hard pressed to convey all the content in a sentence in Chinese into a single grammatical English sentence.

Here we provide an operational characterization of content-heavy sentences in the context of Chinese-English translation. Instead of establishing guidelines for standalone annotation, we repurpose datasets developed for evaluation of machine translation consisting of multiple reference translations for each Chinese sentence. In this cross-lingual analysis, sentences in Chinese are considered content-heavy if their content would be more felicitously expressed in multiple sentences in English.

We first show that, with respect to English, content-heavy Chinese sentences are common. A fifth to a quarter of the sentences in the Chinese news data that we analyze are translated to multiple sentences in English. Moreover our experiments with reader preference indicate that for these sentences, readers strongly prefer multi-sentence translation to a single-sentence translation (§ 4.1). We also compare the difference in machine translation quality for heavy sentences and find that it is considerably lower than overall system performance (§ 4.2). Then we study the connection between heavy sentences and the factors

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1271–1281,
Lisbon, Portugal, 17-21 September 2015.

[Example I] 虽然菲军方在南部的巴西兰岛上部署了5000多兵力，并在美军的帮助下围剿阿布沙耶夫分子，但迄今收效不大。*Although the Philippine army on the southern Basilan island deployed over 5,000 troops, and with the US army's help are hunting down ASG members, but so far achieved little.* **[A]** The Philippine army has already deployed over 5 thousand soldiers on the southern island of Basilan. With the help of U.S. army, these soldiers are searching and suppressing members of Abu Sayyaf. However, there is not much achievement this far. **[B]** The Philippine military has stationed over 5,000 troops on Basilan Island in the southern Philippines and also tried to hunt down ASG members with the help of the United States, yet so far it has little success.	**[Example II]** 端粒是染色体末端的结构，随着细胞老化和失去分裂能力，端粒会逐渐缩短长度，换言之，端粒愈长显示细胞老化愈慢。*Telomeres are chromosome ends structures, with cell aging and losing division ability, telomeres will gradually decrease length, in other words, telomeres the longer shows cell aging the slower.* **[A]** Telomeres are structures at the ends of chromosomes, which gradually reduce in length with the aging of the cells and their loss of the ability to divide. In other words, longer telomeres indicate the slower aging of the cells. **[B]** Telomeres are the physical ends of chromosomes. As cells age and lose the ability to divide, the telomeres shrink gradually. That is to say, longer telomeres indicate that cells are aging more slowly.

Table 1: Examples of Chinese sentences expressed in multiple English sentences.

used in prior work to split a Chinese sentence into multiple sentences, showing that they do not fully determine the empirically defined content-heavy status (§ 5). Finally, we present an effective system to automatically identify content-heavy sentences in Chinese (§ 6, 7, 8).

2 Related work

The need for identifying content-heavy sentences arises in many specialized domains, including dialog systems, machine translation, text simplification and Chinese language processing but it is usually addressed in an implicit or application specific way. In contrast, we focus on identifying heavy sentences as a standalone task, providing a unifying view of the seemingly disparate strands of prior work. We now overview the literature which motivated our work.

Sentence planning. In text generation, a sentence planner produces linguistic realizations of a list of propositions (Rambow and Korelsky, 1992). One subtask is to decide whether to package the same content into one or more sentences. In the example below (Pan and Shaw, 2005), the multi-sentence expression B is much easier to process:

[A] This is a 1 million dollar 3 bedroom, 2 bathroom, 2000 square foot colonial with 2 acre of land, 2 car garage, annual taxes 8000 dollars in Armonk and in the Byram Hills school district.

[B] This is a 3 bedroom, 2 bathroom, 2000 square foot colonial located in Armonk with 2 acres of land. The asking price is 1 million dollar and the annual taxes are 8000 dollars. The house is located in the Byram Hills School District.

Identifying sentence [A] as heavy would be useful in selecting the best realization.

A crucial difference between our task and its counterpart in sentence planning is that traditional text generation systems have access to rich semantic information about the type of propositions the system needs to convey, while in our task we have access only to Chinese text. In some dialog systems, content selection is treated as an optimization problem, balancing the placement of full-stops and the insertion or deletion of propositions with the similarity of the resulting output and an existing corpus of acceptable productions (Pan and Shaw, 2005). Others formulate the problem as a supervised ranking task, in which different possible content realizations are generated, including variation in the number of sentences (Walker et al., 2001; Stent et al., 2004). With the introduction of the concept of content-heavy sentences, we can envision dialog systems addressing the sentence realization task in two steps, first predicting if the semantic content will require multiple sentences, then having different rankers for expressing the content in one or multiple sentences. In that case the ranker will need to capture only sentence-level information and the discourse-level decision to use multiple sentences will be treated separately.

Text simplification. "Text simplification, defined narrowly, is the process of reducing the linguistic complexity of a text, while still retaining the original information content and meaning" (Siddharthan, 2014). An important aspect of simplification is syntactic transformation in which sentences deemed difficult are re-written as multiple sentences (Chandrasekar et al., 1996; Aluísio et al., 2008). Our task may be viewed as identifying sentences in one language that will require simplification when translated, for the benefit of the speakers of the target language. In rule-based simplification systems, splitting is performed al-

ways when a given syntactic construction such as relative clause, apposition or discourse connective are detected (Chandrasekar et al., 1996; Siddharthan, 2006; De Belder and Moens, 2010). Most recently, text simplification has been addressed as a monolingual machine translation task from complex to simple language (Specia, 2010; Coster and Kauchak, 2011; Wubben et al., 2012). However simplification by repackaging the content into multiple sentences is not naturally compatible with the standard view of statistical MT in which a system is expected to produce a single output sentence for a single input sentence. Some of the recent systems using MT techniques separately model the need for sentence splitting (Zhu et al., 2010; Woodsend and Lapata, 2011; Narayan and Gardent, 2014). Identifying heavy sentences in simplification is equivalent to identifying sentences that require syntactic simplification.

Sentence structure and MT. Prior work in machine translation has discussed the existence of sentences in Chinese which would result in a poor translation if translated in one sentence in English. The main factors proposed to characterize such problematic sentences are sentence length (Xu and Tan, 1996) and the presence of given syntactic constructions (Xu et al., 2005; Yin et al., 2007; Jin and Liu, 2010). Mishra et al. (2014) used rules involving similar factors to distinguish sentences in Hindi that need simplification prior to translation.

In each of these approaches, the identified sentences are segmented into smaller units. Similar to work in text simplification, the simplification rules are applied to all sentences meeting certain criteria, normally to all sentences longer than a predefined threshold or where certain conjunctions or coordinations are present. In contrast, the model we propose here can be used to predict when segmentation is at all necessary.

Our approach to the problem is more compatible with the empirical evidence we presented in our prior work (Li et al., 2014) where we analyzed the output of Chinese to English machine translation and found that there is no correlation between sentence length and MT quality. Rather we showed that the quality of translation was markedly inferior, compared to overall translation quality, for sentences that were translated into multiple English sentences. This prior work was carried over a dataset containing a single reference translation for each Chinese sentence. In the work presented in this paper, we strengthen our findings by examining multiple reference translations for each Chinese sentence. We define heavy sentences based on agreement of translator choices and reader preferences.

Commas in Chinese. Often a comma in a sentence can be felicitously replaced by a full stop. Such commas offer a straightforward way to split a long sentence into multiple shorter ones by replacing the comma with a full stop. Monolingual text simplification systems often try to identify such commas. They are particularly common in Chinese and replacing them with full stops leads to improvements in the accuracy of syntactic parsing (Jin et al., 2004; Li et al., 2005). Moreover, existing syntactically parsed corpora conveniently provide numerous examples of these full-stop commas, and thus training data for systems to identify them (Xue and Yang, 2011; Yang and Xue, 2012). In this paper, we systematically study the relationship between the presence of full-stop commas in the sentence and whether it is content-heavy for Chinese to English translation.

3 Data

In this work we use three news datasets: the newswire portion of the NIST 2012 Open Machine Translation Evaluation (OpenMT) (Group, 2013), Multiple-Translation Chinese (MTC) parts 1-4 (Huang et al., 2002; Huang et al., 2003; Ma, 2004; Ma, 2006), and the Chinese Treebank (Xue et al., 2005). In OpenMT and MTC, multiple reference translations in English are available for each Chinese segment (sentence).

To study the relationship between content-heavy sentences and reader preference for multi-sentence translations (§ 4.1), we use OpenMT (688 segments) and MTC parts 2-4 (2,439 segments), both of which provide four English translations for each Chinese segment. This analysis forms the basis for labeling heavy sentences for supervised training and evaluation (§ 5, 6, 7).

The Chinese Treebank (CTB) has been used in prior work as data for identifying full-stop commas. Moreover, 52 documents in MTC part 1 were drawn from the CTB. The intersection of the two datasets allows us to directly analyze the relationship between heavy sentences and full-stop commas in Chinese (§ 5). Furthermore we use this intersection as test set to identify heavy sentences so we can directly compare with models developed

for comma disambiguation. To be consistent with the rest of the MTC data, we use 4 out of the 11 translators in part 1 in these experiments.[1]

Our model for Chinese full-stop comma recognition is trained following the features and training sets specified in Xue and Yang (2011)[2], excluding the overlapping MTC/CTB documents mentioned above. There are 12,291 sentences in training that contain at least one comma. A classifier for detecting heavy sentences is trained on OpenMT and MTC (excluding the test set). A quick inspection of both datasets reveals that Chinese sentences without a comma were never translated into multiple sentences by more than one translator. Therefore in our experiments we consider only sentences that contain at least one comma. There are 301 test sentences, 511 training sentences in OpenMT and 2418 in MTC. Sentences are processed by the Stanford NLP packages[3]. CTB gold-standard parses are used to obtain full-stop commas and to train comma disambiguation models.

4 Content-heavy sentences: definition

In this section we provide an operational definition for which sentences should be considered content-heavy, based on the choices made by translators and the fluency preferences of readers when a sentence is translated into a single or multiple sentences. We further demonstrate the difference in machine translation quality when translating content-heavy sentences compared to other sentences.

4.1 Content-heaviness and multi-sentence translations

First we quantify how often translators choose to translate a Chinese sentence into multiple English sentences. Content-heavy Chinese sentences are those for which there is a strong preference to produce multiple sentences when translating to English (at the end of the section we present specific criteria).

Obviously, splitting a sentence into multiple ones is often possible but is not necessarily preferred. In Table 2, we show in the "%data" columns the percentage of source sentences split in translation by 0, 1, 2, 3 and all 4 translators. For about 20% of segments in OpenMT and 15% in MTC, at least three of the translators produce a multi-sentence translation, a rate high enough to warrant closer inspection of the problem.

	OpenMT		MTC	
#ref multi	%data	%best multi	%data	%best multi
0	65.4	0	58.9	0
1	7.4	23.5	20.4	20.1
2	7.0	66.7	8.3	56.7
3	9.2	88.9	7.9	89.6
4	11.0	100	4.6	100

Table 2: Percentage of sentences for which a given number of translators prefer to use multiple sentences in English, along with percentage of times a multi-sentence translation was selected as most fluent and comprehensible by readers.

Next, we conduct a study to find out what level of translator agreement leads to strong reader preference for the same information to be presented in multiple sentences.

For each Chinese segment with one, two or three multi-sentence reference translations, we ask five annotators on Mechanical Turk to rank the reference translations according to their general flow and understandability. The annotators saw only the four randomly ordered English translations and were not shown the Chinese original, with the following instruction:

Below are 1-2 sentence snippets that describe the same content. Some are more readable and easier to understand than others. Your task is to rank them from the best to worst in terms of wording or flow (organization). There can be ties, but you have to pick one that is the best.

We obtain reader preference for each segment in the following manner: for each annotator, we take the highest ranked translation and check whether it consists of multiple sentences. In this way we have five binary indicators. We say readers prefer a sentence to have a multi-sentence translation in terms of flow and comprehensibility if the majority of these five indicators are positive.

In the "%best multi" columns of Table 2, we tabulate the percentage of segments with majority preference for multi-sentence translation, stratified by the number of translators who split the content. Obviously the more multi-sentence translations there are, the higher the probability that the readers will select one as the best translation. We are interested in knowing for which conditions the

[1] We did not use translator IDs as parameters in any of our systems.

[2] Document IDs 41-325, 400-454, 500-554, 590-596, 600-885, 900, 1001-1078, 1100-1151.

[3] The Stanford segmenter (Tseng et al., 2005), parser (Levy and Manning, 2003) and the CoreNLP package (Manning et al., 2014)

Criteria	%data(Y)	Y	N	Δbleu
heavy	27.2	15.34	19.24	**3.9**

Table 3: Percentage of data for heavy sentences along with BLEU scores for heavy and non-heavy sentences and their difference.

preference for multi-sentence translation exceeds the probability of randomly picking one.

When only one (out of four) translations is multi-sentence, the best translations chosen by the majority of readers contain multiple sentences less often than in random selection from the available translations. When two out of the four reference translations are multi-sentence, the reader preference towards them beats chance by a good margin. The difference between chance selection and reader preference for multiple sentences grows steadily with the number of reference translations that split the content. These data suggest that when at least two translators perform a multi-sentence translation, breaking down information in the source sentence impacts the quality of the translation.

Hence we define content-heavy sentences in Chinese to be those for which at least two out of four reference translations consist of multiple sentences.

4.2 A challenge for MT

We now quantitatively show that heavy sentences are particularly problematic for machine translation. We collect translations for each segment in OpenMT and MTC from the Bing Translator. We split the sentences into two groups, heavy and other, according to the gold standard label explained in the previous section. We then compare the BLEU score for sentences in a respective group, where each group is in turn used as a test set. The difference in BLEU scores (Δbleu) is a strong indicator whether these sentences are challenging for MT systems.

In Table 3 we show the BLEU scores and Δbleu for sentences that are heavy (Y) and non-heavy (N). Also included in the table is the percentage of heavy sentences in all the data.

Translations for heavy sentences received a BLEU score that is 3.9 points lower than those that are not. This clearly illustrates the challenge and potential for improvement for MT systems posed by content-heavy sentences. Therefore the ability to reliably recognize them provides a first step towards developing a better translation approach for such sentences.

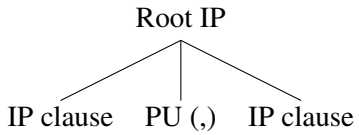

Figure 1: Coordinating IP structure at the root.

heavy	fs-comma	No fs-comma
N	19	180
Y	40	62

Table 4: Count of heavy and non-heavy sentences with and without full-stop commas.

5 Comma usage and heavy sentences

In Chinese, commas can sometimes act as sentence boundaries, similar to the function of an English period. In Xue and Yang (2011), the authors showed that these full-stop commas can be identified in the constituent parse tree as coordinating IPs at the root level, shown in Figure 1. Fancellu and Webber (2014) demonstrated that it is beneficial to split sentences containing negation on these types of commas, translate the resulting shorter sentences separately, then stitch the resulting translations together. They report that this approach prevented movement of negation particles beyond their scope. Here we study the degree to which the content-heavy status of a sentence is explained by the presence of a full-stop comma in the sentence. We show that they are interrelated but not equivalent.

Corpus analysis. First we study how often a heavy sentence contains a full-stop comma and vice versa, using the overlapping MTC/CTB documents. We show in Table 4 the number of heavy and non-heavy sentences with and without full-stop commas[4]. When there is a full-stop comma in the sentence, there is a higher chance that the sentence is content-heavy. Yet of the 102 heavy sentences in this data, fewer than 40% contain full-stop commas; of the 242 sentences without full-stop commas, more than a quarter are heavy. Therefore, although comma usage in the Chinese sentence may provide clues for detecting content heaviness, the two phenomena are not equivalent

[4]For the study we exclude sentences without a comma. A χ^2 test for the strength of association between the presence of full stop commas and heavy sentence status shows high significance.

and heavy sentences are not fully explained by the presence of full-stop commas.

Learning with full-stop commas. Here we evaluate the usefulness of using full-stop commas as training data to predict whether a sentence is content-heavy. From the analysis presented above we know that the two tasks are not equivalent. Nevertheless we would like to test directly if the Chinese Treebank—the large (but noisy for the task at hand) data available for comma function disambiguation—would lead to better results than learning on the cleaner but much smaller datasets for which multiple translations are available.

We use logistic regression as our classification model[5]. The performance of identifying heavy sentences on the MTC/CTB overlapping test set is compared using the following methods:

[Parallel] A classifier is trained using four English translations for each Chinese sentence (OpenMT and MTC training set). Following the definition in Section 4.1, content-heavy sentences are those translated into multiple English sentences by two or more translators.

[Oracle comma] A test sentence is assigned to class "heavy" if there is a full-stop comma in its corresponding gold standard parse tree.

[Predicted comma] We train a comma disambiguation system on CTB to predict if a comma is a full-stop comma. In testing, a sentence is marked "heavy" if it contains a predicted full-stop comma.

Features. We reimplemented the per-comma features used in Xue and Yang (2011)[6]. As in their best performing system, features are extracted from gold-standard parse trees during training and from automatic parsing during testing. These include: words and part-of-speech tags immediately before and after the comma; left- and right-sibling node labels of the parent of the comma; ordered ancestor node labels above the comma; punctuation tokens ordered from left to right of the sentence; whether the comma has a coordinating IP structure; whether the comma's parent is a child of the root of the tree; whether there is a subordination before the comma; whether the difference in number of words before and after the comma is greater than or equal to seven.

[5]We use the Liblinear package (Fan et al., 2008).

[6]For *predicted comma*, our reimplementation of Xue and Yang (2011) gave practically identical results to those reported in the original paper on the test set that they used.

Training	A	P	R
parallel	75.75	69.86	50
oracle comma	73.09	67.8	39.2
predicted comma	74.42	66.67	49.02

Table 5: Performance for identify heavy sentences using multiple reference data (parallel) vs. full-stop comma oracle labels (oracle comma) and predicted full-stop commas (predicted comma).

For *parallel*, feature values are accumulated from all the commas in the sentence. For binary features, we use an *or* operation on the feature values for each individual comma.

Results and comparison. In Table 5, we show the accuracy, precision and recall for identifying content-heavy sentences using the three methods described above. We do not include the majority baseline here because it assumes no sentences are content heavy.

Interestingly, the system using oracle information in each test sentence for full-stop commas performs the worst. The system trained to identify full-stop commas outperform the oracle system with about 10% better in recall and less than 1% lower in precision. This finding strongly suggests that the features used for learning capture certain characteristics of heavy sentences even with non-ideal training labels. The best performance is obtained learning directly on parallel corpora with multiple reference translations. Note that we try to provide the best possible setting for full-stop comma prediction, using much more training data, gold-standard parses, same-domain training and testing, as well as the reimplementation of state-of-the-art system. These settings allow us to conservatively interpret the results listed here, which confirm that content-heaviness is different from using a full-stop comma in the Chinese sentence. It is more advantageous—leading to higher precision and overall accuracy—to learn from data where translators encode their interpretation in the form of multi-sentence translations.

6 Features to characterize content-heavy sentences

In this section, we experiment with a wide range of features from the sentence string, part-of-speech tags and dependency parse trees.

Baseline. Intuitively, sentence length can be an indication of too much content that needs to be

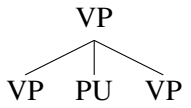

Figure 2: Multiple VP structures

repackaged into multiple sentences. Therefore as our baseline we train a decision tree using the number of words[7] in a Chinese sentence.

Sentence structure cues. We collect potential signals for structural complexity: punctuation, conjunctions, prepositional phrases and relative clauses. As features we count the number of commas, conjunction, preposition and postposition part-of-speech tags. In Chinese "DE" often marks prepositional phrases or relative clauses among other functions (Chang et al., 2009a). Here we include a simple count the number of "DEG" tags in the sentence.

Dependencies. Dependency grammar captures both syntactic and semantic relationship between words and are shown to improve reordering in MT (Chang et al., 2009b). To account for such relational information we include two feature classes: the percentage of each dependency type and the typed dependency pairs themselves. For the latter we use the universal part-of-speech tags (Petrov et al., 2012) for each word rather than the word itself to avoid too detailed and sparse representations. For example, the relation *dobj(处理/handle, 事情/matter)* becomes feature *dobj(verb, noun)*.

Furthermore, we use dependency trees to extract four features for potentially complex constructions. First, we indicate the presence of noun phrases with heavy modifiers on the left. These are frequently used in Chinese and would require a relative clause or an additional sentence in English. Specifically we record the maximum number of dependents for the nouns in the sentence. The second type of construction is the use of serial verb phrases, illustrated in Figure 2. We record the number of dependents of the head verb of the sentence. The third feature class is the typed dependencies (over universal POS tags) whose edge crosses a comma. Finally, we also record the maximum number of dependents in the sentence to capture the general phrasal complexity in the sentence.

[7] obtained using the Stanford Chinese Word Segmenter (Tseng et al., 2005)

Features	Training	A	P	R
baseline	MTC+OpenMT	71.43	73.5	24.5
full set	OpenMT	76.41	66.67	**60.78**
full set	MTC	78.41	74.03	55.9
full set	MTC+OpenMT	**80.73**	**79.73**	57.84

Table 6: Accuracy, precision and recall (for the content heavy class) of binary classification using proposed features to identify content-heavy sentences.

Parts-of-speech. POS information captures numerous aspects of the sentence such as the frequency of different classes of words used and the transition between them. Historically they are also shown to be helpful for phrase boundary detection (Taylor and Black, 1998). Here, we first convert all Chinese POS tags into their corresponding universal tags. We then use the percentage of each tag and tag bigram as two feature classes. To capture the transition of each phrase and clause in the sentence, we construct functional POS trigrams for each sentence by removing all nouns, verbs, adjectives, adverbs, numbers and pronouns in the sentence. Percentages of these sequences are used as feature values.

Comma disambiguation features. We also incorporate most of the features proposed by Xue and Yang (2011), aggregated in the same way as the *parallel* method (cf. Section 5). These include: POS tags immediately before and after the comma; left- and right-sibling node labels of the parent of the comma; the punctuation tokens ordered from left to right in the sentence, whether the comma has a coordinating IP structure; whether the comma's parent is a child of the root of the tree; whether there is a subordination before the comma; whether the difference in number of words before and after the comma is greater than or equal to seven.

7 Results

7.1 Recognizing content-heavy sentences

We train a logistic regression model as in the *parallel* method in Section 5 using features illustrated above. In Table 6, we show the performance of detecting heavy sentences using four systems: the baseline system using the number of words in the sentence and three systems using our full feature set, trained on MTC, OpenMT and both.

The baseline performance is characterized by a remarkably poor recall. It becomes appar-

#ref multi	≥ 0	≥ 1	≥ 2	≥ 3	4
#seg	301	187	102	58	25
precision	79.73	84.29	100	100	100
recall	57.85	57.84	57.84	68.98	76
posterior	0.29	0.40	0.53	0.61	0.67

Table 7: Number of segments, precision, recall and posterior probability (for the content-heavy class) for examples where at least 0-4 translators split the sentence.

ent that length alone cannot characterize content-heaviness. On the other hand, using the full feature set achieves an accuracy of above 80%, a precision close to 80% and a recall about 58%. The improvement in precision and recall over using oracle full-stop commas (Table 5) are about 12% and 19%. When compared with using features tuned for comma disambiguation from Xue and Yang (2011) (Table 5), our full feature set achieved a 5% increase in accuracy, about 10% increase in precision and 8% increase in recall.

We also demonstrate the usefulness of having more multi-reference translation data by comparing training using MTC and OpenMT individually and both. Remarkably, using only the very small dataset of OpenMT is sufficient to produce a predictor that is more accurate than all of the methods listed in Section 5. Adding these examples to MTC drastically improves precision by more than 13% with a less than 3% drop on recall.

Finally, we consider the portions of our test set for which at least n translators provided a multi-sentence translation (n ranges from 0 to 4). In Table 7 we show the respective precision, recall and the average posterior probability from the classifier for marking a sentence as content-heavy. There is a clear trend that the classifier is more confident and has higher precision for sentences where more translators produce multi-sentence translations. Although the model is not highly confident in all groups, the precision of the predictions are remarkably high. Miss rate also decreases when more translators translate the source into multiple sentences.

7.2 Post-hoc feature analysis

Here we identify which of the feature classes from our full set are most helpful by performing forward feature selection: in each iteration, the feature class that improves accuracy the most is selected. The process is repeated until none of the remaining feature classes lead to improvement when added to the model evaluated at the previous iteration. We use our test data as the evaluation set for forward selection, but we do so only to evaluate features, not to modify our system.

Five feature classes are selected using this greedy procedure. The first selected class is the typed dependencies over universal POS tags. Remarkably, this single feature class achieves 76.6% accuracy, a number already reasonably high and better than features used in Xue and Yang (2011). The second feature added is whether there is a comma of coordinating IP structure in the automatic parse tree of the sentence. It gives a further 1.7% increase in accuracy, showing that the comma structure provide useful information as features for detecting heavy sentences. Note that this feature does not represent full stop commas, i.e., it does not record whether the comma is under the root level of the parse tree. The next selected class is typed dependencies over universal POS tags that have an edge across commas in the sentence, with an 1% increase in accuracy. The fourth feature selected is the number of prepositions and postposition POS tags in the sentence, improving the accuracy about 1%. Finally, part-of-speech tags before each comma are added, with a 0.3% improvement of accuracy.

The results from forward selection analysis reveal that the dependency structure of a sentence captures the most helpful information for heavy sentence identification. The interplay between punctuation and phrase structure gives further important enhancements to the model. The final accuracy, precision and recall after forward selection are 0.804, 0.8209, 0.5392, respectively. This overall performance shows that forward selection yields a sub-optimal feature set, suggesting that the other features are also informative.

8 A challenge for MT: revisited

It is important to know whether a predictor for content-heavy sentences is good at identifying challenging sentences for applications such as machine translation. Here, we would like to revisit Section 4.2 and see if *predicted* heavy sentences are harder to translate.

For all the source sentences in OpenMT and MTC, we compare five criteria for dividing the test data in two subsets: whether the sentence contains a full-stop comma or not; whether the sentence is longer than the baseline decision tree threshold

Criteria	%data(Y)	Y	N	Δbleu
fs-comma	21.6	16.01	18.43	2.42
length threshold	8.6	15.38	18.3	2.92
pred-heavy (0.5)	22.72	15.81	18.77	2.96
pred-heavy (0.55)	19.72	15.47	18.76	3.29
pred-heavy (0.6)	16.67	14.95	18.77	3.82
oracle heavy	27.4	15.34	19.24	3.9

Table 8: Data portion, BLEU scores and differences for sentences with/without a full-stop comma, are/are not longer than the length threshold, are/are not content heavy.

(47 words) or not; whether the sentence is predicted to be content-heavy with posterior probability threshold of 0.5, 0.55 and 0.6. Predictions for the training portion is obtained using 10-fold cross-validation. In the same manner as Table 3, Table 8 shows the percentage of data that satisfies each criterion, BLEU scores of Bing translations for sentences that satisfy a criterion and those that do not, as well as the difference of BLEU between the two subsets (Δbleu). As reference we also include numbers listed in Table 3 using oracle content-heavy labels.

First, notice that regardless of the posterior probability threshold, the numbers of sentences predicted to be content-heavy are much larger than that using the length cutoff. These sentences are also collectively translated much worse than the sentences in the other subset. Sentences that contain a predicted full-stop comma are also harder to translate, but show smaller difference in BLEU than when sentence heaviness or length are used as separation criterion. As the posterior probability threshold goes up and the classifier becomes more confident when it identifies heavy sentences, there is a clear trend that system translations for these sentences become worse. These BLEU score comparisons indicate that our proposed model identifies sentences that pose a challenge for MT systems.

9 Conclusion and future work

In this work, we propose a cross-lingual task of detecting content-heavy sentences in Chinese, which are best translated into multiple sentences in English. We show that for such sentences, a multi-sentence translation is preferred by readers in terms of flow and understandability. Content-heavy sentences defined in this manner present practical challenges for MT systems. We further demonstrate that these sentences are not fully explained by sentence length or syntactically defined full-stop commas in Chinese. We propose a classification model using a rich set of features that effectively identify these sentences.

The findings in this paper point out a definite issue in different languages currently underinvestigated in text-to-text generation systems. One possible way to improve MT systems is to incorporate sentence simplification before translation (Mishra et al., 2014). Future work could use our proposed model to detect heavy sentences that needs such pre-processing. Our findings can also inspire informative features for sentence quality estimation, in which the task is to predict the sentence-level fluency (Beck et al., 2014). We have shown that heavy Chinese sentences are likely to lead to hard to read, disfluent sentences in English. Another important future direction lies in text simplification. In our inspection of parallel Wikipedia/Simple Wikipedia data (Kauchak, 2013), around 23.6% of the aligned sentences involve a single sentence on one side and multiple sentences on another. A similar analysis using ideas from this work can be useful in identifying sentences that needs simplification in the first place.

Acknowledgements

We would like to express our gratitude to Bonnie Webber for her detailed comments on earlier versions of this paper. Her encouragement and support were essential in seeing the work through to publication. We would also like the reviewers for their thoughtful suggestions which we have tried to incorporate in the final version. The work was partially supported by NSF CAREER grant IIS-0953445.

Abstract

Parameter tuning is a key problem for statistical machine translation (SMT). Most popular parameter tuning algorithms for SMT are agnostic of decoding, resulting in parameters vulnerable to search errors in decoding. The recent research of "search-aware tuning" (Liu and Huang, 2014) addresses this problem by considering the partial derivations in every decoding step so that the promising ones are more likely to survive the inexact decoding beam. We extend this approach from phrase-based translation to syntax-based translation by generalizing the evaluation metrics for partial translations to handle tree-structured derivations in a way inspired by inside-outside algorithm. Our approach is simple to use and can be applied to most of the conventional parameter tuning methods as a plugin. Extensive experiments on Chinese-to-English translation show significant BLEU improvements on MERT, MIRA and PRO.

1 Introduction

Efforts in parameter tuning algorithms for SMT, such as MERT (Och, 2003; Galley et al., 2013), MIRA (Watanabe et al., 2007; Chiang et al., 2009; Cherry and Foster, 2012; Chiang, 2012), and PRO (Hopkins and May, 2011) have improved the translation quality considerably in the past decade. These tuning algorithms share the same characteristic that they treat the decoder as a black box. This decoding insensitiveness has two effects: 1) the parameter tuning algorithm can be more general to choose the most effective decoding paradigm for different language pairs; 2) however, it also means that the learned parameters may not fit the decoding algorithm well, so that promising partial translations might be pruned out due to the beam search decoding.

Recent researches reveal that the parameter tuning algorithms tailored for specific decoding algorithms can be beneficial in general structured prediction problems (Huang et al., 2012), and in machine translation (Yu et al., 2013; Zhao et al., 2014; Liu and Huang, 2014). Particularly, Liu and Huang (2014) show that by requiring the conventional parameter tuning algorithms to consider the final decoding results (full translations) as well as the intermediate decoding states (partial translations) at the same time, the inexact decoding can be significantly improved so that correct intermediate partial translations are more likely to survive the beam. However, the underlying phrase-based decoding model suffers from limited distortion, and thus, may not be flexible enough for translating language pairs that are syntactically different, which require long distance reordering.

In order to better handle long distance reordering which beyonds the capability of phrase-based MT, we extend the search-aware tuning framework from phrase-based MT to syntax-based MT, in particular the hierarchical phrase-based translation model (HIERO) (Chiang, 2007).

One key advantage of search-aware tuning for previous phrase-based MT is the minimal change to existing parameter tuning algorithms, which is achieved by defining BLEU-like metrics for the intermediate decoding states with sequence-structured derivations. To keep our approach simple, we generalize these BLEU-like metrics to handle intermediate decoding states with tree-structured derivations in HIERO, which are calculated by dynamic programming algorithms inspired by the inside-outside algorithm.

We make the following contributions:

1. We extend the framework of search-aware tuning methods from phrase-based translation to syntax-based translation. This extension is simple to be applied to most conventional parameter tuning methods, requiring minimal extra changes to existing algorithms.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1282–1291,
Lisbon, Portugal, 17-21 September 2015.

2. We propose two BLEU metrics and their variants to evaluate partial derivations. In order to efficiently compute the new BLEU metrics, we investigate dynamic programming based algorithms to recover the good partial derivations for search-aware tuning.

3. Our method obtains significant improvements on large-scale Chinese-to-English translation on top of MERT, MIRA and PRO baselines.

2 Hierarchical Phrase-based Decoding

We first briefly describe the hierarchical phrase-based translation (Chiang, 2007), HIERO, by a Chinese-English translation example (Figure 1).

A HIERO decoder translates a source sentence by using a synchronous grammar (Figure 1 (a)) to parse it into a bilingual derivation tree, as shown in Figure 1 (b) and Figure 1 (c). An example rule of the synchronous grammar is

$$r_8 : \mathrm{X} \rightarrow \langle \mathrm{X}_1 \text{ qian } \mathrm{X}_2, \mathrm{X}_2 \text{ before } \mathrm{X}_1 \rangle,$$

where the left-hand-side is a non-terminal symbol, and the right-hand-side is a pair of source and target strings, each of which consists a sequence of lexical terminals and non-terminals. Specifically, the same subscript on both sides denotes a one-to-one correspondence between their non-terminals. We use $|r|$ to denote the arity of rule r, i.e., the number of non-terminals. Usually, the rule used in HIERO system has a maximum arity 2.

Let $\langle x, y \rangle$ be a Chinese-English sentence pair in tuning set, the HIERO decoder will generate a derivation tree for it (Figure 1 (b)), which can be defined recursively in a *functional* way:

$$d = \begin{cases} r & |r| = 0 \\ r(d_1) & |r| = 1 \\ r(d_1, d_2) & |r| = 2 \,, \end{cases} \quad (1)$$

where d is a (partial) derivation, i.e., the (sub-) derivation tree. When r is a fully lexicalized rule ($|r| = 0$), the decoder generates a tree node directly (e.g., $X_{[3,5]}$ in Figure 1 (b)). If $|r| > 0$, a new (partial) derivation will be created by applying r to its children nodes. In our notation, we denote this process as applying a function of rule r to its arguments. For example, node $X_{[1,5]}$ in Figure 1(b) is created by applying rule r_8 in Figure 1(a), where the arguments are $d_1 = X_{[1,2]}$ and $d_2 = X_{[3,5]}$ respectively.

Practically, we organize the partial derivations based on spans in HIERO decoder, and use a beam $B_{[i,j]}$ to keep the k-best partial derivations for each span $[i, j]$:

$$B_{[i,j]} = \mathbf{top}^k_{\mathbf{w}} \left(D_{[i,j]} \right),$$

where $D_{[i,j]}$ is the set of all possible partial derivations for span $[i, j]$, and $\mathbf{top}^k_{\mathbf{w}}(\cdot)$ returns the top k ones according to the current model $\mathbf{w}$. Figure 2 shows an example of the HIERO beam-search decoding.

3 Search-Aware Tuning for HIERO

As we discussed in Section 1, current tuning methods for HIERO system (MERT, MIRA, or PRO) are mostly *search-agnostic*. They only consider the *complete* translations in final beam $B_{[1,|x|]}$, but ignore the partial ones in the intermediate beams. However, because MT decoding is inexact (beam-search), many potentially promising derivations might be pruned before reaching the final beam (e.g., the partial derivation $X_{[1,5]}$ of Figure 1(b) is pruned in beam $B_{[1,5]}$ in Figure 2). Consequently, once we lose these good partial derivations in decoding, it is hard to promote them by these search-agnostic tuning methods.

In order to address this problem, search-aware tuning (Liu and Huang, 2014) aims to promote not only the accurate complete translations in the final beam, but more importantly those promising partial derivations in non-final beams.

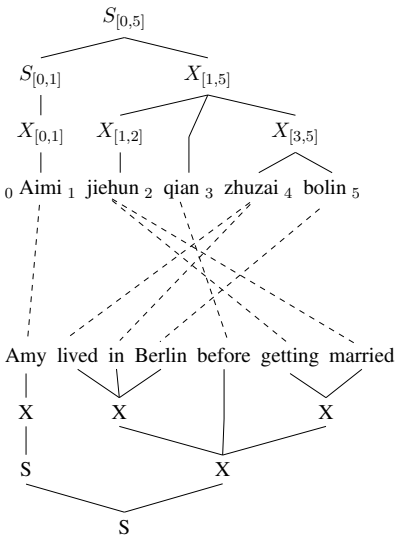
In this section, we apply search-aware tuning to HIERO system. Similar to the phrase-based one, the key challenge here is also the evaluation of partial derivations. Following (Liu and Huang, 2014), we design two different evaluation metrics, *partial* BLEU and *potential* BLEU respectively for HIERO decoding.

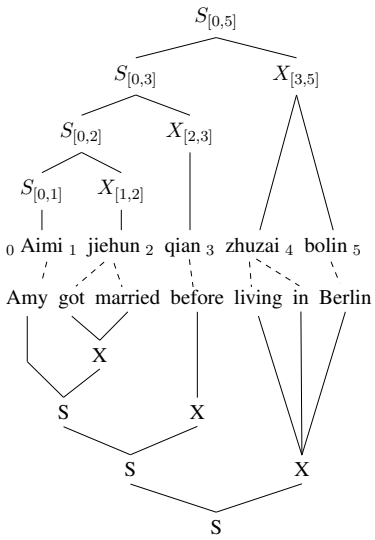
3.1 Partial BLEU

Given a partial derivation d of span $[i, j]$, *partial* BLEU evaluates it by comparing its partial translation $e(d)$ directly with the (full) reference. We explore two different partial BLEU measures here: *full partial* BLEU and *span partial* BLEU.

Full partial BLEU is similar to the one used in (Liu and Huang, 2014), which compares $e(d)$ with the full reference y and computes BLEU score using an adjusted effective reference length proportional to the length of the source span $[i, j]$ (i.e.,

id	rule
r_0	S → ⟨X$_1$, X$_1$⟩
r_1	S → ⟨S$_1$X$_1$, S$_1$X$_1$⟩
r_2	X → ⟨Aimi, Amy⟩
r_2	X → ⟨Aimi, Amy has⟩
r_3	X → ⟨zhuzai bolin, lived in Berlin⟩
r_3	X → ⟨zhuzai bolin, living in Berlin⟩
r_4	X → ⟨qian, before⟩
r_5	X → ⟨qian, former⟩
r_6	X → ⟨jiehun, got married⟩
r_7	X → ⟨jiehun, getting married⟩
r_8	X → ⟨X$_1$ qian X$_2$,X$_2$ before X$_1$⟩
r_9	X → ⟨X$_1$ qian X$_2$,X$_1$ before X$_2$⟩





(a) HIERO rules (b) good derivation (c) bad derivation

Figure 1: An example of HIERO translation.

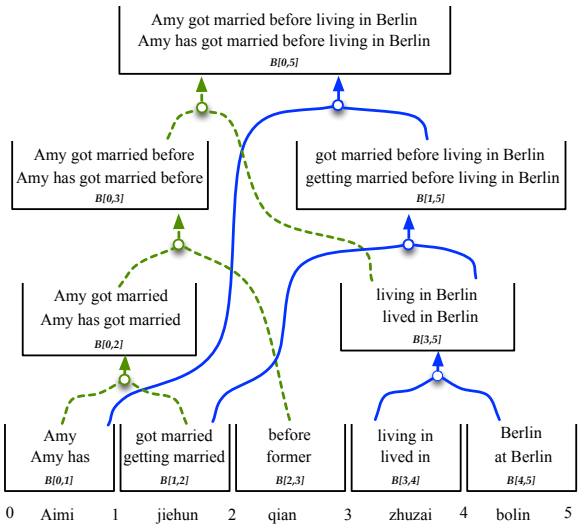


Figure 2: An example of HIERO beam search decoding (beam size = 2). We can see the good derivation (Figure 1(b)) is pruned very early, while the bad derivation (Figure 1(c)) ranks first at the final beam.

the number of translated source words). See (Liu and Huang, 2014) for more details.

Span partial BLEU differs from full partial BLEU by creating a *span reference* for span $[i, j]$ to evaluate its partial derivations, rather than using the full reference. We use word alignment to determine the span references of different spans. Specifically, we first add the tuning set into training data, and then run GIZA++ to get the word alignment. For a pair of source and target span which are consistent with word alignment[1], the string of target span is used as the span reference for the source span.[2] For example, in Figure 1(b), the span reference of source span $[1, 5]$ is "lived in Berlin before getting married".

Partial BLEU is quite an intuitive choice for evaluating partial derivations. However, as Liu and Huang (2014) discussed, partial BLEU only evaluates the partial derivation itself without considering any of its context information, leading to a performance degradation. Thus, in order to take the context information into account, we investigate a more reasonable metric, potential BLEU, in the next section.

3.2 Potential BLEU

Potential BLEU evaluates the partial derivation d by assessing its *potential*, which is a complete translation generated from d, rather than $e(d)$ as in partial BLEU. In phrase-based decoding, Liu

[1]Two spans are consistent with word alignment means that words in one span only align to words in the other span via word alignment, and vice versa.

[2]In practice, there might be several different consistent target spans for a source span due to the unaligned words. We use the longest target span as the span reference which shows the best performance in our experiments.

and Huang (2014) introduce a future string $f(d)$ to denote the translation of the untranslated part, and get the potential of d by concatenating $e(d)$ and $f(d)$.

Different from their work, we define an *outside string* for d in HIERO system. Suppose a complete translation generated from d is $\bar{e}(d)$, it can be decomposed as follows:

$$\bar{e}(d) = \eta(d) \circ e(d) \circ \xi(d) \quad (2)$$

where $\circ$ is an operator that concatenates strings monotonically, $\eta(d)$ and $\xi(d)$ are the left and right parts of $\bar{e}(d)$ apart from $e(d)$, which we call *left* and *right future strings* of d. The pair of $\eta(d)$ and $\xi(d)$ is defined as the outside string of d:

$$O(d) = \langle \eta(d),\ \xi(d) \rangle$$

An example of the outside string is shown in Figure 3. Assume we are evaluating the partial derivation which translates Chinese word "qian" to English word "before", and get a complete translation "Amy lived in Berlin before getting married" from it, then its outside string would be:

$$\langle \text{Amy lived in Berlin,}\ \ \text{getting married} \rangle$$

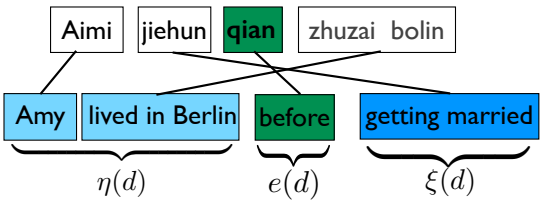

Figure 3: Example of outside string when we use"Amy lived in Berlin before getting married" as the potential for the partial derivation which translates word "qian" to "before".

Theoretically, different partial derivations of the same span could have different outside strings. To simplify the problem, we use the same outside string for all partial derivations of the same span. The outside string for span $[i, j]$ is defined as:

$$O([i,j]) = \langle \eta([i,j]),\ \xi([i,j]) \rangle$$

For a specific partial derivation d of span $[i, j]$, by combining $O([i, j])$ and $e(d)$, we can compute its potential BLEU against the reference. Apparently, different outside string will lead to different potential BLEU score. In the rest of this section, we will explore three different methods to generate outside strings.

3.2.1 Concatenation

In order to generate outside string, one simple and straightforward way is concatenation. For a specific span $[i, j]$, we first get the best translation of its adjacent spans $[0, i]$ and $[j, |x|]$ ($e([0, i])$ and $e([j, |x|])$ respectively).[3] Then for a partial derivation d of span $[i, j]$, we generate the outside string of d by *concatenation*

$$\eta([i,j]) = e([0,i])$$
$$\xi([i,j]) = e([j,|x|])$$
$$\bar{e}_x(d) = e([0,i]) \circ e(d) \circ e([j,|x|])$$

Also take the example of Figure 3, if we perform concatenation on it, the outside string of the corresponding partial derivation is:

$$\langle \text{Amy getting married,}\ \ \text{lived in Berlin} \rangle.$$

Obviously, this outside string is not good, since it does not consider the reordering between spans. In order to incorporate reordering into outside string, we propose a new top-down algorithm in the next subsection.

3.2.2 Top-Down

Top-down method (Algorithm 1) is defined over the derivation tree, and takes the complete translations in the final beam as the potential for computing potential BLEU.

Suppose we have a partial derivation $d = r(d_1, d_2)$ as shown in Formula 1, and the target side string of rule r is:

$$w_1 \cdots w_p\ X_1\ w_q \cdots w_m\ X_2\ w_n \cdots w_l$$

The corresponding *(partial) translation* $e(d)$ of d could be generated by applying an r-based function $e_r(\cdot)$ with d_1 and d_2 as the arguments:

$$e_r(d_1, d_2) = w_1 \cdots w_p\ e(d_1)\ w_q \cdots w_m\ e(d_2)\ w_n \cdots w_l$$

where $e(d_1)$ and $e(d_2)$ are the partial translations of d_1 and d_2. We can further decompose $e_r(d_1, d_2)$ based on $e(d_1)$:

$$\underbrace{w_1 \cdots w_p}_{\eta_d(d_1)}\ \ e(d_1)\ \ \underbrace{w_q \cdots w_m\ \ e(d_2)\ \ w_n \cdots w_l}_{\xi_d(d_1)}.$$

where we call $\eta_d(d_1)$ and $\xi_d(d_1)$ the *partial left and right future strings* of d_1 under d. Similar

[3] For the spans not having translations, we compute a best possible translation for each of them by concatenating the translations of its children spans monotonically.

Algorithm 1 Top-Down Outside String.

```
1: function TopDown(d)
2:   r ← the rule that generates d
3:   for each non-terminal x in rule r do
4:     η(d_x) = η(d) ∘ η_d(d_x)
5:     ξ(d_x) = ξ_d(d_x) ∘ ξ(d)
6:     TopDown(d_x)
7:   return
```

to the outside cost of inside-outside algorithm, we compute the outside string $\langle \eta(d_1), \xi(d_1) \rangle$ for d_1 based on the decomposition:

$$\eta(d_1) = \eta(d) \circ \eta_d(d_1)$$
$$\xi(d_1) = \xi_d(d_1) \circ \xi(d).$$

Similarly, if we decompose $e_r(d_1, d_2)$ based on $e(d_2)$ we have:

$$\underbrace{w_1 \cdots w_p \;\; e(d_1) \;\; w_q \cdots w_m}_{\eta_d(d_2)} \;\; e(d_2) \;\; \underbrace{w_n \cdots w_l}_{\xi_d(d_2)},$$

and the outside string $\langle \eta(d_2), \xi(d_2) \rangle$ for d_2 is:

$$\eta(d_2) = \eta(d) \circ \eta_d(d_2)$$
$$\xi(d_2) = \xi_d(d_2) \circ \xi(d).$$

The top-down method works based on the above decompositions. For a complete translation in the final beam $B_{[0,|x|]}$, the algorithm tracebacks on its derivation tree, and gets the outside string for all spans in the derivation. Taking the span $[1, 2]$ in Figure 1(b) as an example, if we do top-down, its outside string would be:

$$\langle \text{Amy lived in Berlin before}, \;\; \epsilon \rangle.$$

where ϵ denotes the empty string. Compared to the concatenation method, top-down is able to consider the reordering between spans, and thus would be much better. However, since it bases on the k-best list in the final beam, it can only handle the spans appearing in the final k-best derivations. In our experiments, top-down algorithm only covers about 30% of all spans.[4] In order to incorporate more spans into search-aware tuning, we enhance the top-down algorithm and propose guided backtrace algorithm in the next subsection.

3.2.3 Guided Backtrace

The *guided backtrace* algorithm is a variation of top-down method. In guided backtrace, we first introduce a container $s_{[i,j]}$ to keep a best partial derivation for each split point of $[i, j]$ during decoding.[5] Hence, there will be at most $j - i$ partial derivations in $s_{[i,j]}$.[6] For instance, suppose the span is $[2, 5]$, we will keep three partial derivations in $s_{[i,j]}$ for split point 2, 3, and 4 respectively. Different from the similar k-best list in the decoding beam, $s_{[i,j]}$ introduces more diverse partial derivations for backtracing, and thus could help to cover more spans.

After decoding, we employ algorithm 2 to do backtrace. The algorithm starts from the best translation in the final beam. At first, we get the corresponding span of the input partial derivation d (line 2), and the outside string for this span (line 5-6). We then sort the partial derivations in $s_{[i,j]}$ based on their potential Bleu^{+1} (line 12). Thus, the sorting will guide us to first backtrace the partial derivations with better potential Bleu^{+1} scores. Then we traverse all these partial derivations (line 13-14), and do guided backtrace recursively on its child partial derivations (line 16-19). In this process, about 90% of all spans are visited in our experiments. We demand each span will only be visited once (line 3-4),

During the above process, guided backtrace will collect good partial derivations which have better potential Bleu^{+1} scores than the best Bleu^{+1} score *MaxSenBleu* of the final beam (line 10-11) into *goodcands*. Meanwhile, we also collect the good partial derivations from descendant nodes (line 19), and apply rule r to them to form good partial derivations for span $[i, j]$ (line 20-21). At last, we add the top 50 good partial derivations to the beam $B_{[i,j]}$ for tuning (line 22).

The purpose of adding good partial derivations for tuning is to recover the good ones pruned out of the beam. For example, the partial derivation $X_{[1,5]}$ in Figure 1 has been pruned out of the beam $B_{[1,5]}$ in Figure 2. If we only consider the partial derivations in the beam, it is still hard to promote it. After adding good partial derivations, we will have more good targets to do better tuning.

From Algorithm 2, we can also get a new way to compute oracle BLEU score of a translation system. We memorize the string that has the maximum potential Bleu^{+1} score of all strings (line 9). We then collect the best string of all source sen-

[4] We do not consider the hypothesis recombination in top-down algorithm.

[5] If the partial derivation is generated by HIERO rules, we set the split point as the last position of the first non-terminal.

[6] Some split points might not have corresponding partial derivations.

tences in the tuning or test set, and use them to compute BLEU score of the set. This can be seen as an approximation upper bound of the current model and decoder, which we call **guided oracle**.

3.3 Implementation

The major process of search-aware tuning is similar to traditional tuning pipeline. We first decode the source sentence, and then output both the complete translations in the final beam and the partial derivations from the shorter spans as training instances. For potential BLEU, the outputs of partial derivations would be the corresponding complete translations generated by Equation (2). If we use partial BLEU, the outputs are the corresponding partial translations. Each span will serve as a single tuning instance. Different from (Liu and Huang, 2014), we only use the features from partial derivations for tuning.

For the spans that top-down or guided backtrace algorithm cannot get outside strings, we use concatenation for them to maintain consistent number of tuning instances between different tuning iterations. However, since we do not want to spent much effort on them, we only use the one-best partial derivation for each of them.

4 Experiments

To evaluate our method, we conduct experiments on Chinese-to-English translation. The training data includes 1.8M bilingual sentence pairs, with about 40M Chinese words and 48M English words. We generate symmetric word alignment using GIZA++ and the *grow-diag-final-and* strategy. We train a 4-gram language model on the Xinhua portion of English Gigaword corpus by SRILM toolkit (Stolcke, 2002). We use BLEU 4 with "average reference length" to evaluate the translation performance for all experiments.

We use the NIST MT 2002 evaluation data (878 sentences) as the tuning set, and adopt NIST MT04 (1,789 sentences), MT05 (1,082 sentences), MT06 (616 sentences from new portion) and MT08 (691 sentences from new portion) data as the test set.

Our baseline system is an in-house hierarchical phrase-based system. The translation rules are extracted with Moses toolkit (Koehn et al., 2007) by default settings. For the decoder, we set the beam size to 30, nbest list to 50, and 20 as the maximum length of spans for using non-glue rules.

The baseline tuning methods are batch tuning methods based on k-best translations, including MERT (Och, 2003), MIRA (Cherry and Foster, 2012) and PRO (Hopkins and May, 2011) from Moses. Another baseline tuning method is hypergraph-MERT from `cdec` toolkit (Dyer et al., 2010). To guarantee the tuning efficiency, we constrain the minimum length of spans for search-aware tuning to restrict the number of training instances. For the sentences with less than 20 words, we only use the spans longer than 0.75 times sentence length. For the ones with more than 20 words, the minimum span length is set to 18.[7] All results are achieved by averaging three independent runs for fair comparison (Clark et al., 2011).

4.1 Translation Results

Table 1 compares the main results of our MERT-based search-aware tuning with traditional tuning: MERT and hypergraph-MERT.

From the results, we can see that hypergraph-MERT is better than MERT by 0.5 BLEU points, verifying the result of (Kumar et al., 2009). For search-aware tuning, partial BLEU (both full and span one) only gets comparable results with baseline tuning method, confirming our previous analysis in section 3.1, and the results are also consistent with (Liu and Huang, 2014).

[7] As the decoder demands that spans longer than 20 can only be translated by glue rule, for these spans, we only need to consider the ones beginning with 0 in search-aware tuning.

	nist03	nist04	nist05	nist06	nist08	avg.
MERT	34.4	35.9	34.2	31.9	28.2	32.9
MERT-S	34.3	36.1	34.3	32.3	28.5	33.1
hypergraph-MERT	34.5	36.4	34.4	33.0	28.9	33.4
full partial BLEU	34.3	35.9	34.1	32.4	28.1	33.0
span partial BLEU	34.1	36.1	34.5	32.5	28.4	33.1
concatenation	34.3	36.4	34.6	33.1	28.5	33.4
top-down	34.5	36.6	34.5	33.1	28.9	33.5
guided backtrace	**34.9**	**36.9**	**35.2**	**33.7**	**29.1**	**34.0**

Table 1: MERT results: BLEU scores the test sets (nist03, nist04, nist05, nist06, and nist08). MERT-S is an enhanced version of MERT, which uses a beam size 200 and nbest list 200 for tuning, and beam size 30 for testing.

	methods	nist02	nist04
1-best	MERT	36.1	35.9
	guided backtrace	**+0.5**	**+1.0**
k-best Oracle	MERT	43.3	42.8
	guided backtrace	**+1.1**	**+1.2**
Guided Oracle	MERT	48.0	47.2
	guided backtrace	**+1.4**	**+1.4**

Table 2: The oracle BLEU comparison between baseline MERT and guided backtrace.

Compared to partial BLEU, potential BLEU is more helpful. Both concatenation and top-down method are better than MERT on all five test sets. Guided backtrace gets the best performance over all methods. It outperforms traditional MERT by 1.1 BLEU points on average, and better than hypergraph-MERT by 0.6 BLEU points.

4.2 Analysis

In this section, we analyze the results of search-aware tuning by comparing MERT-based baseline and guided backtrace in detail.

Oracle BLEU We first compare the oracle BLEU scores of baseline and guided backtrace in Table 2. In order to get the k-best oracle, we first look for the best Bleu^{+1} translation in the k-best list for each source sentence, and then use these best translations to compute the BLEU score of the entire set. To get the guided oracle, we use the weights from baseline MERT to run Algorithm 2 on tuning set (nist02) and nist04 test set, and generate the best oracle translation (section 3.2.3) for each source sentence for evaluation.

The final oracle BLEU comparison is shown in Table 2. On both nist02 tuning set and nist04 test set, guided backtrace method gains at lease 1.0 BLEU points improvements over traditional MERT on both k-best oracle and guided oracle. Moreover, k-best and guided oracle get more improvements than 1-best, indicating that by search-aware tuning, the decoder could generate a better k-best list, and has a higher upper bound.

	nist02	nist04
MERT	0.3960	0.3791
guided backtrace	0.4098	0.3932

Table 3: The diversity comparison based on k-best list in the final beam on both tuning set (nist02) and nist04 test set. The higher the value is, the more diverse the k-best list is.

Diversity As shown in (Gimpel et al., 2013; Liu and Huang, 2014), diversity is important for MT tuning. An k-best list with higher diversity can better represent the entire decoding space, and thus tuning on it will lead to a better performance.

Similar as (Liu and Huang, 2014), our method encourages the diversity of partial translations in each beam, including the ones in the final beam. We use the metric in (Liu and Huang, 2014) to compare the diversity of traditional MERT and guided backtrace. The metric is based on the n-gram matches between two sentences y and y':

$$\Delta(y, y') = -\sum_{i=1}^{|y|-q} \sum_{j=1}^{|y'|-q} \langle y_{i:i+q} = y'_{j:j+q} \rangle$$

$$d(y, y') = 1 - \frac{2 \times \Delta(y, y')}{\Delta(y, y) + \Delta(y', y')},$$

where $q = n - 1$ and $\langle x \rangle$ equals to 1 if x is true, 0 otherwise. The final diversity results are shown in Table 3. We can see guided backtrace gets a better diversity than traditional MERT.

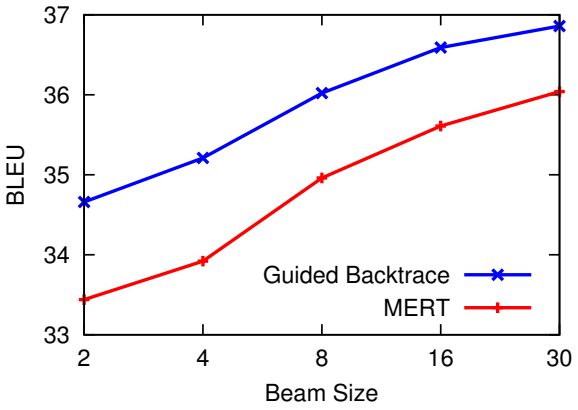

Figure 4: The BLEU comparison between MERT and guided backtrace on nist04 test set over different beam sizes.

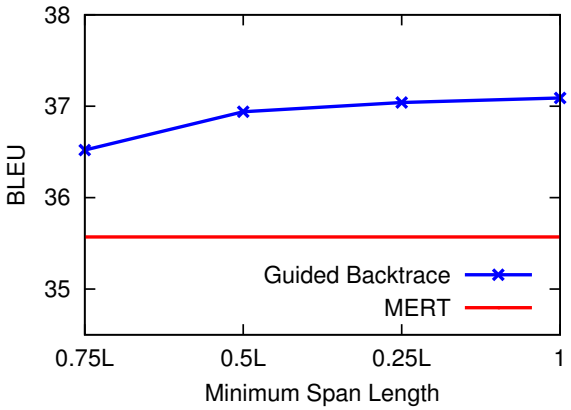

Figure 5: The BLEU comparison between MERT and guided backtrace on nist04 test set over different span sizes. L denotes the sentence length. The value of x-axis refers to the minimum length of spans used for search-aware tuning. More spans will be used in tuning with smaller minimum span length.

Beam Size As we discussed before, search-aware tuning helps to accommodate search errors in decoding, and promotes good partial derivations. Thus, we believe that even with a small beam, these good partial derivations can still survive with search-aware tuning, resulting in a good translation quality. Figure 4 compares the results of different beam sizes $(2, 4, 8, 16, 30)$ between traditional MERT and guided backtrace. The comparison shows that guided backtrace achieves better result than baseline MERT, and when the beam is smaller, the improvement is bigger. Moreover, guided backtrace method with a beam size 8 could achieve comparable BLEU score to traditional MERT with beam size 30.

Span Size For a big tuning set, in order to make the tuning tractable, we constrain the length of spans for search-aware tuning. Intuitively, towards search-aware tuning, more spans will get better results because we have more training instances to guide the tuning process, and accommodate search errors in early decoding stage (shorter spans). To verify this intuition, we perform experiments on a small tuning set, which is generated by selecting the sentences with less than 20 words from the original NIST MT 02 tuning set.

Figure 5 compares the results of traditional MERT and guided backtrace over different minimum span length. The curve in the figure shows that by using more spans for search-aware tuning, we can achieve better translation performance.

4.3 MIRA and PRO Results

Table 4 and Table 5 shows the final results of MIRA and PRO for traditional tuning and search-aware tuning using potential BLEU. We can see that potential BLEU is helpful for tuning. Guided backtrace is also the best one, which outperforms the baseline MIRA and PRO by 0.9 and 0.8 BLEU points on average.

4.4 Efficiency

Table 6 shows the training time comparisons between search-aware tuning and traditional tuning. From this Table, we can see that search-aware tuning slows down the training speed.[8] The slow training is due to three reasons.

Similar to (Liu and Huang, 2014), as search-aware tuning considers partial translations of spans besides the complete translations, it has much more training instances than traditional tuning. In our experiments, although we have constrained the length of spans, we get a total of 38,539 instances for search-aware tuning, while it is 878 for traditional tuning.

Another time consuming factor is the computation of Bleu^{+1} scores. In guided backtrace setting, we need to compute the Bleu^{+1} scores for all candidates of spans we consider. This is why the

[8] Since the tuning set is different for traditional PRO tuning and search-aware tuning, we do not compare them here.

	nist03	nist04	nist05	nist06	nist08	avg.
MIRA	34.5	36.1	34.4	32.1	28.5	33.1
concatenation	34.5	36.5	34.6	33.6	28.9	33.6
top-down	34.4	36.6	34.6	33.5	28.8	33.6

guided backtrace	**35.0**	**36.8**	**34.7**	**33.4**	**29.6**	**33.9**

Table 5: PRO results: BLEU scores on test sets (nist03, nist04, nist05, nist06, and nist08). Similar to (Liu and Huang, 2014), there is also an monster phenomenon (Nakov et al., 2013) in our search-aware tuning setting. Therefore, here we perform search-aware tuning on only 109 short sentences (with less than 10 words) from nist02.

	MERT		MIRA	
	Total	Optim.	Total	Optim.
baseline	17	2	17	2
concatenation	59	44	38	23
top-down	31	14	23	8
guided backtrace	108	45	69	22

Table 6: Comparison on training efficiency. The time (in minutes) is measured at the last iteration of tuning. Column "Total" refers to the time for an entire iteration, while "Optim." is the time of optimization. We use a parallelized MERT for tuning by 24 cores.

decoding of guided backtrace is much slower than baseline or top-down.

Finally, adding good candidates enlarges the k-best lists of training instances, which further slows down the tuning process of guided backtrace.

It should be noted that although search-aware tuning is slower than traditional tuning method, since the decoding is all the same for them in testing time, it does not slow down the testing speed.

5 Conclusion

We have presented an extension of "search-aware tuning" to accommodate search errors in hierarchical phrase-based decoding and promote the promising partial derivations so that they are more likely to survive in the inexact beam search. In order to handle the tree-structured derivations for HIERO system, we generalize the BLEU metrics and propose corresponding partial BLEU and potential BLEU to evaluate partial derivations. Our approach can be used as a plugin for most popular parameter tuning algorithms including MERT, MIRA and PRO. Extensive experiments confirmed substantial BLEU gains from our method.

Part-of-speech Taggers for Low-resource Languages using CCA Features

Abstract

In this paper, we address the challenge of creating accurate and robust part-of-speech taggers for low-resource languages. We propose a method that leverages existing parallel data between the target language and a large set of resource-rich languages without ancillary resources such as tag dictionaries. Crucially, we use CCA to induce latent word representations that incorporate cross-genre distributional cues, as well as projected tags from a full array of resource-rich languages. We develop a probability-based confidence model to identify words with highly likely tag projections and use these words to train a multi-class SVM using the CCA features. Our method yields average performance of 85% accuracy for languages with almost no resources, outperforming a state-of-the-art partially-observed CRF model.

1 Introduction

We address the challenge of creating accurate and robust part-of-speech taggers for low-resource languages. We aim to apply our methods to the hundreds, and potentially thousands, of languages with meager electronic resources. We do not assume the existence of a tag dictionary, or any other sort of prior knowledge of the target language. Instead, we base our methods entirely on the existence of parallel data between the target language and a set of resource-rich languages.

Fortunately, such parallel data exists for just about every written language, in the form of Bible translations. Around 2,500 languages have at least partial Bible translations, and somewhere between 500 and 1,000 languages have complete translations. We have collected such electronic Bible translations for 650 languages. Figure 1 breaks down the number of languages in our collection according to their token count. The majority of our languages have at least 200,000 tokens of Bible translations.

While previous studies (Täckström et al., 2013; Ganchev and Das, 2013) have addressed this general setting, they have typically assumed the existence of a partial tag dictionary as well as large quantities of non-parallel data in the target language. These assumptions are quite reasonable for the dozen most popular languages in the world, but are inadequate for the creation of a truly world-wide repository of NLP tools and linguistic data.

In fact, we argue that such ancillary sources of information are not really necessary once we take into account the vastly multilingual nature of our parallel data. Annotations projected from individual resource-rich languages are often noisy and unreliable, due to systematic differences between the languages in question, as well as word alignment errors. We can thus think of these languages as very lazy and unreliable annotators of our target language. Despite their incompetence, as the number of such annotators increases, their combined efforts converge upon the truth, as idiosyncratic biases and random noise are washed away.

Our assumption throughout will be that we have in our possession a single multilingual corpus (the Bible) consisting of about 200,000 tokens for several hundred languages languages, as well as reasonably accurate POS taggers for about ten "resource-rich" languages. We will tag the Bible data for the resource-rich languages, word-align them to one another, and also word-align them to

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1292–1302,
Lisbon, Portugal, 17-21 September 2015.

the remaining several hundred target languages.

Of course, our goal is not to produce a tagger restricted to the Biblical lexicon. We therefore assume a small unannotated monolingual sample of the target language in an entirely unrelated genre (e.g. newswire). We use this sample transductively to adapt our learned taggers from the Biblical genre. In our experiments, we use the CoNLL 2006 and 2007 shared-task test data for this purpose. Of course tagged data does not exist for truly resource-poor languages, so we evaluate our methodology on the resource-rich languages. Each such language takes a turn playing the role of the target language for testing purposes.

The goal of the paper is to introduce a general "recipe" for successful cross-lingual induction of accurate taggers using meager resources. We faced three major technical challenges:

- First, word alignments across languages are incomplete, and often do not preserve part-of-speech due to language differences.
- Second, when using multiple resource-rich languages, we need to resolve conflicting projections.
- Third, the parallel data at our disposal is of an idiosyncratic genre (the Bible), and we wish to induce a general-purpose tagger.

To address these challenges, we forgo the typical sequence-based learning technique of HMM's and CRF's and instead adopt an instance-learning approach using latent distributional features. To induce these features, we introduced a new method using Canonical Correlation Analysis (CCA) to generalize the aligned information to new words. This method views each word position as consisting of three fundamental views: (1) the token view (word context), (2) the type view, and (3) the projected tags in the local vicinity. We perform a CCA to induce latent continuous vector representations of each view that maximizes their correlations to one another. On the test data, a simple multi-class classifier then suffices to predict accurate tags, even for novel words. This approach outperform a state-of-the-art baseline (Täckström et al., 2013) to achieve average tag accuracy of 85% on newswire text.

2 Related Work

2.1 Multilingual Projection

The idea of projecting annotated resources across languages using parallel data was first proposed by Yarowsky et al. (2001). This early work recognized the noisy nature of automatic word alignments and engineered smoothing and filtering methods to mitigate the effects of cross- lingual variation and alignment errors. More recent work in this vein has dealt with this by instead transferring information at the word type or model structure level, rather than on a token-by-token basis (Das and Petrov, 2011; Durrett et al., 2012). Current state-of-the-art results for indirectly supervised POS performance use a combination of token constraints as well as type constraints mined from Wiktionary (Li et al., 2012; Täckström et al., 2013; Ganchev and Das, 2013). As we argued above, the only widely available source of information for most low-resource languages is in fact their Bible translation. Perhaps surprisingly, our experiments show that this data source suffices to achieve state-of-the-art results.

Several previous authors have considered the advantage of using more than one resource-rich language to alleviate alignment noise.

Fossum and Abney (2005) found that using two source languages project-sources gave better results than simply using more data from one language. McDonald et al. (2011) also found advantages to using multiple language sources for projecting parsing constraints. In more of an unsu-

pervised context (but using small tag dictionaries), adding more languages to the mix has been shown to improve part-of-speech performance across all component languages (Naseem et al., 2009).

In our own previous multilingual work, we have developed the idea that supervised knowledge of some number of languages can help guide the unsupervised induction of linguistic structure, even in the absence of parallel text (Kim et al., 2011; Kim and Snyder, 2012; Kim and Snyder, 2013a; Kim and Snyder, 2013b). We have showed that cross-lingual supervised learning leads to significant performance gains over monolingual models. We point out that the previous tasks have considered as word-level structural analyses and our present case as a sentence-level analysis.

2.2 Word Alignment

Most of the papers surveyed above rely on automatic word alignments to guide the cross-lingual transfer of information. Given our desire to use highly multilingual information to improve projection accuracy, the question of word alignment performance becomes crucial. Our hypothesis is that multiple language projections are beneficial not only in weeding out random errors and idiosyncratic variations, but also in improving the linguistic consistency of the alignments themselves. Instead of simply aligning each source language to the target language in isolation, we will instead use a confidence model to synthesize information from multiple sources.

While there are not many well-known papers that have explored word alignment on a multilingual scale[1], there have been related efforts to *symmetrize* bilingual alignment models, using a variety of techniques ranging from modifications of EM (Liang et al., 2006), posterior-regularized objective function (Ganchev et al., 2010), and by considering relaxations of the hard combinatorial assignment problem (DeNero and Macherey, 2011).

2.3 Canonical Correlation Analysis (CCA)

Our method for generalizing the projections to unseen words and contexts is based on Canonical Correlation Analysis (CCA), a dimensionality reduction technique first introduced by Hotelling (1936). The key idea is to consider two groups of random variables with corresponding observations and to find linear subspaces with highest correlation between the two views. This can be seen as a kind of supervised version of Principal Components Analysis (PCA), where each view is providing supervision for the other. In fact, it can be shown that CCA directly generalizes both multiple linear regression and Fisher's Latent Discriminative Analysis (LDA) (Glahn, 1968).

From a learning theory perspective, CCA is interesting in that it allows us to prove regret-based learning bounds that depend on the "intrinsic" dimensionality of the problem rather than the apparent dimensionality (Kakade and Foster, 2007). This seems especially relevant to natural language processing scenarios, where the ambient dimension is extremely large and sparse, but reductions to dense lower-dimensional spaces may preserve nearly all the relevant semantic and syntactic information. In fact, CCA has recently been adapted to learning latent word representations in an interesting way: by dividing each word position into a token view (which only sees surrounding context) and a type view (which only sees the word itself) and performing a CCA between these two views (Dhillon et al., 2012; Kim et al., 2014; Stratos et al., 2014; Stratos et al., 2015; Kim et al., 2015c). CCA is also used to induce label representations (Kim et al., 2015d) and lexicon representations (Kim et al., 2015b).

Our technique will extend this idea by additionally considering a third *projected tag* view. Crucially, it is this view which pushes the latent representations into coherent part-of-speech categories, allowing us to simply apply multi-class SVM for unseen words in our test set.

3 Tag projection from resource-rich languages

In this section, we describe two methods for incorporating transferred tags from resource-rich languages: sequence-based learning (Täckström et al., 2013; Kim et al., 2015a) and instance-based learning. In the former, the transferred tags are used to train a partially-observed CRF (PO-CRF) by maximizing the probability of a constrained lattice. In contrast, instance-based learning views each word token as an independent classification task, but uses latent distributional information gleaned from surrounding words as features.

[1] Mayer and Cysouw (2012) used multilingual word alignment to compare languages

3.1 A sequence learning example of partially observed CRF (PO-CRF)

A first-order CRF parametrized by $\theta \in \mathbb{R}^d$ defines a conditional probability of a label sequence $y = y_1 \dots y_n$ given an observation sequence $x = x_1 \dots x_n$ as follows:

$$p_\theta(y|x) = \frac{\exp(\theta^\top \Phi(x, y))}{\sum_{y' \in \mathcal{Y}(x)} \exp(\theta^\top \Phi(x, y'))}$$

where $\mathcal{Y}(x)$ is the set of all possible label sequences for x and $\Phi(x, y) \in \mathbb{R}^d$ is a global feature function that decomposes into local feature functions $\Phi(x, y) = \sum_{j=1}^{n} \phi(x, j, y_{j-1}, y_j)$ by the first-order Markovian assumption. Given fully labeled sequences $\{(x^{(i)}, y^{(i)})\}_{i=1}^{N}$, the standard training method is to find θ that maximizes the log likelihood of the label sequences under the model with l_2-regularization:

$$\theta^* = \arg\max_{\theta \in \mathbb{R}^d} \sum_{i=1}^{N} \log p_\theta(y^{(i)}|x^{(i)}) - \frac{\lambda}{2} ||\theta||^2$$

We used an l_2 penalty weight λ of 1. Unfortunately, in our setting, we do not have fully labeled sequences. Instead, for each token x_j in sequence $x_1 \dots x_n$ we have the following two sources of label information:

- A set of allowed label types $\mathcal{Y}(x_j)$. (Label dictionary, type constraints)
- Labels $\tilde{y}_j$ transferred from resource rich languages. (transferred labels, token constraints)

Following previous work of Täckström et al. (2013), we first define a constrained *lattice* $\mathcal{Y}(x, \tilde{y}) = \mathcal{Y}(x_1, \tilde{y}_1) \times \dots \times \mathcal{Y}(x_n, \tilde{y}_n)$ where at each position j a set of allowed label types is given as:

$$\mathcal{Y}(x_j, \tilde{y}_j) = \begin{cases} \{\tilde{y}_j\} & \text{if } \tilde{y}_j \text{ is given} \\ \mathcal{Y}(x_j) & \text{otherwise} \end{cases}$$

And then we can define a conditional probability over label lattices for a given observation sequence x:

$$p_\theta(\mathcal{Y}(x, \tilde{y})|x) = \sum_{y \in \mathcal{Y}(x, \tilde{y})} p_\theta(y|x)$$

Given a label dictionary $\mathcal{Y}(x_j)$ for every token type x_j and training sequences $\{(x^{(i)}, \tilde{y}^{(i)})\}_{i=1}^{N}$ where $\tilde{y}^{(i)}$ is transferred labels for $x^{(i)}$ and, the new training method is to find θ that maximizes the log likelihood of the label lattices:

$$\theta^* = \arg\max_{\theta \in \mathbb{R}^d} \sum_{i=1}^{N} \log p_\theta(\mathcal{Y}(x^{(i)}, \tilde{y}^{(i)})|x^{(i)}) - \frac{\lambda}{2} ||\theta||^2$$

Since this objective is non-convex, we find a local optimum with a gradient-based algorithm. The gradient of this objective at each example $(x^{(i)}, \tilde{y}^{(i)})$ takes an intuitive form:

$$\begin{aligned} &\frac{\partial}{\partial \theta} \log p_\theta(\mathcal{Y}(x^{(i)}, \tilde{y}^{(i)})|x^{(i)}) - \frac{\lambda}{2} ||\theta||^2 \\ &= \sum_{y \in \mathcal{Y}(x^{(i)}, \tilde{y})} p_\theta(y|x^{(i)}) \Phi(x^{(i)}, y) \\ &- \sum_{y \in \mathcal{Y}(x^{(i)})} p_\theta(y|x^{(i)}) \Phi(x^{(i)}, y) - \lambda\theta \end{aligned}$$

This is the same as the standard CRF training except the first term where the gold features $\Phi(x^{(i)}, y^{(i)})$ are replaced by the expected value of features in the constrained lattice $\mathcal{Y}(x^{(i)}, \tilde{y})$.

An important distinction in our setting is that our token and type constraints are generated by only using the transferred tags whereas Täckström et al. (2013) generate type constraints induced from Wiktionary. Our setting is more realistic for at least two reasons; 1) Wiktionary is not always available. 2) transferable information is not limited, but Wiktionary is (e.g., semantic role and named entity).

3.2 Cross-lingual instance-based learning

The proposed method for cross-lingual instance-based learning has three steps:

1. Select training tokens based on the confidence of the projected tag information.
2. Induce distributional features over these words that incorporate all projected tags.
3. Train a multi-class classifier with these induced features to make local predictions for individual tokens.

We will describe each step below.

3.2.1 Selecting training words

Since transferred tags are not always reliable, all words in the parallel data are not necessary helpful in training. Since this method trains on words

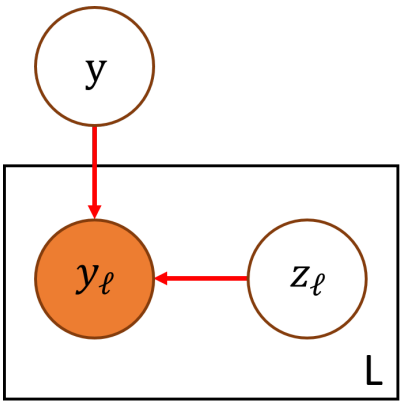

Figure 2: Graphical representation of the confidence model. Unobserved variable y denotes the true target-language tag for a token. Each of the L resource-rich languages displays a project of y, as y_ℓ, with an indicator variable z_ℓ determining the fidelity of the projection.

instead of sequences, it is easy to discard words which have unreliable or highly conflicting projections from different resource-rich languages.

To select our set of training tokens, we define a simple probability-based *confidence* model, illustrated in Figure 2. Suppose we have L resource-rich languages with alignments to the word in question. If the true tag is y, we assume that the projected tag for language ℓ will be identical to y with probability $1 - \epsilon_\ell$, where ϵ_ℓ is a language-specific corruption probability. With probability ϵ_ℓ, the projection will instead be chosen randomly (uniformly).

To make this explicit, we introduce a corruption indicator variable z_ℓ with:

$$P(z_\ell = 1) = \epsilon_\ell$$

Given z_ℓ, the probability of the projected tag y_ℓ is given by:

$$P(y_\ell|y, z_\ell) = \begin{cases} 1 & \text{if } z = 0 \text{ and } y = y_\ell, \\ \frac{1}{m} & \text{if } z = 1, \\ 0 & \text{otherwise.} \end{cases}$$

where m is the total number of possible tags. We can now compute a conditional distribution over the unknown tag y, marginalizing out the unknown corruption variables for each language:

$$p(y|y_1, \ldots, y_n) = \frac{\prod_{\ell=1}^{n} \left[\frac{\epsilon_\ell}{m} + (1 - \epsilon_\ell)\delta(y, y_\ell)\right]}{\frac{1}{m^{n-1}} \sum_{y' \in Y} \prod_{\ell=1}^{n} \left[\frac{\epsilon_\ell}{m} + (1 - \epsilon_\ell)\delta(y', y_\ell)\right]}$$

where Y is all possible tags. For simplicity, we simply set all ϵ_ℓ to 0.1 and use y as a training label when the conditional probability of the most likely value is greater than 0.9.

3.2.2 Inducing distributional features

In this section we discuss our approach for deriving latent distributional features. Canonical Correlation Analysis (CCA) is a general method for inducing new representations for a pair of variables X and Y (Hotelling, 1936). To derive word embeddings using CCA, a natural approach is to define X to represent a word and Y to represent the relevant information about a word, typically context words (Dhillon et al., 2012; Kim et al., 2015c). When they are defined as one-hot encodings, the CCA computation reduces to performing an SVD of the matrix Ω where each entry is

$$\Omega_{w,c} = \frac{\textbf{count}(w, c)}{\sqrt{\textbf{count}(w)\textbf{count}(c)}}$$

where $\textbf{count}(w, c)$ denotes co-occurrence count of word w and context c in the given corpus, $\textbf{count}(w) = \sum_c \textbf{count}(w, c)$, and $\textbf{count}(c) = \sum_w \textbf{count}(w, c)$.

The resulting word representation is given by $U^\top X$ where U is a matrix of the scaled left singular vectors of Ω (See Figure 3). In our work, we use a slightly modified version of this definition by taking square-root of each count:

$$\sqrt{\Omega}_{w,c} = \frac{\textbf{count}(w, c)^{1/2}}{\sqrt{\textbf{count}(w)^{1/2}\textbf{count}(c)^{1/2}}}$$

This has an effect of stabilizing the variance of each term in the matrix, leading to a more efficient estimator. The square-root transformation also transforms the distribution of the count data to look more Gaussian (Bartlett, 1936): since an interpretation of CCA is a latent-variable with normal distributions (Bach and Jordan, 2005), it makes the data more suitable for CCA. It has been observed in past works (e.g., Dhillon et al. (2012)) to significantly improve the quality of the resulting representations.

3.3 Feature Induction Algorithm

We now describe our algorithm for inducing latent distributional features both on the multilingual parallel corpus, as well as the monolingual, newswire test data. This algorithm is described

in detail in Figure 4. The key idea is to perform two CCA steps. The first step incorporates word-distributional information over both the multilingual corpus (the Bible) as well as the external domain monolingual corpus (CONLL data)[2]. This provides us with word representations that are general, and not overly specific to any single genre. However, it does not incorporate any projected tag information. We truncate this first SVD to the first 100 dimensions[3].

After this CCA step is performed, we then replace the words in the multilingual Bible data with their latent representations. We then perform a second CCA between these word representations and vectors representing the projected tags from all resource-rich languages. This step effectively *adapts* the first latent representation to the information contained in the tag projections. We truncate this second SVD to the first 50 dimensions.

We now have word embeddings that can be applied to any corpus, and are designed to maximize correlation both with typical surrounding word context, as well as typical projected tag context. These embeddings serve as our primary feature vectors for training the POS classifier (described in the next section). We concatenate this primary feature vector with the embeddings of the previous and subsequent words, in order to provide context-sensitive POS predictions.

3.3.1 Multi-class classifier

To train our POS tagger, we use a linear multi-class SVM (Crammer and Singer, 2002). It has a parameter $w_y \in \mathbb{R}^d$ for every tag $y \in \mathcal{T}$ and defines a linear score function $s(\mathbf{x}, j, y) := w_y^\top \Phi(\mathbf{x}, j)$. Given any sentence $\mathbf{x}$ and a position j, it predicts $\arg\max_{y \in \mathcal{T}} s(\mathbf{x}, j, y)$ as the tag of x_j. We use the implementation of Fan et al. (2008) with the default hyperparameter configurations for training.

4 Experiments

4.1 Datasets and Experimental Setup

There are more than 4,000 living languages in the world, and one of the most prevalently translated books is the Bible. We now describe the Bible dataset we collected.

[2]For context words, we use 5 words before and after the word occurrence.

[3]Embedding dimension was empirically determined by the singular values.

CCA-PROJ-SPARSE
Input: samples $(x^{(1)}, y^{(1)}) \ldots (x^{(n)}, y^{(n)}) \in \{0,1\}^d \times \{0,1\}^{d'}$, dimension k
Output: projections $A \in \mathbb{R}^{d \times k}$ and $B \in \mathbb{R}^{d' \times k}$

- Calculate $B \in \mathbb{R}^{d \times d'}$, $u \in \mathbb{R}^d$, and $v \in \mathbb{R}^{d'}$:

$$B_{i,j} = \sum_{l=1}^{n} [[x_i^{(l)} = 1]][[y_j^{(l)} = 1]]$$

$$u_i = \sum_{l=1}^{n} [[x_i^{(l)} = 1]] \quad v_i = \sum_{l=1}^{n} [[y_i^{(l)} = 1]]$$

- Define $\hat{\Omega} = \text{diag}(u)^{-1/2} B \text{diag}(v)^{-1/2}$.
- Calculate rank-k SVD $\hat{\Omega}$. Let $U \in \mathbb{R}^{d \times k}$ ($V \in \mathbb{R}^{d' \times k}$) be a matrix of the left (right) singular vector corresponding to the largest k singular values.
- Let $A = \text{diag}(u)^{-1/2} U$ and $B = \text{diag}(v)^{-1/2} V$.

Figure 3: Algorithm for deriving CCA projections from samples of two variables.

Lang	Tagger	Accuracy
BG	Treetagger	0.9909

NL	Treetagger	0.8781
PT	Hunpos	0.9770
AVG	-	0.9415

Table 1: Tagger accuracy on CoNLL data.

We first collect 893 bible volumes spanning several hundred languages that are freely available from three resources (www.bible.is, www.crosswire.org, www.biblegateway.com) and changed to UTF-8 format. The distribution of token in each bible in the unit of a language is in Figure 1.

Note that the Bible scripts are not exactly translated by sentences but by verses. We thus assume that each verse in a chapter has the same meaning if the number of verses is exactly same in a same chapter. We also assume that the whole chapters have the same meaning if the number of chapters in a book are exactly the same. In the same manner, we also assume the volumes that have the same number of chapters are the same. That is, their volume size should be as similar as possible

Input:

- N "labeled" tokens in the Bible domain: word $w^{(i)} \in \mathcal{V}$, corresponding context $C(w^{(i)}) \subset \mathcal{V}$ and (projected) tag set $P^{(i)} \subset \mathcal{T}$ for $i = 1 \dots N$
- N' tokens in data in the test domain: word $v^{(i)} \in \mathcal{V}'$ and corresponding context $C(v^{(i)}) \subset \mathcal{V}'$ for $i = 1 \dots N'$
- CCA dimensions k_1, k_2

Output: embedding $\mathbf{e}(w) \in \mathbb{R}^{k_2}$ for each word $w \in \mathcal{V} \cup \mathcal{V}'$

1. Combine the observed tokens and their context from the Bible and data in the test domain:

$$\mathcal{W}_1 := \left(w : w \in (w^{(i)})_{i=1}^{N} \cup (v^{(i)})_{i=1}^{N'}\right)$$
$$\mathcal{C}_1 := \left(C(w) : w \in (w^{(i)})_{i=1}^{N} \cup (v^{(i)})_{i=1}^{N'}\right)$$

2. Perform rank-k_1 **CCA-PROJ-SPARSE** on $(\mathcal{W}_1, \mathcal{C}_1)$ to derive a word projection matrix $\Phi_{\mathcal{W}_1}$ and a context projection matrix $\Phi_{\mathcal{C}_1}$.

3. Project all word examples in the Bible domain using $\Phi_{\mathcal{W}_1}$. Denote these projected words and the corresponding projected tag sets from all resource-rich languages by

$$\mathcal{W}_2 := \left(\Phi_{\mathcal{W}_1}(w^{(i)}) : i = 1 \dots N\right)$$
$$\mathcal{P}_2 := \left(P^{(i)} : i = 1 \dots N\right)$$

4. Perform rank-k_2 CCA on $(\mathcal{W}_2, \mathcal{P}_2)$ to derive a word projection matrix $\Phi_{\mathcal{W}_2}$ and a tag projection matrix $\Phi_{\mathcal{P}_2}$.

5. Set the embedding $\mathbf{e}(w)$ for each word $w \in \mathcal{V} \cup \mathcal{V}'$ as

$$\mathbf{e}(w) = \Phi_{\mathcal{W}_2}(\Phi_{\mathcal{W}_1}(w))$$

Figure 4: Algorithm for deriving word vectors for the (unannotated) test data that use the projected tags in the Bible data.

with the respect to the number of verses, chapters, and books.

Based upon these assumptions, we choose the best translation in a language based on a comparison to a reference Bible, the Modern King James Version (MKJV) in English. We choose the translation for each language that best matches this reference version in terms of chapter and verse numbering.

There are other factors considered if there are more than one candidates satisfying this matching. We focus on the contents of the bible such as the publication time. For instance, 1599 Geneva Bible in English contains old vocabulary with different spelling systems, causing unexpected errors when tagged by POS annotation tools. Also, some of volumes such as Amplified Bible (AMP) contains extraneous comments on verses themselves, causing errors for word alignments.

After the choice of the best volume, we finally select the 10 resource rich languages[4]. The two criteria to select resource rich languages are having i) the matched bible scripts both on the Old and New testament and ii) reliable parts-of-speech annotation tools. If these two requirements are satisfied, we can freely add more languages as resource rich languages in the future research. We use Hunpos tagger for CS, DA, DE, EN, and PT, Treetagger for BG, ES, IT, and NL, and Meltparser for FR.

4.2 Test Data

We use CoNLL parts-of-speech tagged data (selected resource-rich languages), plus Basque (EU), Hungarian (HU) and Turkish (TR)) as our test data. It consists of 5,000-6,000 hand-labeled tokens. The accuracy of each supervised tagger on this data is about 94% on average. Since there is no French tagged CoNLL data, we exclude French on testing but still use it in Training. The accuracy of each supervised tagger on this data is shown in Table 1.

The tag definitions used in CoNLL data are not exactly matched the ones used in the taggers when converted to universal POS tags. For instance in Spanish, we initially follow mapping of Petrov et al. (2011) for CoNLL data. The 'dp' tag for words *sus, su, mi* are mapped to DET but they are mapped to PRON in the bible data because of the Treetagger definitions. Whenever we find this kind of issues, we analyze them and choose the one of mappings for compatibility. For the 'dp' tag, we choose to map PRON.

4.3 Alignments

We perform two kinds of alignments in our data sets; (i) the verse alignment and (ii) the word alignment. When the tagged bible volumes are prepared, we align verses across all resource rich languages. For verse alignments, we pre-process to remove extraneous information such as inline reference (e.g. [REV 4:16]) and HTML tags. These alignments between two languages

[4]Bulgarian (BG), Czech(CS), Danish (DA), English(EN), German (DE), French (FR), Spanish (ES), Italian (IT), Dutch (NL), and Portuguese (PT)

occurred only when volumes have the exact same number of chapters and verses. For instance, Mark must have 16 chapters and the first chapter of the Mark must have 45 verses in our criteria. The correct number of chapters and verses are pre-defined on MKJV volume, and the number of matched verses on each volume is greater than 30,500.

After performing verse alignments, we then perform word alignments. The quality of tags in resource poor languages is highly dependent on the quality of word alignments because parts-of-speech tags will be projected through this alignment path. First, we use GIZA++ for initial one-to-many alignments and we symmetrize by taking their intersection. This ensures that the resulting alignments are of high quality.

Table 2: Baseline model CONLL performance depending on criterion for selecting tag projection.

In all experiments, we hold out the tags of the test language. EU, HU and TR used projected tags from 10 resource-rich languages, 9 resource-rich languages are used for the remaining languages. In our first experiment, we consider the state-of-the-art PO-CRF baseline. This model trains a partially observed CRF based on a single projected tag for each token. We experiment with different methods of choosing the projected tags. The results are shown in Table 2. The majority method is to choose the most common tag from the projected tags of the current token. We then experiment with taking the union of all projected tags (i.e. only constraining the lattice based on unanimity of the resource-rich languages). Finally, we considered choosing the high confidence tags, based on our confidence model. The confident tags are defined by a method described in Section 3.2.1 If this ratio is greater than 0.9, we assume that this token has high confidence. As the results indicate, this final method yielded the best tagging performance on the CONLL test data, achieving average accuracy of 82%.

In the remaining experiments we will adopt the confidence-based selection criterion for both the baseline as well as our method.

Table 3: Performance on multilingual Bible data

In order to isolate the errors due to projection mismatch versus domain variation, we first test both models on the Bible data itself. To do so, we assume that the tags produced by the test-language's supervised tagger are in fact the ground truth. This experiment allows us to compare to tag projection models using (1) PO-CRF and (2) CCA+SVM. Results are given in Table 3. Unsurprisingly, PO-CRF performs better on the multilingual corpus than on the CONLL data, due to the beneficial constraint of the projected tags. Perhaps interestingly, the CCA+SVM method, which is a simple instance-based classifier using cleverly constructed features, outperforms the sequence labeller, achieving accuracy of nearly 86%[5] .

In our third experiment we use CoNLL test data and compare the PO-CRF models with different settings. See Table 4. This experiment is to show the effects of suffix and Brown cluster features on PO-CRF to relieve the unseen words issue. We also show that the more projecting languages are

[5]Note that some previous researches (Liang et al., 2008; Wisniewski et al., 2014; Moore, 2014) also pointed out that POS tagging does not necessarily require a sequence model for strong performance.

	1 lang (EN) (A)	9/10 langs (W)	9/10 langs (no S/C)	9/10 langs (A)

Table 4: Accuracy of the PO-CRF models on CoNLL data. A, W, no S/C means: all, word, all but no suffix and cluster features are used, respectively.

included the better the results gets.

For the features, we used word identity, suffixes of up to length 3, Brown cluster and three indicators of (1) capitalization for the first character, (2) containing a hyphen or (3) a digit. Especially, Brown clusters was induced from more than 2 million line documents, making the setting unrealistic for resource-poor language.

With just the word features, the averaged performance is 0.6993 and other indicator features increase the performance to 0.7768. Also note that the suffix and Brown cluster features increase the performance from 0.7768 to 0.8314. As reported, PO-CRF mitigates the adverse effects of the unseen word issues and almost meets the performance in the previous experiment (0.8375) of Täckström et al. (2013) by using these features.

In fourth and final experiment, we used the same features for PO-CRF, with Brown clusters induced on a realistically obtainable sized (3k) corpus for a low resource language. We compare directly to our CCA+SVM model (which does not use Brown clustering features at all). We achieved 0.7983 on PO-CRF with all features and our corresponding model on CCA achieved about 0.8474, shown in Table 5. As reported, our model outperforms the PO-CRF with the realistic settings for resource poor languages.

5 Conclusions

We addressed the challenge of POS tagging low-resource languages. Our key idea is to use a massively multilingual corpus. Instead of relying on a single resource-rich language, we leverage the full array of currently available POS taggers. This removes alignment-mismatch noise and identifies a subset of words with highly confident tags. We then use a CCA procedure to induce latent feature representations across domains, incorporating word contexts as well as projected tags. We then train an SVM to predict tags.

Experimentally, we show that this procedure yields accuracy of about 85% for languages with nearly no resources available, beating a state-of-the-art partially observed CRF formulation. In the near future, this technique will enable us to release a suite of POS taggers for hundreds of low-resource languages.

An Improved Tag Dictionary for Faster Part-of-Speech Tagging

Robert C. Moore
Google Inc.
bobmoore@google.com

Abstract

Ratnaparkhi (1996) introduced a method of inferring a tag dictionary from annotated data to speed up part-of-speech tagging by limiting the set of possible tags for each word. While Ratnaparkhi's tag dictionary makes tagging faster but less accurate, an alternative tag dictionary that we recently proposed (Moore, 2014) makes tagging as fast as with Ratnaparkhi's tag dictionary, but with no decrease in accuracy. In this paper, we show that a very simple semi-supervised variant of Ratnaparkhi's method results in a much tighter tag dictionary than either Ratnaparkhi's or our previous method, with accuracy as high as with our previous tag dictionary but much faster tagging—more than 100,000 tokens per second in Perl.

1 Overview

In this paper, we present a new method of constructing tag dictionaries for part-of-speech (POS) tagging. A tag dictionary is simply a list of words[1] along with a set of possible tags for each word listed, plus one additional set of possible tags for all words not listed. Tag dictionaries are commonly used to speed up POS-tag inference by restricting the tags considered for a particular word to those specified by the dictionary.

Early work on POS tagging generally relied heavily on manually constructed tag dictionaries, sometimes agumented with tag statistics derived from an annotated corpus (Leech et al., 1983; Church, 1988; Cutting et al., 1992). Merialdo (1994) relied only on a tag dictionary extracted from annotated data, but he used the annotated tags from his test data as well as his training data to construct his tag dictionary, so his evaluation was not really fair.[2] Ratnaparkhi (1996) seems to have been the first to use a tag dictionary automatically extracted only from training data.

Ratnaparkhi's method of constructing a tag dictionary substantially speeds up tagging compared to considering every possible tag for every word, but it noticeably degrades accuracy when used with a current state-of-the-art tagging model. We recently presented (Moore, 2014) a new method of constructing a tag dictionary that produces a tagging speed-up comparable to Ratnaparkhi's, but with no decrease in tagging accuracy. In this paper, we show that a very simple semi-supervised variant of Ratnaparkhi's method results in a much tighter tag dictionary than either Ratnaparkhi's or our previous method, with accuracy as high as we previously obtained, while allowing much faster tagging—more than 100,000 tokens per second even in a Perl implementation.

1.1 Tag Dictionaries and Tagging Speed

A typical modern POS tagger applies a statistical model to compute a score for a sequence of tags $t_1, \ldots, t_n$ given a sequence of words $w_1, \ldots, w_n$. The tag sequence assigned the highest score by the model for a given word sequence is selected as the tagging for the word sequence. If $\mathcal{T}$ is the set of possible tags, and there are no restrictions on the form of the model, then the time to find the highest scoring tag sequence is potentially $O(n|\mathcal{T}|^n)$ or worse, which would be intractable.

To make tagging practical, models are normally defined to be factorable in a way that reduces the time complexity to $O(n|\mathcal{T}|^k)$, for some small integer k. For models in which all tagging decisions are independent, or for higher-order mod-

[1] According to the conventions of the field, POS tags are assigned to all tokens in a tokenized text, including punctuation marks and other non-word tokens. In this paper, all of these will be covered by the term *word*.

[2] Merialdo (1994, p. 161) acknowledged this: "In some sense this is an optimal dictionary for this data, since a word will not have all its possible tags (in the language), but only the tags it actually had within the text."

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1303–1308,
Lisbon, Portugal, 17-21 September 2015.

els pruned by fixed-width beam search, $k = 1$, so the time to find the highest scoring tag sequence is $O(n|\mathcal{T}|)$. But this linear dependence on the size of the tag set means that reducing the average number of tags considered per token should further speed up tagging, whatever the underlying model or tagger may be.

1.2 Ratnaparkhi's Method

For each word observed in an annotated training set, Ratnaparkhi's tag dictionary includes all tags observed with that word in the training set, with all possible tags allowed for all other words. Ratnaparkhi reported that using this tag dictionary improved per-tag accuracy from 96.31% to 96.43% on his Penn Treebank (Marcus et al., 1993) Wall Street Journal (WSJ) development set, compared to considering all tags for all words.

With a more accurate model, however, we found (Moore, 2014) that while Ratnaparkhi's tag dictionary decreased the average number of tags per token from 45 to 3.7 on the current standard WSJ development set, it also decreased per-tag accuracy from 97.31% to 97.19%. This loss of accuracy can be explained by the fact that 0.5% of the development set tokens are known words with a tag not seen in the training set, for which our model achieved 44.5% accuracy with all word/tag pairs permitted. With Ratnaparkhi's dictionary, accuracy for these tokens is necessarily 0%.

1.3 Our Previous Method

We previously presented (Moore, 2014) a tag dictionary constructed by using the annotated training set to compute a smoothed probability estimate for any possible tag given any possible word, and for each word in the training set, including in the dictionary the tags having an estimated probability greater than a fixed threshold T. In this approach, the probability $p(t|w)$ of tag t given word w is computed by interpolating a discounted relative frequency estimate of $p(t|w)$ with an estimate of $p(t)$ based on "diversity counts", taking the count of a tag t to be the number of distinct words ever observed with that tag. The distribution $p(t)$ is also used to estimate tag probabilities for unknown words, so the set of possible tags for any word not explicitly listed is $\{t|p(t) > T\}$.

If we think of w followed by t as a word bigram, this is exactly like a bigram language model estimated by the interpolated Kneser-Ney (KN) method described by Chen and Goodman (1999). The way tag diversity counts are used has the desirable property that closed-class tags receive a very low estimated probability of being assigned to a rare or unknown word, even though they occur very often with a small number of frequent words. A single value for discounting the count of all observed word/tag pairs is set to maximize the estimated probability of the reference tagging of the development set. When T was chosen to be the highest threshold that preserves our model's 97.31% per tag WSJ development set accuracy, we obtained an average of 3.5 tags per token.

1.4 Our New Approach

We now present a new method that reduces the average number of tags per token to about 1.5, with no loss of tagging accuracy. We apply a simple variant of Ratnaparkhi's method, with a training set more than 4,000 times larger than the Penn Treebank WSJ training set. Since no such hand-annotated corpus exists, we create the training set automatically by running a version of our tagger on the LDC English Gigaword corpus. We thus describe our approach as a semi-supervised variant of Ratnaparkhi's method. Our method can be viewed as an instance of the well-known technique of self-training (e.g., McClosky et al., 2006), but ours is the first use of self-training we know of for learning inference-time search-space pruning.

We introduce two additional modifications of Ratnaparki's approach. First, with such a large training corpus, we find it unnecessary to keep in the dictionary every tag observed with every word in the automatically-annotated data. So, we estimate a probability distribution over tags for each word in the dictionary according to unsmoothed relative tag frequencies, and include for each word in the dictionary only tags whose probability given the word is greater than a fixed threshold.

Second, since our tokenized version of the English Gigaword corpus contains more than 6 million unique words, we reduce the vocabulary of the dictionary to the approximately 1 million words having 10 or more occurrences in the corpus. We treat all other tokens as instances of unknown words, and we use their combined unsmoothed relative tag frequencies to estimate a tag probability distribution for unknown words. We use the same threshold on this distribution as we do for words explicitly listed in the dictionary, to obtain a set of possible tags for unknown words.

2 Experimental Details

In our experiments, we use the WSJ corpus from Penn Treebank-3, split into the standard training (sections 0–18), development (sections 19–21), and test (sections 22-24) sets for POS tagging.

The tagging model we use has the property that all digits are treated as indistinguishable for all features. We therefore also make all digits indistinguishable in constructing tag dictionaries (by internally replacing all digits by "9"), since it does not seem sensible to give two different dictionary entries based on containing different digits, when the tagging model assigns them the same features.

2.1 The Tagging Model

The model structure, feature set, and learning method we use for POS tagging are essentially the same as those in our earlier work, treating POS tagging as a single-token independent multiclass classification task. Word-class-sequence features obtained by supervised clustering of the annotated training set replace the hidden tag-sequence features frequently used for POS tagging, and additional word-class features obtained by unsupervised clustering of a very large unannotated corpus provide information about words not occurring in the training set. For full details of the feature set, see our previous paper (Moore, 2014).

The model is trained by optimizing the multiclass SVM hinge loss objective (Crammer and Singer, 2001), using stochastic subgradient descent as described by Zhang (2004), with early stopping and averaging. The only difference from our previous training procedure is that we now use a tag dictionary to speed up training, while we previously used tag dictionaries only at test time.

Our training procedure makes multiple passes through the training data considering each training example in turn, comparing the current model score of the correct tag for the example to that of the highest scoring incorrect tag and updating the model if the score of the correct tag does not exceed the score of the highest scoring incorrect tag by a specified margin. In our new version of this procedure, we use the KN-smoothed tag dictionary described in Section 1.3. to speed up finding the highest scoring incorrect tag.

Recall that the KN-smoothed tag dictionary estimates a non-zero probability $p(t|w)$ for every possible word/tag pair, and that the possible tags for a given word are determinted by setting a threshold T on this probability. In each pass through the training set, we use the same probability distribution $p(t|w)$ determined from the statistics of the annotated training data, but we employ an adaptive method to determine what threshold T to use in each pass.

For the first pass through the training set, we set an initial threshold T_0 to the highest value such that for every token in the development set, $p(t|w) \geq T_0$, where t is the correct tag for the token and w is the word for the token. At the end of each training pass i, while evaluating the current model on the development set for early stopping using threshold T_{i-1}, we also find the highest probability threshold T_i such that choosing a lower threshold would not enable any additional correct taggings on the development set using the current model. This threshold will normally be higher than T_0, because we disregard tokens in the development set for which the correct tag would not be selected by the model resulting from the previous pass at any threshold. T_i is then used as the threshold for training pass $i + 1$. Whenever the selected threshold leaves only one tag remaining for a particular training example, we skip that example in training.

On the first pass through the training set, use of this method resulted in consideration of an average of 31.36 tags per token, compared to 45 total possible tags. On the second and all subsequent passes, an average of 10.48 tags were considered per token. This sped up training by a factor of 3.7 compared to considering all tags for all tokens, with no loss of tagging accuracy when a development-set-optimized KN-smoothed tag dictionary is also used at test time.

2.2 Tagging the Gigaword Corpus

To construct our new tag dictionary, we need an automatically-tagged corpus several orders of magnitude larger than the hand-tagged WSJ training set. To obtain this corpus we ran a POS tagger on the LDC English Gigaword Fifth Edition[3] corpus, which consists of more than 4 billion words of English text from seven newswire sources. We first removed all SGML mark-up, and performed sentence-breaking and tokenization using the Stanford CoreNLP toolkit (Manning et al, 2014). This produced 4,471,025,373 tokens of

[3] https://catalog.ldc.upenn.edu/LDC2011T07

Tag Dictionary	Accuracy	Tags/Token	Unambig	Tokens/Sec
Pruned KN-smoothed	97.31%	3.48	45.3%	69k
Unpruned semi-supervised	97.31%	1.97	51.7%	82k
Pruned semi-supervised	97.31%	1.51	66.8%	103k

Table 1: WSJ development set token accuracy and tagging speed for different tag dictionaries

6,616,812 unique words. We tagged this corpus using the model described in Section 2.1 and a KN-smoothed tag dictionary as described in Section 1.3, with a threshold $T = 0.0005$. The tagger we used is based on the fastest of the methods described in our previous work (Moore, 2014, Section 3.1). Tagging took about 26 hours using a single-threaded implementation in Perl on a Linux workstation equipped with Intel Xeon X5550 2.67 GHz processors.

2.3 Extracting the Tag Dictionary

We extracted a Ratnaparkhi-like tag dictionary for the 957,819 words with 10 or more occurrences in our corpus. Tokens of all other words in the corpus were treated as unknown word tokens and used to define a set of 24 tags[4] to be used for words not explicitly listed in the dictionary. To allow pruning the dictionary as described in Section 1.4, for each word (including the unknown word), we computed a probability distribution $p(t|w)$ using unsmoothed relative frequencies. As noted above, we treated all digits as indistinguishable in constructing and applying the dictionary.

3 Experimental Results

Tagging the WSJ development set with an unpruned semi-supervised tag dictionary obtained from the automatic tagging of the English Gigaword corpus produced the same tagging accuracy as allowing all tags for all tokens or using the pruned KN-smoothed tag dictionary used in tagging the Gigaword corpus. Additional experiments showed that we could prune this dictionary with a threshold on $p(t|w)$ as high as $T = 0.0024$ without decreasing development set accuracy. In addition to applying this threshold to the tag probabilities for all listed words, we also applied it to the tag probabilities for unknown words, leaving 13 possible tags[5] for those.

Tagging the WSJ development set with these two dictionaries is compared in Table 1 to tagging with our previous pruned KN-smoothed dictionary. The second column shows the accuracy per tag, which is 97.31% for all three dictionaries. The third column shows the mean number of tags per token allowed by each dictionary. The fourth column shows the percentage of tokens with only one tag allowed, which is significant since the tagger need not apply the model for such tokens—it can simply output the single possible tag.

The last column shows the tagging speed in tokens per second for each of the three tag dictionaries, using the fast tagging method we previously described (Moore, 2014), in a single-threaded implementation in Perl on a Linux workstation equipped with Intel Xeon X5550 2.67 GHz processors. Speed is rounded to the nearest 1,000 tokens per second, because we measured times to a precision of only about one part in one hundred. For the pruned KN-smoothed dictionary, we previously reported a speed of 49,000 tokens per second under similar conditions. Our current faster speed of 69,000 tokens per second is due to an improved low-level implementation for computing the model scores for permitted tags, and a slightly faster version of Perl (v5.18.2).

The most restrictive tag dictionary, the pruned semi-supervised dictionary, allows only 1.51 tags per token, and our implementation runs at 103,000 tokens per second on the WSJ development set. For our final experiments, we tested our tagger with this dictionary on the standard Penn Treebank WSJ test set and on the Penn Treebank-3 parsed Brown corpus subset, as an out-of-domain evaluation. For comparison, we tested our previous tagger and the fast version (english-left3words-distsim) of the Stanford tagger (Toutanova et al., 2003; Manning, 2011) recommended for practical use on the Stanford tagger website, which we found to be by far the fastest of the six publicly available taggers tested in our previous work (Moore, 2014). The results of these tests are shown in Table 2.[6]

[4] CC, CD, DT, FW, IN, JJ, JJR, JJS, MD, NN, NNP, NNPS, NNS, PRP, RB, RBR, RP, UH, VB, VBD, VBG, VBN, VBP, and VBZ

[5] CD, FW, JJ, NN, NNP, NNPS, NNS, RB, VB, VBD, VBG, VBN, and VBZ

[6] In Table 2, "OOV" has the standard meaning of a token

Tagger	WSJ Tokens/Sec	All WSJ Accuracy	OOV WSJ Accuracy	Brown Tokens/Sec	All Brown Accuracy	OOV Brown Accuracy
This work	102k	97.36%	91.09%	96k	96.55%	89.25%
Our previous	51k/54k/69k	97.34%	90.98%	40k/43k/56k	96.54%	89.36%
Stanford fast	80k	96.87%	89.69%	50k	95.53%	87.38%

Table 2: WSJ test set and Brown corpus tagging speeds and token accuracies

For our previous tagger, we give three speeds: the speed we reported earlier, a speed for a duplicate of the earlier experiment using the faster version of Perl that we use here, and a third measurement including both the faster version of Perl and our improved low-level tagger implementation.

With the pruned semi-supervised dictionary, our new tagger has slightly higher all-token accuracy than our previous tagger on both the WSJ test set and Brown corpus set, and it is much more accurate than the fast Stanford tagger. The accuracy on the standard WSJ test set is 97.36%, one of the highest ever reported. The new tagger is also much faster than either of the other taggers, achieving a speed of more than 100,000 tokens per second on the WSJ test set, and almost 100,000 tokens per second on the out-of-domain Brown corpus data.

4 Conclusions

Our method of constructing a tag dictionary is technically very simple, but remarkably effective. It reduces the mean number of possible tags per token by 57% and increases the number of unambiguous tokens by by 47%, compared to the previous state of the art (Moore, 2014) for a tag dictionary that does not degrade tagging accuracy. When combined with our previous work on fast high-accuracy POS tagging, this tag dictionary produces by far the fastest POS tagger reported with anything close to comparable accuracy.

{anas.shahrour,salamkhalifa,nizar.habash}@nyu.edu

Abstract

We present an approach to Arabic automatic diacritization that integrates syntactic analysis with morphological tagging through improving the prediction of case and state features. Our best system increases the accuracy of word diacritization by 2.5% absolute on all words, and 5.2% absolute on nominals over a state-of-the-art baseline. Similar increases are shown on the full morphological analysis choice.

1 Introduction

Modern Standard Arabic (MSA) orthography generally omits diacritical marks which encode lexical as well as syntactic (case) information. The task of Arabic automatic diacritization is about the automatic restoration of the missing diacritics. Diacritization improvement in Arabic has important implications for downstream processing for Arabic natural language processing, e.g. speech recognition (Ananthakrishnan et al., 2005; Biadsy et al., 2009), speech synthesis (Elshafei et al., 2002), and machine translation (Diab et al., 2007; Zbib et al., 2010).

Previous efforts on diacritization utilized morphological tagging techniques to disambiguate word forms. Habash et al. (2007a) observe that while such techniques work relatively well on lexical diacritics (located on word stems), they are much worse for syntactic case diacritics (typically word final). They suggest that syntactic analysis may help with automatic diacrtization, but stop short of testing the idea, and instead demonstrate that complex linguistic features and rules are needed to model complex Arabic case using gold syntactic analyses. In this paper, we develop an approach for improving the quality of automatic Arabic diacritization through the use of automatic syntactic analysis. Our approach combines handwritten rules for case assignment and agreement with machine learning of case and state adjustment on the output of a state-of-the-art morphological tagger. Our best system increases the accuracy of word diacrtization by 2.5% absolute overall, and 5.2% absolute on nominals over a state-of-the-art baseline.

2 Linguistic Background

Arabic automatic processing, and specifically diacritization is hard for a number of reasons.

First, Arabic words are morphologically rich. The morphological analyzer we use represents Arabic words with 15 features (Pasha et al., 2014).[1] We focus on case and state in this paper. In our data set, *case* has five values: nominative (n), accusative (a), genitive (g), undefined (u) and not applicable (na). Cases n, a and g are usually expressed with an overt morpheme. Case u is used to mark words without an overt morpheme expression of case (e.g., invariable nouns such as شَكوَى *šakwaý* 'complaint'), or those not assigned a case in the manual annotations. Most of the missing assignments are for foreign proper nouns, which often do not receive case markers. However, this is not done consistently in the training data we use. Case na is used for non-nominals. *State* is a nominal feature that has four values: definite (d), indefinite (i), construct (c) and not applicable (na). State generally reflects the definiteness in nominals (d vs i) and whether a nominal is the head of genitive construction (aka *Idafa*) (c). State na is used for non-nominals.[2] For the most part, case and state realize as a single word-final morpheme, e.g., the suffix اً **Aã** in كِتَابًا *kitAbAã*[3] is a morpheme indicating the word is (cas:a, stt:i).

Second, undiacritized Arabic words are highly ambiguous: in our training data, words had an average of 12.8 analyses per word, most of which are associated with different diacritizations. Some diacritization differences reflect different analysis

[1] Lemma (lex), Part-of-Speech (pos), Gender (gen), Number (num), Case (cas), State (stt), Person (per), Aspect (asp), Voice (vox), Mood (mod), four proclitics (prc$n$), and one enclitic (enc0).

[2] For a detailed discussion of Arabic case and state, see (Smrž, 2007; Habash et al., 2007a).

[3] Arabic transliteration is presented in the Habash-Soudi-Buckwalter scheme (Habash et al., 2007b).

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1309–1315,
Lisbon, Portugal, 17-21 September 2015.

lemmas; while others are due to morpho-syntactic differences. For example, the undiacritized version of the word we used above (كتابا *ktAbA*) has two other diacritizations and analyses: كُتَّابًا *kut∼AbAã* (cas:a stt:i) 'writers' (different lemma) and كِتَابَا *kitAbA* (cas:n stt:c num:d) 'two books of [...]' (different features).

Third, Arabic has complex case/state assignment and agreement patterns that interact with the sentence's syntax. For example, a noun may get its case by being subject of a verb and its state by being the head of an idafa construction; while adjectives modifying this noun agree with it in its case, their state is determined by the state of the last element in the idafa chain the noun heads.

For more information on Arabic orthography, morphology, and syntax, see Habash (2010).

3 Related Work

Much work has been done on Arabic diacritization (Vergyri and Kirchhoff, 2004; Nelken and Shieber, 2005; Zitouni et al., 2006; Habash and Rambow, 2007; Alghamdi and Muzafar, 2007; Rashwan et al., 2009; Bebah et al., 2014; Hadj Ameur et al., 2015; Abandah et al., 2015; Bouamor et al., 2015). We refer the reader to the extensive literature review by Abandah et al. (2015), and focus on systems we compare with.

Most of the previous approaches cited above utilize different sequence modeling techniques that use varying degrees of knowledge from shallow letter and word forms to deeper morphological information; none to our knowledge make use of syntax. Habash and Rambow (2007) approach diacritization as a part of the morphological disambiguation problem, where they select the optimal full morphological tag for Arabic in context and use it to select from a list of possible analyses produced by a morphological analyzer. They use independent taggers for all features; and language models for lemmas and diacritized surface forms. Their work is part of the state-of-the-art Arabic morphological tagger MADAMIRA (Pasha et al., 2014). Our paper is most closely related to Habash and Rambow (2007) and Pasha et al. (2014). We extend their work using additional syntactic features to improve morphological disambiguation accuracy. We demonstrate improvements in terms of both full morphological analysis choice (lemmatization, tokenization, all features) as well as word diacritization.

Most recently, Abandah et al. (2015) presented a recurrent neural network approach to diacritize full sentences with impressive results. We do not compare to their effort here but we note that they use an order of magnitude more diacritized data than we do, and they focus on diacritization only as opposed to full morphological analysis.

In related work on modeling Arabic case and syntax, Habash et al. (2007a) compared rule-based and machine learning approaches to capture the complexity of Arabic case assignment and agreement. They demonstrated their results on gold syntactic analyses showing that given good syntactic representations, case prediction can be done at a high degree of accuracy. Alkuhlani et al. (2013) later extended this work to cover all morphological features, including state. Additionally, Marton et al. (2013) demonstrated that in the context of syntactic dependency parsing, case is the best feature to use *in gold settings* and is the worst feature to use *in predicted settings*. In this paper we use automatic (i.e. not gold) syntactic features to improve case prediction, which improves morphological analysis and word diacrtization.

4 Approach

Motivation We are motivated by an error analysis we conducted of 1,200 words of the MADAMIRA system output. We found a large number of surprising *syntactically impossible* case errors such as genitive nouns following verbs or construct nouns followed by non-genitives. We explain these errors by MADAMIRA's contextual models being limited to a small window of neighboring words and with no modeling of syntax, which leads to a much worse performance on case and diacritization compared to lemmas and POS (almost 10% absolute drop from 96% to 86%).

Proposed Solution Our approach is to provide better prediction of case and state using models with access to additional information, in particular syntactic analysis and rules. The predicted case and state values are then used to re-tag the MADAMIRA output by selecting the best match in its ranked morphological analyses. We limit our retagging to nominals. Since what we are learning to predict is how to correct MADAMIRA's baseline choice (as opposed to a generative model of case-state), we also re-apply the model on its output to fix primarily propagated agreement errors in a manner similar to Habash et al. (2007a)'s agreement classifier.[4]

[4]We optimized for a re-application limit, which we found invariably to be +1 time or +2 times in our *DevTest* experi-

5 Experimental Results

We present next our experimental results and compare five case-state prediction techniques. The results for these techniques are compared to our state-of-the-art baseline system, which has been compared to a number of other approaches.

5.1 Experimental Setup

Data We used the Penn Arabic Treebank (PATB, parts 1, 2 and 3) (Maamouri et al., 2004; Maamouri et al., 2006; Maamouri et al., 2009) split into *Train*, *Dev* and (blind) *Test* along the recommendations of Diab et al. (2013) which were also used in the baseline system. The morphological feature representations we use are derived from the PATB analyses following the approach used in the MADA and later MADAMIRA systems (Habash and Rambow, 2005; Habash and Rambow, 2007; Pasha et al., 2014). We further divide *Dev* into two parts with equal number of sentences: *DevTrain* (30K words) for training our case-state classifiers, and *DevTest* (33K words) for development testing. The *Test* set has 63K words.[5]

Evaluation Metrics We report our accuracy in terms of two metrics: a. **Diac**, the percentage of correctly fully diacrtized words; and b. **All**, the percentage of words for which a full morphological analysis (lemma, POS, all inflectional and clitic features, and diacritization) is correctly predicted. We report the results on all words (**All Words**) as well as on nominals[6] with no u case in the gold (henceforth, **Nominals**). We do not report on case and state prediction accuracy, nor on the character-level diacritization.

Morphological Analysis, Baseline and Topline For our baseline, we use the morphological analysis and disambiguation tool MADAMIRA (Pasha et al., 2014), which produces a contextually ranked list of analyses for each word. We computed an oracular topline using the PATB gold case and state values in the retagging process.

ments. We do not report more on this due to space limitations. Because of the need to have the same of number of parse tree tokens for reapplication in the models using syntax, we constrain the retagging to maintain the same clitic signature (number of clitics) in the MADAMIRA baseline top analysis.

[5]To address the concern that we are using more "training" data than our baseline, we compared the performance of MADAMIRA's release (baseline) to a version that was trained on Train + *DevTrain*. The small increase in training data made no significant difference from the baseline system in terms of our metrics.

[6]Nominals consists of nouns (including noun_quant and noun_num), adjectives, proper nouns, adverbs, and pronouns.

	All Words		**Nominals**	
System	**Diac**	**All**	**Diac**	**All**

Syntax Rules+Classifier	**89.7**	**87.1**	**86.4**	**82.5**

Table 1: Results on *DevTest*.

Syntactic Analysis For syntactic features, we trained an Arabic dependency parser using MaltParser (Nivre et al., 2007) on the Columbia Arabic Treebank (CATiB) version of the PATB (Habash and Roth, 2009). The *Train* data followed the same splits mentioned above. The Nivre "eager" algorithm was used in all experiments. The CATiB dependency tree has six simple POS tags and eight relations (Habash and Roth, 2009; Habash et al., 2009). The PATB tokenization as well as the CATiB POS tags were produced by the baseline system MADAMIRA and used as input to the parser. We also used the well performing yet simple CATiBex expansion of the CATiB tags as implemented in the publicly available parsing pipeline from Marton et al. (2013). Our parser's performance on the PATB *Dev* set is comparable to Marton et al. (2013): 84.2% labeled attachment, 86.6% unlabeled attachment, and 93.6% label accuracy.

Machine Learning Technique Given the small size of *DevTrain*, we opted to train unlexicalized models that we expect to capture morpho-syntactic abstractions. We tried a number of machine learning techniques and settled on using the J48 Decision tree classifier with its default settings in WEKA (Hall et al., 2009; Quinlan, 1993) for all of the classification experiments in this paper.

5.2 Case and State Classification Techniques

We detail and report on five case-state classification techniques we experimented with. All results on the *DevTest* are presented in Table 1.

Morphology Rules We created a simple manual word-morphology based classifier that handled the most salient case errors seen in our pilot study (Section 4) and whose correction has a high precision. The scope of the rules was limited to word bigrams and included three conditions: (i) post-

verbal genitive nouns are changed to the first non-genitive analysis available from MADAMIRA; (ii) post-construct state non-genitive nouns should become genitive; and (iii) adjectives agreeing with the nouns they follow in gender, number, and definiteness, but not in case should match the nouns' case. The collective improvement of all the rules applied in the order presented above adds up to 0.6% absolute on All Word Diac, and 1.2% absolute on Nominal Diac.

Morphology-based Classifier We trained a classifier to predict a correction of the baseline case and state of a word using the *DevTrain* data set. For features, we included all the non-lexical morphological features (all features mentioned in *footnote 1* except for lemma). Clitic feature values were binarized to indicate if a clitic is present or not. We used *Nil* values for all out-of-vocabulary words in MADAMIRA. BOS and EOS placeholders were used for sentence boundaries. We excluded all *DevTrain* words whose predicted POS switches from nominal to non-nominal or vice versa, but kept them as part of other words' context. This minimizes noise and sparsity in the training data, especially given its small size and the rarity of such examples. We experimented with adding features from neighboring words within a window size of +/- 2 words. The best performing setup was with window size +/- 1. This classifier makes around 0.5% absolute gain over the simple word morphology rules.

Syntax Rules Inspired by Habash et al. (2007a)'s simple set of rules for determining case on gold dependency trees, we re-implemented these rules to work with our different dependency representation and extended them to include state assignment in a manner similar to Alkuhlani et al. (2013).[7] These rules improve over the baseline by 4.5% absolute in Nominal Diac accuracy, but produce no gains in All Words setting. An investigation of the error patterns reveals the main reason to be the rules' inability to predict the problematic u case.

Syntax-based Classifier We trained a classifier to predict a correction of the case and state of a word on a parsed version of the *DevTrain* data set. Since the syntactic parse separates most clitics in the PATB tokenization, we align the tree tokens with the word morphology before extracting classifier features. The features we used are the token's morphological features (same as those used for words in the morphology-based classifier), the parent and grandparent's features, the relations between token and parent, and between parent and grandparent, and the features of the neighboring +/- n tokens. The tokenized clitics are only used as context features (tree and surface). We tested all combinations of values of n as 0, 1, 2, and 3 and of including parent and grandparent features. The best performing setting was with including the parent and grandparent as well as a window of +/- 1 tokens. The syntax-based classifier improves over the morphology-based classifier but it trails behind syntax rules in terms of Nominal Diac. Its All Word Diac accuracy is the highest so far.

Combination of Syntax Rules and Classifier We combine the last two approaches to exploit their complementary performance by including the syntax rule predictions as features in the syntax-based classifier. The resulting system is our best performer achieving *DevTest* accuracy improvements of 2.3% absolute (All Word Diac), and 4.5% absolute (Nominal Diac).

5.3 Blind Test Results

The results of applying the best approach and settings on our blind *Test* set are presented in Table 2. While the baseline on *Test* is slightly higher than *DevTest*, the performance on all metrics are comparable. The increase in Diac accuracy on All Words is 2.5% absolute and on Nominals is 5.2% absolute. The corresponding relative reductions in error to the oracle toplines are 30% and 34%. Similar increases are shown on the full morphological analysis choice.

	All Words		**Nominals**	
System	**Diac**	**All**	**Diac**	**All**
Oracle Topline	96.3	94.4	97.9	95.6
Baseline	88.1	86.0	82.4	79.4
Syntax Rules+Classifier	**90.6**	**88.5**	**87.6**	**84.5**

Table 2: Results on the blind *Test* set.

[7] For nominal case assignment, our rules are: (i) default case is a; (ii) children of $root$ are n; (iii) object of preposition and idafa children are assigned g; (iv) predicates not headed by verbs are assigned n; and (v) subjects and topics not headed (or grand-headed) by a class of words called *Ân∼a and her sisters* are assigned n. After case assignment, we apply two case agreement rules: (i) for all nominals modifying case-assigned nominals (i.e., with tree relation mod), copy the case of the modified nominal; and (ii) for all nominals conjoined to case-assigned nominals (i.e., with tree chain $nominal\text{-}conjunction\text{-}nominal$), copy the case of the heading nominal. For state, we assign d to words with the definite article proclitic, and c to words heading an idafa construction. All other nominals are assigned state i.

Figure 1: Examples of corrections from our best performing system.

5.4 Error Analysis and Examples

We manually investigated the types of errors in the first 100 errors in the *DevTest* in our best system's output. In about a quarter of the cases (23%), all of which proper nouns, the gold reference was not fully diacritized, making it impossible to evaluate. In an additional 7%, typographical errors in the input including missing sentence breaks led to bad parses which are the likely cause of error. The rest of the errors are system failures: 31% are connected with syntactic tree errors (although a third of these are due to agreement-propagated errors over correct trees); 28% are due to other morphological analysis issues (half are out-of-vocabulary and 4% are no-analysis cases); and 11% are other case selection errors unrelated to the above-mentioned issues.

Figure 1 shows four examples from the *DevTest* where the analysis of our best system for the underlined words is different from baseline. Examples (a), (b), and (c) are cases where our best system's analysis matched the gold. The dependency relation also matched the gold and was the likely cause of correction. In example (d), our best system incorrectly changed the correct baseline analysis in agreement with the wrong dependency relation provided by the parser, which is the likely cause of error.

6 Conclusion and Future Work

We have demonstrated the value of using automatic syntactic analysis as part of the task of automatic diacritization and morphological tagging of Arabic. Our best solution is a hybrid approach that combines statistical parsing and manual syntactic rules as part of a machine learning model for correcting case and state features.

In the future, we plan to investigate the development of joint morphological disambiguation and syntactic parsing models. We will also work on improving the quality of Arabic parsing which is behind many of the errors according to our error analysis. Other possible directions include using more sophisticated machine learning techniques and richer lexical features. We also plan to host a demo and make our system available through the website of the Computational Approaches to Modeling Language (CAMeL) Lab: `www.camel-lab.com`.

Combining Discrete and Continuous Features for Deterministic Transition-based Dependency Parsing

Meishan Zhang and **Yue Zhang**
Singapore University of Technology and Design
{meishan_zhang, yue_zhang}@sutd.edu.sg

Abstract

We investigate a combination of a traditional linear sparse feature model and a multi-layer neural network model for deterministic transition-based dependency parsing, by integrating the sparse features into the neural model. Correlations are drawn between the hybrid model and previous work on integrating word embedding features into a discrete linear model. By analyzing the results of various parsers on web-domain parsing, we show that the integrated model is a better way to combine traditional and embedding features compared with previous methods.

1 Introduction

Transition-based parsing algorithms construct output syntax trees using a sequence of shift-reduce actions. They are attractive in computational efficiency, allowing linear time decoding with deterministic (Nivre, 2008) or beam-search (Zhang and Clark, 2008) algorithms. Using rich non-local features, transition-based parsers achieve state-of-the-art accuracies for dependency parsing (Zhang and Nivre, 2011; Zhang and Nivre, 2012; Bohnet and Nivre, 2012; Choi and McCallum, 2013; Zhang et al., 2014).

Deterministic transition-based parsers works by making a sequence of greedy local decisions (Nivre et al., 2004; Honnibal et al., 2013; Goldberg et al., 2014; Gómez-Rodríguez and Fernández-González, 2015). They are attractive by very fast speeds. Traditionally, a linear model has been used for the local action classifier. Recently, Chen and Manning (2014) use a neural network (*NN*) to replace linear models, and report improved accuracies.

A contrast between a neural network model and a linear model is shown in Figure 1 (a) and (b).

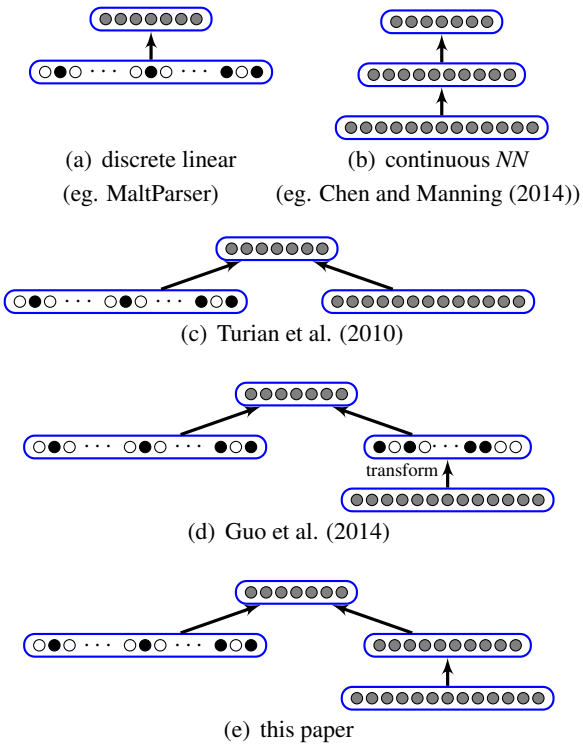

Figure 1: Five deterministic transition-based parsers with discrete and continuous features.

A neural network model takes continuous vector representations of words as inputs, which can be pre-trained using large amounts of unlabeled data, thus containing more information. In addition, using an extra hidden layer, a neural network is capable of learning non-linear relations between automatic features, achieving feature combinations automatically.

Discrete manual features and continuous features complement each other. A natural question that arises from the contrast is whether traditional discrete features and continuous neural features can be integrated for better accuracies. We study this problem by constructing the neural network shown in Figure 1 (e), which incorporates the discrete input layer of the linear model (Figure 1 (a)) into the *NN* model (Figure 1 (b)) by conjoining

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1316–1321,
Lisbon, Portugal, 17-21 September 2015.

it with the hidden layer. This architecture is connected with previous work on incorporating word embeddings into a linear model.

In particular, Turian et al. (2010) incorporate word embeddings as real-valued features into a CRF model. The architecture is shown in Figure 1(c), which can be regarded as Figure 1(e) without the hidden layer. Guo et al. (2014) find that the accuracies of Turian et al can be enhanced by discretizing the embedding features before combining them with the traditional features. They use simple binarization and clustering to this end, finding that the latter works better. The architecture is shown in Figure 1(d). In contrast, Figure 1(e) directly combines discrete and continuous features, replacing the hard-coded transformation function of Guo et al. (2014) with a hidden layer, which can be tuned by supervised training.[1]

We correlate and compare all the five systems in Figure 1 empirically, using the SANCL 2012 data (Petrov and McDonald, 2012) and the standard Penn Treebank data. Results show that the method of this paper gives higher accuracies than the other methods. In addition, the method of Guo et al. (2014) gives slightly better accuracies compared to the method of Turian et al. (2010) for parsing task, consistent with Guo et al's observation on named entity recognition (NER). We make our C++ code publicly available under GPL at `https://github.com/SUTDNLP/NNTransitionParser`.

2 Parser

We take Chen and Manning (2014), which uses the arc-standard transition system (Nivre, 2008). Given an POS-tagged input sentence, it builds a projective output y by performing a sequence of state transition actions using greedy search. Chen and Manning (2014) can be viewed as a neutral alternative of MaltParser (Nivre, 2008).

Although not giving state-of-the-art accuracies, deterministic parsing is attractive for its high parsing speed (1000+ sentences per second). Our incorporation of discrete features does not harm the overall speed significantly. In addition, deterministic parsers use standard neural classifiers, which allows isolated study of feature influences.

[1]Yet another alternative structure is to directly combine the two types of inputs, and replacing the input layer of (b) using them. Wang and Manning (2013) compared this architecture with (c) using a CRF network, finding that the latter works better for NER and chunking.

3 Models

Following Chen and Manning (2014), training of all the models using a cross-entropy loss objective with a L2-regularization, and mini-batched AdaGrad (Duchi et al., 2011). We unify below the five deterministic parsing models in Figure 1.

3.1 Baseline linear (*L*)

We build a baseline linear model using logistic regression (Figure 1(a)). Given a parsing state x, a vector of discrete features $\Phi_d(x)$ is extracted according to the *arc-standard* feature templates of Ma et al. (2014a), which is based on the *arc-eager* templates of Zhang and Nivre (2011). The score of an action a is defined by

$$\text{Score}(a) = \sigma\big(\Phi_d(x) \cdot \overrightarrow{\theta}_{d,a}\big),$$

where σ represents the sigmoid activation function, $\overrightarrow{\theta}_d$ is the set of model parameters, denoting the feature weights with respect to actions, a can be SHIFT, LEFT(l) and RIGHT(l).

3.2 Baseline Neural (*NN*)

We take the Neural model of Chen and Manning (2014) as another baseline (Figure 1(b)). Given a parsing state x, the words are first mapped into continuous vectors by using a set of pre-trained word embeddings. Denote the mapping as $\Phi_e(x)$. In addition, denote the hidden layer as Φ_h, and the ith node in the hidden as $\Phi_{h,i}$ ($0 \leq i \leq |\Phi_h|$). The hidden layer is defined as

$$\Phi_{h,i} = \big(\Phi_e(x) \cdot \overrightarrow{\theta}_{h,i}\big)^3,$$

where $\overrightarrow{\theta}_h$ is the set of parameters between the input and hidden layers. The score of an action a is defined as

$$\text{Score}(a) = \sigma\big(\Phi_h(x) \cdot \overrightarrow{\theta}_{c,a}\big),$$

where $\overrightarrow{\theta}_{c,a}$ is the set of parameters between the hidden and output layers. We use the *arc-standard* features Φ_e as Chen and Manning (2014), which is also based on the *arc-eager* templates of Zhang and Nivre (2011), similar to those of the baseline model *L*.

3.3 Linear model with real-valued embeddings (*Turian*)

We apply the method of Turian et al. (2010), combining real-valued embeddings with discrete features in the linear baseline (Figure 1(c)). Given a

state x, the score of an action a is defined as

$$\text{Score}(a) = \sigma\Big(\big(\Phi_d(x) \oplus \Phi_e(x)\big) \cdot (\overrightarrow{\theta}_{d,a} \oplus \overrightarrow{\theta}_{c,a}) \Big),$$

where $\oplus$ is the vector concatenation operator.

3.4 Linear model with transformed embeddings (*Guo*)

We apply the method of Guo et al. (2014), combining embeddings into the linear baseline by first transforming into discrete values. Given a state x, the score of an action is defined as

$$\text{Score}(a) = \sigma\Big(\big(\Phi_d(x) \oplus d(\Phi_e(x))\big) \cdot (\overrightarrow{\theta}_{d,a} \oplus \overrightarrow{\theta}_{c,a}) \Big),$$

where d is a transformation function from real-value to binary features. We use clustering of embeddings for d as it gives better performances according to Guo et al. (2014). Following Guo et al. (2014), we use compounded clusters learnt by K-means algorithm of different granularities.

3.5 Directly combining linear and neural features (*This*)

We directly combine linear and neural features (Figure 1(e)). Given a state x, the score of an action is defined as

$$\text{Score}(a) = \sigma\Big(\big(\Phi_d(x) \oplus \Phi_h(x)\big) \cdot (\overrightarrow{\theta}_{d,a} \oplus \overrightarrow{\theta}_{c,a}) \Big),$$

where Φ_h is the same as the *NN* baseline. Note that like d in Guo, Φ_h is also a function that transforms embeddings Φ_e. The main difference is that it can be tuned in supervised training.

4 Web Domain Experiments

4.1 Setting

We perform experiments on the SANCL 2012 web data (Petrov and McDonald, 2012), using the Wall Street Journal (WSJ) training corpus to train the models and the WSJ development corpus to tune parameters. We clean the web domain texts following the method of Ma et al. (2014b). Automatic POS tags are produced by using a CRF model trained on the WSJ training corpus. The POS tags are assigned automatically on the training corpus by ten-fold jackknifing. Table 1 shows the corpus details.

Domain	#Sent	#Word	TA
WSJ-train	30,060	731,678	97.03
WSJ-dev	1,336	32,092	96.88
WSJ-test	1,640	35,590	97.51
answers	1,744	28,823	91.93
newsgroups	1,195	20,651	93.75
reviews	1,906	28,086	92.66

Figure 2: Dev results on fine-tuning (UAS).

Following Chen and Manning (2014), we use the pre-trained word embedding released by Collobert et al. (2011), and set $h = 200$ for the hidden layer size, $\lambda = 10^{-8}$ for L2 regularization, and $\alpha = 0.01$ for the initial learning rate of Adagrad.

4.2 Development Results

Fine-tuning of embeddings. Chen and Manning (2014) fine-tune word embeddings in supervised training, consistent with Socher et al. (2013). Intuitively, fine-tuning embeddings allows in-vocabulary words to join the parameter space, thereby giving better fitting to in-domain data. However, it also forfeits the benefit of large-scale pre-training, because out-of-vocabulary (OOV) words do not have their embeddings fine-tuned. In this sense, the method of Chen and Manning resembles a traditional supervised sparse linear model, which can be weak on OOV.

On the other hand, the semi-supervised learning methods such as Turian et al. (2010) and Guo et al. (2014), do not fine-tune the word embeddings. Embeddings are taken as inputs rather than model

Table 2: Main results on SANCL. All systems are deterministic.

parameters. Therefore, such methods can expect better cross-domain accuracies.

We empirically compare the models *NN*, *Turian* and *This* by fine-tuning (+T) and not fine-tuning (-T) word embeddings, and the results are shown in Figure 2. As expected, the baseline NN model gives better accuracies on WSJ with fine-tuning, but worse cross-domain accuracies. Interestingly, our combined model gives consistently better accuracies with fine-tuning. We attribute this to the use of sparse discrete features, which allows the model to benefit from large-scale pre-trained embeddings without sacrificing in-domain performance. The observation on *Turian* is similar. For the final experiments, we apply fine-tuning on the *NN* model, but not to the *Turian* and *This*. Note also tat for all experiments, the POS and label embedding features of Chen and Manning (2014) are fine-tuned, consistent with their original method.

Dropout rate. We test the effect of dropout (Hinton et al., 2012) during training, using a default ratio of 0.5 according to Chen and Manning (2014). In our experiments, we find that the dense *NN* model and our combined model achieve better performances by using dropout, but the other models do not benefit from dropout.

4.3 Final Results

The final results across web domains are shown in Table 2. Our logistic regression linear parser and re-implementation of Chen and Manning (2014) give comparable accuracies to the perceptron ZPar[2] and Stanford NN Parser[3], respectively.

It can be seen from the table that both *Turian* and *Guo*[4] outperform *L* by incorporating embedding features. *Guo* gives overall higher improvements, consistent with the observation of Guo et al. (2014) on NER. Our methods gives significantly[5] better results compared with *Turian* and *Guo*, thanks to the extra hidden layer.

Our OOV performance is higher than *NN*, because the embeddings of OOV words are not tuned, and hence the model can handle them effectively. Interestingly, *NN* gives higher accuracies on web domain out-of-embedding-vocabulary (OOE) words, out of which 54% are in-vocabulary.

Note that the accuracies of our parsers are lower than the best systems in the SANCL shared task, which use ensemble models. Our parser enjoys the fast speed of deterministic parsers, and in particular the baseline *NN* parser (Chen and Manning, 2014).

5 WSJ Experiments

For comparison with related work, we conduct experiments on Penn Treebank corpus also. We use the WSJ sections 2-21 for training, section 22 for development and section 23 for testing. WSJ constituent trees are converted to dependency trees using Penn2Malt[6]. We use auto POS tags consistent with previous work. The ZPar POS-tagger is used to assign POS tags. Ten-fold jackknifing is performed on the training data to assign POS automatically. For this set of experiments, the parser hyper-parameters are taken directly from the best settings in the Web Domain experiments.

The results are shown in Table 3, together with some state-of-the-art deterministic parsers. Comparing the *L*, *NN* and *This* models, the observations are consistent with the web domain.

Chen and Manning (2014)	91.17	89.99
Honnibal et al. (2013)	91.30	90.00
Ma et al. (2014a)*	91.32	–

Table 3: Main results on WSJ. All systems are deterministic.

Our combined parser gives accuracies competitive to state-of-the-art deterministic parsers in the literature. In particular, the method of Chen and Manning (2014) is the same as our *NN* baseline. Note that Zhou et al. (2015) reports a UAS of 91.47% by this parser, which is higher than the results we obtained. The main results include the use of different batch size during, while Zhou et al. (2015) used a batch size of 100,000, we used a batch size of 10,000 in all experiments. Honnibal et al. (2013) applies dynamic oracle to the deterministic transition-based parsing, giving a UAS of 91.30%. Ma et al. (2014a) is similar to ZPar local, except that they use the *arc-standard* transitions, while ZPar-local is based on *arc-eager* transitions. Ma et al. (2014a)* uses a special method to process punctuations, leading to about 1% UAS improvements over the vanilla system.

Recently, Dyer et al. (2015) proposed a deterministic transition-based parser using LSTM, which gives a UAS of 93.1% on Stanford conversion of the Penn Treebank. Their work shows that more sophisticated neural network structures with long term memories can significantly improve the accuracy over local classifiers. Their work is orthogonal to ours.

6 Related Work

As discussed in the introduction, our work is related to previous work on integrating word embeddings into discrete models (Turian et al., 2010; Yu et al., 2013; Guo et al., 2014). Along this line, there has also been work that uses a neural network to automatically vectorize the structures of a sentence, and then taking the resulting vector as features in a linear NLP model (Socher et al., 2012; Tang et al., 2014; Yu et al., 2015). Our results show that the use of a hidden neural layer gives superior results compared with both direct integration and integration via a hard-coded transformation function (e.g binarization or clustering).

There has been recent work integrating continuous and discrete features for the task of POS tagging (Ma et al., 2014b; Tsuboi, 2014). Both models have essentially the same structure as our model. In contrast to their work, we systematically compare various ways to integrate discrete and continuous features, for the dependency parsing task. Our model is also different from Ma et al. (2014b) in the hidden layer. While they use a form of restricted Boltzmann machine to pre-train the embeddings and hidden layer from large-scale ngrams, we fully rely on supervised learning to train complex feature combinations.

Wang and Manning (2013) consider integrating embeddings and discrete features into a neural CRF. They show that combined neural and discrete features work better without a hidden layer (i.e. Turian et al. (2010)). They argue that nonlinear structures do not work well with high dimensional features. We find that using a hidden layer specifically for embedding features gives better results compared with using no hidden layers.

7 Conclusion

We studied the combination of discrete and continuous features for deterministic transition-based dependency parsing, comparing several methods to incorporate word embeddings and traditional sparse features in the same model. Experiments on both in-domain and cross-domain parsing show that directly adding sparse features into a neural network gives higher accuracies compared with all previous methods to incorporate word embeddings into a traditional sparse linear model.

Abstract

Many NLP systems use dependency parsers as critical components. Jonit learning parsers usually achieve better parsing accuracies than two-stage methods. However, classical joint parsing algorithms significantly increase computational complexity, which makes joint learning impractical. In this paper, we proposed an efficient dependency parsing algorithm that is capable of capturing multiple edge-label features, while maintaining low computational complexity. We evaluate our parser on 14 different languages. Our parser consistently obtains more accurate results than three baseline systems and three popular, off-the-shelf parsers.

1 Introduction

Natural language processing (NLP) systems, like machine translation (Xie et al., 2011), resource-low languages processing (McDonald et al., 2013; Ma and Xia, 2014), word sense disambiguation (Fauceglia et al., 2015) , and entity coreference resolution (Durrett and Klein, 2013), are becoming more sophisticated, in part because of utilizing syntacitc knowledges such as dependency parsing trees.

Dependency parsers predict dependency structures and dependency type labels on each edge. However, most graph-based dependency parsing algorithms only produce unlabeled dependency trees, particularly when higher-order factorizations are used (Koo and Collins, 2010; Ma and Zhao, 2012b; Martins et al., 2013; Ma and Zhao, 2012a). A two-stage method (McDonald, 2006) is often used because the complexity of some joint learning models is unacceptably high. On the other hand, joint learning models can benefit from edge-label information that has proven to be important to provide more accurate tree structures and labels (Nivre and Scholz, 2004).

Previous studies explored the trade-off between computational costs and parsing performance. Some work (McDonald, 2006; Carreras, 2007) simplified labeled information to only single label features. Other work (Johansson and Nugues, 2008; Bohnet, 2010) used richer label features but increased systems' complexities significantly, while achieving better parsing accuracy. Yet, there are no previous work addressing the problem of good balance between parsing accuracy and computational costs for joint parsing models.

In this paper, we propose a new dependency parsing algorithm that can utilize edge-label information of more than one edge, while simultaneously maintaining low computational complexity. The component needed to solve this dilemma is an inner-to-outer greedy approximation to avoid an exhaustive search. The contributions of this work are (i) showing the effectiveness of edge-label information on both UAS and LAS. (ii) proposing a joint learning parsing model which achieves both effectiveness and efficience. (iii) giving empirical evaluations of this parser on different treebanks over 14 languages.

2 Joint Parsing Algorithm

2.1 Basic Notations

In the following, x represents a generic input sentence, and y represents a generic dependency tree. Formally, for a sentence x, dependency parsing is the task of finding the dependency tree y with the highest-score for x:

$$y^*(x) = \underset{y \in \mathcal{Y}(x)}{\operatorname{argmax}} \operatorname{Score}(x, y). \quad (1)$$

Here $\mathcal{Y}(x)$ denotes the set of possible dependency trees for sentence x.

In this paper, we adopt the second-order sibling factorization (Eisner, 1996; McDonald and

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1322–1328,
Lisbon, Portugal, 17-21 September 2015.

Pereira, 2006), in which each sibling part consists of a tuple of indices (h, m, c) where (h, m) and (h, c) are a pair of adjacent edges to the same side of the head h. By adding labele information to this factorization, $\mathrm{Score}(x, y)$ can be rewritten as:

$$\begin{aligned}\mathrm{Score}(x, y) &= \sum_{(h,m,c,l_1,l_2)\in y} \mathrm{S_{sib}}(h, m, c, l_1, l_2) \\ &= \sum_{(h,m,c,l_1,l_2)\in y} \lambda^T \mathbf{f}(h, m, c, l_1, l_2)\end{aligned} \quad (2)$$

where $\mathrm{S_{sib}}(h, m, c, l_1, l_2)$ is the score function for the sibling part (h, m, c) with l_1 and l_2 being the labels of edge (h, m) and (h, c), respectively. $\mathbf{f}$ are feature functions and λ is the parameters of parsing model.

2.2 Exact Search Parsing

The unlabeled sibling parser introduces three types of dynamic-programming structures: *complete* spans $C_{(s,t)}$, which consist of the headword s and its descendents on one side with the endpoint t, *incomplete* spans $I_{(s,t)}$, which consist of the dependency (s, t) and the region between the head s and the modifier t, and *sibling* spans $S_{(s,t)}$, which represent the region between successive modifiers s and t of some head. To capture label information, we have to extend each incomplete span $I_{s,t}$ to $I_{s,t,l}$ to store the label of dependency edge from s to t. The reason is that there is an edge shared by two adjacent sibling parts (e.g. (h, m, c) and (h, c, c') share the edge (h, c)). So the incomplete span $I_{(s,t)}$ does not only depend on the label of dependency (s, t), but also the label of the dependency (s, r) for each split point r. The dynamic-programming procedure for new incomplete spans[1] are

$$I_{(s,t,l)} = \max_{s<r\le t} S_{(r,t)} + \max_{l'\in L} I_{(s,r,l')} + \mathrm{S_{sib}}(s, r, t, l', l) \quad (3)$$

where L is set of all edge labels. Then we have,

$$I_{(s,t)} = \max_{l\in L} I_{(s,t,l)} \quad (4)$$

$$l^*_{(s,t)} = \operatorname*{argmax}_{l\in L} I_{(s,t,l)} \quad (5)$$

The graphical specification of the this parsing algorithm is provided in Figure 1 (a). The computational complexity of the exactly searching algorithm is $O(|L|^2 n^3)$ time and $O(|L|n^2)$ space. In practice, $|L|$ is probably large. For English, the number of edge labels in Stanford Basic Dependencies (De Marneffe et al., 2006) is 45, and the number in the treebank of CoNLL-2008 shared task is 70. So it is impractical to perform an exhaustive search for parsing, and more efficient approximating algorithms are needed.

[1] Symmetric right-headed versions are elided for brevity

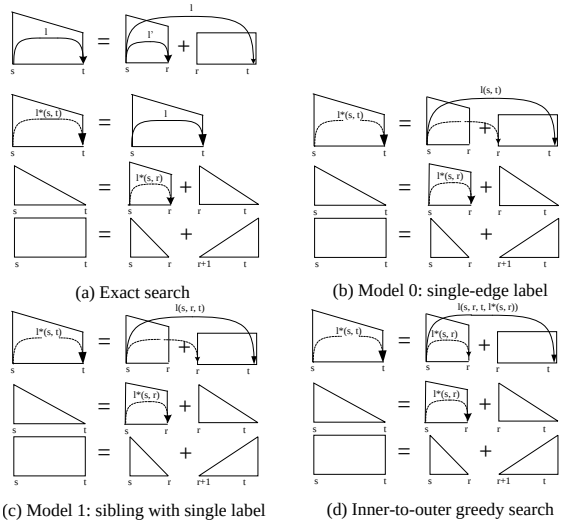

Figure 1: The dynamic-programming structures and derivation of four parsing algorithms. $I_{(s,t,l)}$ and $I_{(s,t)}$ are depicted as trapezoids with solid and dashed lines, respectively. $C_{(s,t)}$ are depicted as triangles and $S_{(s,t)}$ are depicted as boxes. Symmetric right-headed versions are elided for brevity.

2.3 Two Intermediate Models

In this section, we describe two intuitive simplifications of the labeled parsing model presented above. For the two simplified parsing models, efficient algorithms are available.

2.3.1 Model 0: Single-edge Label

In this parsing model, labeled features are restricted to a single edge. Specifically,

$$\mathrm{S_{sib}}(h, m, c, l_1, l_2) = \mathrm{S_{sib}}(h, c, l_2).$$

Then the dynamic-programming derivation for each incomplete span becomes

$$\begin{aligned}I_{(s,t)} &= \max_{s<r\le t} \left\{ I_{(s,r)} + S_{(r,t)} + \max_{l\in L} \mathrm{S_{sib}}(s, t, l) \right\} \\ &= \max_{s<r\le t} \left\{ I_{(s,r)} + S_{(r,t)} + \mathrm{S_{sib}}(s, t, l(s, t)) \right\}\end{aligned}$$

where $l(s, t) = \operatorname*{argmax}_{l\in L} \mathrm{S_{sib}}(s, t, l)$.

In this case, therefore, we do not have to extend incomplete spans. The computational cost to calculate $l(s, t)$ is $O(|L|n^2)$ time, so the computational complexity of this algorithm is $O(n^3 + |L|n^2)$ time and $O(n^2)$ space.

2.3.2 Model 1: Sibling with Single Label

As remarked in McDonald (2006), Model 0 can be slightly enriched to include single label features associated with a sibling part. Formally,

$$\mathrm{S}_{\mathrm{sib}}(h, m, c, l_1, l_2) = \mathrm{S}_{\mathrm{sib}}(h, m, c, l_2).$$

Now, the dynamic-programming derivation is

$$I_{(s,t)} = \max_{s<r\leq t} \left\{ I_{(s,r)} + S_{(r,t)} + \mathrm{S}_{\mathrm{sib}}(s, r, t, l(s, r, t)) \right\}$$

where $l(s, r, t) = \operatorname*{argmax}_{l \in L} \mathrm{S}_{\mathrm{sib}}(s, r, t, l)$.

The additional algorithm to calculate the best edge label $l(s, r, t)$ takes $O(|L|n^3)$ time. Therefore, this algorithm requires $O(|L|n^3)$ time and $O(n^2)$ space[2]. Figure 1 (b) and Figure 1 (c) provide the graphical specifications for Model 0 and Model 1, respectively.

2.4 Inner-to-outer Greedy Search

Though the two intermediate parsing models, model 0 and model 1, encode edge-label information and have efficient parsing algorithms, the labeled features they are able to capture are relatively limited due to restricting their labeled feature functions to a single label. Our experimental results show that utilizing these edge-label information yields a slight improvement of parsing accuracy (see Section 3 for details). In this section, we describe our new labeled parsing model that can exploit labeled features involving two edge-labels in a sibling part. To achieve efficient search, we adopt an method characterized by inferring labels of outer parts from the labels of inner ones.

Formally, consider the maximization problem in Eq 3. It can be treated as a two-layer maximization: first fixes a split point r and maximizes over all edge-label l, then maximizes over all possible split points. Our approach approximates the maximization in the first layer:

$$\begin{aligned} & \max_{l' \in L} I_{(s,r,l')} + \mathrm{S}_{\mathrm{sib}}(s, r, t, l', l) \\ \approx \quad & I_{(s,r)} + \mathrm{S}_{\mathrm{sib}}(s, r, t, l^*_{(s,r)}, l) \end{aligned} \tag{6}$$

Then the dynamic-programming derivation for each incomplete span is

$$I_{(s,t)} = \max_{s<r\leq t} I_{(s,r)} + S_{(r,t)} + \max_{l \in L} \mathrm{S}_{\mathrm{sib}}(s, r, t, l^*_{(s,r)}, l) \tag{7}$$

To compute $I_{(s,t)}$, we need to calculate

$$l(s, r, t, l^*_{(s,r)}) = \operatorname*{argmax}_{l \in L} \mathrm{S}_{\mathrm{sib}}(s, r, t, l^*_{(s,r)}, l), \tag{8}$$

which is similar to the calculation of $l(s, r, t)$ in Model 1. The only difference between them is $l^*_{(s,r)}$ that can be calculated in previous derivations. Thus, their computation costs are almost the same.

The procedure of our algorithm to derivate incomplete spans can be regarded as two steps. At the first step, the algorithm goes through all possible split points (Eq 7). Then at the second step, at each split point r, it calculate the label $l(s, r, t, l^*_{(s,r)})$ (Eq 8) based on the sibling part (s, r, t) and the label $l^*_{(s,r)}$ which is the "best" label for dependency edge (s, r) based on incomplete span $I_{(s,r)}$. The key insight of this algorithm is the inner-to-outer dynamic-programming structure: inner modifiers (r) of a head (s) and their "best" labels ($l^*_{(s,r)}$) are generated before outer ones (t). Thus, using already computed "best" labels of inner dependency edges makes us get rid of maximizing over two labels, l' and l. Moreover, we do not have to extend each incomplete span by the augmentation with a "label" index. This makes the space complexity remains $O(n^2)$, which is important in practice. The graphical specification is provided in Figure 1 (d).

3 Experiments

3.1 Setup

We conduct our experiments on 14 languages, including the English treebank from CoNLL-2008 shared task (Surdeanu et al., 2008) and all 13 treebanks from CoNLL-2006 shared task (Buchholz and Marsi, 2006). We train our parser using The k-best version of the Margin Infused Relaxed Algorithm (MIRA) (Crammer and Singer, 2003; Crammer et al., 2006; McDonald, 2006). In our experiments, we set $k = 1$ and fix the number of iteration to 10, instead of tuning these parameters on development sets. Following previous work, all experiments are evaluated on the metrics of unlabeled attachment score (UAS) and Labeled attachment score (LAS), using the official scorer[3] of CoNLL-2006 shared task.

3.2 Non-Projective Parsing

The parsing algorithms described in the paper fall into the category of *projective* dependency parsers, which exclude crossing dependency edges. Since the treebanks from CoNLL shared tasks contain non-projective edges, we use the "mountain-

[2] We do not have to store $l(s, r, t)$, as each $l(s, r, t)$ will be calculated exactly once.

Table 1: UAS and LAS of non-projective versions of our parsing algorithms on 14 treebanks from CoNLL shared tasks, together with three baseline systems and the best systems for each language reported in CoNLL shared tasks. MD06 is McDonald et al. (2006), RD06 is Riedel et al. (2006), JN08 is Johansson and Nugues (2008), and NV06 is Nivre et al. (2006) Bold indicates the best result for a language. Red values represent statistically significant improvements over two-stage baseline system on the corresponding metrics with $p < 0.01$, using McNemar's test. Blue values indicate statistically significant improvements with $p < 0.05$.

climbing" non-projective parsing algorithm proposed in McDonald and Pereira (2006). This approximating algorithm first searches the highest scoring projective parse tree and then it rearranges edges in the tree until the rearrangements do not increase the score for the tree anymore [4].

3.3 Results and Comparison

Table 1 illustrates the parsing results our parser with non-projective parsing algorithm, together with three baseline systems—the two-stage system (McDonald, 2006) and the two intermediate models, Model 0 and Model 1—and the best systems reported in CoNLL shared tasks for each language. Our parser achieves better parsing performance on both UAS and LAS than all the three baseline systems for 12 languages. The two exceptions are Portuguese and Turkish, on which our parser achieves better LAS and comparable UAS.

Comparing with the best systems from CoNLL, our parser achieves better performance on both UAS and LAS for 9 languages. Moreover, the average UAS of our parser over the 14 languages is better than that of the best systems in CoNLL. It should be noted that the best results for 14 languages in CoNLL are not from one single system, but different systems that achieved best results for different languages. The system of McDonald et al. (2006) achieved the best average parsing performance over 13 languages (excluding English) in CoNLL-2006 shared tasks. Its average UAS and LAS are 87.03% and 80.83%, respectively, while our average UAS and LAS excluding English are 87.79% and 81.29%. So our parser shows significant improvement over the single best system reported in CoNLL-2006 shared task.

[4] Additional care is required in the non-projective approximation since a change of one edge could result in a label change for multiple edges

System	UAS	LAS
MaltParser	89.3	86.9
MSTParser	90.7	87.6

This Paper	**92.4**	**89.9**

Table 2: Parsing performance on PTB. The results for MaltParser, MSTParser and DNNParser are from table 5 of Chen and Manning (2014).

3.4 Experiments on PTB

To make a thorough empirical comparison with previous studies, we also evaluate our system on the English Penn Treebanks (Marcus et al., 1993) with Stanford Basic Dependencies (De Marneffe et al., 2006). We compare our parser with three off-the-shelf parsers: MaltParser (Nivre and Scholz, 2004; Zhang and Clark, 2008; Zhang and Nivre, 2011), MSTParser (McDonald et al., 2005), and the parser using Neural Networks

Label	Description	F1 (UAS) TST	Ours	diff	F1 (LAS) TST	Ours	diff
MNR	Adverbial of manner	54.01	66.10	12.10	52.23	62.15	9.92
OPRD	Predicative complement of raising/control verb	86.61	96.92	10.31	86.61	89.89	3.28
APPO	Apposition	77.40	82.62	5.22	72.74	77.03	4.29
ADV	General adverbial	73.33	77.65	4.32	69.86	73.14	3.28
AMOD	Modifier of adjective or adverbial	75.49	79.58	4.09	72.60	76.91	4.30
TMP	Temporal adverbial or nominal modifier	73.47	76.76	3.29	64.50	68.59	4.09
DIR	Adverbial of direction	62.42	65.02	2.60	62.42	64.61	2.19
LOC	Locative adverbial or nominal modifier	75.78	78.35	2.57	63.11	65.83	2.72
OBJ	Object	91.69	94.08	2.39	90.62	93.23	2.61

Table 3: Top 10 dependency labels on which our algorithm achieves most improvements on the F1 score of UAS, together with the corresponding improvements of LAS. "TST" indicates the two-stage system. The first column is the label name in the treebank. The second column is the label's description from Surdeanu et al. (2008).

(DNNParser) (Chen and Manning, 2014). The results are listed in Table 2. Clearly, our parser is superior in terms of both UAS and LAS.

3.5 Analysis

To better understand the performance of our parser, we analyze the distribution of our parser's UAS and LAS over different dependency labels on the English CoNLL treebank, compared with the ones of the two-stage model. Table 3 lists the top 10 dependency labels on which our algorithm achieves most improvements on the F1 score of UAS, together with the corresponding improvements of LAS.

From Table 3 we can see among the 10 labels, there are 5 labels — "MNR", "ADV", "TMP", "DIR", "LOC" — which are a specific kind of adverbials. This illustrates that our parser performs well on the recognition of different kinds of adverbials. Moreover, the label "OPRD" and "OBJ" indicate dependency relations between verbs and their modifiers, too. In addition, our parser also significantly improves the accuracy of appositional relations ("APPO").

4 Conclusion

We proposed a new dependency parsing algorithm which can jointly learn dependency structures and edge labels. Our parser is able to use multiple edge-label features, while maintaining low computational complexity. Experimental results on 14 languages show that our parser significantly improves the accuracy of both dependency structures (UAS) and edge labels (LAS), over three baseline systems and three off-the-shelf parsers. This demonstrates that jointly learning dependency structures and edge labels can benefit both performance of tree structures and labeling accuracy. Moreover, our parser outperforms the best systems of different languages reported in CoNLL shared task for 9 languages.

In future, we are interested in extending our parser to higher-order factorization by increasing horizontal context (e.g., from siblings to "tri-siblings") and vertical context (e.g., from siblings to "grand-siblings") and validating its effectiveness via a wide range of NLP applications.

Abstract

We propose *online unsupervised domain adaptation (DA)*, which is performed *incrementally* as data comes in and is applicable when batch DA is not possible. In a part-of-speech (POS) tagging evaluation, we find that online unsupervised DA performs as well as batch DA.

1 Introduction

Unsupervised domain adaptation is a scenario that practitioners often face when having to build robust NLP systems. They have labeled data in the source domain, but wish to improve performance in the target domain by making use of *unlabeled data* alone. Most work on unsupervised domain adaptation in NLP uses *batch learning*: It assumes that a large corpus of unlabeled data of the target domain is available before testing. However, batch learning is not possible in many real-world scenarios where incoming data from a new target domain must be processed immediately. More importantly, in many real-world scenarios the data does not come with neat domain labels and it may not be immediately obvious that an input stream is suddenly delivering data from a new domain.

Consider an NLP system that analyzes emails at an enterprise. There is a constant stream of incoming emails and it changes over time – without any clear indication that the models in use should be adapted to the new data distribution. Because the system needs to work in real-time, it is also desirable to do any adaptation of the system *online*, without the need of stopping the system, changing it and restarting it as is done in batch mode.

In this paper, we propose *online unsupervised domain adaptation* as an extension to traditional unsupervised DA. In online unsupervised DA, domain adaptation is performed incrementally as data comes in. Specifically, we adopt a form of *representation learning*. In our experiments, the incremental updating will be performed for representations of words. Each time a word is encountered in the stream of data at test time, its representation is updated.

To the best of our knowledge, the work reported here is the first study of online unsupervised DA. More specifically, we evaluate online unsupervised DA for the task of POS tagging. We compare POS tagging results for three distinct approaches: static (the baseline), batch learning and online unsupervised DA. Our results show that online unsupervised DA is comparable in performance to batch learning while requiring no retraining or prior data in the target domain.

2 Experimental setup

Tagger. We reimplemented the FLORS tagger (Schnabel and Schütze, 2014), a fast and simple tagger that performs well in DA. It treats POS tagging as a window-based (as opposed to sequence classification), multilabel classification problem. FLORS is ideally suited for online unsupervised DA because its representation of words includes distributional vectors – these vectors can be easily updated in both batch learning and online unsupervised DA. More specifically, a word's representation in FLORS consists of four feature vectors: one each for its suffix, its shape and its left and right distributional neighbors. Suffix and shape features are standard features used in the literature; our use of them is exactly as described by Schnabel and Schütze (2014).

Distributional features. The i^{th} entry x_i of the left distributional vector of w is the weighted number of times the *indicator word* c_i occurs immediately to the left of w:

$$x_i = \text{tf}\left(\text{freq}\left(\text{bigram}(c_i, w)\right)\right)$$

where c_i is the word with frequency rank i in the corpus, $\text{freq}\left(\text{bigram}(c_i, w)\right)$ is the number of occurrences of the bigram "$c_i\ w$" and we weight non-

Table 1: BATCH and ONLINE accuracies are comparable and state-of-the-art. Best number in each column is bold.

zero frequencies logarithmically: $\mathrm{tf}(x) = 1 + \log(x)$. The right distributional vector is defined analogously. We restrict the set of indicator words to the $n = 500$ most frequent words. To avoid zero vectors, we add an entry x_{n+1} to each vector that counts omitted contexts:

$$x_{501} = \mathrm{tf}(\textstyle\sum_{j:j>n} \mathrm{freq}\,(\mathrm{bigram}(c_j, w)))$$

Let $f(w)$ be the concatentation of the two distributional and suffix and shape vectors of word w. Then FLORS represents token v_i as follows:

$$f(v_{i-2}) \oplus f(v_{i-1}) \oplus f(v_i) \oplus f(v_{i+1}) \oplus f(v_{i+2})$$

where $\oplus$ is vector concatenation. FLORS then tags token v_i based on this representation.

FLORS assumes that the association between distributional features and labels does not change fundamentally when going from source to target. This is in contrast to other work, notably Blitzer et al. (2006), that carefully selects "stable" distributional features and discards "unstable" distributional features. The hypothesis underlying FLORS is that basic distributional POS properties are relatively stable across domains – in contrast to semantic and other more complex tasks. The high performance of FLORS (Schnabel and Schütze, 2014) suggests this hypothesis is true.

Data. *Test set.* We evaluate on the development sets of six different TDs: five SANCL (Petrov and McDonald, 2012) domains – newsgroups, weblogs, reviews, answers, emails – and sections 22-23 of WSJ for in-domain testing.

We use two *training sets* of different sizes. In condition *l:big* (big labeled data set), we train FLORS on sections 2-21 of Wall Street Journal (WSJ). Condition *l:small* uses 10% of l:big.

Data for word representations. We also vary the size of the datasets that are used to compute the word representations before the FLORS model is trained on the training set. In condition *u:big*, we compute distributional vectors on the joint corpus of all labeled and unlabeled text of source and target domains (except for the test sets). We also include 100,000 WSJ sentences from 1988 and 500,000 sentences from Gigaword (Parker, 2009). In condition *u:0*, only labeled training data is used.

Methods. We implemented the following modification compared to the setup in (Schnabel and Schütze, 2014): distributional vectors are kept in memory as count vectors. This allows us to increase the counts during online tagging.

We run experiments with three versions of FLORS: STATIC, BATCH and ONLINE. All three methods compute word representations on "data for word representations" (described above) before the model is trained on one of the two "training sets" (described above).

STATIC. Word representations are not changed during testing.

BATCH. Before testing, we update count vectors by $\mathrm{freq}\,(\mathrm{bigram}(c_i, w))$ += $\mathrm{freq}^*\,(\mathrm{bigram}(c_i, w))$, where $\mathrm{freq}^*(\cdot)$ denotes the number of occurrences of the bigram "c_i w" in the entire test set.

ONLINE. Before tagging a test sentence, both left and right distributional vectors are updated via $\mathrm{freq}\,(\mathrm{bigram}(c_i, w))$ += 1 for each appearance of bigram "c_i w" in the sentence. Then the sentence is tagged using the updated word representations. As tagging progresses, the distributional representations become increasingly specific to the target domain (TD), converging to the representations that BATCH uses at the end of the tagging process.

In all three modes, suffix and shape features are always fully specified, for both known and unknown words.

3 Experimental results

Table 1 compares performance on SANCL for a number of baselines and four versions of FLORS: S&S, Schnabel and Schütze (2014)'s version of FLORS, "S&S (reimpl.)", our reimplementation of that version, and BATCH and ONLINE, the two versions of FLORS we use in this paper. Compar-

Table 2: ONLINE / BATCH accuracies are generally better than STATIC (see bold numbers) and improve with both more training data and more unlabeled data.

ing lines "S&S" and "S&S (reimpl.)" in the table, we see that our reimplementation of FLORS is comparable to S&S's. For the rest of this paper, our setup for BATCH and ONLINE differs from S&S's in three respects. (i) We use Gigaword as additional unlabeled data. (ii) When we train a FLORS model, then the corpora that the word representations are derived from do not include the test set. The set of corpora used by S&S for this purpose includes the test set. We make this change because application data may not be available at training time in DA. (iii) The word representations used when the FLORS model is trained are derived from all six SANCL domains. This simplifies the experimental setup as we only need to train a single model, not one per domain. Table 1 shows that our setup with these three changes (lines BATCH and ONLINE) has state-of-the-art performance on SANCL for domain adaptation (bold numbers).

Table 2 investigates the effect of sizes of labeled and unlabeled data on performance of ONLINE and BATCH. We report accuracy for all (ALL) tokens, for tokens occurring in both l:big and l:small (KN), tokens occurring in neither l:big nor l:small (OOV) and tokens ocurring in l:big, but not in l:small (SHFT).[1] Except for some minor variations in a few cases, both using more labeled data and using more unlabeled data improves tagging accuracy for both ONLINE and BATCH. ONLINE and BATCH are generally better or as good as STATIC (in bold), always on ALL and OOV, and with a few exceptions also on KN and SHFT.

ONLINE performance is comparable to BATCH performance: it is slightly worse than BATCH on u:0 (largest ALL difference is .29) and at most .02 different from BATCH for ALL on u:big. We ex-

[1] We cannot give the standard, single OOV evaluation number here since OOVs are different in different conditions, hence the breakdown into three measures.

		unknowns				unseens				known words

Table 3: Error rates (err) and standard deviations (std) for tagging. † (resp. $*$): significantly different from ONLINE error rate above&below (resp. from "u:0" error rate to the left).

plain below why ONLINE is sometimes (slightly) *better* than BATCH, e.g., for ALL and condition l:small/u:big.

3.1 Time course of tagging accuracy

The ONLINE model introduced in this paper has a property that is unique compared to most other work in statistical NLP: its *predictions change* as it tags text because its *representations change.*

To study this time course of changes, we need a large application domain because subtle changes will be too variable in the small test sets of the SANCL TDs. The only labeled domain that is big enough is the WSJ corpus. We therefore reverse the standard setup and train the model on the dev sets of the five SANCL domains (*l:big*) or on the first 5000 labeled words of reviews (*l:small*). In this reversed setup, *u:big* uses the five unlabeled SANCL data sets and Gigaword as before. Since variance of performance is important, we run on 100 randomly selected 50% samples of WSJ and report average and standard deviation of tagging error over these 100 trials.

The results in Table 3[2] show that error rates are only slightly worse for ONLINE than for BATCH or the same. In fact, l:small/u:0 known error rate (.1186) is *lower* for ONLINE than for BATCH (similar to what we observed in Table 2). This will be discussed at the end of this section.

Table 3 includes results for "unseens" as well as unknowns because Schnabel and Schütze (2014) show that unseens cause at least as many errors as unknowns. We define *unseens* as words with a tag that did not occur in training; we compute unseen error rates on *all occurrences* of unseens, i.e., occurrences with both seen and unseen tags are included. As Table 3 shows, the error rate for unknowns is greater than for unseens which is in turn greater than the error rate on known words.

[2]Significance test: test of equal proportion, $p < .05$

Examining the single conditions, we can see that ONLINE fares better than STATIC in 10 out of 12 cases and only slightly worse for l:small/u:big (unseens, known words: .1086 vs .1084, .0802 vs .0801). In four conditions it is significantly better with improvements ranging from .005 (.1404 vs .1451: l:big/u:0, unknown words) to $>$.06 (.3094 vs .3670: l:small/u:0, unknown words).

The differences between ONLINE and STATIC in the other eight conditions are negligible. For the six u:big conditions, this is not surprising: the Gigaword corpus consists of news, so the large unlabeled data set is in reality the same domain as WSJ. Thus, if large unlabeled data sets are available that are similar to the TD, then one might as well use STATIC tagging since the extra work required for ONLINE/BATCH is unlikely to pay off.

Using more labeled data (comparing l:small and l:big) always considerably decreases error rates. We did not test for significance here because the differences are so large. By the same token, using more unlabeled data (comparing u:0 and u:big) also consistently decreases error rates. The differences are large and significant for ONLINE tagging in all six cases (indicated by $*$ in the table).

There is no large difference in variability ONLINE vs. BATCH (see columns "std"). Thus, given that it has equal variability and higher performance, ONLINE is preferable to BATCH since it assumes no dataset available prior to the start of tagging.

Figure 1 shows the time course of tagging accuracy.[3] BATCH and STATIC have constant error rates since they do not change representations during tagging. ONLINE error decreases for unknown words – approaching the error rate of BATCH – as

[3]In response to a reviewer question, the initial (leftmost) errors of ONLINE and STATIC are *not* identical; e.g., ONLINE has a better chance of correctly tagging the very first occurrence of an unknown word because that very first occurrence has a meaningful (as opposed to random) distributed representation.

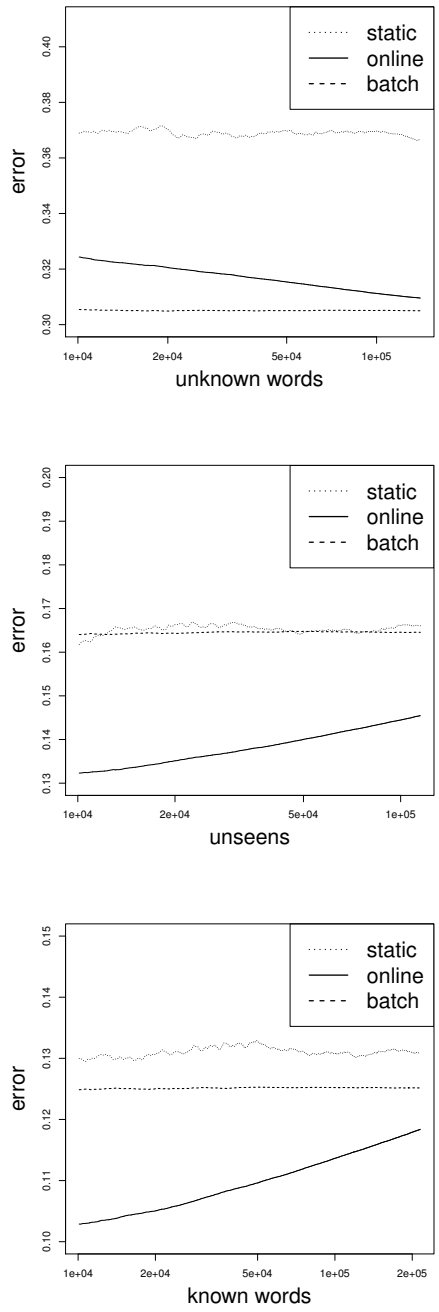

Figure 1: Error rates for unknown words, words with unseen tags and known words for l:small/u:0. The x axis represents the number of tokens of the respective type (e.g., number of tokens of unknown words).

more and more is learned with each additional occurrence of an unknown word (top).

Interestingly, the error of ONLINE *increases* for unseens and known words (middle&bottom panels) (even though it is always below the error rate of BATCH). The reason is that the BATCH update swamps the original training data for l:small/u:0 because the WSJ test set is bigger by a large factor than the training set. ONLINE fares better here because in the beginning of tagging the updates of the distributional representations consist of small increments. We noticed this in Table 2 too: there, ONLINE outperformed BATCH in some cases on KN for l:small/u:big. In future work, we plan to investigate how to weight distributional counts from the target data relative to that from the (labeled und unlabeled) source data.

4 Related work

Online learning usually refers to *supervised* learning algorithms that update the model each time after processing a few training examples. Many supervised learning algorithms are online or have online versions. Active learning (Lewis and Gale, 1994; Tong and Koller, 2001; Laws et al., 2011) is another supervised learning framework that processes training examples – usually obtained interactively – in small batches (Bordes et al., 2005).

All of this work on *supervised online learning* is not directly relevant to this paper since we address the problem of *unsupervised DA*. Unlike online supervised learners, we keep the statistical model unchanged during DA and adopt a representation learning approach: each unlabeled context of a word is used to update its representation.

There is much work on unsupervised DA for POS tagging, including work using constraint-based methods (Subramanya et al., 2010; Rush et al., 2012), instance weighting (Choi and Palmer, 2012), self-training (Huang et al., 2009; Huang and Yates, 2010), and co-training (Kübler and Baucom, 2011). All of this work uses batch learning. For space reasons, we do not discuss supervised DA (e.g., Daumé III and Marcu (2006)).

5 Conclusion

We introduced online updating of word representations, a new domain adaptation method for cases where target domain data are read from a stream and BATCH processing is not possible. We showed that online unsupervised DA performs as well as batch learning. It also significantly lowers error rates compared to STATIC (i.e., no domain adaptation). Our implementation of FLORS is available at `cistern.cis.lmu.de/flors`

Abstract

We describe an approach for machine learning-based empty category detection that is based on the phrase structure analysis of Japanese. The problem is formalized as tree node classification, and we find that the path feature, the sequence of node labels from the current node to the root, is highly effective. We also find that the set of dot products between the word embeddings for a verb and those for case particles can be used as a substitution for case frames. Experiments show that the proposed method outperforms the previous state-of the art method by 68.6% to 73.2% in terms of F-measure.

1 Introduction

Empty categories are phonetically null elements that are used for representing dropped pronouns ("pro" or "small pro"), controlled elements ("PRO" or "big pro") and traces of movement ("T" or "trace"), such as WH-questions and relative clauses. They are important for pro-drop languages such as Japanese, in particular, for the machine translation from pro-drop languages to non-pro-drop languages such as English. Chung and Gildea (2010) reported their recover of empty categories improved the accuracy of machine translation both in Korean and in Chinese. Kudo et al. (2014) showed that generating zero subjects in Japanese improved the accuracy of preordering-based translation.

State-of-the-art statistical syntactic parsers had typically ignored empty categories. Although Penn Treebank (Marcus et al., 1993) has annotations on PRO and trace, they provide only labeled bracketing. Johnson (2002) proposed a statistical pattern-matching algorithm for post-processing the results of syntactic parsing based on minimal unlexicalized tree fragments from empty node to its antecedent. Dienes and Dubey (2003) proposed a machine learning-based "trace tagger" as a preprocess of parsing. Campbell (2004) proposed a rule-based post-processing method based on linguistically motivated rules. Gabbard et al. (2006) replaced the rules with machine learning-based classifiers. Schmid (2006) and Cai et al. (2011) integrated empty category detection with the syntactic parsing.

Empty category detection for pro (dropped pronouns or zero pronoun) has begun to receive attention as the Chinese Penn Treebank (Xue et al., 2005) has annotations for pro as well as PRO and trace. Xue and Yang (2013) formalized the problem as classifying each pair of the location of empty category and its head word in the dependency structure. Wang et al. (2015) proposed a joint embedding of empty categories and their contexts on dependency structure. Xiang et al. (2013) formalized the problem as classifying each IP node (roughly corresponds to S and SBAR in Penn Treebank) in the phrase structure.

In this paper, we propose a novel method for empty category detection for Japanese that uses conjunction features on phrase structure and word embeddings. We use the Keyaki Treebank (Butler et al., 2012), which is a recent development. As it has annotations for pro and trace, we show our method has substantial improvements over the state-of-the-art machine learning-based method (Xiang et al., 2013) for Chinese empty category detection as well as linguistically-motivated manually written rule-based method similar to (Campbell, 2004).

2 Baseline systems

The Keyaki Treebank annotates the phrase structure with functional information for Japanese sentences following a scheme adapted from the Annotation manual for the Penn Historical Corpora and

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1335–1340,
Lisbon, Portugal, 17-21 September 2015.

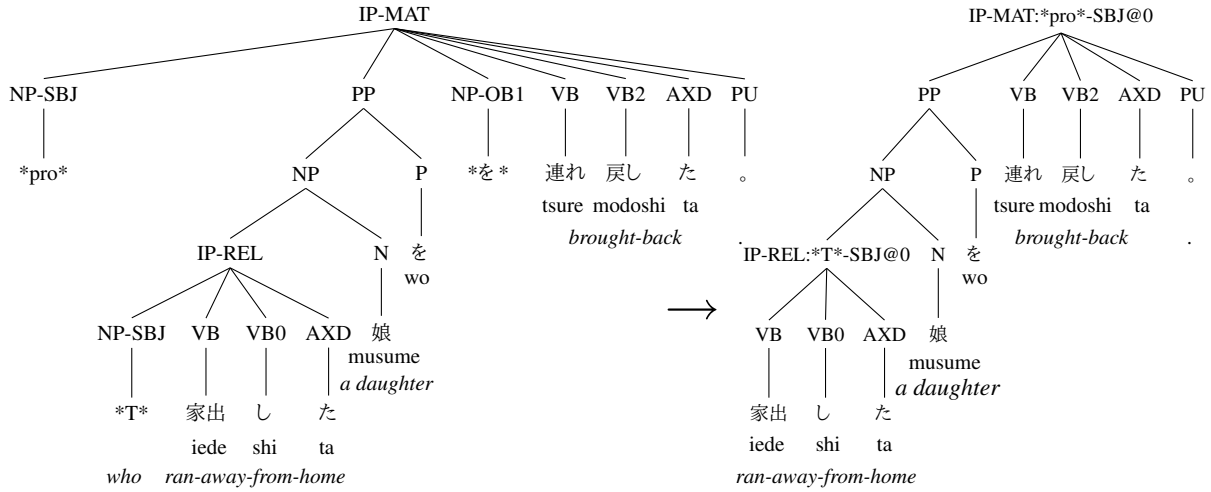

Figure 1: An annotation example of 家出した娘を 連れ戻した。*(*pro* brought back a daughter who ran away from home.)* in Keyaki Treebank. (The left tree is the original tree and the right tree is a converted tree based on Xiang et al.'s (2013) formalism)

the PCEEC (Santorini, 2010). There are some major changes: the VP level of structure is typically absent, function is marked on all clausal nodes (such as IP-REL and CP-THT) and all NPs that are clause level constituents (such as NP-SBJ). Disambiguation tags are also used for clarifying the functions of its immediately preceding node, such as NP-OBJ *を *(wo) for PP, however, we removed them in our experiment.

Keyaki Treebank has annotation for trace markers of relative clauses (*T*) and dropped pronouns (*pro*), however, it deliberately has no annotation for control dependencies (PRO) (Butler et al., 2015). It has also fine grained empty categories of *pro* such as *speaker* and *hearer*, but we unified them into *pro* in our experiment.

HARUNIWA(Fang et al., 2014) is a Japanese phrase structure parser trained on the treebank. It has a rule-based post-processor for adding empty categories, which is similar to (Campbell, 2004). We call it RULE in later sections and use it as one of two baselines.

We also use Xiang et al's (2013) model as another baseline. It formulates empty category detection as the classification of IP nodes. For example, in Figure 1, empty nodes in the left tree are removed and encoded as additional labels with its position information to IP nodes in the right tree. As we can uniquely decode them from the extended IP labels, the problem is to predict the labels for the input tree that has no empty nodes.

Let $T = t_1 t_2 \cdots t_n$ be the sequence of nodes produced by the post-order traversal from root node, and e_i be the empty category tag associated with t_i. The probability model of (Xiang et al., 2013) is formulated as MaxEnt model:

$$P(e_1^n|T) = \prod_{i=1}^{n} P(e_i|e_1^{i-1}, T) = \prod_{i=1}^{n} \frac{\exp(\boldsymbol{\theta} \cdot \boldsymbol{\phi}(e_i, e_1^{i-1}, T))}{Z(e_1^{i-1}, T)} \quad (1)$$

where $\boldsymbol{\phi}$ is a feature vector, $\boldsymbol{\theta}$ is a weight vector to $\boldsymbol{\phi}$ and Z is normalization factor:

$$Z(e_1^{i-1}, T) = \sum_{e \in \mathcal{E}} \exp(\boldsymbol{\theta} \cdot \boldsymbol{\phi}(e, e_1^{i-1}, T))$$

where $\mathcal{E}$ represents the set of all empty category types to be detected.

Xiang et al. (2013) grouped their features into four types: tree label features, lexical features, empty category features and conjunction features as shown in Table 1. As the features for (Xiang et al., 2013) were developed for Chinese Penn Treebank, we modify their features for Keyaki Treebank: First, the traversal order is changed from post-order (bottom-up) to pre-order (top-down). As PROs are implicit in Keyaki Treebank, the decisions on IPs in lower levels depend on those on higher levels in the tree. Second, empty category features are extracted from ancestor IP nodes, not from descendant IP nodes, in accordance with the first change.

Table 2 shows the accuracies of Japanese empty category detection, using the original and our modification of the (Xiang et al., 2013) with ablation test. We find that the conjunction features

Tree label features	
1	current node label
2	parent node label
3	grand-parent node label
4	left-most child label or POS tag
5	right-most child label or POS tag
6	label or POS tag of the head child
7	the number of child nodes
8	one level CFG rule
9	left-sibling label or POS tag (up to two siblings)
10	right-sibling label or POS tag (up to two siblings)
Lexical features	
11	left-most word under the current node
12	right-most word under the current node
13	word immediately left to the span of the current node
14	word immediately right to the span of the current node
15	head word of the current node
16	head word of the parent node
17	is the current node head child of its parent? (binary)
Empty category features	
18	predicted empty categories of the left sibling
19*	the set of detected empty categories of ancestor nodes
Conjunction features	
20	current node label with parent node label
21*	current node label with features computed from ancestor nodes
22	current node label with features computed from left-sibling nodes
23	current node label with lexical features

Table 1: List of features of Xiang et al.'s (2013). (* indicates the features we changed for the Keyaki Treebank)

Features	F(Gold)	Δ
original (Xiang et al., 2013)	68.2	−0.40
modified (Xiang et al., 2013)	68.6	-
− Tree label	68.6	−0.00
− Empty category	68.3	−0.30
− Lexicon	68.6	−0.00
− Conjunction	58.5	−10.1

Table 2: Ablation result of (Xiang et al., 2013)

are highly effective compared to the three other features. This observation leads to the model proposed in the next section.

3 Proposed model

In the proposed model, we use combinations of path features and three other features, namely head word feature, child feature and empty category feature. Path feature (PATH) is a sequence of non-terminal labels from the current node to the ancestor nodes up to either the root node or the nearest CP node. For example, in Figure 1, if the current node is IP-REL, four paths are extracted; IP-REL, IP-REL → NP, IP-REL → NP → PP and IP-REL → NP → PP → IP-MAT.

Head word feature (HEAD) is the surface form of the lexical head of the current node. Child feature (CHILD) is the set of labels for the children of the current node. The label is augmented with the surface form of the rightmost terminal node if it is a function word. In the example of Figure 1, if the current node is IP-MAT, HEAD is 連れ (tsure) and CHILD includes: PP-を (wo), VB, VB2, AXD-た (ta) and PU-。. Empty category feature (EC) is a set of empty categories detected in the ancestor IP nodes. For example in Figure 1, if the current node is IP-REL, EC is *pro*.

We then combine the PATH with others. If the current node is the IP-MAT node in right-half of Figure 1, the combination of PATH and HEAD is:IP-MAT× 連れ (tsure) and the combinations of PATH and CHILD are: IP-MAT×PP-を (wo), IP-MAT×VB, IP-MAT×VB2, IP-MAT×AXD-た (ta) and IP-MAT×PU-。.

3.1 Using Word Embedding to approximate Case Frame Lexicon

A case frame lexicon would be obviously useful for empty category detection because it provides information on the type of argument the verb in question takes. The problem is that case frame lexicon is not usually readily available. We propose a novel method to approximate case frame lexicon for languages with explicit case marking such as Japanese using word embeddings. According to (Pennington et al., 2014), they designed their embedding model GloVe so that the dot product of two word embeddings approximates the logarithm of their co-occurrence counts. Using this characteristic, we can easily make a feature that approximate the case frame of a verb. Given a set of word embeddings for case particles $q_1, q_2, \cdots, q_N \in Q$, the distributed case frame feature (DCF) for a verb w_i is defined as:

$$\tilde{v_i} = w_i \cdot (q_1, q_2, \cdots, q_N) \quad (2)$$

$$v_i = \frac{\tilde{v_i}}{||\tilde{v_i}||} \quad (3)$$

In our experiment, we used a set of high frequency case particles が (ga), は (ha), も (mo), の (no), を (wo), に (ni), へ (he) and から (kara) as Q.

are 22,639 sentences in Keyaki Treebank. We used 1,000 sentences as the development set, 1,003 sentences as the test set. They were taken from the files blog_KNB.psd (blog), spoken_CIAIR.psd (transcript), newswire_MAINICHI-1995.psd (newswire) to balance the domain. The remaining 20,646 sentences are used for training. Further statistics are shown in Table 3.

We used GloVe as word embedding, Wikipedia articles in Japanese as of January 18, 2015, are used for training, which amounted to 660 million words and 23.4 million sentences. By using the development set, we set the dimension of word embedding and the window size for co-occurrence counts as 200 and 10, respectively.

4.2 Result and Discussion

We tested in two conditions: gold parse and system parse. In gold parse condition, we used the trees of Keyaki Treebank without empty categories as input to the systems. In system parse condition, we used the output of the Berkeley Parser model of HARUNIWA before rule-based empty category detection[1]. We evaluated them using the word-position-level identification metrics described in (Xiang et al., 2013). It projects the predicted empty category tags to the surface level. An empty node is regarded as correctly predicted surface position in the sentence, type (T or pro) and function (SBJ, OB1 and so on) are matched with the reference.

To evaluate the effectiveness of the proposed distributed case frame (DCF), we used an existing case frame lexicon (Kawahara and Kurohashi, 2006) and tested three different ways of encoding the case frame information: BIN encodes each case as binary features. SET encodes each combination of required cases as a binary feature. DIST is a vector of co-occurrence counts for each case particle, which can be thought of an unsmoothed version of our DCF.

Table 4 shows the accuracies of various empty category detection methods, for both gold parse and system parse. In the gold parse condition, the two baselines, the rule-based method (RULE) and the modified (Xiang et al., 2013) method, achieved the F-measure of 62.6% and 68.6% respectively.

We also implemented the third baseline based on (Johnson, 2002). Minimal unlexicalized tree fragments from empty node to its antecedent were extracted as pattern rules based on corpus statistics. For *pro*, which has no antecedent, we used the statistics from empty node to the root. Although the precision of the method is high, the recall is very low, which results in the F-measure of 38.1%.

Among the proposed models, the combination of path feature and child feature (PATH $\times$ CHILD) even outperformed the baselines. It reached 73.2% with all features. As for the result of system-parse condition, the F-measure dropped considerably from 73.2% to 54.7% mostly due to the parsing errors on the IP nodes and its function.

We find that there are no significant differences among the different encodings of the case frame lexicon, and the improvement brought by the proposed distributed case frame is comparable to the existing case frame lexicon.

Table 5 shows the ablation result of the proposed model. It indicates conjunction between PATH and CHILD feature is most effective.

	F(Gold)	Δ	F(System)	Δ
Proposed	72.1	-	53.9	-
$-$CHILD	47.4	-24.7	33.7	-20.2
$-$EC	70.8	-1.3	52.4	-1.5
$-$HEAD	70.0	-2.1	51.6	-2.3

Table 5: Ablation result of PATH $\times$ (CHILD + EC + HEAD) model

[1]There are two models available in HARUNIWA, namely the BitPar model (Schmid, 2004) and Berkeley Parser binary branching model (Petrov and Klein, 2007). The output of the later is first flattened, then added disambiguation tags and empty categories using tsurgeon script (Levy and Andrew, 2006).

5 Conclusion

In this paper, we proposed a novel model for empty category detection in Japanese using path features and the distributed case frames. Although it achieved fairly high accuracy for the gold parse, there is much room for improvement when applied to the output of a syntactic parser. Since the accuracy of the empty category detection implemented as a post-process highly depends on that of the underlying parser, we want to explore models that can solve them jointly, such as the lattice parsing approach of (Cai et al., 2011). We would like to report the results in the future version of this paper.

Abstract

We present a new treebank of English and French technical forum content which has been annotated for grammatical errors and phrase structure. This double annotation allows us to empirically measure the effect of errors on parsing performance. While it is slightly easier to parse the corrected versions of the forum sentences, the errors are not the main factor in making this kind of text hard to parse.

1 Introduction

The last five years has seen a considerable amount of research carried out on web and social media text parsing, with new treebanks being created (Foster et al., 2011; Seddah et al., 2012; Mott et al., 2012; Kong et al., 2014), and new parsing systems developed (Petrov and McDonald, 2012; Kong et al., 2014). In this paper we explore a particular source of user-generated text, namely, posts from technical support forums, which are a popular means for customers to resolve their queries about a product. An accurate parser for this kind of text can be used to inform forum-level question-answering, machine translation and quality estimation of machine translation.

We create a 2000-sentence treebank called *Foreebank* which contains sentences from the Symantec Norton English and French technical support forums.[1] The phrase structure of the sentences is annotated *and* any grammatical errors are marked in the trees. Marking the grammatical errors allows us to precisely measure the amount of grammatical noise in this kind of text, and joint error and syntactic annotation allows us to determine its effect on parsing.

Foster (2010) explored the effect of spelling errors on parsing performance of conversational forum text. We extend this study to include grammatical errors, focusing on more technical content. Foster et al. (2008) explored the effect of artificially generated grammatical errors on Wall Street Journal parsing. We concentrate on forum text rather than newspaper text, and, crucially, examine the effect of *real* grammatical errors. We find that the level of grammatical noise is lower than expected, with capitalisation and punctuation errors being the most frequent. While correcting all the errors does result in a performance increase of 1.5% for English and 0.8% for French, the major challenge in parsing these sentences seems not to be "bad language" (Eisenstein, 2013) per se.

The main contribution of the paper is the Foreebank data set itself[2] but we also carry out preliminary parsing experiments evaluating the accuracy of a PCFG-LA parser on Foreebank, examining the effect of grammatical errors on parsing and experimenting with different training sets.

2 Related Work

Other treebanks of English web text include the English Web Treebank (aka Google Web Treebank) (Mott et al., 2012), the small treebank of tweets and football discussion forum posts described in Foster et al. (2011) and the tweet dependency bank described in Kong et al. (2014). The English Web Treebank is a corpus of over 250K words, selected from blogs, newsgroups, emails, local business reviews and Yahoo! answers. It adapts the Penn Treebank (Marcus et al., 1994) and Switchboard (Taylor, 1996) annotation guidelines to address the phenomena specific

to this type of text. The annotation of the 1000-sentence treebank described in Foster et al. (2011) is based on the Penn Treebank, whereas the annotation of the treebank described in Kong et al. (2014) is dependency-based. The *French Social Media Bank* developed by Seddah et al. (2012) is a treebank of 1,700 French sentences from various type of social media including Facebook, Twitter and discussion forums (video game and medical). An extended version of the FTB-UC annotation guidelines (Candito and Crabbé, 2009) is employed during annotation and subcorpora containing particularly noisy utterances are identified.

The main difference between Foreebank and other web/social media treebanks is that grammatical errors in the Foreebank sentences are marked and corrected as part of the annotation process. Error annotation not only provides more insight into this type of text but it also enables us to directly measure the effect of these errors on parsing accuracy and leaves open the possibility of performing joint parsing and error detection by directly learning the error annotation during parser training.

A learner corpus (Granger, 2008) contains utterances produced by language learners and serves as a resource for second language acquisition, computational linguistic and computer-aided language learning research. Examples include the International Corpus of Learner English (Granger, 1993), the Cambridge Learner Corpus (Nicholls, 1999; Yannakoudakis et al., 2011), the NUS Corpus of Learner English (Dahlmeier et al., 2013) and the German Falko corpus (Lüdeling, 2008; Rehbein et al., 2012). We can compare Foreebank to a learner corpus since both contain utterances that are potentially ungrammatical and because in a learner corpus the errors are often annotated, as they are in Foreebank. In the last five years, there have been several shared tasks in grammatical error correction including the Helping Our Own (HOO) shared tasks of 2011 and 2012 (Dale and Kilgariff, 2011; Dale et al., 2012), and the CoNLL 2013 and 2014 shared tasks (Ng et al., 2013; Ng et al., 2014). With the exception of HOO 2011, all shared tasks involve error-annotated sentences from learner corpora. Annotation schemes vary but most involve marking the span of an error, classifying the error according to some taxonomy designed with L2 utterances in mind, and sometimes providing the correction or "target hypothesis" (Hirschmann et al., 2007).

Regarding syntactic annotation of learner data, Dickinson and Ragheb (2009) propose a dependency annotation scheme based on the CHILDES scheme (Sagae et al., 2007) developed for first language learners. They treat the developing language of learners as an interlanguage, as suggested by Díaz-Negrillo et al. (2010), and annotate it as is. They use two POS tags and two dependency labels for error cases: one for the surface form and one for the intended form. Rosén and De Smedt (2010) criticise the approach of Dickinson and Ragheb (2009) involving "annotating language text as is" arguing that interpretation of the language is required at all annotation levels. They use NorGram, a Norwegian Lexical-Functional Grammar, to annotate a learner corpus with constituency structure, functional structure and semantic structure, in order to provide a means to search for contexts in which learner errors occur. Nagata et al. (2011) describe an English learner corpus which has been manually annotated with shallow syntax, introducing two new POS tags and two new chunk labels for errors.

3 Building the Foreebank

The Foreebank treebank contains 1000 English sentences and 1000 French sentences. The English sentences come from the Symantec Norton technical support user forum. Half of the French sentences come from the French Norton forum and the other half are human translations of sentences from the English forum. Four annotators were involved in the annotation process. Their main task was to correct automatically parsed phrase structure trees using an annotation tool developed for this project.[3] The English annotators were guided by the Penn Treebank bracketing guidelines and a Foreebank-adapted version of the English Web Treebank bracketing guidelines. The French annotators used the French treebank (FTB) (Abeillé et al., 2003) guidelines, following the SPMRL strategy for multiword expressions (Seddah et al., 2013; Candito and Crabbé, 2009). The two primary annotators, one for French and one for English, annotated all the data for their language. The two secondary annotators annotated a 100-sentence subset. Inter-annotator agreement was calculated by measuring the Parseval

[3]The Stanford parser (Klein and Manning, 2003) was used to parse the English data and the Berkeley parser (Petrov et al., 2006) was used for the French sentences.

Table 1: Foreebank Error Suffixes. The last two columns refer to their frequency.

F1 of trees produced by the secondary annotators against those produced by the primary annotators. For English this was 88 and for French it was 86.7.

Prior to correcting a parse tree produced by the automatic parser, the annotators are asked to correct any errors they find in the sentence.[4] The corrected text is entered in a field of the annotation tool. As part of the syntactic annotation process, errors are marked by appending an error suffix to the preterminals of the affected words in the tree. The error suffixes used in Foreebank are listed in Table 1 and an example tree from Foreebank is shown in Figure 1. There are three kinds of substitution error suffixes: `C` for marking problems with capitalisation, `S` for marking spelling errors and `W` for marking the wrong form of a word which encompasses inflection errors (*they* instead of *them*), real-word spelling errors (*test* instead of *text*) and lexical choice errors (*desk* instead of *chair*). The POS tag of the corrected form is used in the tree instead of the POS tag of the incorrect form.[5] Although this annotation scheme contains fewer error types than the taxonomies used for learner corpora, its granularity increases when the error suffixes are interpreted in the syntactic context in which they occur. For example, we can distinguish a missing determiner (`DT_D`) from a missing preposition (`IN_D`).

The "sentences" that the annotators see are the result of passing the forum text through an automatic sentence splitter (NLTK[6]) and tokeniser (in-house). This is another important difference between Foreebank and the English Web Treebank (EWT). In the EWT, sentence boundary detection and tokenisation has been carried out manually before annotation. Both approaches are valid but ours was chosen in order to stay closer to the more realistic scenario of less than perfect automatic preprocessing tools. This means that annotators have a special class of errors that result from noisy sentence splitting and tokenisation that must be marked during annotation.

There are two types of sentence splitting errors: merged sentences such as (1) in which a sentence boundary was not detected before the word *When* due to the use of a comma instead of a full stop, and split sentences such as (2).

(1) `7. Combofix will start, **When** it is scanning don't move the mouse cursor inside the box,`

(2) `The questions to <CompanyName>:`

[4] Minimal correction is encouraged to prevent annotators from rewriting the sentence in their preferred writing style. Instead they are instructed to just focus on fixing the errors.

[5] An alternative would have been to use one POS tag for the erroneous form and one for the corrected form, either combined a la Nagata et al. (2011) or separate a la Dickinson and Ragheb (2009).

[6] `http://www.nltk.org/`

Merged sentences are gathered under one root node with the error suffix `M` (e.g. `S_M`) , and split sentences are annotated as if they are standalone.

Tokenisation problems can also be categorised as merged (3) or split (4 and 5). Merged tokens are treated as a combination of a spelling error (*whenI* instead of *when*) and a deleted token (*I*). When the split is morphological as in (4), they are tagged with the POS tag of the whole intended token, along with the error suffix `B` (for "broken"). So in (4), the POS tag of *anti* would be annotated as `NN_B` and the POS tag of *vir* as `NN_B`. When there is no such clean morphological break (as in (5)), the first token is treated as a spelling error and the second as an extraneous token.

(3) **whenI** tried to use ...

(4) he should buy **anti vir** programs

(5) **i t** keeps causing <*ProductName*> to lock up ...

4 Analysing the Foreebank

Table 2 presents the average and the maximum sentence length in Foreebank, and, for comparison, WSJ and FTB. It also gives the out-of-vocabulary (OOV) rate of these data sets with respect to the WSJ and FTB. The Foreebank sentences are shorter on average than the WSJ and FTB sentences. The table also shows that the OOV rate of Foreebank with respect to WSJ/FTB is high: 33.3% for English and 39.1% for French. These numbers can be compared to the OOV rate of the WSJ test set with respect to its training set which is 13.2% and the FTB which is 20.6%. The higher OOV rate for the French Foreebank compared to the English is most likely due to the larger size of the WSJ compared to the FTB. The OOV rate of the English Foreebank is more than 2.5 times as large as that of the WSJ test set, while the OOV rate of the French Foreebank is less than 2 times as large as that of the FTB test set. This suggests that a bigger performance drop due to unknown words should be expected in parsing the English Foreebank sentences than the French.

The last four columns in Table 1 display the absolute and relative frequency of each error suffix. In sum, it seems that capitalisation is the major error type in Foreebank especially in the French data. Deleted tokens are also a major source of problem on the English side. Most of the capitalisation errors involve proper nouns (e.g. product names) and most of the deleted tokens are cases

	FB$_{en}$	WSJ	FB$_{fr}$	FTB
Avg. sentence length	15.4	23.8	19.6	28.4
Max. sentence length	89	141	86	260
OOV rate (%)	31.6	-	33.6	-

Table 2: Characteristics of the English (FB$_{en}$) and French (FB$_{fr}$) Foreebank compared with those of the WSJ and FTB.

English	FB$_{en}$ All	WSJ Test	**French**	FB$_{fr}$ All	FTB Test
WSJ$_{all}$	77.0	-	FTB$_{all}$	76.3	-
WSJ$_{train}$	75.4	89.6	FTB$_{train}$	76.0	81.3

Table 3: Foreebank and WSJ/FTB test set results.

of missing punctuation. Overall, the errors occur on only a small fraction of the tokens in both data sets. We also calculate the edit distance between each Foreebank sentence and its correction by summing the number of error suffixes and dividing by the maximum of the original and corrected sentence lengths. The average edit distance for the English section of Foreebank is 0.04 and for the French section is 0.03. Despite the existence of some near-to-incomprehensible sentences, the overall error level is very low.

5 Parsing the Foreebank

We first evaluate newswire-trained parsers on Foreebank, using our in-house PCFG-LA parser with the max-rule parsing algorithm (Petrov and Klein, 2007) and 6 split-merge cycles. The English model is trained on the entire WSJ and the French model on the entire FTB. For comparison, we parse the WSJ/FTB and so we additionally use models trained only on the training sections. We remove the error suffixes and any D-suffixed nodes (representing deleted words) from the gold Foreebank trees before evaluation. The results are shown in Table 3. As expected, we see a significant drop for both languages when we move from in-domain data to Foreebank. Compared to parsing the English side of Foreebank, the performance drop for French is relatively smaller: the former drops 14.2 points from 89.6 F_1 points to 75.4 and the latter 5.3 points from 81.3 to 76. This suggests that, either the French parsing model is better generalisable to the forum text, or alternatively, that the FTB test set is more distant from its training set than the WSJ one. The second hypoth-

esis is more likely because 1) it is on par with the OOV rate observed in Section 4, and 2) the performance of the English and French parsers are close on Foreebank but further apart on the newswire test sets. The effect of using the entire WSJ and FTB instead of only their training sections is also worth noting. While adding the WSJ development and test sets (about 5,500 sentences, a 14% increase) improves the F_1 of English parsing by 1.6 points, the 2,500 FTB development and test sentences (a 25% increase) have little effect on the French parsing, suggesting that either these new sentences are still not enough or do not bring additional information to the parsing model.

Since the annotators correct the errors made by the forum users, we are able to parse the corrected versions of the Foreebank sentences and examine how accurately they are parsed compared to the original sentences. We use the WSJ_{all} and FTB_{all} parsing models described above. Correcting the user errors before parsing leads to an improved parsing F_1 of 78.6 for the English sentences, an increase of 1.6 points (2%). A smaller impact is observed on the French sentences where the edited sentences receive an F_1 of 77.1 (an increase of 0.8 points). Referring to the distribution of error suffixes in Table 1, this suggests that the inserted and deleted tokens may have a larger effect on parser error than the substituted tokens, as their number is higher for English. Many substitution errors are capitalisation errors, typically involving a confusion between proper and common nouns, which tends not to affect the surrounding tree.

The simplest method to improve the accuracy of parsing Foreebank is to use it as supplementary training data. We do this using a 5-fold cross validation, in which Foreebank is randomly split into five parts, with each part used for the evaluation of the parsers trained on WSJ/FTB plus the other four parts. The results are shown in Table 4. Combining the larger treebank and Foreebank improves the F_1 by 2.6 points for English and 3.2 for French. Considering that Foreebank is orders of magnitude smaller than the WSJ/FTB, these gains are encouraging. We try to overcome the small size of Foreebank by 1) using the EWT as training data, and 2) increasing the weight of Foreebank by training on multiple copies of it. The EWT is not a substitute for the WSJ but it does provide a modest improvement when used in conjunction with Foreebank and WSJ. The replication of Foreebank trees has mixed results, providing a 0.5 point improvement for English and none for French.

English		**French**	
Training Set	F_1	Training Set	F_1
WSJ_{all}	77.0	FTB_{all}	76.3
WSJ_{all}+FB_{en}	79.6	FTB_{all}+FB_{fr}	**79.5**
WSJ_{all}+5FB_{en}	80.1	FTB_{all}+5FB_{fr}	**79.5**
EWT	75.0	-	-
EWT+FB_{en}	79.0	-	-
WSJ_{all}+FB_{en}+EWT	**80.3**	-	-
FB_{en}	71.1	FB_{fr}	72.4
FB_{en_suf}	70.2	FB_{fr_suf}	71.8

Table 4: Training on Foreebank/WSJ/EWT/FTB and testing on Foreebank

In all experiments up to now, we have excluded the error suffixes from the Foreebank trees (during training and testing). We next try to directly learn trees containing the error suffixes (except for deleted tokens). That is, we use the original Foreebank trees containing the error suffixes for training and evaluate against Foreebank trees containing the error suffixes. The second last row of Table 4 shows the 5-fold CV results when the version of Foreebank without the error suffixes is used for training and the last row the results when the error suffixes are included. Including the suffixes decreases the accuracy, most likely due to the increased data sparsity caused by the suffixed tags.

6 Conclusion

We have introduced a treebank of technical forum sentences for English and French, based on an annotation strategy adapted to suit user-generated text in a realistic NLP setting. By marking the errors on the trees, we studied their prevalence as well as their impact on parsing and found that despite their low frequency, they do negatively affect parser performance, while not being the most important factor. Our next steps include learning error suffixes during a prior tagging phase and experimenting with the French Social Media Bank.

Abstract

We present a semi-supervised approach to improve dependency parsing accuracy by using bilexical statistics derived from auto-parsed data. The method is based on estimating the attachment potential of head-modifier words, by taking into account not only the head and modifier words themselves, but also the words surrounding the head and the modifier. When integrating the learned statistics as features in a graph-based parsing model, we observe nice improvements in accuracy when parsing various English datasets.

1 Introduction

We are concerned with semi-supervised dependency parsing, namely how to leverage large amounts of unannotated data, in addition to annotated Treebank data, to improve dependency parsing accuracy. Our method (Section 2) is based on parsing large amounts of unannotated text using a baseline parser, extracting word-interaction statistics from the automatically parsed corpus, and using these statistics as the basis of additional parser features. The automatically-parsed data is used to acquire statistics about lexical interactions, which are too sparse to estimate well from any realistically-sized Treebank. Specifically, we attempt to infer a function $assoc(head, modifer)$ measuring the "goodness" of head-modifier relations ("how good is an arc in which *black* is a modifier of *jump*"). A similar approach was taken by Chen et al. (2009) and Van Noord et al. (2007). We depart from their work by extending the scoring to include a wider lexical context. That is, given the sentence fragment in Figure 1, we score the (incorrect) dependency arc (*black*, *jump*) based on the triplets (*the black fox*, *will jump over*). Learning a function between word triplets raises an extreme data sparsity issue, which we deal with by decomposing the interaction between triplets to a sum of interactions between word pairs. The decomposition we use is inspired by recent work in word-embeddings and dense vector representations (Mikolov et al., 2013a; Mnih and Kavukcuoglu, 2013). Indeed, we initially hoped to leverage the generalization abilities associated with vector-based representations. However, we find that in our setup, reverting to direct count-based statistics achieve roughly the same results (Section 3).

Our derived features improve the accuracy of a first-order dependency parser by 0.75 UAS points (absolute) when evaluated on the in-domain WSJ test-set, obtaining a final accuracy of 92.32 UAS for a first-order parser. When comparing to the strong baseline of using Brown-clusters based features (Koo et al., 2008), we find that our triplets-based method outperform them by over 0.27 UAS points. This is in contrast to previous works (e.g. (Bansal et al., 2014)) in which improvements over using Brown-clusters features were achieved only by adding to the cluster-based features, not by replacing them. As expected, combining both our features and the brown-cluster features result in some additional gains.

2 Our Approach

Our departure point is a graph-based parsing model (McDonald et al., 2005):

$$parse(x) = \underset{y \in \mathcal{Y}(x)}{\operatorname{argmax}}\, score(x, y)$$

$$score(x, y) = w \cdot \Phi(x, y) = \sum_{part \in y} w \cdot \phi(x, part)$$

Given a sentence x we look for the highest-scoring parse tree y in the space $\mathcal{Y}(x)$ of valid dependency trees over x. The score of a tree is determined by a linear model parameterized by a weights vector w, and a feature function $\Phi(x, y)$. To make the search

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1348–1353,
Lisbon, Portugal, 17-21 September 2015.

Features in $\phi^{ij}_{lex}(x,y)$
$\texttt{bin}(S^{ij}(x,y))$
$\texttt{bin}(S^{ij}(x,y)) \circ \texttt{dist}(x,y)$
$\texttt{bin}(S^{ij}(x,y)) \circ \texttt{pos}(x) \circ \texttt{pos}(y)$
$\texttt{bin}(S^{ij}(x,y)) \circ \texttt{pos}(x) \circ \texttt{pos}(y) \circ \texttt{dist}(x,y)$

Table 1: All features are binary indicators. x and y are token indices. S^{ij} is estimated from auto-parsed corpora as described in the text. The values of $S(\cdot,\cdot)$ are in the range $(0,1)$, which is split by $\texttt{bin}$ into 10 equally-spaced intervals. $\texttt{dist}$ is the signed and binned sentence-distance between x and y. $\texttt{pos}(x)$ is the part of speech of token x. $\circ$ indicates a concatenation of features.

tractable, the feature function is decomposed into local feature functions over tree-parts $\phi(x, part)$. The features in ϕ are standard graph-based dependency parsing features, capturing mostly structural information from the parse tree.

We extend the scoring function by adding an additional term capturing the strength of *lexical* association between head word h and modifier word m in each dependency arc:

$$score(x,y) = \sum_{part \in y} w \cdot \phi(x, part) + \sum_{(h,m) \in y} assoc(h,m)$$

The association function $assoc$ is also modeled as a linear model $assoc(h,m) = w_{lex} \cdot \phi_{lex}(h,m)$. While the weights w_{lex} are trained jointly with w based on supervised training data, the features in ϕ_{lex} do not look at h and m directly, but instead rely on a quantity $S(h,m)$ that reflects the "goodness" of the arc (h,m). The quantity $S(h,m)$ ranges between 0 and 1, and is estimated based on large quantities of auto-parsed data. Given a value for $S(h,m)$, ϕ_{lex} is composed of indicator functions indicating the binned ranges of $S(h,m)$, possibly conjoined with information such as the binned surface distance between the tokens h and m and their parts of speech. The complete specification of ϕ_{lex} we use is shown in Table 1 (the meaning of the ij indices will be discussed in Section 2.2).

2.1 Estimating $S(h,m)$

One way of estimating $S(h,m)$, which was also used in (Chen et al., 2009), is using rank statistics. Let D be the list of observed (h,m) pairs sorted by their frequencies, and let $rank(h,m)$ be the index of the pair (h,m) in D. We now set:

$$S_{\text{RANK}}(h,m) = \frac{rank(h,m)}{|D|}$$

While effective, this approach has two related shortcomings: first, it requires storing counts for all the pairs (h,m) appearing in the auto-parsed data, resulting in memory requirement that scales quadratically with the vocabulary size. Second, even with very large auto-parsed corpora many plausible head-modifier pairs are likely to be unobserved.

An alternative way of estimating $S(h,m)$ that does not require storing all the observed pairs and that has a potential of generalizing beyond the seen examples is using a log-bilinear embedding model similar to the skip-gram model presented by Mikolov et al. (2013b) to embed word pairs such that compatible pairs receive high scores. The model assigns two disjoint sets of d-dimensional continuous latent vectors, u and v, where $u_h \in R^d$ is an embedding of a head word h, and $v_m \in R^d$ is an embedding of a modifier word m. The embedding is done by trying to optimize the following corpus-wide objective that is maximizing the dot product of the vectors of observed (h,m) pairs and minimizing the dot product of vectors of random h and m pairs. Formally:

$$\sum_{h,m \in C} \left[ln\left(\sigma\left(u_h \cdot v_m\right)\right) - \sum_{i=1}^{k} \mathbb{E}_{m_i \sim P_m} ln\left(\sigma\left(u_h \cdot v_{m_i}\right)\right) \right]$$

where $\sigma(x) = 1/(1+e^{-x})$, and k is the number of negative samples, drawn from the corpus-based Unigram distribution P_m. For further details, see (Mikolov et al., 2013b; Goldberg and Levy, 2014). We then take:[1]

$$S_{\text{EMBED}}(h,m) = \sigma(u_h \cdot v_m)$$

In contrast to the counts based method, this model is able to estimate the strength of a pair of words even if the pair did not appear in the corpus due to sparsity.

Finally, Levy and Goldberg (2014b) show that the skip-grams with negative-sampling model described above achieves its optimal solution when $u_h \cdot v_m = PMI(h,m) - \log\ k$. This gives rise to another natural way of estimating S:

[1] The embedding we derive are very similar to the ones described in (Levy and Goldberg, 2014a; Bansal et al., 2014), and which were used by Bansal et al.(2014) for deriving semi-supervised parsing features. An important difference from these previous work is that after training, they keep only one set of vectors (u or v) and ignore the other, basing the features on the derived vector representations. In contrast, we keep both sets of vectors and are interested in the association measure induced by the dot product $u_h \cdot v_m$.

Figure 1: Illustration of the bilexical information including context. When scoring the (incorrect) arc between h^0 and m^0, we take into account also the surrounding words h^{-1}, h^{+1}, m^{-1} and m^{+1}.

$$S_{\text{PMI}}(h,m) = \sigma(PMI(h,m)) = \frac{p(h,m)}{p(h,m)+p(h)p(m)}$$

where $p(h,m)$, $p(h)$ and $p(m)$ are unsmoothed maximum-likelihood estimates based on the auto-parsed corpus.

Like S_{RANK} and unlike S_{EMBED}, S_{PMI} requires storing statistics for all observed word pairs, and is not able of generalizing beyond (h,m) pairs seen in the auto-parsed data. However, as we see in Section 3, this method performing similarly in practice, suggesting that the generalization capabilities of the embedding-based method do not benefit the parsing task.

2.2 Adding additional context

Estimating the association between a pair of words is effective. However, we would like to go a step further and take into account also the context in which these words occur. Specifically, our complete model attempts to estimate the association between word trigrams centered around the head and the modifier words.

A naive solution that defines each trigram as its own vocabulary item will increase the vocabulary size by two orders of magnitude and result in severe data sparsity. An alternative solution would be to associate each word in the triplet (h^{-1}, h^0, h^{+1}) with its own unique vocabulary item, and likewise for modifier words. In the embeddings-based model, this results in 6 vector sets $u^{-1}, u^0, u^{+1}, v^{-1}, v^0, v^{+1}$, where v^{-1}_{dog}, for example, represents the word "dog" when it appears to the left of the modifier word, and u^{+1}_{walk} the word "walk" when it appears to the right of the head word.[2] This amounts to only a 3-fold increase in the required vocabulary size. We then model the strength of association between $h^{-1}h^0h^{+1}$ and $m^{-1}m^0m^{+1}$ as a weighted sum of pairwise interactions:[3]

$$assoc(h^{-1}h^0h^{+1}, m^{-1}m^0m^{+1}) = \sum_{i=-1}^{1}\sum_{j=-1}^{1} \alpha_{ij}\ assoc_{ij}(h^i, m^j)$$

As before, the pairwise association measure $assoc_{ij}(h^i, m^j)$ is modeled as a linear model:

$$assoc_{ij}(h^i, m^j) = w^{ij}_{lex} \cdot \phi^{ij}_{lex}(h^i, m^j)$$

Where ϕ^{ij}_{lex} is again defined in terms of a goodness function $S^{ij}(x,y)$. For example, $S^{-1,+1}(the, over)$ corresponds to the goodness of a head-modifier arc where the word to the left of the head word is "the" and the word to the right of the modifier word is "over". $S^{ij}(h^i, m^j)$, the goodness of the arc induced by the pair (h^i, m^j), can be estimated by either S_{RANK}, S_{EMBED} or S_{PMI} as before. For example, in the embeddings model we set $S^{ij}(x,y) = \sigma(u^i_x \cdot v^j_y)$.

We update the bilexical features to include context as explained above. Instead of learning α and w_{lex} coefficients separately, we absorb the α_{ij} terms into w_{lex}, learning both at the same time:

$$\begin{aligned} &assoc(h^{-1}h^0h^{+1}, m^{-1}m^0m^{+1}) = \\ &\sum_{i\in\{-1,0,1\}}\sum_{j\in\{-1,0,1\}} \alpha_{ij} \cdot assoc_{ij}(h^i, m^j) = \\ &\sum_{i\in\{-1,0,1\}}\sum_{j\in\{-1,0,1\}} \alpha_{ij} \cdot w^{ij}_{lex} \cdot \phi^{ij}_{lex}(h^i, m^j) = \\ &\sum_{i\in\{-1,0,1\}}\sum_{j\in\{-1,0,1\}} w'^{ij}_{lex} \cdot \phi^{ij}_{lex}(h^i, m^j) \end{aligned}$$

Finally, the parser selects a dependency tree which maximizes the following:

$$\begin{aligned} w' \cdot \Phi(x,y) = &\sum_{part\in y} w \cdot \phi(x, part) \\ &+ \sum_{(h,m)\in y}\sum_{i=-1}^{1}\sum_{j=-1}^{1} w^{ij}_{lex} \cdot \phi^{ij}_{lex}(h^i, m^j) \end{aligned}$$

[2] Sentences are padded by special sentence-boundary symbols.

[3] In the word embeddings literature, it is common to represent a word triplet as the sum of the individual component vectors, resulting in $u_{x,y,z} \cdot v_{a,b,c} = (u^{-1}_x + u^0_y + u^{+1}_z) \cdot (v^{-1}_a + v^0_b + v^{+1}_c)$. Expanding the terms will result in a very similar formulation to our proposal, but we allow the extra flexibility of associating a different strength α_{ij} with each pairwise term.

Table 2: Parsing accuracies (UAS, excluding puctuation) of the different models on various corpora. All models are trained on the PTB training set. Dev and Test are sections 22 and 23. Brown is the Brown portion of the PTB. The other columns correspond to the test portions of the Google Web Treebanks. Automatic POS-tags are assigned in all cases. HM indicates using $assoc(h, m)$ and TRIP using $assoc(h^{-1}h^0h^1, m^{-1}m^0m^1)$. + BROWN indicate using features based on Brown clustering.

3 Experiments and Results

Data Our experiments are based on the Penn Treebank (PTB) (Marcus et al., 1993) as well as the Google Web Treebanks (LDC2012T13), covering both in-domain and out-of-domain scenarios. We use the Stanford-dependencies representation (de Marneffe and Manning, 2008). All the constituent-trees are converted to Stanford-dependencies based on the settings of Version 1.0 of the Universal Treebank (McDonald et al., 2013).[4] These are based on the Stanford Dependencies converter but use some non-default flags, and change some of the dependency labels. All of the models are trained on section 2-21 of the WSJ portion of the PTB. For in-domain data, we evaluate on sections 22 (Dev) and 23 (Test). All of the parameter tuning were performed on the Dev set, and we report test-set numbers only for the "most interesting" configurations. For out-of-domain data, we use the Brown portion of the PTB (Brown), as well as the test-sets of different domains available in the Google Web Treebank: Answers, Blogs, Emails, Reviews and Newsgroups.

All trees have automatically assigned part-of-speech tags, assigned by the TurboTagger POS-tagger.[5] The train-set POS-tags were derived in a 10-fold jacknifing, and the different test datasets receive tags from a tagger trained on sections 2-21.

For auto-parsed data, we parse the text of the BLLIP corpus (Charniak, 2000) using our baseline parser. This is the same corpus used for deriving Brown clusters for use as features in (Koo et al., 2008). We use the clusters provided by Terry Koo[6]. Parsing accuracy is measured by unlabeled attachment score (UAS) excluding punctuations.

Implementation Details We focus on first-order parsers, as they are the most practical graph-based parsers in terms of running time in realistic parsing scenarios. Our base model is a re-implementation of a first-order projective Graph-based parser (McDonald et al., 2005), which we extend to support the semi-supervised ϕ_{lex} features. The parser is trained for 10 iterations of online-training with passive-aggressive updates (Crammer et al., 2006). For the Brown-cluster features, we use the feature templates described by (Koo et al., 2008; Bansal et al., 2014).

The embedding vectors are trained using the freely available `word2vecf` software[7], by conjoining each word with its relative position (-1, 0 or 1) and treating the head words as "words" and the modifier words to be "contexts". The words are embedded into 300-dimensional vectors. All code and vectors will be available at the first author's website.

Results The results are shown in Table 2. The second block (HM) compares the baseline parser to a parser including the $assoc(h, m)$ lexical component, using various ways of computing $s(h, m)$. We observe a clear improvement above the baseline from using the lexical component across all domains. The different estimation methods perform very similar to each other.

In the third block (TRIP) we switch to the triplet-based lexical association. With S_{RANK},

[5] `http://www.ark.cs.cmu.edu/TurboParser/`

[6] `http://people.csail.mit.edu/maestro/papers/bllip-clusters.gz`

[7] `http://www.bitbucket.org/yoavgo/word2vecf`

there is very little advantage over looking at just pairs. However, with S_{EMBED} or S_{PMI} the improvement of using the triplet-based method over using just the head-modifier pairs is clear. The counting-based PMI method performs on par with the Embedding based approximation of it.

The second line of the first block (Base+Brown) represents the current state-of-the-art in semi-supervised training of graph-based parsing: using Brown-cluster derived features (Koo et al., 2008; Bansal et al., 2014). The Brown-derived features provide similar (sometimes larger) gains to using our HM method, and substantially smaller gains than our TRIP method. To the best of our knowledge, we are the first to show a semi-supervised method that significantly outperforms the use of Brown-clusters without using Brown-clusters as a component.

As expected, combining our features and the Brown-based features provide an additional improvement, as can be seen in the last block of Table 2 (Base+Brown+TRIP).

4 Related Work

Semi-supervised approaches to dependency parsing can be roughly categorized into two groups: those that use unannotated data and those that use automatically-parsed data. Our proposed method falls in the second group.

Among the words that use unannotated data, the dominant approach is to derive either word clusters (Koo et al., 2008) or word vectors (Chen and Manning, 2014) based on unparsed data, and use these as additional features for a supervised parsing model. While the word representations used in such methods are not specifically designed for the parsing task, they do provide useful features for parsing, and in particular the method of (Koo et al., 2008), relying on features derived using the Brown-clustering algorithm, provides very competitive state-of-the-art results. To the best of our knowledge, we are the first to show a substantial improvement over using Brown-clustering derived features without using Brown-cluster features as a component.

Among the words that use auto-parsed data, a dominant approach is self-training (McClosky et al., 2006), in which a parser A (possibly an ensemble) is used to parse large amounts of data, and a parser B is then trained over the union of the gold data and the auto-parsed data produced by parser A. In the context of dependency-parsing, successful uses of self-training require parser A to be stronger than parser B (Petrov et al., 2010) or use a selection criteria for training only on high-quality parses produced by parser A (Sagae and Tsujii, 2007; Weiss et al., 2015). In contrast, our work uses the same parser (modulo the feature-set) for producing the auto-parsed data and for training the final model, and does not employ a high-quality parse selection criteria when creating the auto-parsed corpus. It is possible that high-quality parse selection can improve our proposed method even further.

Works that derive features from auto-parsed data include (Sagae and Gordon, 2009; Bansal et al., 2014). Such works assign a representation (either cluster or vector) for individual word in the vocabulary based on their syntactic behavior. In contrast, our learned features are designed to capture *interactions* between words. As discussed in sections (1) and (2), most similar to ours is the work of (Chen et al., 2009; Van Noord, 2007). We extend their approach to take into account not only direct word-word interactions but also the lexical surroundings in which these interactions occur.

Another recent approach that takes into account various syntactic interactions was recently introduced by Chen et al. (2014), who propose to learn to embed complex features that are being used in a graph-based parser based on other features they co-occur with in auto-parsed data. Similar to our approach, the embedded features are then used as additional features in a conventional graph-based model. The approaches are to a large extent complementary, and could be combined.

Finally, our work adds additional features to a graph-based parser which is based on a linear-model. Recently, progress in dependency parsing has been made by introducing non-linear, neural-network based models (Pei et al., 2015; Chen and Manning, 2014; Weiss et al., 2015; Dyer et al., 2015; Zhou et al., 2015). Adapting our approach to work with such models is an interesting research direction.

5 Conclusions

We presented a semi-supervised method for dependency parsing and demonstrated its effectiveness on a first-order graph-based parser. Taking into account not only the (head,modifier) word-pair but also their immediate surrounding words add a clear benefit to parsing accuracy.

Abstract

We extend and improve upon recent work in structured training for neural network transition-based dependency parsing. We do this by experimenting with novel features, additional transition systems and by testing on a wider array of languages. In particular, we introduce set-valued features to encode the predicted morphological properties and part-of-speech confusion sets of the words being parsed. We also investigate the use of joint parsing and part-of-speech tagging in the neural paradigm. Finally, we conduct a multi-lingual evaluation that demonstrates the robustness of the overall structured neural approach, as well as the benefits of the extensions proposed in this work. Our research further demonstrates the breadth of the applicability of neural network methods to dependency parsing, as well as the ease with which new features can be added to neural parsing models.

1 Introduction

Transition-based parsers (Nivre, 2008) are extremely popular because of their high accuracy and speed. Inspired by the greedy neural network transition-based parser of Chen and Manning (2014), Weiss et al. (2015) and Zhou et al. (2015) concurrently developed structured neural network parsers that use beam search and achieve state-of-the-art accuracies for English dependency parsing.[1] While very successful, these parsers have made use only of a small fraction of the rich options provided inside the transition-based framework: for example, all of these parsers use virtually identical atomic features and the *arc-standard* transition system.

In this paper we extend this line of work and introduce two new types of features that significantly improve parsing performance: (1) a set-valued (i.e., bag-of-words style) feature for each word's morphological attributes, and (2) a weighted set-valued feature for each word's k-best POS tags. These features can be integrated naturally as atomic inputs to the embedding layer of the network and the model can learn arbitrary conjunctions with all other features through the hidden layers. In contrast, integrating such features into a model with discrete features requires non-trivial manual tweaking. For example, Bohnet and Nivre (2012) had to carefully discretize the real-valued POS tag score in order to combine it with the other discrete binary features in their system. Additionally, we also experiment with different transition systems, most notably the *integrated* parsing and part-of-speech (POS) tagging system of Bohnet and Nivre (2012) and also the *swap* system of Nivre (2009).

We evaluate our parser on the CoNLL '09 shared task dependency treebanks, as well as on two English setups, achieving the best published numbers in many cases.

2 Model

In this section, we review the baseline model, and then introduce the features (which are novel) and the transition systems (taken from existing work) that we propose as extensions. We measure the impact of each proposed change on the development sets of the multi-lingual CoNLL '09 shared task treebanks (Hajič et al., 2009). For details on our experimental setup, see Section 3.

2.1 Baseline Model

Our baseline model is the structured neural network transition-based parser with beam search of Weiss et al. (2015). We use a feed-forward network with embedding, hidden and softmax layers. The input consists of a sequence of matrices

[1] There is of course a much longer tradition of neural network dependency parsing models, going back at least to Titov and Henderson (2007).

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1354–1359,
Lisbon, Portugal, 17-21 September 2015.

Table 1: Ablation study on CoNLL'09 dev set. All scores in this table are LAS with beam 32. The first three rows use a pipeline of tagging and then parsing, while the last two rows use integrated parsing and tagging. Chinese and English have no morphology features provided in the dataset, so we omit morphology for those languages.

extracted deterministically from a transition-based parse configuration (consisting of a stack and a buffer). Each matrix $\mathbf{X}^g$, corresponds to a feature *group* g (one of *words*, *tags*, or *labels*), and has dimension $F^g \times V^g$. Here, X^g_{fv} is 1 if the f'th feature takes on value v for group g, i.e. each row $\mathbf{X}^g$ is a one-hot vector. These features are embedded and then concatenated to form the embedding layer, which in turn is input to the first hidden layer. The concatenated embedding layer can then be written as follows:

$$\mathbf{h}_0 = [\mathbf{X}^g\mathbf{E}^g \mid g \in \{\text{word}, \text{tag}, \text{label}\}] \quad (1)$$

where $\mathbf{E}^g$ is a (learned) $V^g \times D^g$ embedding matrix for group g, and D^g is the embedding dimension for group g. Beyond the embedding layer, there are two non-linear hidden layers (with non-linearity introduced using a rectified linear activation function), and a softmax layer that outputs class probabilities for each possible decision.

Training proceeds in two stages: We first train the network as a classifier by extracting decisions from gold derivations of the training set, as in Chen and Manning (2014). We then train a structured perceptron using the output of all network activations as features, as in Weiss et al. (2015). We use structured training and beam search during inference in all experiments. We train our models only on the treebank training set and do not use tri-training or other semi-supervised learning approaches (aside from using pre-trained word embeddings).

2.2 New Features

Prior work using neural networks for dependency parsing has not ventured beyond the use of one-hot feature activations for each feature type-location pair. In this work, we experiment with set-valued features, in which a set (or *bag*) of features for a given location fire at once, and are embedded into the same embedding space. Note that for both of the features we introduce, we extract features from the same 20 tokens as used in the *tags* and *words* features from Weiss et al. (2015), i.e. various locations on the stack and input buffer.

BN'12 ($k = 3$)	-	93.06	99.32	97.77	97.63	-	-

Table 2: POS tagging results on the CoNLL '09 test set for integrated POS tagging and parsing. We compare the accuracy of our baseline CRF tagger, 'Linear' (our re-implementation of Bohnet and Nivre (2012, BN'12)), 'Neural' (the neural parser presented in this work), and results reported by BN'12.

Morphology. It is well known that morphological information is very important for parsing morphologically rich languages (see for example Bohnet et al. (2013)). We incorporate morphological information into our model using a set-valued feature function. We define the feature group *morph* as the matrix $\mathbf{X}^{morph}$ such that, for $1 \le f \le F^{morph}$, $1 \le v \le F^{morph}$,

$$\mathbf{X}^{morph}_{f,v} = \begin{cases} 1/N_f, & \text{token } f \text{ has attribute } v \\ 0, & \text{otherwise} \end{cases}, \quad (2)$$

where N_f is the number of morphological features active on the token indexed by f. In other words, we embed a bag of features into a shared embedding space by *averaging* the individual feature embeddings.

***k*-best Tags.** The non-linear network models of Weiss et al. (2015) and Chen and Manning (2014) embed the 1-best tag, according to a first-stage tagger, for a select set of tokens for any configuration. Inspired by the work of Bohnet and Nivre (2012), we embed the *set* of top tags according to a first-stage tagger. Specifically, we define the feature group *ktags* as the matrix $\mathbf{X}^{ktags}$ such that, for $1 \le f \le F^{ktags}$, $1 \le v \le V^{ktags}$,

$$\mathbf{X}^{ktags}_{f,v} = \begin{cases} P(POS = v \mid f), & v \in \text{top } k \text{ tags for } f \\ 0, & \text{otherwise} \end{cases}, \quad (3)$$

where $P(POS = v \mid f)$ is the marginal probability that the token indexed by f has the tag indexed by v, according to the first-stage tagger.

Table 3: Final CoNLL '09 test set results. The results not from this work were solicited from the respective authors.

Results. The contributions of our new features for pipelined arc-standard parsing are shown in Table 1. Morphology features (+*morph*) contributed a labeled accuracy score (LAS) gain of 2.9% in Czech, 1.5% in Spanish, and 0.9% in Catalan. Adding the k-best tag feature (+*morph* +*ktags*) provides modest gains (and modest losses), peaking at 0.54% LAS for Spanish. This feature proves more beneficial in the integrated transition system, discussed in the next section. We note the ease with which we can obtain these gains in a multilayer embedding framework, without the need for any hand-tuning.

2.3 Integrating Parsing and Tagging

While past work on neural network transition-based parsing has focused exclusively on the *arc-standard* transition system, it is known that better results can often be obtained with more sophisticated transition systems that have a larger set of possible actions. The *integrated arc-standard* transition system of Bohnet and Nivre (2012) allows the parser to participate in tagging decisions, rather than being forced to treat the tagger's tags as given, as in the arc-standard system. It does this by replacing the *shift* action in the arc-standard system with an action $shift_p$, which, aside from shifting the top token on the buffer also assigns it one of the k best POS tags from a first-stage tagger. We also experiment with the *swap* action of Nivre (2009), which allows reordering of the tokens in the input sequence. This transition system is able to produce non-projective parse trees, which is important for some languages.

Results. The effect of using the integrated transition system is quantified in the bottom part of Table 1. The use of both 1) +*morph* +*kbest* features and 2) integrated parsing and tagging achieves the best score for 5 out of 7 languages tested. The use of integrated parsing and tagging provides, for example, a 0.8% LAS gain in German.

3 Experiments

In this section we provide final test set results for our baseline and full models on three standard setups from the literature: *CoNLL '09*, *English WSJ* and *English Treebank Union*.

3.1 General Setup

To train with predicted POS tags, we use a CRF-based POS tagger to generate 5-fold jack-knifed POS tags on the training set and predicted tags on the dev, test and tune sets; our tagger gets comparable accuracy to the Stanford POS tagger (Toutanova et al., 2003) with 97.44% on the WSJ test set. The candidate tags allowed by the integrated transition system on every $shift_p$ action are chosen by taking the top 4 tags for a token according to the CRF tagger, sorted by posterior probability, with no minimum posterior probability for a tag to be selected. We report unlabeled attachment score (UAS) and labeled attachment score (LAS). Whether punctuation is included in the evaluation is specified in each subsection.

We use 1024 units in all hidden layers, a choice made based on the development set. We found network sizes to be of critical importance for the accuracy of our models. For example, LAS improvements can be as high as 0.98% in *CoNLL'09* German when increasing the size of the two hidden layers from 200 to 1024. We use $B = 16$ or $B = 32$ based on the development set performance per language. For ease of experimentation, we deviate from Bohnet and Nivre (2012) and use a single unstructured beam, rather than separate beams for POS tag and parse differences.

We train our neural networks on the standard training sets only, except for initializing with word

embeddings generated by word2vec and using cluster features in our POS tagger. Unlike Weiss et al. (2015) we train our model only on the treebank training set and do not use tri-training, which can likely further improve the results.

3.2 CoNLL '09

Our multilingual evaluation follows the setup of the CoNLL '09 shared task[2] (Hajič et al., 2009). As standard, we use the supplied predicted morphological features from the shared task data; however, we predict k-best tags with our own POS tagger since k-best tags are not part of the given data. We follow standard practice and include all punctuation in the evaluation. We used the (integrated) arc-standard transition system for all languages except for Czech where we added a swap transition, obtaining a 0.4% absolute improvement in UAS and LAS over just using arc-standard.

Results. In Table 3, we compare our models to the winners of the CoNLL '09 shared task, Gesmundo et al. (2009), Bohnet (2009), Che et al. (2009), Ren et al. (2009), as well as to more recent results on the same datasets. It is worth pointing out that Gesmundo et al. (2009) is itself a neural net parser. Our models achieve higher labeled accuracy than the winning systems in the shared task in all languages. Additionally, our pipelined neural network parser always outperforms its linear counterpart, an in-house reimplementation of the system of Zhang and Nivre (2011), as well as the more recent and highly accurate parsers of Zhang and McDonald (2014) and Lei et al. (2014). For the integrated models our neural network parser again outperforms its linear counterpart (Bohnet and Nivre, 2012), however, in some cases the addition of graph-based and cluster features (Bohnet and Nivre, 2012)+G+C can lead to even better results. The improvements in POS tagging (Table 2) range from 0.3% for English to 1.4% absolute for Chinese and are always higher for the neural network models compared to the linear models.

Table 5: Final English Treebank Union test set results.

3.3 English WSJ

We experiment on English using the Wall Street Journal (WSJ) part of the Penn Treebank (Marcus et al., 1993), with standard train/test splits. We convert the constituency trees to Stanford style dependencies (De Marneffe et al., 2006) using version 3.3.0 of the converter. We use predicted POS tags and exclude punctuation from the evaluation, as is standard for English.

Results. The results shown in Table 4, we find that our full model surpasses, to our knowledge, all previously reported supervised parsing models for the Stanford dependency conversions. It surpasses its linear analog, the work of Bohnet and Nivre (2012) on Stanford Dependencies UAS by 0.9% UAS and by 1.14% LAS. It also outperforms the pipeline neural net model of Weiss et al. (2015) by a considerable margin and matches the semi-supervised variant of Weiss et al. (2015).

3.4 English Treebank Union

Turning to cross-domain results, and the "Treebank Union" datasets, we use an identical setup to the one described in Weiss et al. (2015). This setup includes the WSJ with Stanford Dependencies, the OntoNotes corpus version 5 (Hovy et al., 2006), the English Web Treebank (Petrov and McDonald, 2012), and the updated and corrected Question Treebank (Judge et al., 2006). We train on the union of each corpora's training set and test on each domain separately.

Results. The results of this evaluation are shown in Table 5. As for the WSJ we find that the integrated transition system combined with our novel

features performs better than previous work and in particular the model of Weiss et al. (2015), which serves as the starting point for this work. The improvements on the out-of-domain Web and Question corpora are particularly promising.

4 Conclusions

Weiss et al. (2015) presented a parser that advanced the state of the art for English Stanford dependency parsing. In this paper we showed that this parser can be significantly improved by introducing novel set features for morphology and POS tag ambiguities, which are added with almost no feature engineering effort. The resulting parser is already competitive in the multi-lingual setting of the CoNLL'09 shared task, but can be further improved by utilizing an integrated POS tagging and parsing transition system. We find that for all settings the dense neural network model produces higher POS tagging and parsing accuracy gains than its sparse linear counterpart.

Acknowledgements. We thank Bernd Bohnet for running his parser on additional data sets, and Emily Pitler for helpful comments.

Abstract

Model combination techniques have consistently shown state-of-the-art performance across multiple tasks, including syntactic parsing. However, they dramatically increase runtime and can be difficult to employ in practice. We demonstrate that applying constituency model combination techniques to n-best lists instead of n different parsers results in significant parsing accuracy improvements. Parses are weighted by their probabilities and combined using an adapted version of Sagae and Lavie (2006). These accuracy gains come with marginal computational costs and are obtained on top of existing parsing techniques such as discriminative reranking and self-training, resulting in state-of-the-art accuracy: 92.6% on WSJ section 23. On out-of-domain corpora, accuracy is improved by 0.4% on average. We empirically confirm that six well-known n-best parsers benefit from the proposed methods across six domains.

1 Introduction

Researchers have proposed many algorithms to combine parses from multiple parsers into one final parse (Henderson and Brill, 1999; Zeman and Žabokrtskỳ, 2005; Sagae and Lavie, 2006; Nowson and Dale, 2007; Fossum and Knight, 2009; Petrov, 2010; Johnson and Ural, 2010; Huang et al., 2010; McDonald and Nivre, 2011; Shindo et al., 2012; Narayan and Cohen, 2015). These new parses are substantially better than the originals: Zhang et al. (2009) combine outputs from multiple n-best parsers and achieve an F_1 of 92.6% on the WSJ test set, a 0.5% improvement over their best n-best parser. Model combination approaches tend to fall into the following categories: *hybridization*, where multiple parses are combined into a single parse; *switching*, which picks a single parse according to some criteria (usually a form of voting); *grammar merging* where grammars are combined before or during parsing; and *stacking*, where one parser sends its prediction to another at runtime. All of these have at least one of the caveats that (1) overall computation is increased and runtime is determined by the slowest parser and (2) using multiple parsers increases the system complexity, making it more difficult to deploy in practice. In this paper, we describe a simple hybridization extension ("fusion") which obtains much of hybridization's benefits while using only a single n-best parser and minimal extra computation. Our method treats each parse in a single parser's n-best list as a parse from n separate parsers. We then adapt parse combination methods by Henderson and Brill (1999), Sagae and Lavie (2006), and Fossum and Knight (2009) to fuse the constituents from the n parses into a single tree. We empirically show that six n-best parsers benefit from parse fusion across six domains, obtaining state-of-the-art results. These improvements are complementary to other techniques such as reranking and self-training. Our best system obtains an F_1 of 92.6% on WSJ section 23, a score previously obtained only by combining the outputs from multiple parsers. A reference implementation is available as part of BLLIP Parser at `http://github.com/BLLIP/bllip-parser/`

2 Fusion

Henderson and Brill (1999) propose a method to combine trees from m parsers in three steps: populate a chart with constituents along with the number of times they appear in the trees; remove any constituent with count less than $m/2$ from the chart; and finally create a final tree with all the remaining constituents. Intuitively their method

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1360–1366,
Lisbon, Portugal, 17-21 September 2015.

constructs a tree with constituents from the majority of the trees, which boosts precision significantly. Henderson and Brill (1999) show that this process is guaranteed to produce a valid tree. Sagae and Lavie (2006) generalize this work by reparsing the chart populated with constituents whose counts are above a certain threshold. By adjusting the threshold on development data, their generalized method balances precision and recall. Fossum and Knight (2009) further extend this line of work by using n-best lists from multiple parsers and combining productions in addition to constituents. Their model assigns sums of joint probabilities of constituents and parsers to constituents. Surprisingly, exploiting n-best trees does not lead to large improvement over combining 1-best trees in their experiments.

Our extension takes the n-best trees from a parser as if they are 1-best parses from n parsers, then follows Sagae and Lavie (2006). Parses are weighted by the estimated probabilities from the parser. Given n trees and their weights, the model computes a constituent's weight by summing weights of all trees containing that constituent. Concretely, the weight of a constituent spanning from ith word to jth word with label ℓ is

$$c_\ell(i \to j) = \sum_{k=1}^{n} W(k) C_\ell^k(i \to j) \qquad (1)$$

where $W(k)$ is the weight of kth tree and $C_\ell^k(i \to j)$ is one if a constituent with label ℓ spanning from i to j is in kth tree, zero otherwise. After populating the chart with constituents and their weights, it throws out constituents with weights below a set threshold t. Using the threshold $t = 0.5$ emulates the method of Henderson and Brill (1999) in that it constructs the tree with the constituents in the majority of the trees. The CYK parsing algorithm is applied to the chart to produce the final tree.

Note that populating the chart is linear in the number of words and the chart contains substantially fewer constituents than charts in well-known parsers, making this a fast procedure.

2.1 Score distribution over trees

We assume that n-best parsers provide trees along with some kind of scores (often probabilities or log probabilities). Given these scores, a natural way to obtain weights is to normalize the probabilities. However, parsers do not always provide accurate estimates of parse quality. We may obtain better performance from parse fusion by altering this distribution and passing scores through a nonlinear function, $f(\cdot)$. The kth parse is weighted:

$$W(k) = \frac{f(\text{SCORE}(k))}{\sum_{i=1}^{n} f(\text{SCORE}(i))} \qquad (2)$$

where $\text{SCORE}(i)$ is the score of ith tree.[1] We explore the family of functions $f(x) = x^\beta$ which can smooth or sharpen the score distributions. This includes a tunable parameter, $\beta \in \mathbb{R}_0^+$:

$$W(k) = \frac{\text{SCORE}(k)^\beta}{\sum_{i=1}^{n} \text{SCORE}(i)^\beta} \qquad (3)$$

Employing $\beta < 1$ flattens the score distribution over n-best trees and helps over-confident parsers. On the other hand, having $\beta > 1$ skews the distribution toward parses with higher scores and helps under-confident parsers. Note that setting $\beta = 0$ weights all parses equally and results in majority voting at the constituent level. We leave developing other nonlinear functions for fusion as future work.

3 Experiments

Corpora: Parse fusion is evaluated on British National Corpus (BNC), Brown, GENIA, Question Bank (QB), Switchboard (SB) and Wall Street Journal (WSJ) (Foster and van Genabith, 2008; Francis and Kučera, 1989; Kim et al., 2003; Judge et al., 2006; Godfrey et al., 1992; Marcus et al., 1993). WSJ is used to evaluate in-domain parsing, the remaining five are used for out-of-domain. For divisions, we use tune and test splits from Bacchiani et al. (2006) for Brown, McClosky's test PMIDs[2] for GENIA, Stanford's test splits[3] for QuestionBank, and articles 4000–4153 for Switchboard.

Parsers: The methods are applied to six widely used n-best parsers: Charniak (2000), Stanford (Klein and Manning, 2003), BLLIP (Charniak and Johnson, 2005), Self-trained BLLIP (McClosky et al., 2006)[4], Berkeley (Petrov et al., 2006), and Stanford RNN (Socher et al., 2013). The list of parsers and their accuracies on the WSJ test set is reported in Table 1. We convert to Stanford

[1] For parsers that return log probabilities, we turn these into probabilities first.

[4] Using the '`WSJ+Gigaword-v2`' BLLIP model.

Parser	F_1	UAS	LAS
Stanford	85.4	90.0	87.3
Stanford RNN[5]	89.6	92.9	90.4
Berkeley	90.0	93.5	91.2
Charniak	89.7	93.2	90.8
BLLIP	91.5	94.4	92.0
Self-trained BLLIP	92.2	94.7	92.2

Table 1: Six parsers along with their 1-best F_1 scores, unlabeled attachment scores (UAS) and labeled attachment scores (LAS) on WSJ section 23.

Dependencies (basic dependencies, version 3.3.0) and provide dependency metrics (UAS, LAS) as well.

Supervised parsers are trained on the WSJ training set (sections 2–21) and use section 22 or 24 for development. Self-trained BLLIP is self-trained using two million sentences from Gigaword and Stanford RNN uses word embeddings trained from larger corpora.

Parameter tuning: There are three parameters for our fusion process: the size of the n-best list ($2 < n \leq 50$), the smoothing exponent from Section 2.1 ($\beta \in [0.5, 1.5]$ with 0.1 increments), and the minimum threshold for constituents ($t \in [0.2, 0.7]$ with 0.01 increments). We use grid search to tune these parameters for two separate scenarios. When parsing WSJ (in-domain), we tune parameters on WSJ section 24. For the remaining corpora (out-of-domain), we use the tuning section from Brown. Each parser is tuned separately, resulting in 12 different tuning scenarios. In practice, though, in-domain and out-of-domain tuning regimes tend to pick similar settings within a parser. Across parsers, settings are also fairly similar (n is usually 30 or 40, t is usually between 0.45 and 0.5). While the smoothing exponent varies from 0.5 to 1.3, setting $\beta = 1$ does not significantly hurt accuracy for most parsers.

To study the effects of these parameters, Figure 1 shows three slices of the tuning surface for BLLIP parser on WSJ section 24 around the optimal settings ($n = 30, \beta = 1.1, t = 0.47$). In each graph, one of the parameters is varied while the other is held constant. Increasing n-best size improves accuracy until about $n = 30$ where there seems to be sufficient diversity. For BLLIP, the smoothing exponent (β) is best set around 1.0, with accuracy falling off if the value deviates too much. Finally, the threshold parameter is empirically optimized a little below $t = 0.5$ (the value suggested by Henderson and Brill (1999)). Since score values are normalized, this means that constituents need roughly half the "score mass" in order to be included in the chart. Varying the threshold changes the precision/recall balance since a high threshold adds only the most confident constituents to the chart (Sagae and Lavie, 2006).

[5]Socher et al. (2013) report an F_1 of 90.4%, but this is the result of using an ensemble of two RNNs (p.c.). We use a single RNN in this work.

Parser	WSJ	Brown
BLLIP	90.6	85.7
+ Fusion	91.0	86.0
+ Majority voting ($\beta = 0$)	89.1	83.8
+ Rank-based weighting	89.3	84.1

Table 2: F_1 of a baseline parser, fusion, and baselines on development sections of corpora (WSJ section 24 and Brown tune).

Baselines: Table 2 gives the accuracy of fusion and baselines for BLLIP on the development corpora. Majority voting sets $n = 50, \beta = 0, t = 0.5$ giving all parses equal weight and results in constituent-level majority voting. We explore a rank-based weighting which ignores parse probabilities and weight parses only using the rank: $W_{\text{rank}}(k) = 1/(2^k)$. These show that accurate parse-level scores are critical for good performance.

Final evaluation: Table 3 gives our final results for all parsers across all domains. Results in blue are significant at $p < 0.01$ using a randomized permutation test. Fusion generally improves F_1 for in-domain and out-of-domain parsing by a significant margin. For the self-trained BLLIP parser, in-domain F_1 increases by 0.4% and out-of-domain F_1 increases by 0.4% on average. Berkeley parser obtains the smallest gains from fusion since Berkeley's n-best lists are ordered by factors other than probabilities. As a result, the probabilities from Berkeley can mislead the fusion process.

We also compare against model combination using our reimplementation of Sagae and Lavie (2006). For these results, all six parsers were given equal weight. The threshold was set to 0.42 to optimize model combination F_1 on development data (similar to Setting 2 for constituency parsing in Sagae and Lavie (2006)). Model combination

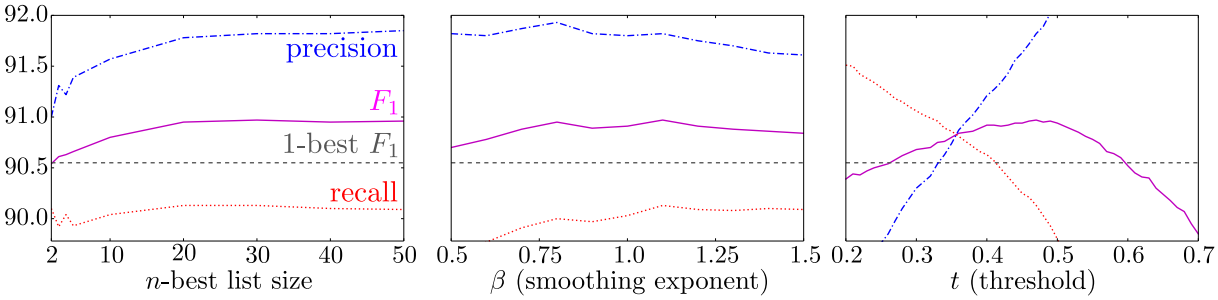

Figure 1: Tuning parameters independently for BLLIP and their impact on F_1 for WSJ section 24 (solid purple line). For each graph, non-tuned parameters were set at the optimal configuration for BLLIP ($n = 30$, $\beta = 1.1$, $t = 0.47$). The dashed grey line represents the 1-best baseline at 90.6% F_1.

Parser	BNC	Brown	GENIA	SB	QB	WSJ
Stanford	78.4 / 79.6	80.7 / 81.6	73.1 / 73.9	67.0 / 67.9	78.6 / 80.0	85.4 / 86.2
Stanford RNN	82.0 / 82.3	84.0 / 84.3	76.0 / 76.2	70.7 / 71.2	82.9 / 83.6	89.6 / 89.7
Berkeley	82.3 / 82.9	84.6 / 84.6	76.4 / 76.6	74.5 / 75.1	86.5 / 85.9	90.0 / 90.3
Charniak	82.5 / 83.0	83.9 / 84.6	74.8 / 75.7	76.8 / 77.6	85.6 / 86.3	89.7 / 90.1
BLLIP	84.1 / 84.7	85.8 / 86.0	76.7 / 77.1	79.2 / 79.5	88.1 / 88.9	91.5 / 91.7
Self-trained BLLIP	85.2 / 85.8	87.4 / 87.7	77.8 / 78.2	80.9 / 81.7	89.5 / 89.5	92.2 / 92.6
Model combination	86.6	87.7	79.4	80.9	89.3	92.5

Table 3: Evaluation of the constituency fusion method on six parsers across six domains. x/y indicates the F_1 from the baseline parser (x) and the baseline parser with fusion (y) respectively. Blue indicates a statistically significant difference between fusion and its baseline parser ($p < 0.01$).

performs better than fusion on BNC and GENIA, but surprisingly fusion outperforms model combination on three of the six domains (not usually not by a significant margin). With further tuning (e.g., specific weights for each constituent-parser pair), the benefits from model combination should increase.

Multilingual evaluation: We evaluate fusion with the Berkeley parser on Arabic (Maamouri et al., 2004; Green and Manning, 2010), French (Abeillé et al., 2003), and German (Brants et al., 2002) from the SPMRL 2014 shared task (Seddah et al., 2014) but did not observe any improvement. We suspect this has to do with the same ranking issues seen in the Berkeley Parser's English results. On the other hand, fusion helps the parser of Narayan and Cohen (2015) on the German NEGRA treebank (Skut et al., 1997) to improve from 80.9% to 82.4%.

Runtime: As discussed in Section 2, fusion's runtime overhead is minimal. Reranking parsers (e.g., BLLIP and Stanford RNN) already need to perform n-best decoding as input for the reranker. Using a somewhat optimized implementation fusion in C++, the overhead over BLLIP parser is less than 1%.

Discussion: Why does fusion help? It is possible that a parser's n-list and its scores act as a weak approximation to the full parse forest. As a result, fusion seems to provide part of the benefits seen in forest reranking (Huang, 2008).

Results from Fossum and Knight (2009) imply that fusion and model combination might not be complementary. Both n-best lists and additional parsers provide syntactic diversity. While additional parsers provide greater diversity, n-best lists from common parsers are varied enough to provide improvements for parse hybridization.

We analyzed how often fusion produces completely novel trees. For BLLIP on WSJ section 24, this only happens about 11% of the time. Fusion picks the 1-best tree 72% of the time. This means that for the remaining 17%, fusion picks an existing parse from the rest of the n-list, acting similar to a reranker. When fusion creates unique trees, they are significantly better than the original 1-best trees (for the 11% subset of WSJ 24, F_1 scores are 85.5% with fusion and 84.1% without, $p < 0.003$). This contrasts with McClosky et al. (2012) where novel predic-

tions from model combination (stacking) were worse than baseline performance. The difference is that novel predictions with fusion better incorporate model confidence whereas when stacking, a novel prediction is less trusted than those produced by one or both of the base parsers.

Preliminary extensions: Here, we summarize two extensions to fusion which have yet to show benefits. The first extension explores applying fusion to dependency parsing. We explored two ways to apply fusion when starting from constituency parses: (1) fuse constituents and then convert them to dependencies and (2) convert to dependencies then fuse the dependencies as in Sagae and Lavie (2006). Approach (1) does not provide any benefit (LAS drops between 0.5% and 2.4%). This may result from fusion's artifacts including unusual unary chains or nodes with a large number of children — it is possible that adjusting unary handling and the precision/recall tradeoff may reduce these issues. Approach (2) provided only modest benefits compared to those from constituency parsing fusion. The largest LAS increase for (2) is 0.6% for the Stanford Parser, though for Berkeley and Self-trained BLLIP, dependency fusion results in small losses (-0.1% LAS). Two possible reasons are that the dependency baseline is higher than its constituency counterpart and some dependency graphs from the n-best list are duplicates which lowers diversity and may need special handling, but this remains an open question.

While fusion helps on top of a self-trained parser, we also explored whether a fused parser can self-train (McClosky et al., 2006). To test this, we (1) parsed two million sentences with BLLIP (trained on WSJ), (2) fused those parses, (3) added the fused parses to the gold training set, and (4) retrained the parser on the expanded training. The resulting model did not perform better than a self-trained parsing model that didn't use fusion.

4 Conclusions

We presented a simple extension to parse hybridization which adapts model combination techniques to operate over a single parser's n-best list instead of across multiple parsers. By weighting each parse by its probability from the n-best parser, we are able to better capture the confidence at the constituent level. Our best configuration obtains state-of-the-art accuracy on WSJ with an F_1 of 92.6%. This is similar to the accuracy obtained from actual model combination techniques but at a fraction of the computational cost. Additionally, improvements are not limited to a single parser or domain. Fusion improves parser accuracy for six n-best parsers both in-domain and out-of-domain.

Future work includes applying fusion to n-best dependency parsers and additional (parser, language) pairs. We also intend to explore how to better apply fusion to converted dependencies from constituency parsers. Lastly, it would be interesting to adapt fusion to other structured prediction tasks where n-best lists are available.

Acknowledgements

We are grateful to Shay Cohen and Shashi Narayan who gave us early access to their parser's German results. We would also like to thank Mohit Bansal, Yoav Goldberg, Siddharth Patwardhan, and Kapil Thadani for helpful discussions and our anonymous reviewers for their insightful comments and suggestions.

Abstract

We introduce an extension to the bag-of-words model for learning words representations that take into account both syntactic and semantic properties within language. This is done by employing an attention model that finds within the contextual words, the words that are relevant for each prediction. The general intuition of our model is that some words are only relevant for predicting local context (e.g. function words), while other words are more suited for determining global context, such as the topic of the document. Experiments performed on both semantically and syntactically oriented tasks show gains using our model over the existing bag of words model. Furthermore, compared to other more sophisticated models, our model scales better as we increase the size of the context of the model.

1 Introduction

Learning word representations using raw text data have been shown to improve many NLP tasks, such as part-of-speech tagging (Collobert et al., 2011), dependency parsing (Chen and Manning, 2014; Kong et al., 2014) and machine translation (Liu et al., 2014; Kalchbrenner and Blunsom, 2013; Devlin et al., 2014; Sutskever et al., 2014). These embeddings are generally learnt by defining an objective function, which predicts words conditioned on the context surrounding those words. Once trained, these can be used as features (Turian et al., 2010), as initializations of other neural networks (Hinton and Salakhutdinov, 2012; Erhan et al., 2010; Guo et al., 2014).

The continuous bag-of-words (Mikolov et al., 2013) is one of the many models that learns word representations from raw textual data. While these models are adequate for learning semantic features, one of the problems of this model is the lack of sensitivity for word order, which limits their ability of learn syntactically motivated embeddings (Ling et al., 2015a; Bansal et al., 2014). While models have been proposed to address this problem, the complexity of these models ("Structured skip-n-gram" and "CWindow") grows linearly as size of the window of words considered increases, as a new set of parameters is created for each relative position. On the other hand, the continuous bag-of-words model requires no additional parameters as it builds the context representation by summing over the embeddings in the window and its performance is an order of magnitude higher than of other models.

In this work, we propose an extension to the continuous bag-of-words model, which adds an attention model that considers contextual words differently depending on the word type and its relative position to the predicted word (distance to the left/right). The main intuition behind our model is that the prediction of a word is only dependent on certain words within the context. For instance, in the sentence *We won the game! Nicely played!*, the prediction of the word *played*, depends on both the syntactic relation from *nicely*, which narrows down the list of candidates to verbs, and on the semantic relation from *game*, which further narrows down the list of candidates to verbs related to games. On the other hand, the words *we* and *the* add very little to this particular prediction. On the other hand, the word *the* is important for predicting the word *game*, since it is generally followed by nouns. Thus, we observe that the same

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1367–1372,
Lisbon, Portugal, 17-21 September 2015.

word can be informative in some contexts and not in others. In this case, distance is a key factor, as the word the is informative to predict the immediate neighboring words, but not distance ones.

2 Attention-Based Continuous Bag-of-words

2.1 Continuous Bag-Of-Words (CBOW)

The work in (Mikolov et al., 2013) is frequently used to learn word embeddings. It defines projection matrix $\mathbf{W} \in \Re^{d \times |V|}$ where d is the embedding dimension with the vocabulary V. These parameters are optimized by by maximizing the likelihood that words are predicted from their context. Two models were defined, the skip-gram model and the continuous bag-of-words model. In this work, we focus on the continuous bag-of-words model. The CBOW model predicts the center word w_0 given a representation of the surrounding words $\mathbf{w}_{-b}, \ldots, \mathbf{w}_{-1}, \mathbf{w}_1, \mathbf{w}_b$, where b is a hyperparameter defining the window of context words. The context vector is obtained by averaging the embeddings of each word $\mathbf{c} = \frac{1}{2b} \sum_{i \in [-b,b]-\{0\}} \mathbf{w}_i$ and the prediction of the center word $\mathbf{w}_0$ is obtained by performing a softmax over all the vocabulary V. More formally, define the output matrix $\mathbf{O} \in \Re^{|V| \times d_w}$, which maps the context vector $\mathbf{c}$ into a $|V|$-dimensional vector representing the predicted word, and maximizes the following probability:

$$p(\mathbf{v}_0 \mid \mathbf{w}_{[-b,b]-\{0\}}) = \frac{\exp \mathbf{v}_0^\top \mathbf{O}\mathbf{c}}{\sum_{\mathbf{v} \in V} \exp \mathbf{v}^\top \mathbf{O}\mathbf{c}} \quad (1)$$

where $\mathbf{O}\mathbf{c}$ corresponds to the projection of the context vector $\mathbf{c}$ onto the vocabulary V and $\mathbf{v}$ is a one-hot representation. For larger vocabularies it is inefficient to compute the normalizer $\sum_{\mathbf{v} \in V} \exp \mathbf{v}^\top \mathbf{O}\mathbf{c}$. Solutions for problem are using the hierarchical softmax objective function (Mikolov et al., 2013) or resorting to negative sampling to approximate the normalizer (Goldberg and Levy, 2014).

The continuous bag-of-words model differs from other proposed models in the sense that its complexity does not rise substantially as we increase the window b, since it only requires two extra additions to compute $\mathbf{c}$, which correspond to d_w operations each. On the other hand, the skip-n-gram model requires two extra predictions corresponding to $d_w \times V$ operations each, which is an order of magnitude more expensive even when subsampling V. However, the drawback the bag-of-words model is that it does not learn embeddings that are prone for learning syntactically oriented tasks, mainly due to lack of sensitivity to word order, since the context is defined by a sum of surrounding words. Extensions are proposed in (Ling et al., 2015a), where the sum if replaced by the concatenation of the word embeddings in the order these occur. However, this model does not scale well as b increases as it requires $V \times d_w$ more parameters for each new word in the window.

Finally, setting a good value for b is difficult as larger values may introduce a degenerative behavior in the model, as more effort is spent predicting words that are conditioned on unrelated words, while smaller values of b may lead to cases where the window size is not large enough include words that are semantically related. For syntactic tasks, it has been shown that increasing the window size can adversely impact in the quality of the embeddings (Bansal et al., 2014; Lin et al., 2015).

2.2 CBOW with Attention

We present a solution to these problems while maintaining the efficiency underlying the bag-of-words model, and allowing it to consider contextual words within the window in a non-uniform way. We first rewrite the context window c as:

$$\mathbf{c} = \sum_{i \in [-b,b]-\{0\}} a_i(w_i)\mathbf{w}_i \quad (2)$$

where we replace the average of the word embeddings with a weighted sum of the individual word embeddings within the context. That is, each word is w_i at relative position i is attributed an attention level representing how much the attention model believes this it is important to look at in order to predict the center word. The attention $a_i(w)$ given to word $w \in V$ at the relative position i is computed as:

$$a_i(w) = \frac{\exp k_{w,i} + s_i}{\sum_{j \in [-b,b]-\{0\}} \exp k_{w,j} + s_j} \quad (3)$$

where $\mathbf{K} \in \Re^{|V| \times 2b}$ (with elements $k_{i,j}$) is a set of parameters that which determines the importance of each word type in each (relative) position, $\mathbf{s} \in \Re^{2b}$ is a bias, which is conditioned only on the relative position. As this is essentially a softmax over context words, the default bag-of-words model can be seen as a special case of this model

where all parameters $\mathbf{K}$ and $\mathbf{s}$ are fixed at zero. Computing the attention of all words in the input requires $2b$ operations, as it simply requires retrieving one value from the lookup matrix $\mathbf{K}$ for each word and one value from the bias $\mathbf{s}$ for each word in the window. Considering that these models must be trainable on billions of tokens, efficiency is paramount. Although more sophisticated attentional models are certainly imaginable (Bahdanau et al., 2014), ours is a good balance of computational efficiency and modeling expressivity.

2.3 Parameter Learning

Gradients of the loss function with respect to the parameters $(\mathbf{W}, \mathbf{O}, \mathbf{K}, \mathbf{s})$ are computed with backpropagation, and parameters are updated after each training instance using a fixed learning rate.

3 Experiments

3.1 Word Vectors

We used a subsample from an English Wikipedia dump[1] containing 10 million documents, containing a total of 530 million tokens. We built word embeddings using the original CBOW and our proposed attentional model on this dataset.

In both cases, word vectors were constructed using window size $b = 20$, which enables us to capture longer-range dependencies between words. We set the embedding size $d_w = 50$ and used a negative sampling rate of 10. Finally, the vocabulary was reduced to words with more than 40 occurrences. In terms of computational speed, the original bag-of-words implementation was able to compute approximately 220k words per second, while our model computes approximately 100k words per second. The slowdown is tied to the fact that we are computing the gradients, the attention model parameters, as well as the word embeddings. On the other hand, the skip-n-gram model process words at only 10k words per second, as it must predict every word in the window b.

Figure 1 illustrates the attention model for the prediction of the word *south* in the sentence *antartica has little rainfall with the south pole making it a continental desert*. Darker cell indicate higher attention values from $a(i, w)$. We can observe that function words (has, the and a) tend to be attributed very low attentions, as these are generally less predictive power. On the other hand,

[1]Collected in September of 2014

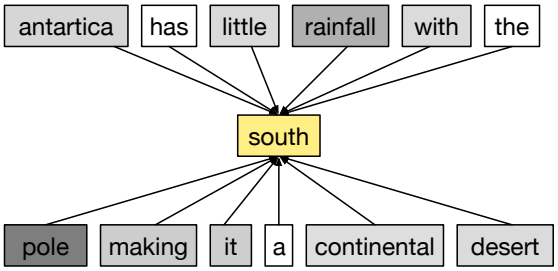

Figure 1: Illustration of the inferred attention parameters for a sentence from our training data when predicting the word *south*; darker cells indicate higher weights.

content words, such as antartica, rainfall, continental and desert are attributed higher weights as these words provide hints that the predicted word is likely to be related to these words. Finally, the word *pole* is assigned the highest attention as it close to the predicted word, and there is a very likely chance that *south* will precede *pole*.

3.2 Syntax Evaluation

For syntax, we evaluate our embeddings in the domain of part-of-speech tagging in both supervised (Ling et al., 2015b) and unsupervised tasks (Lin et al., 2015). This later task is newly proposed, but we argue that success in it is a compelling demonstration of separation of words into syntactically coherent clusters.

Part-of-speech induction. The work in (Lin et al., 2015) attempts to infer POS tags with a standard bigram hmm, which uses word embeddings to infer POS tags without supervision. We use the same dataset, obtained from the ConLL 2007 shared task (Nivre et al., 2007) Scoring is performed using the V-measure (Rosenberg and Hirschberg, 2007), which is used to predict syntactic classes at the word level. It has been shown in (Lin et al., 2015) that word embeddings learnt from structured skip-ngrams tend to work better at this task, mainly because it is less sensitive to larger window sizes. These results are consistent with our observations found in Table 1, in rows "Skip-ngram" and "SSkip-ngram". We can observe that our attention based CBOW model (row "CBOW Attention") improves over these results for both tasks and also the original CBOW model (row "CBOW").

	POS Induction	POS Tagging	Sentiment Analysis
CBOW	50.40	97.03	71.99
Skip-ngram	33.86	97.19	**72.10**
SSkip-ngram	47.64	**97.40**	69.96
CBOW Attention	**54.00**	97.39	71.39

Table 1: Results for unsupervised POS induction, supervised POS tagging and Sentiment Analysis (one per column) using different types of embeddings (one per row).

Part-of-speech tagging. The evaluation is performed on the English PTB, with the standard train (Sections 0-18), dev (Sections 19-21) and test (Sections 22-24) splits. The model is trained with the Bidirectional LSTM model presented in (Ling et al., 2015b) using the same hyper-parameters. Results on the POS accuracy on the test set are reported on Table 1. We can observe our model can obtain similar results compared to the structured skip-ngram model on this task, while training the model is significantly faster. The gap between the usage of different embeddings is not as large as in POS induction, as this is a supervised task, where pre-training generally leads to smaller improvements.

3.3 Semantic Evaluation

To evaluate the quality of our vectors in terms of semantics, we use the sentiment analysis task **(Senti)** (Socher et al., 2013), which is a binary classification task for movie reviews. We simply use the mean of the word vectors of words in a sentence, and use them as features in an ℓ_2-regularized logistic regression classifier. We use the standard training/dev/test split and report accuracy on the test set in table 1.

We can see that in this task, our models do not perform as well as the CBOW and Skipngram model, which hints that our model is learning embeddings that learn more towards syntax. This is expected as it is generally uncommon for embeddings to outperform existing models on both syntactic and semantic tasks simultaneously, as embeddings tend to be either more semantically or syntactically oriented. It is clear that the skipngram model learns embeddings that are more semantically oriented as it performs badly on all syntactic tasks. The structured skip-ngram model on the other hand performs badly on the syntactic tasks, but we observe a large drop on this semantically oriented task. Our attention-based model, on the other hand, out performs all other models on syntax-based tasks, while maintaining a competitive score on semantic tasks. This is an encouraging result that shows that it is possible to learn representations that can perform well on both semantic and syntactic tasks.

4 Related Work

Many methods have been proposed for learning word representations. Earlier work learns embeddings using a recurrent language model (Collobert et al., 2011), while several simpler and more lightweight adaptations have been proposed (Huang et al., 2012; Mikolov et al., 2013). While most of the learnt vectors are semantically oriented, work has been done in order to extend the model to learn syntactically oriented embeddings (Ling et al., 2015a). Attention models are common in vision related tasks (Tang et al., 2014), where models learn to pay attention to certain parts of a image in order to make accurate predictions. This idea has been recently introduced in many NLP tasks, such as machine translation (Bahdanau et al., 2014). In the area of word representation learning, no prior work that uses attention models exists to our knowledge.

5 Conclusions

In this work, we presented an extension to the CBOW model by introducing an attention model to select relevant words within the context to make more accurate predictions. As consequence, the model learns representations that are both syntactic and semantically motivated that do not degrade with large window sizes, compared to the original CBOW and skip-ngram models. Efficiency is maintained by learning a position-based attention model, which can compute the attention of surrounding words with a relatively small number of operations. Finally, we show improvements on syntactically oriented tasks, without degrading results significantly on semantically oriented tasks.

An Improved Non-monotonic Transition System for Dependency Parsing

Matthew Honnibal

mark.johnson@mq.edu.edu.au

Abstract

Transition-based dependency parsers usually use transition systems that monotonically extend partial parse states until they identify a complete parse tree. Honnibal et al. (2013) showed that greedy one-best parsing accuracy can be improved by adding additional non-monotonic transitions that permit the parser to "repair" earlier parsing mistakes by "over-writing" earlier parsing decisions. This increases the size of the set of complete parse trees that each partial parse state can derive, enabling such a parser to escape the "garden paths" that can trap monotonic greedy transition-based dependency parsers.

We describe a new set of non-monotonic transitions that permits a partial parse state to derive a larger set of completed parse trees than previous work, which allows our parser to escape from a larger set of garden paths. A parser with our new non-monotonic transition system has 91.85% directed attachment accuracy, an improvement of 0.6% over a comparable parser using the standard monotonic arc-eager transitions.

1 Introduction

Recent work from Dyer et al. (2015) and Weiss et al. (2015) show that neural network models can improve greedy transition-based parsers dramatically, even beyond the 20% error reduction reported by Chen and Manning (2014). Improvements on beam-search parsing are much more limited, due to the difficulty of applying neural networks to structured prediction.

We suggest that the lack of a ready search solution may present the next barrier to further improvements in accuracy. Some degree of search flexibility seems inherently necessary, no matter how powerful the local model becomes, as even the human sentence processor can be 'garden pathed' by local structural ambiguities.

We take inspiration from Frazier and Rayner (1982) and other psycholinguists and propose repair actions as a light-weight alternative to beam-search. In a transition-based dependency parser, transitions map parse states to parse states, ultimately producing completed parse trees. This process is non-deterministic, since usually more than one transition can apply to a parse state. This means that each partial parse state can be associated with a set of complete parse trees (i.e., the complete parses that can be produced by applying sequences of transitions to the partial parse state). In general adding additional transitions (monotonic or non-monotonic) increases the number of complete parse trees that any given partial parse state can derive.

We explore adding non-monotonic parsing transitions to a greedy arc-eager dependency parser in this paper, in order to permit the parser to recover from attachment errors made early in the parsing process. These additional non-monotonic transitions permit the parser to modify what would have been irrevocable parsing decisions in the monotonic arc-eager system when later information justifies this action. Thus one effect of adding the non-monotonic parsing transitions is to effectively delay the location in the input where the parser must ultimately commit to a particular attachment.

Our transition-system builds on the work of Honnibal et al. (2013) and Nivre and Fernandez-Gonzalez (2014), who each present modifications

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1373–1378,
Lisbon, Portugal, 17-21 September 2015.

to the arc-eager transition system that introduce some non-monotonic behaviour, resulting in small improvements in accuracy. However, these systems only apply non-monotonic transitions to a relatively small number of configurations, so they can only have a small impact on parse accuracy.

We introduce a non-monotonic transition system that combines ideas from these two approaches, and allows substantially more repair capability (and hence search flexibility). We observe a 0.6% improvement in accuracy on the OntoNotes corpus, which is an error reduction of 6.25% over a competitive baseline. A parser using our transition system is guaranteed to run in linear time, and the modifications to the algorithm have no negative impact on run-time in our implementation.

Very recently there has been considerable success in applying neural network models to predict which transition to apply in greedy one-best transition-based parsing. In their preprints, both Dyer et al. (2015) and Weiss et al. (2015) report error reductions of around 20-30% for greedy one-best parsing, and much more modest improvements for transition-based parsers with beam search. Because the neural network approaches improve the local model that predicts which transition to apply next, while this paper suggests changes to the transition system itself, it is reasonable to expect that the improvements reported here are largely orthogonal to those obtained using the neural network techniques. In future work we would like to explore integrating such neural network models of transition prediction with the extended transition system proposed here.

2 Improved non-monotonic transition system

Our transition-system is based on the tree-constrained arc-eager system of Nivre and Fernandez-Gonzalez (2014), which extends the classic arc-eager system (Nivre, 2003) with a new non-monotonic operation that they call "Unshift". They introduce the Unshift action to repair configurations where the buffer is exhausted and the stack contains multiple words that are without incoming arcs (i.e. without governors). The original arc-eager configuration outputs partial parses in this situation.

Nivre and Fernandez-Gonzalez restrict their Unshift action, such that it can only be applied when the buffer is exhausted and the word on top of the stack has no incoming arc. In this configuration, the Unshift action is the only action that can be applied. The use of the new action is therefore entirely deterministic, and they do not need to produce example configurations for the Unshift action during training. They train their model with what Goldberg and Nivre (2012) term a 'static oracle', which can only label configurations that are consistent with the gold-standard parse.

We take the Nivre and Fernandez-Gonzalez (2014) Unshift operation, and import it into the non-monotonic parsing model of Honnibal et al. (2013), which uses a dynamic oracle to determine the gold-standard actions for configurations produced by the parser. This training strategy is critical to the success of a non-monotonic transition system. The model cannot learn to recover from previous errors if the training data cannot contain configurations that result from incorrect actions.

Honnibal et al. (2013) allow the parser to correct prior misclassifications between the Shift and Right-Arc actions. Both of these actions push the first word of the buffer onto the stack, but the Right-Arc action also adds an arc. After the Right-Arc is applied, the top two words of the stack are connected.

In the original arc-eager system, the presence or absence of this arc determines which of the two pop moves, Reduce or Left-Arc, is valid. If the arc is present, then Left-Arc is excluded; if it is absent, the Reduce action is excluded. Honnibal et al. (2013) argue that these deterministic constraints are unmotivated when the parser is trained using a dynamic, instead of static, oracle. Instead of a constraint, they suggest that consistency be achieved by refining the logic of the actions, so that they have a broader applicability. Instead of preventing the Left-Arc from applying when the word on top of the stack has an incoming arc, they update the definition of the Left-Arc so that it first deletes the existing arc if necessary. A corresponding change is made to the Reduce action: if the model predicts Reduce when the word on top of the stack has no incoming arc, the 'missing' arc is inserted. The arc is labelled by noting the best-scoring Right-Arc label on each Shift action, so that the label can be assigned during non-monotonic Reduce.

We show that the Nivre and Fernandez-Gonzalez Unshift operation serves as a far superior non-monotonic Reduce action than the one

Notation			
$(\sigma, \beta, \mathbf{A}, \mathbf{S})$ is a configuration, where $\sigma \vert s$ is a stack of word indices with topmost element s $b \vert \beta$ is a buffer of word indices with first element b $\mathbf{A}$ is a vector of head indices $\mathbf{A}(i) = j$ denotes an arc $w_j \rightarrow w_i$ $\mathbf{S}$ is a bit-vector used to prevent Shift/Unshift cycles			
Initial	$([\,], [1...n], \mathbf{A}(1) = 1)$		
Terminal	$([i], [\,], \mathbf{A})$		
Shift	$(\sigma, b \vert \beta, \mathbf{A}, \mathbf{S}(b) = 0)$	$\Rightarrow$	$(\sigma \vert b, \beta, \mathbf{A}, \mathbf{S}(b) = 1)$
Right-Arc	$(\sigma \vert s, b \vert \beta, \mathbf{A}, \mathbf{S})$	$\Rightarrow$	$(\sigma \vert s \vert b, \beta, \mathbf{A}(b) = s, \mathbf{S})$
Reduce	$(\sigma \vert s, \beta, \mathbf{A}(s) \neq 0, \mathbf{S})$	$\Rightarrow$	$(\sigma, \beta, \mathbf{A}, \mathbf{S})$
Unshift	$(\sigma \vert s, \beta, \mathbf{A}(s) = 0, \mathbf{S})$	$\Rightarrow$	$(\sigma, s \vert \beta, \mathbf{A}, \mathbf{S})$
Left-Arc	$(\sigma \vert s, b \vert \beta, \mathbf{A}, \mathbf{S})$	$\Rightarrow$	$(\sigma, s \vert \beta, \mathbf{A}(s) = b, \mathbf{S}$

Table 1: Our non-monotonic transition system, which integrates the Unshift action of Nivre and Fernandez-Gonzalez (2014) into the model of Honnibal et al. (2013).

Honnibal et al. use in their system, and that the resulting transition system improves parse accuracy by considerably more than either the Honnibal et al or Nivre et al systems do.

2.1 Definition of Transition System

The hybrid transition system is defined in Table 1. Arcs are stored in a vector, $\mathbf{A}$, where the entry $\mathbf{A}(i) = j$ denotes an arc $w_j \rightarrow w_i$. Words are pushed from the buffer β onto the stack σ, using either the Shift or the Right-Arc actions.

If a word was pushed with the Shift action, it will not have an incoming arc. The new Unshift action will then be valid, at any point at which the word is on top of the stack — even after many actions have been performed.

The Unshift action pops the top word of the stack, s, and places it at the start of the buffer. Parsing then proceeds as normal. To prevent cycles, the Shift action checks and sets a bit in the new boolean vector $\mathbf{S}$. The Shift action is invalid if $\mathbf{S}(b) = 1$, for a word b at the front of the buffer. This bit will be set if the word was previously Shifted, and then Unshifted.

At worst, each word can be pushed and popped from the stack twice, so parsing is guaranteed to terminate after a maximum of $4n$ transitions for a sentence of length n.

The terminal condition is reached when the buffer is exhausted and exactly one word remains on the stack. This word will be deemed the root of the sentence. No 'dummy' root token is necessary, removing the need to choose whether the token is placed at the beginning or end of the buffer (Ballesteros and Nivre, 2013).

Note that if the two words each seem like the governor of the sentence, such that the parser deems all incoming arcs to these words unlikely, the transition system is guaranteed to arrive at a configuration where these two words are adjacent to each other. The model can then predict an arc between them, initiated by either word.

2.2 Dynamic Training Oracle

Goldberg and Nivre (2013) describe three questions that need to be answered in order to implement their training algorithm.

Exploration Policy: *When do we follow an incorrect transition, and which one do we follow?*
We always follow the predicted transition, i.e. their two hyper-parameters are set $k = 1$ and $p = 1.0$.

Optimality: *What constitutes an optimal transition in configurations from which the gold tree is not reachable?*
We follow Honnibal et al. (2013) in defining a transition as optimal if it:

1. Renders no additional arcs unreachable using the *monotonic* arc-eager transitions; and
2. Renders no additional arcs unreachable using the *non-monotonic* transitions.

Said another way, we mark a transition as optimal if it leads to an analysis with as few errors as possible, and in cases of ties, uses as few non-monotonic transitions as possible.

For example, given the input string *I saw Jack*, consider a configuration where *saw* is on the stack, *Jack* is at the front of the buffer, and *I* is attached to *saw*. The gold arcs are *saw* → *I* and *saw* → *Jack*. In the monotonic system, the Shift action would make the gold arc *saw* → *Jack* newly unreachable. In our system, this arc is still reachable after Shift, via the Unshift action, but we consider the Shift move non-optimal, so that the non-monotonic actions are reserved as "repair" operations.

Oracle: *Given a definition of optimality, how do we calculate the set of optimal transitions in a given configuration?*

Goldberg and Nivre (2013) show that with the monotonic arc-eager actions, the following arcs are reachable from an arbitrary configuration:

1. Arcs $\{w_i \rightarrow w_j : i \in \sigma,\ j \in \beta\}$ — i.e. all arcs from stack words to buffer words;
2. Arcs $\{w_i \rightarrow w_j : i \in \beta,\ j \in \sigma,\ \mathbf{A}(j) = 0\}$ — i.e. all arcs from buffer words to headless stack words;
3. Arcs $\{w_i \rightarrow w_j : i \in \beta,\ j \in \beta\}$ — i.e. all arcs between words in buffer.

Our non-monotonic actions additionally allow the following arcs to be reached:

4. Arcs $\{w_i \rightarrow w_j : i \in \beta,\ j \in \sigma, \mathbf{A}(j) \neq 0\}$ (LeftArc can now "clobber" existing heads)
5. Arcs $\{w_i \rightarrow w_j$ or $w_j \rightarrow w_i : i, j \in \sigma, i < j, \mathbf{A}(j) = 0\}$ — i.e. if a word i is on the stack, it can reach an arc to or from a word j ahead of it on the stack if that word does not have a head set.

In practice, we therefore only need to add two rules to determine the set of optimal transitions:

1. If σ_0 has a head, and its true head is in the buffer, the Reduce action is now non-optimal.
2. If σ_0 does not have a head, and its true head is in the stack, the LeftArc action is now non-optimal.

The oracle calculation is simple because the system preserves the *arc decomposition* property that Goldberg and Nivre (2013) prove for the arc eager system: if two arcs of a projective tree are individually reachable from a configuration, a projective tree that includes both arcs is also reachable. To see that this property is preserved in our system, consider that an arc $h \rightarrow d$ between two stack words is only unreachable if $h < d$ and $A(d) \neq 0$. But a projective tree with arc $h \rightarrow d$ cannot also have an arc $x \rightarrow y$ such that $h < x < d < y$. So there can be no other arc part of the same projective tree as $h \rightarrow d$ that would require d to be assigned to some other head.

3 Training Procedure

We follow Honnibal et al. (2013) in using the dynamic oracle-based search-and-learn training strategy introduced by Goldberg and Nivre (2012). A dynamic oracle is a function that labels configurations with gold-standard actions. Importantly, a dynamic oracle can label arbitrary configurations, while a so-called 'static' oracle can only assign labels to configurations that are part of gold-standard derivations.

We employ the dynamic oracle in an online learning strategy, similar to imitation-based learning, where the examples are configurations produced by following the current model's predictions. The configurations are labelled by the dynamic oracle, which determines which of the available actions excludes the fewest gold-standard arcs.

Often, multiple actions will be labelled as gold-standard for a given configuration. This implies either spurious ambiguity (the same analysis reachable via different derivations) or previous errors, such that the best parse reachable by different actions are equally bad. When this occurs, we base the perceptron update on the highest-scoring gold-standard label.

3.1 Single class for Unshift/Reduce

The Unshift and Reduce actions are applicable to a disjoint set of configurations. If the word on top of the stack already has an incoming arc, the Reduce move is valid; otherwise, the Unshift move is valid. For the purpose of training and prediction, we therefore model these actions as a single class, which we interpret based on the configuration. This allows us to learn the Unshift action more effectively, as it is allowed to share a representation with the Reduce move. In preliminary development, we found that assigning a distinct class to the Unshift action was not effective. We plan to evaluate this option more rigorously in future work.

4 Experiments

We implemented a greedy transition-based parser, and used rich contextual features following Zhang and Nivre (2011). We extended the feature set to include Brown cluster features, using the cluster prefix trick described by Koo and Collins (2010). Brown clusters are a standard way to improve the cross-domain performance of supervised linear models. The use of Brown cluster features accounts for the 0.7% improvement in accuracy observed between our baseline parser and the Goldberg and Nivre (2012) result shown in Table 2. The two models are otherwise the same.

Part-of-speech tags were predicted using a greedy averaged perceptron model that achieved 97.2% accuracy on the evaluation data. Most previous work uses a n-way jack-knifing to train the stacked tagger/parser model. For convenience, we instead train the tagger at the same time as the parser, as both allow online learning. We find this makes no difference to accuracy.

Our parsers are trained and evaluated on the same data used by Tetreault et al. (2015) in their recent 'bake-off' of leading dependency parsing models. Specifically, we use the OntoNotes corpus converted into dependencies using the ClearNLP 3.1 converter, with the train / dev / test split of the CoNLL 2012 shared task.

5 Results

We implemented three previous versions of the arc-eager transition system, in order to evaluate the effect of our proposed transition-system on parser accuracy. The four systems differ only in their transition system — they are otherwise identical. All use identical features, and all are trained with the dynamic oracle.

Orig. Arc Eager (Nivre, 2003): the original arc-eager system, which constrains the Reduce and Left-Arc actions to ensure monotonicity; **Prev. Non-Monotic** (Honnibal et al., 2013): relaxes the monotonicity constraints, allowing Left-Arc to "clobber" existing arcs, and inserting missing arcs on Reduce with a simple heuristic; **Tree Constrained** (Nivre and Fernandez-Gonzalez, 2014): adds an Unshift action to the arc-eager system, that is only employed when the buffer is exhausted; **This work**: merges the Unshift action into our previous non-monotonic transition system.

Transition System	Search	UAS	LAS
Orig. Arc Eager	Greedy	91.25	89.40
Tree Constrained	Greedy	91.40	89.50
Prev. Non-Monotonic	Greedy	91.36	89.52
This work	Greedy	91.85	89.91
Chen and Manning (2014)	Greedy	89.59	87.63
Goldberg and Nivre (2012)	Greedy	90.54	88.75
Choi and Mccallum (2013)	Branch	92.26	90.84
Zhang and Nivre (2011)	Beam_{32}	92.24	90.50
Bohnet (2010)	Graph	92.50	90.70

Table 2: Our non-monotonic transition system improves accuracy by 0.6% unlabelled attachment score, for a final score of 91.85 on the OntoNotes corpus.

Table 2 shows the unlabelled and labelled attachment scores of the parsers on the evaluation data. The two previous non-monotonic systems, Prev. Non-monotonic and Tree Constrained, were slightly more accurate than the Orig. Arc Eager system. Our new transition-system had a much bigger impact, improving UAS by 0.6% and LAS by 0.51%. To put the scores in context, we have also included figures reported in a recent survey of the current state-of-the-art (Tetreault et al., 2015). Our parser out-performs existing greedy parsers, and is much more efficient than non-greedy parsers.

6 Conclusions and Future Work

This paper integrates innovations from Honnibal et al. (2013) and Nivre and Fernandez-Gonzalez (2014) to produce a novel non-monotonic set of transitions for transition-based dependency parsing. Doing this required us to use the dynamic oracle of Goldberg and Nivre (2012) during training in order to produce configurations that exercise the non-monotonic transitions. We show that this combination of innovations results in a parser with 91.85% directed accuracy, which is an improvement of 0.6% directed accuracy over an equivalent arc-standard parser. Interestingly, the Honnibal et al and Nivre et al innovations applied on their own only produce improvements of 0.11% and 0.15% respectively, so it seems that these improvements taken together do interact synergistically.

Because our innovation largely affects the search space of a greedy one-best parser, it is likely to be independent of the recent improvements in parsing accuracy that come from using neural networks to predict the best next parsing transition. In future work we plan to combine such neural network models with a version of our parser that incorporates a much larger set of non-monotonic parsing transitions.

Abstract

The multilingual Paraphrase Database (PPDB) is a freely available automatically created resource of paraphrases in multiple languages. In statistical machine translation, paraphrases can be used to provide translation for out-of-vocabulary (OOV) phrases. In this paper, we show that a graph propagation approach that uses PPDB paraphrases can be used to improve overall translation quality. We provide an extensive comparison with previous work and show that our PPDB-based method improves the BLEU score by up to 1.79 percent points. We show that our approach improves on the state of the art in three different settings: when faced with limited amount of parallel training data; a domain shift between training and test data; and handling a morphologically complex source language. Our PPDB-based method outperforms the use of distributional profiles from monolingual source data.

1 Introduction

Translation coverage is a major concern in statistical machine translation (SMT) which relies on large amounts of parallel, sentence-aligned text. In (Callison-Burch et al., 2006), even with a training data size of 10 million word tokens, source vocabulary coverage in unseen data does not go above 90%. The problem is worse with multi-word OOV phrases. Copying OOVs to the output is the most common solution. However, even noisy translations of OOVs can improve reordering and language model scores (Zhang et al., 2012). Transliteration is useful but not a panacea for the OOV problem (Irvine and Callison-Burch, 2014b). We find and remove the named entities, dates, etc. in the source and focus on the use of paraphrases to help translate the remaining OOVs. In Sec. 5.2 we show that handling such OOVs correctly does improve translation scores.

In this paper, we build on the following research: *Bilingual lexicon induction* is the task of learning translations of words from monolingual data in source and target languages (Schafer and Yarowsky, 2002; Koehn and Knight, 2002; Haghighi et al., 2008). The *distributional profile* (DP) approach uses context vectors to link words as potential paraphrases to translation candidates (Rapp, 1995; Koehn and Knight, 2002; Haghighi et al., 2008; Garera et al., 2009). DPs have been used in SMT to assign translation candidates to OOVs (Marton et al., 2009; Daumé and Jagarlamudi, 2011; Irvine et al., 2013; Irvine and Callison-Burch, 2014a). Graph-based semi-supervised methods extend this approach and propagate translation candidates across a graph with phrasal nodes connected via weighted paraphrase relationships (Razmara et al., 2013; Saluja et al., 2014; Zhao et al., 2015). Saluja et al. (2014) extend paraphrases for SMT from the words to phrases, which we also do in this work. *Bilingual pivoting* uses parallel data instead of context vectors for paraphrase extraction (Mann and Yarowsky, 2001; Schafer and Yarowsky, 2002; Bannard and Callison-Burch, 2005; Callison-Burch et al., 2006; Zhao et al., 2008; Callison-Burch, 2008). Ganitkevitch and Callison-Burch (2014) published a large-scale multilingual Paraphrase Database (PPDB) `http://paraphrase.org` which includes lexical, phrasal, and syntactic paraphrases (available for 22 languages with up to 170 million paraphrases each).

To our knowledge, this paper is the first comprehensive study of the use of PPDB for statistical machine translation model training. Our framework has three stages: 1) a novel graph construction approach for PPDB paraphrases linked

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1379–1390,
Lisbon, Portugal, 17-21 September 2015.

with phrases from parallel training data. 2) Graph propagation that uses PPDB paraphrases. 3) An SMT model that incorporates new translation candidates. Sec. 3 explains these three stages in detail.

Using PPDB has several advantages: 1) Resources such as PPDB can be built and used for many different tasks including but not limited to SMT. 2) PPDB contains many features that are useful to rank the strength of a paraphrase connection and with more information than distributional profiles. 3) Paraphrases in PPDB are often better than paraphrases extracted from monolingual or comparable corpora because a large-scale multilingual paraphrase database such as PPDB can pivot through a large amount of data in many different languages. It is not limited to using the source language data for finding paraphrases which distinguishes it from previous uses of paraphrases for SMT.

PPDB is a natural resource for paraphrases. However, PPDB was not built with the specific application to SMT in mind. Other applications such as text-to-text generation have used PPDB (Ganitkevitch et al., 2011) but SMT brings along a specific set of concerns when using paraphrases: translation candidates should be transferred suitably across paraphrases. There are many cases, e.g. when faced with different word senses where transfer of a translation is not appropriate. Our proposed methods of using PPDB use graph propagation to transfer translation candidates in a way that is sensitive to SMT concerns.

In our experiments (Sec. 5) we compare our approach with the state-of-the-art in three different settings in SMT: 1) when faced with limited amount of parallel training data; 2) a domain shift between training and test data; and 3) handling a morphologically complex source language. In each case, we show that our PPDB-based approach outperforms the distributional profile approach.

2 Paraphrase Extraction

Our goal is to produce translations for OOV phrases by exploiting paraphrases from the multilingual PPDB (Ganitkevitch and Callison-Burch, 2014) by using graph propagation. Since our approach relies on phrase-level paraphrases we compare with the current state of the art approaches that use monolingual data and distributional profiles to construct paraphrases and use graph propagation (Razmara et al., 2013; Saluja et al., 2014).

2.1 Paraphrases from Distributional Profiles

A *distributional profile* (DP) of a word or phrase was first proposed in (Rapp, 1995) for SMT. Given a word f, its distributional profile is:

$$DP(f) = \{\langle A(f, w_i)\rangle \mid w_i \in V\}$$

V is the vocabulary and the surrounding words w_i are taken from a monolingual corpus using a fixed window size. We use a window size of 4 words based on the experiments in (Razmara et al., 2013). DPs need an association measure $A(\cdot, \cdot)$ to compute distances between potential paraphrases. A comparison of different association measures appears in (Marton et al., 2009; Razmara et al., 2013; Saluja et al., 2014) and our preliminary experiments validated the choice of the same association measure as in these papers, namely *Pointwise Mutual Information* (Lin, 1998) (PMI). For each potential context word w_i:

$$A(f, w_i) = log_2 \frac{P(f, w_i)}{P(f)P(w_i)} \quad (1)$$

To evaluate the similarity between two phrases we use cosine similarity. The cosine coefficient of two phrases f_1 and f_2 is:

$$S(f_1, f_2) = cos(DP(f_1), DP(f_2)) = \frac{\sum_{w_i \in V} A(f_1, w_i)A(f_2, w_i)}{\sqrt{\sum_{w_i \in V} A(f_1, w_i)^2}\sqrt{\sum_{w_i \in V} A(f_2, w_i)^2}} \quad (2)$$

where V is the vocabulary. Note that in Eqn. (2) w_i's are the words that appear in the context of f_1 or f_2, otherwise the PMI values would be zero.

Considering all possible candidate paraphrases is very expensive. Thus, we use the heuristic applied in previous works (Marton et al., 2009; Razmara et al., 2013; Saluja et al., 2014) to reduce the search space. For each phrase we keep candidate paraphrases which appear in one of the surrounding context (e.g. *Left__Right*) among all occurrences of the phrase.

2.2 Paraphrases from bilingual pivoting

Bilingual pivoting uses parallel corpora between the source language, F, and a pivot language T. If two phrases, f_1 and f_2, in a same language are paraphrases, then they share a translation in other languages with $p(f_1|f_2)$ as a paraphrase score:

$$S(f_1, f_2) = p(f_1|f_2) = \sum_t p(f_1|t)p(t|f_2) \quad (3)$$

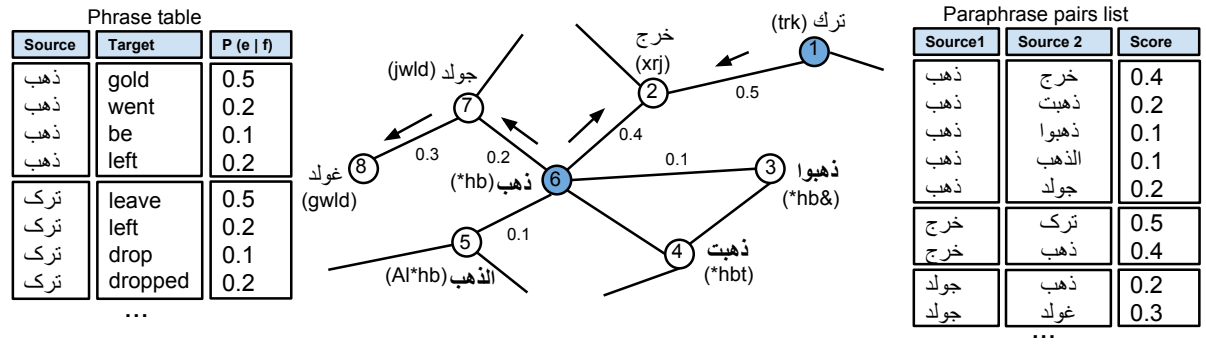

Figure 2: A small sample of the real graph constructed from the Arabic PPDB for Arabic to English translation. Filled nodes (1 and 6) are phrases from the SMT phrase table (unfilled nodes are not). Edge weights are set using a log-linear combination of scores from PPDB. Phrase #6 has different senses ('gold' or 'left'); and it has a paraphrase in phrase #7 for the 'gold' sense and a paraphrase in phrase #2 for the 'left' sense. After propagation, phrase #2 receives translation candidates from phrase #6 and phrase #1 reducing the probability of translation from unrelated senses (like the 'gold' sense). Phrase #8 is a misspelling of phrase #7 and is also captured as a paraphrase. Phrase #6 propagates translation candidates to phrase #8 through phrase #7. Morphological variants of phrase #6 (shown in bold) also receive translation candidates through graph propagation giving translation candidates for morphologically rich OOVs.

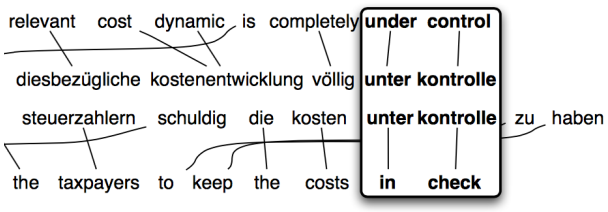

Figure 1: English paraphrases extracted by pivoting over German shared translation (Bannard and Callison-Burch, 2005).

where t is a phrase in language T. $p(f_1|t)$ and $p(t|f_2)$ are taken from the phrase table extracted from parallel data for languages F and T. In Fig. 1 from (Bannard and Callison-Burch, 2005) we see that paraphrase pairs like (*in check*, *under control*) can be extracted by pivoting over the German phrase *unter kontrolle*.

The multilingual Paraphrase Database (PPDB) (Ganitkevitch and Callison-Burch, 2014) is a published resource for paraphrases extracted using bilingual pivoting. It leverages syntactic information and other resources to filters and scores each paraphrase pair using a large set of features. These features can be used by a log linear model to score paraphrases (Zhao et al., 2008). We used a linear combination of these features using the equation in Sec. 3 of (Ganitkevitch and Callison-Burch, 2014) to score paraphrase pairs. PPDB version 1 is broken into different levels of coverage. The smaller sizes contain only better-scoring, high-precision paraphrases, while larger sizes aim for high coverage.

Algorithm 1 PPDB Graph Propagation for SMT

```
PhrTable = PhraseTableGeneration();
ParaDB = ParaphraseExtraction();                    (Sec. 2)
InitGraph = GraphConstruct(PhrTable, ParaDB);       (Sec. 3.1)
PropGraph = GraphPropagation(InitGraph);            (Sec. 3.2)
for phrase ∈ {OOVs} do
    newTrans = TranslationFinder(PropGraph, phrase);
    Augment(PhrTable, newTrans);                    (Sec. 3.3)
TuneMT(PhrTable);
```

3 Methodology

After paraphrase extraction we have paraphrase pairs, (f_1, f_2) and a score $S(f_1, f_2)$ we can induce new translation rules for OOV phrases using the steps in Algo. (1): 1) A graph of source phrases is constructed as in (Razmara et al., 2013); 2) translations are propagated as labels through the graph as explained in Fig. 2; and 3) new translation rules obtained from graph-propagation are integrated with the original phrase table.

3.1 Graph Construction

We construct a graph $G(V, E, W)$ over all source phrases in the paraphrase database and the source language phrases from the SMT phrase table extracted from the available parallel data. V corresponds to the set of vertices (source phrases), E is the set of edges between phrases and W is weight of each using the score function S defined in Sec. 2. V has two types of nodes: seed (labeled) nodes, V_s, from the SMT phrase table, and regular nodes, V_r. Note that in this step OOVs are part of these regular nodes, and we try to find translation in the propagation step for all of these regular nodes. In graph construction and propagation,

we do not know which phrasal nodes correspond to OOVs in the dev and test set. Fig. 2 shows a small slice of the actual graph used in one of our experiments; This graph is constructed using the paraphrase database on the right side of the figure. Filled nodes have a distribution over translations (the possible "labels" for that node). In our setting, we consider the translation e to be the "label" and so we propagate the labeling distribution $p(e|f)$ which is taken from the feature function for the SMT log-linear model that is taken from the SMT phrase table and we propagate this distribution to unlabeled nodes in the graph.

3.2 Graph Propagation

Considering the translation candidates of known phrases in the SMT phrase table as the "labels" we apply a soft label propagation algorithm in order to assign translation candidates to "unlabeled" nodes in the graph, which include our OOV phrases. As described by the example in Fig. 2 we wish two outcomes: 1) transfer of translations (or "labels") to unlabeled nodes (OOV phrases) from labeled nodes, and 2) smoothing the label distribution at each node. We use the Modified Adsorption (MAD) algorithm (Talukdar and Crammer, 2009) for graph propagation. Suppose we have m different possible labels plus one *dummy label*, a soft label $\hat{Y} \in \Delta^{m+1}$ is a $m+1$ dimension probability vector. The dummy label is used when there is low confidence on correct labels. Based on MAD, we want to find soft label vectors for each node by optimizing the objective function below:

$$\begin{aligned}\min_{\hat{Y}} \mu_1 \sum_{v \in V_s} P_{1,v} ||Y_v - \hat{Y}||_2^2 + \\ \mu_2 \sum_{v \in V, u \in N(v)} P_{2,v} W_{v,u} ||\hat{Y}_v - \hat{Y}_u||_2^2 + \\ \mu_3 \sum_{v \in V} P_{3,v} ||\hat{Y}_v - R_v||_2^2\end{aligned} \quad (4)$$

In this objective function, μ_i and $P_{i,v}$ are hyper-parameters ($\forall v : \Sigma_i P_{i,v} = 1$). $R_v \in \Delta^{m+1}$ is our prior belief about labeling. First component of the function tries to minimize the difference of new distribution to the original distribution for the seed nodes. The second component insures that nearby neighbours have similar distributions, and the final component is to make sure that the distribution does not stray from a prior distribution. At the end of propagation, we wish to find a label distribution for our OOV phrases. We describe in Sec. 4.2.2 the reasons for choosing MAD over other graph propagation algorithms. The MAD graph propagation generalizes the approach used in (Razmara et al., 2013). The Structured Label Propagation algorithm (SLP) was used in (Saluja et al., 2014; Zhao et al., 2015) which uses a graph structure on the target side phrases as well. However, we have found that in our diverse experimental settings (see Sec. 5) MAD had two properties we needed compared to SLP: one was the use of graph random walks which allowed us to control translation candidates and MAD also has the ability to penalize nodes with a large number of edges (also see Sec. 4.2.2).

3.3 Phrase Table Integration

After propagation, for each potential OOV phrase we have a list of possible translations with corresponding probabilities. A potential OOV is any phrase which does not appear in training, but could appear in unseen data. We do not look at the dev or test data to produce the augmented phrase table. The original phrase table is now augmented with new entries providing translation candidates for potential OOVs; Last column in Table 2 shows how many entries have been added to the phrase table for each experimental settings. A new feature is added to the standard SMT log-linear discriminative model and introduced into the phrase table. This new feature is set to either 1.0 for the phrase table entries that already existed; or ℓ_i which is the log probability (from graph propagation) for the translation candidate i for potential OOVs. In case the dummy label exists with high probability or the label distribution is uniform, an identity rule is added to the phrase table (copy over source to target).

4 Analysis of the Framework

4.1 Propagation of poor translations

Automatic paraphrase extraction generates many possible paraphrase candidates and many of them are likely to be false positives for finding translation candidates for OOVs. Distributional profiles rely on context information which is not sufficient to derive accurate paraphrases for many phrases and this results in many low quality paraphrase candidates. Bilingual pivoting uses word alignments which can also introduce errors depending on the size and quality of the bilingual data used. Alignment errors also introduce poor translations.

Size	Nodes	Edges	Max Neigh.	Ave Neigh.
S	23K	31K	32	1.38
M	41K	69K	33	1.69
L	74K	199K	67	2.69
XL	103K	548K	330	5.33
XXL	122K	2073K	1231	16.968
XXXL	125K	7558K	5255	60.27

Table 1: Statistics of the graph constructed using the English lexical PPDB. We have built similar graphs for French and Arabic.

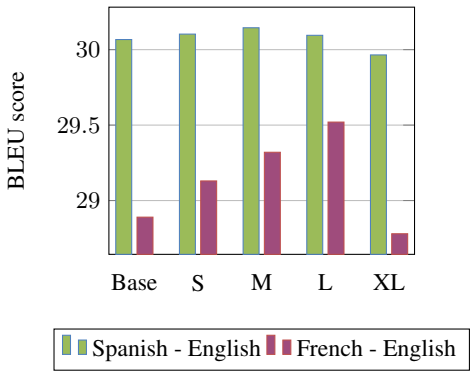

Figure 3: Effect of PPDB size on improving BLEU score for Spanish and French

In graph propagation, these errors may be propagated and result in poor translations for OOVs.

We could address this issue by aggressively pruning the potential paraphrase candidates to improve the precision. However, this results in a dramatic drop in coverage and many OOV phrases do not obtain any translation candidates. We use a combination of the following three steps to augment our graph propagation framework.

4.1.1 Graph pruning and PPDB sizes

Pruning the graph avoids error propagation by removing unreliable edges. Pruning removes edges with an edge weight lower than a minimum threshold or by limiting the number of neighbours to the top-K edges (Talukdar, 2009). PPDB has different sizes with different levels of accuracy and coverage. We can do graph pruning simply by choosing to use different sizes of PPDB. As we can see in Fig. 3 results vary from language to language depending on the pruning used. For instance, the L size results in the best score for French-English. We choose the best size of PPDB for each language based on a separate held-out set and independently from each of the SMT-based tasks in our experimental results. Our conclusion from our experiments with the different sizes of PPDB is that removing phrases (or nodes in our graph) is not desirable. However, removing unreliable edges is useful. As seen in Table 1, increasing the size of PPDB leads to a rapid increase in nodes followed by a larger number of edges in the very large PPDB sizes.

4.1.2 Pruning the translation candidates

Another solution to the error propagation issue is to propagate all translation candidates but when providing translations to OOVs in the final phrase table to eliminate all but the top L translations for each phrase (which is the usual *ttable* limit in phrase-based SMT (Koehn et al., 2003)). Based on a development set, separate from the test sets we used, we found that the best value of L was 10.

4.1.3 External Resources for Filtering

Applying more informative filters can be also used to improve paraphrase quality. This can be done through additional features for paraphrase pairs. For example, edit distance can be used to capture misspelled paraphrases. We use a Named Entity Recognizer to exclude names, numbers and dates from the paraphrase candidates. Even after removing these tokens, 3.32% of tokens of test set are still OOVs . In addition, we use a list of stop words to remove nodes which have too many connections. These two filters improve our results (more in Sec. 5).

4.2 Path sensitivity

Graph propagation has been used in many NLP tasks like POS tagging, parsing, etc. but propagating translations in a graph as labels is much more challenging. Due to huge number of possible labels (translations) and many low quality edges, it is very likely that many wrong translations are rapidly propagated in few steps. Razmara et al. (2013) show that unlabeled nodes inside the graph, called *bridge nodes*, are useful for the transfer of translations when there is no other connection between an OOV phrase and a node with known translation candidates. However, they show that using the full graph with long paths of bridge nodes hurts performance. Thus the propagation has to be constrained using *path sensitivity*. Fig. 4 shows this issue in a part of an English para-

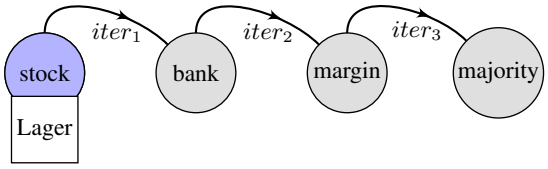

Figure 4: Sensitivity issue in graph propagation for translations. "Lager" is a translation candidate for "stock", which is transferred to "majority" after 3 iterations.

phrase graph. After three iterations, German translation "Lager" reaches "majority" which is totally irrelevant as a translation candidate. Transfer of translation candidates should prefer close neighbours and only with a very low probability to other nodes in the graph.

4.2.1 Pre-structuring the graph

Razmara et al. (2013) avoid a fully connected graph structure. They pre-structure the graph into bipartite graphs (only connections between phrases with known translation and OOV phrases) and tripartite graphs (connections can also go from a known phrasal node to an OOV phrasal node through one node that is a paraphrase of both but does not have translations, i.e. it is an unlabeled node). In these pre-structured graphs there are no connections between nodes of the same type (known, OOV or unlabeled). We apply this method in our low resource setting experiments (Sec. 5.3) to compare our bipartite and tripartite results to Razmara et al. (2013). In the rest of the experiments we use the tripartite approach since it outperforms the bipartite approach.

4.2.2 Graph random walks

Our goal is to limit the number of hops in the propagation of translation candidates preferring closely connected and highly probable edge weights. Optimization for the Modified Adsorption (MAD) objective function in Sec. 3.2 can be viewed as a controlled random walk (Talukdar et al., 2008; Talukdar and Crammer, 2009). This is formalized as three actions: *inject*, *continue* and *abandon* with corresponding pre-defined probabilities P_{inj}, P_{cont} and P_{abnd} respectively as in (Talukdar and Crammer, 2009). A random walk through the graph will transfer labels from one node to another node, and probabilities P_{cont} and P_{abnd} control exploration of the graph. By reducing the values of P_{cont} and increasing P_{abnd} we can control the label propagation process to optimize the quality of translations for OOV phrases. Again, this is done on a held-out development set and not on the test data. The optimal values in our experiments for these probabilities are $P_{inj} = 0.9, P_{cont} = 0.001, P_{abnd} = 0.01$.

4.2.3 Early stopping of propagation

In Modified Adsorption (MAD) (see Sec. 3.2) nodes in the graph that are closely linked will tend to similar label distributions as the number of iterations increase (even when the path lengths increase). In our setting, smoothing the label distribution helps in the first few iterations, but is harmful as the number of iterations increase due to the factors shown in Fig. 4. We use *early stopping* which limits the number of iterations. We varied the number of iterations from 1 to 10 on a held-out dev set and found that 5 iterations was optimal.

5 Evaluation

We first show the effect of OOVs on translation quality, then evaluate our approach in three different SMT settings: low resource SMT, domain shift, and morphologically complex languages. In each case, we compare results of using paraphrases extracted by Distributional Profile (DP) and PPDB in an end-to-end SMT system.
Important: no subset of the test data sentences are used in the bilingual corpora for paraphrase extraction process.

5.1 Experimental Setup

We use CDEC[1] (Dyer et al., 2010) as an end-to-end SMT pipeline with its standard features[2]. `fast_align` (Dyer et al., 2013) is used for word alignment, and weights are tuned by minimizing BLEU loss on the dev set using MIRA (Crammer and Singer, 2003). This setup is used for most of our experiments: oracle (Sec. 5.2), domain adaptation (Sec. 5.4) and morphologically complex languages (Sec. 5.5). But as we wish to fairly compare our approach with Razmara et al. (2013) on low resource setting, we follow their setup in Sec. 5.3: Moses (Koehn et al., 2007) as SMT pipeline, GIZA++ (Och and Ney, 2003) for word alignment and MERT (Och, 2003) for tuning. We add our own feature to the SMT log-linear model as described in Sec. 3.3.

Experiments	OOV type/token	Rules added
Case 1	1830 / 2163	7.0K
Case 2 - Med.	2294 / 4190	7.8K
Case 2 - Sci.	5272 / 14121	10.4K
Case 3	1543 / 1895	8.1K

Table 2: Statistics of settings in Sec. 5. Last column shows how many rules added in the phrase table integration step.

KenLM (Heafield, 2011) is used to train a 5-gram language model on English Gigaword (V5: LDC2011T07). For scalable graph propagation we use the Junto framework[3]. We use maximum phrase length 10. For our experiments we use the Hadoop distributed computing framework executed on a cluster with 12 nodes (each node has 8 cores and 16GB of RAM). Each graph propagation iteration takes about 3 minutes.

For French, we apply a simple heuristic to detect named entities: words that are capitalized in the original dev/test set that do not appear at the beginning of a sentence are named entities. Based on eyeballing the results, this works very well in our data. For Arabic, AQMAR is used to exclude named-entities (Mohit et al., 2012). For each of the experimental settings below we show the OOV statistics in Table 2.

5.2 Impact of OOVs: Oracle experiment

This oracle experiment shows that translation of OOVs beyond named entities, dates, etc. is potentially very useful in improving output translation. We trained a SMT system on 10K French-English sentences from the Europarl corpus(v7) (Koehn, 2005). WMT 2011 and WMT 2012 are used as dev and test data respectively. Table 4 shows the results in terms of BLEU on dev and test. The first row is baseline which simply copies OOVs to output. The second and third rows show the result of augmenting phrase-table by adding translations for single-word OOVs and phrases containing OOVs. The last row shows the oracle result where dev and test sentences exist inside the training data and all the OOVs are known (Fully observers cannot avoid model and search errors).

5.3 Case 1: Limited Parallel Data

In this experiment we use a setup similar to (Razmara et al., 2013). To have fair comparison, we use 10K French-English parallel sentences, randomly chosen from Europarl to train translation system, as reported in (Razmara et al., 2013). ACL/WMT 2005[4] is used for dev and test data. We re-implement their paraphrase extraction method (DP) to extract paraphrases from French side of Europarl (2M sentences). We use unigram nodes to construct graphs for both DP and PPDB. In bipartite graphs, each node is connected to at most 20 nodes. For tripartite graphs, each node is connected to 15 labeled and 5 unlabeled nodes.

Fr-En	Dev	Test
Baseline	27.90	28.08
+ Lexical OOV	28.10	28.31
+ Phrasal OOV	28.50	28.85
Fully observed	46.88	49.21

Table 4: The impact of translating OOVs.

For intrinsic evaluation, we use Mean-Reciprocal-Rank (MRR) and Recall. MRR is the mean of reciprocal rank of the candidate list compared to the gold list (Eqn. 5). Recall shows percentage of gold list covered by the candidate list (Eqn. 6). Gold translations for OOVs are given by concatenating the test data to training and running a word aligner.

$$\text{MRR} = \frac{1}{|O|}\sum_{i=1}^{|O|}\frac{1}{rank_i} \text{ for } O = \{\text{OOVs}\} \quad (5)$$

$$\text{Recall} = \frac{|\{\text{gold list}\} \cap \{\text{candidate list}\}|}{|\{\text{gold list}\}|} \quad (6)$$

Table 5 compares DP and PPDB in terms of BLEU, MRR and Recall. It indicates that PPDB (large size) outperforms DP in both intrinsic and extrinsic evaluation measures. Although tripartite graph did not improve the results for DP, it results in statistically significantly better BLEU score for PPDB in comparison to DP (evaluated by MultEval (Clark et al., 2011)). Thus we use tripartite graph in the rest of experiments. The last row in the table shows the result of combining DP and PPDB by multiplying the normalized scores of both paraphrase lists.

This setting is included for three reasons: 1) we exploit the small data size to explore different choices in our approach such as, e.g. choosing bipartite versus tripartite graph structures; 2)

Table 3: Examples comparing DP versus PPDB outputs on the test sets. NNs refer to nearest neighbours in the graph for OOV phrase. Each row respectively corresponds to experimental settings (cases 1 to 3).

System	MRR	Recall	BLEU
baseline	-	-	28.89
DP-bipartite	5.34	11.90	29.27
DP-tripartite	5.34	11.95	29.27
PPDB_{fr} (L)-bipartite	**12.05**	22.08	29.46
PPDB_{fr} (L)-tripartite	10.22	**22.87**	**29.52**
Combined-tripartite	-	-	29.28

Table 5: Results of PPDB and DP techniques.

to show how well our PPDB approach does compared to the DP approach in terms of MRR and recall; and 3) to show applicability of our approach for a low-resource language. However we used French instead of a language which is truly resource-poor due to the lack of available paraphrases for a true resource poor language, e.g. Malagasy.

5.4 Case 2: Domain Adaptation

Domain adaptation is another case that suffers from massive number of OOVs. We compare our approach with Marginal Matching (Irvine et al., 2013), a state of the art approach in SMT domain adaptation. We use their setup and data and compare our results to their reported results (Irvine et al., 2013). 250K lines of Hansard parliamentary proceeding are used for training MT. Dev and test sets are available for two different domains: Medical and Science domains. For medical domain random subset of EMEA corpus (Tiedemann, 2009) and for the science domain a corpus of scientific articles (Carpuat et al., 2012) has been used. Unigram paraphrases using DP are extracted from French side of Europarl.

Table 6 compares the results in terms of BLEU score. In both medical and science domains, graph-propagation approach using PPDB (large) performs significantly better than DP ($p < 0.02$), and has comparable results to Marginal Matching.

Systems	Science	Medical
baseline	22.20	25.32
DP-tripartite	22.76	25.81
PPDB_{fr} (L)-tripartite	22.97	**27.11**
Marginal Matching	**23.62**	26.97

Table 6: BLEU scores for domain adaptation.

Systems	BLEU
baseline	29.59
DP-tripartite	30.08
$\text{PPDB}_{\text{arabic}}$ (L)-tripartite	**31.12**

Table 7: BLEU score results for Arabic-English.

Marginal Matching performs better in science domain but graph-propagation approach with PPDB outperforms it in medical domain getting a $+1.79$ BLEU score improvement over the baseline.

5.5 Case 3: Morphologically Rich Languages

Both Distribution Profiling and Bilingual Pivoting propose morphological variants of a word as paraphrase pairs. Even more so in PPDB due to pivoting over English. We choose Arabic-English task for this experiment. We train the SMT system on 685K sentence pairs (randomly selected from LDC2007T08 and LDC2008T09) and use NIST OpenMT 2012 for dev and test data. Arabic side of 1M sentences of LDC2007T08 and LDC2008T09 is used to extract unigram paraphrases for DP. Table 7 shows that PPDB (large; with phrases) resulted in $+1.53$ BLEU score improvement over DP which only slightly improved over baseline.

6 Related Work

Sentence level paraphrasing has been used for generating alternative reference translations (Madnani et al., 2007; Kauchak and Barzilay, 2006), or augmenting the training data with sentential para-

phrases (Bond et al., 2008; Nakov, 2008; Mirkin et al., 2009). Phrase level paraphrasing was done using crowdsourcing (Resnik et al., 2010) or by using paraphrases in lattice decoding (Onishi et al., 2010; Du et al., 2010).

Daumé and Jagarlamudi (2011) apply a generative model to domain adaptation based on canonical correlation analysis Haghighi et al. (2008). However, they use artificially created monolingual corpora very related to the same domain as test data. Irvine and Callison-Burch (2014a) generate a large, noisy phrase table by composing unigram translations which are obtained by a supervised method (Irvine and Callison-Burch, 2013). Comparable monolingual data is used to re-score and filter the phrase table. Zhang and Zong (2013) use a large manually generated lexicon for domain adaptation. In contrast to these methods, our method is unsupervised.

Alexandrescu and Kirchhoff (2009) use a graph-based semi-supervised model determine similarities between sentences, then use it to rerank the n-best translation hypothesis. Liu et al. (2012) extend this model to derive some features to be used during decoding. These approaches are orthogonal to our approach. Saluja et al. (2014) use Structured Label Propagation (Liu et al., 2012) in two parallel graphs constructed on source and target paraphrases. In their case the graph construction is extremely expensive. Leveraging a morphological analyzer, they reach significant improvement on Arabic. We can not directly compare our results to (Saluja et al., 2014) because they exploit several external resources such as a morphological analyzer and also had different sizes of training and test. In experiments (Sec. 5) we obtained comparable BLEU score improvement on Arabic-English by using bilingual pivoting only on source phrases. (Saluja et al., 2014) also use methods similar to (Habash, 2008) that expand the phrase table with spelling and morphological variants of OOVs in test data. We do not use the dev/test data to augment the phrase table.

Using comparable corpora to extract parallel sentences and phrases (Munteanu and Marcu, 2006; Smith et al., 2010; Tamura et al., 2012) are orthogonal to the approach we discuss here.

Bilingual and multilingual word and phrase representation using neural networks have been applied to machine translation (Zou et al., 2013; Mikolov et al., 2013a; Zhang et al., 2014). However, most of these methods focus on frequent words or an available bilingual phrase table (Zou et al., 2013; Zhang et al., 2014; Gao et al., 2014). Mikolov et al. (2013a) learn a global linear projection from source to target using representation of frequent words on both sides. This model can be used to generate translations for new words, but a large amounts of bilingual data is required to create such a model. (Mikolov et al., 2013b) also uses bilingual data to project new translation rules. Zhao et al. (2015) extend Mikolov's model to learn one local linear projection for each phrase. Their model reaches comparable results to Saluja et al. (2014) while works faster. Alkhouli et al. (2014) use neural network phrase representation for paraphrasing OOVs and find translation for them using a phrase-table created from limited parallel data. Our experimental settings is different from the approaches in (Alkhouli et al., 2014; Mikolov et al., 2013a; Mikolov et al., 2013b).

7 Conclusion and Future work

In future work, we would like to include translations for infrequent phrases which are not OOVs. We would like to explore new propagation methods that can directly use confidence estimates and control propagation based on label sparsity. We also would like to expand this work for morphologically rich languages by exploiting other resources like morphological analyzer and campare our approach to the current state of art approaches which are using these types of resources. In conclusion, we have shown significant improvements to the quality of statistical machine translation in three different cases: low resource SMT, domain shift, and morphologically complex languages. Through the use of semi-supervised graph propagation, a large scale multilingual paraphrase database can be used to improve the quality of statistical machine translation.

Acknowledgments

The authors would like to thank Chris Callison-Burch and Juri Ganitkevitch for providing us the latest version of PPDB, the anonymous reviewers for their comments. The research was supported by the Natural Sciences and Engineering Research Council of Canada (NSERC RGPIN 262313 and RGPAS 446348) to the last author.

xingwsuda@gmail.com, {dyxiong, minzhang}@suda.edu.cn

Abstract

In hierarchical phrase-based translation, coarse-grained nonterminal Xs may generate inappropriate translations due to the lack of sufficient information for phrasal substitution. In this paper we propose a framework to refine nonterminals in hierarchical translation rules with real-valued semantic representations. The semantic representations are learned via a weighted mean value and a minimum distance method using phrase vector representations obtained from large scale monolingual corpus. Based on the learned semantic vectors, we build a semantic nonterminal refinement model to measure semantic similarities between phrasal substitutions and nonterminal Xs in translation rules. Experiment results on Chinese-English translation show that the proposed model significantly improves translation quality on NIST test sets.

1 Introduction

Hierarchical phrase-based translation (Chiang, 2007) explores formal synchronous context free grammar (SCFG) rules for translation. Two types of nonterminal symbols are used in translation rules: nonterminal X in ordinary SCFG rules and nonterminal S in glue rules that are specially introduced to concatenate nonterminal Xs in a monotonic manner. The same generic symbol X for all ordinary nonterminals makes it difficult to distinguish and select proper translation rules.

In order to address this issue, researchers either use syntactic labels to annotate nonterminal Xs (Zollmann and Venugopal, 2006; Zollmann and Vogel, 2011; Li et al., 2012; Hanneman and Lavie, 2013), or employ syntactic information from parse trees to refine nonterminals with real-valued vectors (Venugopal et al., 2009; Huang et al., 2013). In addition to syntactic knowledge, semantic structures are also leveraged to refine nonterminals (Gao and Vogel, 2011). All these efforts focus on incorporating linguistic knowledge into hierarchical translation rules.

Unfortunately, syntactic or semantic parsers for many languages are not accessible due to the lack of labeled training data. In contrast, a large amount of unlabeled data are easily available. Therefore, can we mine syntactic or semantic properties for nonterminals from unlabeled data? Or can we exploit these data to refine nonterminals for SMT?

Learning semantic representations for terminals (words, multi-word phrases or sentences) from unlabeled data has achieved substantial progress in recent years (Mitchell and Lapata, 2008; Turian et al., 2010; Socher et al., 2010; Mikolov et al., 2013c; Blunsom et al., 2014). These representations have been used successfully in various NLP tasks. However, there is no attempt to learn semantic representations for nonterminals from unlabeled data. In this paper we propose a framework to learn semantic representations for nonterminal Xs in translation rules. Our framework is established on the basis of real-valued vector representations learned for multi-word phrases, which are substituted with nonterminal Xs during hierarchical rule extraction. We propose a weighted mean value and a minimum distance method to obtain nonterminal representations from representations of their phrasal substitutions. We further build a semantic nonterminal refinement model with semantic representations of nonterminals to compute similarities between phrasal substitutions and nonterminals. In doing so, we want to enhance phrasal substitution and translation rule selection during decoding.

The big challenge here is that thousands of tar-

Lisbon, Portugal, 17-21 September 2015.

get phrasal substitutions will be generated for one single nonterminal during decoding. Computing vector representations for all these phrases will be very time-consuming. We therefore introduce two different methods to handle it. In the first method, we project representations of source phrases onto their target counterparts linearly/nonlinearly via a neural network. These projected vectors are used as approximations to real target representations to compute semantic similarities. In the second method, we decode sentences in two passes. The first pass collects target phrase candidates from n-best translations of sentences generated by the baseline. The second pass calculates vector representations of these collected target phrases and then computes similarities between them and target-side nonterminals.

Our contributions are two-fold. First, we learn semantic representations for nonterminals from their phrasal substitutions with two different methods. This is the first time, to the best of our knowledge, to induce semantic representations for nonterminals from unlabeled data in the context of SMT. Second, we successfully address the issue of time-consuming target-side phrase-nonterminal similarity computation mentioned above. We incorporate both source-/target-side semantic nonterminal refinement model and their combination based on learned nonterminal representations into translation system. Experiment results show that our method can achieve an improvement of 1.16 BLEU points over the baseline system on NIST MT evaluation test sets.

The rest of this paper is organized as follows. Section 2 briefly reviews related work. Section 3 presents our approach of learning semantic vectors for nonterminals, followed by Section 4 describing the details of our semantic nonterminal refinement model. Section 5 introduces the integration of the proposed model into SMT. Experiment results are reported in Section 6. Finally, we conclude our work in Section 7.

2 Related Work

A variety of approaches have been explored for nonterminal refinement in hierarchical phrase-based translation. These approaches can be categorized into two groups: 1) augmenting the nonterminal symbol X with informative labels, and 2) attaching distributional linguistic knowledge to each nonterminal in hierarchical rules. The former only allows substitution operations with matched labels. The latter normally builds an additional model as a new feature of the log-linear model to incorporate attached knowledge.

Among approaches which directly refine the single label to more fine-grained labels, syntactic and semantic knowledge are explored in various ways. The syntactically augmented translation model (SAMT) proposed by Zollmann and Venugopal (2006) uses syntactic categories extracted from target-side parse trees to augment nonterminals in hierarchical rules. Unfortunately, there is a data sparseness problem in this model due to thousands of extracted syntactic categories. One solution to address this issue is to reduce the number of syntactic categories. Zollmann and Vogel (2011) use word tags, generated by either POS tagger or unsupervised word class induction, instead of syntactic categories. Hanneman and Lavie (2013) coarsen the label set by introducing a label collapsing algorithm to SAMT grammars (Zollmann and Venugopal, 2006). Yet another solution is easing restrictions on label matching. Shen et al. (2009) penalize substitution with unmatched labels while Chiang (2010) uses soft match features to model substitutions with various labels. Similar to Zollmann and Venugopal (2006), Hoang and Koehn (2010) decorate some hierarchical rules with source-side syntax information and use undecorated, decorated, and partially decorated rules in their translation model. Mylonakis and Sima'an (2011) employ source-side syntax-based labels to define a joint probability synchronous grammar. Combinatory Categorial Grammar (CCG) labels or CCG contextual labels are also used to enrich nonterminals (Almaghout et al., 2011; Weese et al., 2012). Li et al. (2012) incorporate head information extracted from source-side dependency structures into translation rules. Besides, semantic knowledge is also used to refine nonterminals. Gao and Vogel (2011) utilize target-side semantic roles to form SRL-aware SCFG rules. Most of approaches introduced here explicitly require syntactic or semantic parsers trained on manually labeled data.

On the other hand, efforts have also been directed towards attaching distributional linguistic knowledge to nonterminals. Venugopal et al. (2009) propose a preference grammar to annotate nonterminals based on preference distributions of syntactic categories. Huang et al. (2010) learn la-

tent syntactic distributions for each nonterminal. They use these distributions to decorate nonterminal Xs in SCFG rules with a real-valued feature vectors and utilize these vectors to measure the similarities between source phrases and applied rules. Similar to this work, Huang et al. (2013) utilize treebank tags based on dependency parsing to learn latent distributions. Cao et al. (2014) attach translation rules with dependency knowledge, which contains both dependency relations inside rules and dependency relations between rules and their contexts.

The difference of our work from these studies is that our semantic representations are learned from unlabeled bilingual (or monolingual) data and do not depend on any linguistic resources, e.g., parsers. We also believe that our model is able to exploit both syntactic and semantic information for nonterminals since vector representations learned in our way are able to capture both syntactic and semantic properties (Turian et al., 2010; Socher et al., 2010).

3 Learning Semantic Representations for Nonterminals

In our framework, semantic representations for nonterminal Xs are automatically induced from word-aligned parallel corpus. In this section, we detail the essential component of our approach, i.e., how to learn semantic vectors for nonterminals and how to project source semantic vectors onto target language semantic space. Before discussing nonterminal representations, we briefly introduce vector representations for words and phrases.

3.1 Prerequisite: Learning Words and Phrases Representations

We employ a neural method, specifically the continuous bag-of-words model (Mikolov et al., 2013a) to learn high-quality vector representations for words. Once we complete the training of the continuous bag-of-words model, word embeddings form an embedding matrix $M \in \mathbb{R}^{d \times |V|}$, where d is a pre-determined embedding dimensionality and each word w in the vocabulary V corresponds to a vector $\vec{v} \in \mathbb{R}^d$. Given the embedding matrix M, mapping words to vectors can be done by simply looking up their respective columns in M.

We further feed these learned word embeddings to recursive autoencoders (RAE) (Socher et al., 2011) for learning phrase representations. In traditional RAE (shown in Figure 1), given two input children representation vectors $\vec{c_1} \in \mathbb{R}^d$ and $\vec{c_2} \in \mathbb{R}^d$, their parent representation $\vec{p}$ can be calculated as follows:

$$\vec{p} = f^{(1)}(W^{(1)}[\vec{c_1}; \vec{c_2}] + b^{(1)}) \quad (1)$$

where $[\vec{c_1}; \vec{c_2}] \in \mathbb{R}^{2d}$ is the concatenation of vectors of two children, $W^{(1)} \in \mathbb{R}^{d \times 2d}$ is a weight matrix, $b^{(1)} \in \mathbb{R}^d$ is a bias term, and $f^{(1)}$ is an element-wise activation function such as $tanh$. The above output representation $\vec{p}$ can be used as a child vector to construct the representation for a larger subphrase. This process is repeated until a binary tree covering the whole input phrase is generated.

In order to evaluate how well the parent vector represents its children, we can reconstruct the children in a reconstruction layer:

$$[\vec{c_1}'; \vec{c_2}'] = f^{(2)}(W^{(2)}\vec{p} + b^{(2)}) \quad (2)$$

where $\vec{c_1}'$ and $\vec{c_2}'$ are the reconstructed children, $W^{(2)}$ is a weight matrix for reconstruction, $b^{(2)}$ is a bias term for reconstruction, and $f^{(2)}$ is an element-wise activation function.

For each node in the generated binary tree, we compute Euclidean distance between the original input vectors and the reconstructed vectors to measure the reconstruction error:

$$E_{rec}([\vec{c_1}; \vec{c_2}]) = \frac{1}{2}\|[\vec{c_1}; \vec{c_2}] - [\vec{c_1}'; \vec{c_2}']\|^2 \quad (3)$$

By minimizing the total reconstruction error over all nonterminal nodes, we can learn parameters of RAE.

Socher et al. (2011) propose a greedy unsupervised RAE as an extension to the above traditional RAE. The main difference is that in the unsupervised RAE there is no tree structure which is given for traditional RAE. It can learn both representations and tree structures of phrases or sentences. In this work, we adopt the unsupervised RAE to learn vector representations for phrases.

3.2 Inducing Nonterminal Representations from Phrase Representations

As we extract hierarchical rules from phrases by replacing subphrases with nonterminal symbols, a nonterminal X is generalized from a number of

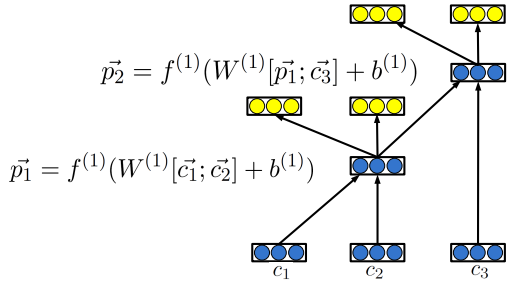

Figure 1: The architecture of a recursive autoencoder, adapted from (Socher et al., 2011). Blue nodes are original vectors and yellow nodes are reconstructed vectors which are used to compute reconstruction errors.

subphrases. We believe that these subphrases determine syntactic and semantic properties of the nonterminal X. We therefore enrich each nonterminal X with a semantic vector induced from vector representations of phrases that are replaced by the nonterminal during rule extraction.

For an SCFG rule, we can learn semantic vectors for nonterminals on both the source and target side. Due to the space limitation, we introduce the procedure of learning nonterminal vectors on the source side. Semantic vectors on the target side can be learned analogically.

For each source-side nonterminal X of a hierarchical rule, we collect all source subphrases replaced by X in a source subphrase set $P = \{p_1, p_2, \cdots, p_m\}$. We also count the number of times of these phrases being replaced by nonterminal X on training data during rule extraction. We collect these numbers in a count set $C = \{c_1, c_2, \cdots, c_m\}$. Based on the phrase set P, count set C and learned phrase vector representations in P, we can compute a semantic vector $\vec{v_x}$ for nonterminal X in each SCFG rule.

We propose two general approaches to obtain semantic vectors for nonterminals: a weighted mean value method and a minimum distance method. Given phrase vector representations $\vec{P_r} = \{\vec{p_1}, \vec{p_2}, \ldots, \vec{p_m}\}$, we calculate the semantic vector for a nonterminal generalized from these phrases as follows.

Weighted mean value method (MV) computes semantic vector $\vec{v_x}$ as:

$$\vec{v_x} = \frac{\sum_{i=1}^{m} c_i \cdot \vec{p_i}}{\sum_{i=1}^{m} c_i} \quad (4)$$

Minimum distance method (MD) finds a point in semantic space to minimize the sum of Euclidean distances of vectors in $\vec{P_r}$ to this point. Formally,

$$\vec{v_x} = \underset{\vec{v_x}}{\operatorname{argmin}} \sum_{i=1}^{m} \sqrt{\sum_{j=1}^{d} (p_{ij} - v_{xj})^2} \quad (5)$$

We use the stochastic gradient descent algorithm to find the minimal distance and the point $\vec{v_x}$. The component v_{xj} can be updated by $v_{xj} \leftarrow v_{xj} + \lambda \frac{\partial f}{\partial v_{xj}}$ where f is $\sum_{i=1}^{m} \sqrt{\sum_{j=1}^{d} (p_{ij} - v_{xj})^2}$ and λ is the learning rate.

Similar to the center of gravity, the semantic vector $\vec{v_x}$ learned by this method acts as a semantic centroid for all vectors of phrases that are substituted by X. Nonterminals in different hierarchical translation rules will have different semantic centroids. These centroids will help translation model capture semantic diversity to a certain degree.

3.3 Mapping Source-Side Representations onto Target-Side Semantic Space

As we discussed in Section 1, directly learning vector representations for target phrases is very costly in practice. Inspired by Mikolov et al. (2013b), we adopt vector projection to alleviate this problem. Different from mapping representations from the source side to the target side by learning a linear matrix on word alignments (Mikolov et al., 2013b), we project source multiword phrase representations onto the target semantic space in a nonlinear manner as we believe that nonlinear relations between languages are more reasonable. Specifically, we use a neural network to achieve this goal. Our neural network is a multilayer feed-forward neural network with one hidden layer. The functional form can be written in the following equation:

$$\vec{p} = \tanh(W^{(4)}(\tanh(W^{(3)} s\vec{r}c) + b^{(3)}) + b^{(4)}) \quad (6)$$

where $s\vec{r}c$ is the input vector which is learned in the source semantic space, $W^{(3)}$ denotes the weight matrix for connections between input and hidden neurons and $W^{(4)}$ denotes the weight matrix for links between hidden neurons and output, $b^{(3)}$ and $b^{(4)}$ are bias terms. To train the neural network, we optimize the following objective:

$$J = \underset{W^{(3)}, W^{(4)}}{\operatorname{argmin}} \frac{1}{N} \sum_{i=1}^{N} \|t\vec{r}g_i - \vec{p_i}\|^2 + R(\theta) \quad (7)$$

where N is the number of training examples, $\vec{trg}_i$ is the target vector representation for the ith example learned by RAE and $\vec{p}_i$ is the output of the neural network for the source vector representation $\vec{src}_i$ of ith example. $R(\theta)$ is the regularizer on parameters:

$$R(\theta) = \frac{\lambda_L}{2}\|W\|^2 \tag{8}$$

where W denotes parameters for parameter matrices $W^{(3)}$, $W^{(4)}$ and bias terms $b^{(3)}$, $b^{(4)}$.

4 Semantic Nonterminal Refinement Model

In this section, we describe our semantic nonterminal refinement model on the basis of induced real-valued semantic vectors for nonterminals.

4.1 Nonterminal Representations in Hierarchical Rules

We incorporate learned semantic representations of nonterminals into hierarchical rules. In particular, ordinary hierarchical rules take the following form:

$$X \rightarrow \langle aX_sb, cX_td \rangle \tag{9}$$

where *a*/*b*, *c*/*d* are strings of terminals on the source and target side, s and t are placeholders denoting the nonterminal X on the source or target side, X_s and X_t are aligned to each other.

Representations for nonterminals can be on either the source or target side. They are attached to hierarchical rules as follows:

$$X \rightarrow \langle aX_sb, cX_td, \vec{v_{xs}}, \vec{v_{xt}} \rangle \tag{10}$$

where $\vec{v_{x.}}$ is the source- or target-side semantic representation for nonterminal. In this way, we keep original translation rules intact and decorate nonterminals with their semantic representations.

4.2 The Model

The proposed semantic nonterminal refinement model estimates the semantic similarity between a phrase p and nonterminal X. The phrase p and nonterminal X will have a high similarity score in the representation space if they are semantically similar. The higher semantic similarity scores are, the more compatible nonterminals are with corresponding phrases.

There is another nonterminal S in glue rules, which are formalized as follows:

$$S \rightarrow \langle S_1X_2, S_1X_2 \rangle \tag{11}$$

$$S \rightarrow \langle X_1, X_1 \rangle \tag{12}$$

This nonterminal S is different from X. We therefore treat it as a special case in the computation of semantic similarity.

In this work, we explore two approaches to compute similarity: one based on cosine similarity and the other based on Euclidean distance.

Given a phrase vector representation $\vec{p}$ and nonterminal X semantic vector $\vec{v_x}$, **Cosine Similarity** (CS) is computed as:

$$cos(\vec{p}, \vec{v_x}) = \frac{\vec{p} \cdot \vec{v_x}}{\|\vec{p}\|\|\vec{v_x}\|} \tag{13}$$

We set α for the Cosine Similarity between the glue rule and its corresponding phrase as follows:

$$SeSim = \begin{cases} cos(\vec{p}, \vec{v_x}) & hierarchical\,rules \\ \alpha & glue\,rules \end{cases} \tag{14}$$

As for **Euclidean Distance** (ED), it is computed according to the following formula:

$$dist(\vec{p}, \vec{v_x}) = \sqrt{\sum_{i=1}^{d}(p_i - v_{xi})^2} \tag{15}$$

and similarly we set β for glue rules:

$$SeSim = \begin{cases} dist(\vec{p}, \vec{v_x}) & hierarchical\,rules \\ \beta & glue\,rules \end{cases} \tag{16}$$

5 Decoding

We incorporate the proposed model as a new feature into the hierarchical phrase-based translation system. Specifically, two features are added into the baseline system:

1. Source-side semantic similarity between source phrases and nonterminals
2. Target-side semantic similarity between target phrases and nonterminals

We compute source- and target-side similarities based on representations of nonterminals and phrasal substitutions for each applied rule, and sum up these similarities to calculate the total score of a derivation on the two features.

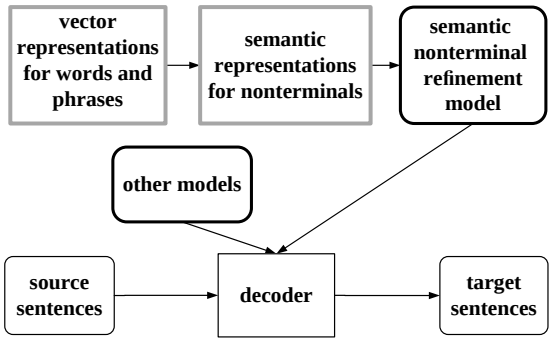

Figure 2: Architecture of SMT system with the proposed semantic nonterminal refinement model.

The integration of the source-side semantic nonterminal refinement model into the decoder is trivial. For the target-side model, however, we have to consider the efficiency issue as we mentioned in Section 1. We introduce two different methods to integrate the target-side model into the decoder: 1) projection and 2) two-pass decoding. In the first integration method, a mapping neural network is trained to map source phrase representations onto the target semantic space as described in Section 3.3. The projection can be linear if we remove the hidden layer in the projection neural network. This is similar to the mapping matrix learned by Mikolov et al. (2013b). We calculate semantic similarities between projected representations of phrases and those of nonterminals. In the two-pass decoding, we collect target phrase candidates from 100-best translations for each source sentence generated by the baseline in the first pass and learn vector representations for these target phrase candidates. Then in the second pass, we decode source sentence with our target semantic nonterminal refinement model using learned target phrase vector representations. If a target phrase appears in the collected set, the target-side semantic nonterminal refinement model will calculate the semantic similarity between the target phrase and the corresponding nonterminal on the target semantic space; otherwise the model will give a penalty. This is because this phrase is not a desirable phrase as it is not used in 100-best translations.

The weights of these two features are tuned by the Minimum Error Rate Training (MERT)(Och, 2003), together with weights of other sub-models on a development set. Figure 2 shows the architecture of SMT system with the proposed semantic nonterminal refinement model.

6 Experiment

In this section, we conducted a series of experiments on Chinese-to-English translation using large-scale bilingual training data, aiming at the following questions:

1. Which approach is better for learning nonterminal representations, weighted mean value or minimum distance?

2. Can the target-side semantic nonterminal refinement model improve translation quality? And which method is better for integrating the target-side semantic model into translation, projection or two-pass decoding?

3. Does the combination of source and target semantic nonterminal refinement models provide further improvement?

6.1 Setup

Our training corpus contains 2.9M sentence pairs with 80.9M Chinese words and 86.4M English words from LDC data[1]. We used NIST MT03 as our development set, NIST MT06 as our development test set and MT08 as our final test set.

We ran Giza++ on the training corpus in both Chinese-to-English and English-to-Chinese directions and applied the "grow-diag-final" refinement rule (Koehn et al., 2003) to obtain word alignments. We used the SRI Language Modeling Toolkit[2] (Stolcke and others, 2002) to train our language models. MERT (Och, 2003) was adopted to tune feature weights of the decoder. We used the case-insensitive BLEU[3] as our evaluation metric. In order to alleviate the instability of MERT , we followed Clark et al. (2011) to perform three runs of MERT and reported average BLEU scores over the three runs for all our experiments.

We used word2vec toolkit[4] to train our word embeddings and set the vector dimension d to 30. In our training experiment, we used the continuous bag-of-words model with a context window of size 5. The monolingual corpus, which was used to pre-train word embeddings, is extracted from

[1]The corpora include LDC2003E14, LDC2004T07, LDC2005T06, LDC2005T10 and LDC2004T08 (Hong Kong Hansards/Laws/News).

the above parallel corpus in SMT. To train vector representations for multi-word phrases, we randomly selected 1M bilingual sentences [5] as training set and used the unsupervised greedy RAE following (Socher et al., 2011). We used a learning rate of 10^{-3} for our minimum distance method that learned the centroid of phrase representations as the vector representation of the corresponding nonterminal.

For projection neural network in Section 3.3, we set 300 units for the hidden layer and dimensionality of 30 for both input and output vectors. Learning rate was set to 10^{-3} and the regularization coefficient λ_L was set to 10^{-3}. To construct the training set for the projection neural network, we selected phrase pairs from our rule table and used their representations on the source and target side as training examples. We randomly selected 5M examples as training set, 10k examples as development set and 10k examples as test set. The multi-layer projection neural network was trained with the back-propagation and stochastic gradient descent algorithm with a mini-batch size of 5k.

Our baseline system is an in-house hierarchical phrase-based system (Chiang, 2007). The features used in the baseline system includes a 4-gram language model trained on the Xinhua section of the English Gigaword corpus, a 3-gram language model trained on the target part of the bilingual training data, bidirectional translation probabilities, bidirectional lexical weights, a word count, a phrase count and a glue rule count.

In order to compare our proposed models with previous methods on nonterminal refinement, we re-implemented a syntax mismatch model (Syn-Mis) which was used by Huang et al. (2013) and integrated it into hierarchical phrase-based system. Syn-Mis model decorates each nonterminal with a distribution of head POS tags and uses this distribution to measure the degree of syntactic compatibility of translation rules with corresponding source spans. In order to obtain head POS tags for Syn-Mis model, we used the Stanford dependency parser [6] (Chang et al., 2009) to parse Chinese sentences in our training corpus and NIST development/test sets.

[5] We choose bilingual sentences because we want to obtain bilingual training examples to train our projection neural network as described in Section 3.3.

6.2 Different Approaches to Learn Vector Representations for Nonterminals

Our first group of experiments were carried out to investigate which approach is more appropriate to learn semantic vectors for nonterminals. We only used the source-side semantic nonterminal refinement model in these experiments. In order to validate the effectiveness of the proposed approaches for learning nonterminal semantic vectors, we combined the minimum distance method (MD) with the Euclidean Distance (ED) because both of them are distance-based, and combined the weighted mean value method (MV) with the Cosine Similarity model (CS) as they belong to vector-based approaches. We chose α = 1.0, 0, -1.0 and β = 0, 0.5, 1.0 for glue rules to study the impact of these parameters. We compared our model with the baseline and Syn-Mis model.

Results are shown in Table 1. From Table 1, we observe that the proposed two approaches are able to achieve significant improvements over the baseline. (MV + CS) and (MD + ED) achieve up to an absolute improvement of 1.09 and 0.81 (when α = 0 and β = 0.5) BLEU points respectively over the baseline on the development test set MT06. And the approach (MV + CS) with α = 0 outperforms Syn-Mis by 0.4 BLEU points on MT06 without using any syntactic information. The approach (MV + CS) achieves better performance and it is more efficient than (MD + ED) where the computation of semantic centroids is time-consuming. Therefore, we adopt the approach (MV + CS) with α = 0 to learn semantic vectors for nonterminals and compute semantic similarities in the following experiments.

	MT06	MT08	Avg
Baseline	30.54	23.58	27.06
Linear Projection	30.70	23.66	27.18
Nonlinear Projection	31.16	24.11*	27.64
Two-pass decoding	31.29+	24.24*	27.77

Table 2: Comparison of two-pass decoding, linear and nonlinear projection methods for integrating the target-side semantic nonterminal refinement model in terms of BLEU scores. "*" and "+" : significantly better than Baseline at significance level $p < 0.01$ and $p < 0.05$ respectively.

6.3 Effect of the Target Semantic Nonterminal Refinement Models

In the second set of experiments, we further validate the effectiveness of semantic nonterminal vectors learned on the target side. In these experiments, learning vector representations and computing semantic similarities were performed on the target language semantic space. We also compared the two integration methods discussed in Section 5 for the target-side model. With regard to the projection method, we further compared the linear projection (the projection neural network without hidden layer) with the nonlinear projection (with hidden layer). Experiment results are shown in Table 2.

From Table 2, we can see that

- Two-pass decoding achieves the highest BLEU scores, which are higher than those of the baseline by 0.75 and 0.66 BLEU points on MT06 and MT08 respectively. The reason may be that noisy translation candidates are filtered out in the first pass. This finding is consistent with many other multiple-pass systems in natural language processing, e.g., two-pass parsing (Zettlemoyer and Collins, 2007).

- Nonlinear projection achieves an improvement of 0.62 BLEU points over the baseline on MT06. It outperforms linear projection method on both sets. These empirical results support our assumption that nonlinear relations between languages are more reasonable than linear relations.

- The results prove that the target-side semantic nonterminal refinement model is also able to improve the baseline system, although the gain is less than that of the source-side counterpart.

	MT06	MT08	Avg
Baseline	30.54	23.58	27.06

Table 3: BLEU scores of the combination of the source- and target-side semantic nonterminal refine model. "*" and "+" : significantly better than Baseline at significance level $p < 0.01$ and $p < 0.05$ respectively.

6.4 Combination of the Source and Target Models

Finally, we integrated both the source- and target-side semantic nonterminal refinement models into the baseline system. In this experiment, we adopted nonlinear projection to obtain target semantic vector representations for target phrases. These two models collectively achieve a gain of up to 1.16 BLEU points over the baseline and 0.41 BLEU points over Syn-Mis model on average, which is shown in Table 3.

7 Conclusion

We have presented a framework to refine nonterminal X in hierarchical translation rules with semantic representations. The semantic vectors are derived from vector representations of phrasal substitutions, which are automatically learned using an unsupervised RAE. As the semantic nonterminal refinement model is capable of selecting more semantically similar translation rules, it achieves statistically significant improvements over the baseline on Chinese-to-English translation. Experiment results have shown that

- Using (MV + CS) approach to learn semantic representations for nonterminals can achieve better performance than (MD + ED) in terms of BLEU scores.

- Target-side semantic nonterminal refinement model is able to substantially improve translation quality over the baseline. Two-pass de-

coding method is superior to the projection method.

- The simultaneous incorporation of the source- and target-side models can achieve further improvements over a single-side model.

For the future work, we are interested in learning bilingual representations (Lauly et al., 2014; Gouws et al., 2014) for nonterminals. We also would like to extend our work by using more contextual lexical information to derive semantic vectors for nonterminals.

Abstract

We propose a conversion of bilingual sentence pairs and the corresponding word alignments into novel linear sequences. These are joint translation and reordering (JTR) uniquely defined sequences, combining interdepending lexical and alignment dependencies on the word level into a single framework. They are constructed in a simple manner while capturing multiple alignments and empty words. JTR sequences can be used to train a variety of models. We investigate the performances of n-gram models with modified Kneser-Ney smoothing, feed-forward and recurrent neural network architectures when estimated on JTR sequences, and compare them to the operation sequence model (Durrani et al., 2013b). Evaluations on the IWSLT German→English, WMT German→English and BOLT Chinese→English tasks show that JTR models improve state-of-the-art phrase-based systems by up to 2.2 BLEU.

1 Introduction

Standard phrase-based machine translation (Och et al., 1999; Zens et al., 2002; Koehn et al., 2003) uses relative frequencies of phrase pairs to estimate a translation model. The phrase table is extracted from a bilingual text aligned on the word level, using e.g. GIZA++ (Och and Ney, 2003). Although the phrase pairs capture internal dependencies between the source and target phrases aligned to each other, they fail to model dependencies that extend beyond phrase boundaries. Phrase-based decoding involves concatenating target phrases. The burden of ensuring that the result is linguistically consistent falls on the language model (LM).

This work proposes word-based translation models that are potentially capable of capturing long-range dependencies. We do this in two steps: First, given bilingual sentence pairs and the associated word alignments, we convert the information into uniquely defined linear sequences. These sequenecs encode both word reordering and translation information. Thus, they are referred to as *joint translation and reordering* (JTR) sequences. Second, we train an n-gram model with modified Kneser-Ney smoothing (Chen and Goodman, 1998) on the resulting JTR sequences. This yields a model that fuses interdepending reordering and translation dependencies into a single framework.

Although JTR n-gram models are closely related to the operation sequence model (OSM) (Durrani et al., 2013b), there are three main differences. To begin with, the OSM employs minimal translation units (MTUs), which are essentially atomic phrases. As the MTUs are extracted sentence-wise, a word can potentially appear in multiple MTUs. In order to avoid overlapping translation units, we define the JTR sequences on the level of words. Consequently, JTR sequences have smaller vocabulary sizes than OSM sequences and lead to models with less sparsity. Moreover, we argue that JTR sequences offer a simpler reordering approach than operation sequences, as they handle reorderings without the need to predict gaps. Finally, when used as an additional model in the log-linear framework of phrase-based decoding, an n-gram model trained on JTR sequences introduces only one single feature to be tuned, whereas the OSM additionally uses 4 supportive features (Durrani et al., 2013b). Experimental results confirm that this simplification does not make JTR models less expressive, as their performance is on par with the OSM.

Due to data sparsity, increasing the n-gram order of count-based models beyond a certain point becomes useless. To address this, we resort to neu-

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1401–1411,
Lisbon, Portugal, 17-21 September 2015.

ral networks (NNs), as they have been successfully applied to machine translation recently (Sundermeyer et al., 2014; Devlin et al., 2014). They are able to score any word combination without requiring additional smoothing techniques. We experiment with feed-forward and recurrent translation networks, benefiting from their smoothing capabilities. To this end, we split the linear sequence into two sequences for the neural translation models to operate on. This is possible due to the simplicity of the JTR sequence. We show that the count and NN models perform well on their own, and that combining them yields even better results.

In this work, we apply n-gram models with modified Kneser-Ney smoothing during phrase-based decoding and neural JTR models in rescoring. However, using a phrase-based system is not required by the model, but only the initial step to demonstrate the strength of JTR models, which can be applied independently of the underlying decoding framework. While the focus of this work is on the development and comparison of the models, the long-term goal is to decode using JTR models without the limitations introduced by phrases, in order to exploit the full potential of JTR models. The JTR models are estimated on word alignments, which we obtain using GIZA++ in this paper. The future aim is to also generate improved word alignments by a joint optimization of both the alignments and the models, similar to the training of IBM models (Brown et al., 1990; Brown et al., 1993). In the long run, we intend to achieve a consistency between decoding and training using the introduced JTR models.

2 Previous Work

In order to address the downsides of the phrase translation model, various approaches have been taken. Mariño et al. (2006) proposed a bilingual language model (BILM) that operates on bilingual n-grams, with an own n-gram decoder requiring monotone alignments. The lexical reordering model introduced in (Tillmann, 2004) was integrated into phrase-based decoding. Crego and Yvon (2010) adapted the approach to BILMs. The bilingual n-grams are further advanced in (Niehues et al., 2011), where they operate on non-monotone alignments within a phrase-based translation framework. Compared to our JTR models, their BILMs treat jointly aligned source words as minimal translation units, ignore unaligned source words and do not include reordering information.

Durrani et al. (2011) developed the OSM which combined dependencies on bilingual word pairs and reordering information into a single framework. It used an own decoder that was based on n-grams of MTUs and predicted single translation or reordering operations. This was further advanced in (Durrani et al., 2013a) by a decoder that was capable of predicting whole sequences of MTUs, similar to a phrase-based decoder. In (Durrani et al., 2013b), a slightly enhanced version of OSM was integrated into the log-linear framework of the Moses system (Koehn et al., 2007). Both the BILM (Stewart et al., 2014) and the OSM (Durrani et al., 2014) can be smoothed using word classes.

Guta et al. (2015) introduced the extended translation model (ETM), which operates on the word level and augments the IBM models by an additional bilingual word pair and a reordering operation. It is implemented into the log-linear framework of a phrase-based decoder and shown to be competitive with a 7-gram OSM.

The JTR n-gram models proposed within this work can be seen as an extension of the ETM. Nevertheless, JTR models utilize linear sequences of dependencies and combine the translation of bilingual word pairs and reoderings into a single model. The ETM, however, features separate models for the translation of individual words and reorderings and provides an explicit treatment of multiple alignments. As they operate on linear sequences, JTR count models can be implemented using existing toolkits for n-gram language models, e.g. the KenLM toolkit (Heafield et al., 2013).

An HMM approach for word-to-phrase alignments was presented in (Deng and Byrne, 2005), showing performance similar to IBM Model 4 on the task of bitext alignment. Feng et al. (2013) propose several models which rely only on the information provided by the source side and predict reorderings. Contrastingly, JTR models incorporate target information as well and predict both translations and reorderings jointly in a single framework.

Zhang et al. (2013) explore different Markov chain orderings for an n-gram model on MTUs in rescoring. Feng and Cohn (2013) present another generative word-based Markov chain translation model which exploits a hierarchical Pitman-Yor process for smoothing, but it is only applied to induce word alignments. Their follow-up work (Feng et al., 2014) introduces a Markov-model on

MTUs, similar to the OSM described above.

Recently, neural machine translation has emerged as an alternative to phrase-based decoding, where NNs are used as standalone models to decode source input. In (Sutskever et al., 2014), a recurrent NN was used to encode a source sequence, and output a target sentence once the source sentence was fully encoded in the network. The network did not have any explicit treatment of alignments. Bahdanau et al. (2015) introduced soft alignments as part of the network architecture. In this work, we make use of hard alignments instead, where we encode the alignments in the source and target sequences, requiring no modifications of existing feed-forward and recurrent NN architectures. Our feed-forward models are based on the architectures proposed in (Devlin et al., 2014), while the recurrent models are based on (Sundermeyer et al., 2014). Further recent research on applying NN models for extended context was carried out in (Le et al., 2012; Auli et al., 2013; Hu et al., 2014). All of these works focus on lexical context and ignore the reordering aspect covered in our work.

3 JTR Sequences

The core idea of this work is the interpretation of a bilingual sentence pair and its word alignment as a linear sequence of K joint translation and reordering (JTR) tokens g_1^K. Formally, the sequence $g_1^K(f_1^J, e_1^I, b_1^I)$ is a uniquely defined interpretation of a given source sentence f_1^J, its translation e_1^I and the inverted alignment b_1^I, where b_i denotes the ordered sequence of source positions j aligned to target position i. We drop the explicit mention of (f_1^J, e_1^I, b_1^I) to allow for a better readability. Each JTR token is either an aligned bilingual word pair $\langle f, e\rangle$ or a reordering class $\Delta_{j'j}$.

Unaligned words on the source and target side are processed as if they were aligned to the empty word ε. Hence, an unaligned source word f generates the token $\langle f, \varepsilon\rangle$, and an unaligned target word e the token $\langle \varepsilon, e\rangle$.

Each word of the source and target sentences is to appear in the corresponding JTR sequence exactly once. For multiply-aligned target words e, the first source word f that is aligned to e generates the token $\langle f, e\rangle$. All other source words f', that are also aligned to e, are processed as if they were aligned to the artificial word σ. Thus, each of these f' generates a token $\langle f', \sigma\rangle$. The same approach is applied to multiply-aligned source words. Similar to Feng and Cohn (2013), we classify the reordered source positions j' and j by $\Delta_{j'j}$:

$$\Delta_{j'j} = \begin{cases} \text{step backward } (\leftarrow), & j = j' - 1 \\ \text{jump forward } (\curvearrowright), & j > j' + 1 \\ \text{jump backward } (\curvearrowleft), & j < j' - 1. \end{cases}$$

The reordering classes are illustrated in Figure 1.

Figure 1: Overview of the different reordering classes in JTR sequences.

3.1 Sequence Conversion

Algorithm 1 presents the formal conversion of a bilingual sentence pair and its alignment into the corresponding JTR sequence g_1^K. At first, g_1^K is initialized by an empty sequence (line 2). For each target position $i = 1, \ldots, I$ it is extended by at least one token. During the generation process, we store the last visited source position j' (line 4). If a target word e_i is

- unaligned, we align it to the empty word ε and append $\langle \varepsilon, e_i \rangle$ to the current g_1^K (line 8),
- if it is aligned to the same f_j as e_{i-1}, we only add $\langle \sigma, e_i \rangle$ (line 14),
- otherwise we append $\langle f_j, e_i \rangle$ (line 20) and
- in case there are more source words aligned to e_i, we additionally append $\langle f_j, \sigma \rangle$ for each of these (line 24).

Before a token $\langle f_j, e_i \rangle$ is generated, we have to check whether the alignment step from j' to j is monotone (line 16). In case it is not, we have to deal with reorderings (line 34). We define that a token $\langle f_{j-1}, \varepsilon \rangle$ is to be generated right before the generation of the token containing f_j. Thus, if f_{j-1} is not aligned, we first determine the contiguous sequence of unaligned predecessors $f_{j_0}^{j-1}$ (line 38). Next, if the step from j' to j_0 is not monotone, we add the corresponding reordering class (line 43). Afterwards we append all $\langle f_{j_0}, \varepsilon \rangle$ to $\langle f_{j-1}, \varepsilon \rangle$. If f_{j-1} is aligned, we do not have to process unaligned source words and only append the corresponding reordering class (line 49).

Figure 2 illustrates the generation steps of a JTR sequence, whose result is presented in Table 1. The alignment steps are denoted by the arrows connecting the alignment points. The first dashed alignment point indicates the $\langle \varepsilon, , \rangle$ token that is generated right after the $\langle \texttt{Feld}, \texttt{field} \rangle$ token. The second dashed alignment point indicates the $\langle \texttt{ein}, \varepsilon \rangle$ token, which corresponds to the unaligned source word `ein`. Note, that the $\langle \texttt{ein}, \varepsilon \rangle$ token has to be generated right before $\langle ., . \rangle$ is generated. Therefore, there is no forward jump from $\langle \texttt{Code}, \texttt{code} \rangle$ to $\langle ., . \rangle$, but a monotone step to $\langle \texttt{ein}, \varepsilon \rangle$ followed by $\langle ., . \rangle$.

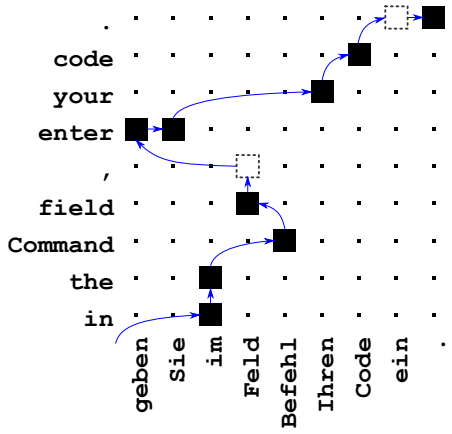

Figure 2: This example illustrates the JTR sequence g_1^K for a German→English sentence pair including the word-to-word alignment.

3.2 Training of Count Models

As the JTR sequence g_1^K is a unique interpretation of a bilingual sentence pair and its alignment, the probability $p(f_1^J, e_1^I, b_1^I)$ can be computed as:

$$p(f_1^J, e_1^I, b_1^I) = p(g_1^K). \tag{1}$$

The probability of g_1^K can be factorized and approximated by an n-gram model.

$$p(g_1^K) = \prod_{k=1}^{K} p(g_k | g_{k-n+1}^{k-1}) \tag{2}$$

Within this work, we first estimate the Viterbi alignment for the bilingual training data using GIZA++ (Och and Ney, 2003). Secondly, the conversion presented in Algorithm 1 is applied to obtain the JTR sequences, on which we estimate an n-gram model with modified Kneser-Ney smoothing as described in (Chen and Goodman, 1998) using the KenLM toolkit[1] (Heafield et al., 2013).

Table 1: The left side of this table presents the JTR tokens g_k corresponding to Figure 2. The right side shows the source and target tokens s_k and t_k obtained from the JTR tokens g_k. They are used for the training of NNs (cf. Section 4).

3.3 Integration into Phrase-based Decoding

Basically, each phrase table entry is annotated with both the word alignment information, which also allows to identify unaligned source words, and the corresponding JTR sequence. The JTR model is added to the log-linear framework as an additional n-gram model. Within the phrase-based decoder, we extend each search state such that it additionally stores the JTR model history.

In comparison to the OSM, the JTR model does not predict gaps. Local reorderings within phrases are handled implicitly. On the other hand, we represent long-range reorderings between phrases by the coverage vector and limit them by reordering constraints.

Phrase-pairs ending with unaligned source words at their right boundary prove to be a problem during decoding. As shown in Subsection 3.1, the conversion from word alignments to JTR sequences assumes that each token corresponding to an unaligned source word is generated immediately before the token corresponding to the closest aligned source position to its right. However, if a phrase ends with an unaligned f_j as its rightmost source word, the generation of the $\langle f_j, \varepsilon\rangle$ token has to be postponed until the next word f_{j+1} is to be translated or, even worse, f_{j+1} has already been translated before.

To address this issue, we constrained the phrase table extraction to discard entries with unaligned source tokens at the right boundary. For IWSLT De→En, this led to a baseline weaker by 0.2 BLEU than the one described in Section 5. In order to have an unconstrained and fair baseline, we thereafter removed this constraint and forced such deletion tokens to be generated at the end of the sequence. Hence, we accept that the JTR model might compute the wrong score in these special cases.

4 Neural Networks

Usually, smoothing techniques are applied to count-based models to handle unseen events. A neural network does not suffer from this, as it is able to score unseen events without additional smoothing techniques. In the following, we will describe how to adapt JTR sequences to be used with feed-forward and recurrent NNs.

The first thing to notice is the vocabulary size, mainly determined by the number of bilingual word pairs, which constituted atomic units in the count-based models. NNs that compute probability values at the output layer evaluate a softmax function that produces normalized scores that sum up to unity. The softmax function is given by:

$$p(e_i|e_1^{i-1}) = \frac{e^{o_{e_i}(e_1^{i-1})}}{\sum_{w=1}^{|V|} e^{o_w(e_1^{i-1})}} \quad (3)$$

where o_{e_i} and o_w are the raw unnormalized output layer values for the words e_i and w, respectively, and $|V|$ is the vocabulary size. The output layer is a function of the context e_1^{i-1}. Computing the denominator is expensive for large vocabularies, as it requires computing the output for all words. Therefore, we split JTR tokens g_k and use individual words as input and output units, such that the NN receives jumps, source and target words as input and outputs target words and jumps. Hence, the resulting neural model is not a LM, but a translation model with different input and output vocabularies. A JTR sequence g_1^K is split into its source and target parts s_1^K and t_1^K. The construction of the JTR source sequence s_1^K proceeds as follows: Whenever a bilingual pair is encountered, the source word is kept and the target word is discarded. In addition, all jump classes are replaced by a special token δ. The JTR target sequence t_1^K is constructed similarly by keeping the target words and dropping source words, and the jump classes are also kept. Table 1 shows the JTR source and target sequences corresponding to JTR sequence of Figure 2.

Due to the design of the JTR sequence, producing the source and target JTR sequences is straightforward. The resulting sequences can then be used with existing NN architectures, without further modifications to the design of the networks. This results in powerful models that require little effort to implement.

4.1 Feed-forward Neural JTR

First, we will apply a feed-forward NN (FFNN) to the JTR sequence. FFNN models resemble count-based models in using a predefined limited context size, but they do not encounter the same smoothing problems. In this work, we use a FFNN similar to that proposed in (Devlin et al., 2014), defined as:

$$p(t_1^K|s_1^K) \approx \prod_{k=1}^{K} p(t_k|t_{k-n}^{k-1}, s_{k-n}^{k}). \quad (4)$$

It scores the JTR target word t_k at position k using the current source word s_k, and the history of n JTR source words. In addition, the n JTR target words preceding t_k are used as context. The FFNN computes the score by looking up the vector embeddings of the source and target context words, concatenating them, then evaluating the rest of the network. We reduce the output layer to a shortlist of the most frequent words, and compute word class probabilities for the remaining words.

4.2 Recurrent Neural JTR

Unlike feed-forward NNs, recurrent NNs (RNNs) enable the use of unbounded context. Following (Sundermeyer et al., 2014), we use bidirectional recurrent NNs (BRNNs) to capture the full JTR source side. The BRNN uses the JTR target side as well as the full JTR source side as context, and it is given by:

$$p(t_1^K|s_1^K) = \prod_{k=1}^{K} p(t_k|t_1^{k-1}, s_1^K) \quad (5)$$

This equation is realized by a network that uses forward and backward recurrent layers to capture the complete source sentence. By a forward layer we imply a recurrent hidden layer that processes a given sequence from left to right, while a backward layer does the processing backwards, from right to left. The source sentence is basically split at a given position k, then past and future representations of the sentence are recursively computed by the forward and backward layers, respectively. To include the target side, we provide the forward layer with the target input t_{k-1} as well, that is, we aggregate the embeddings of the input source word s_k and the input target word t_{k-1} before they are fed into the forward layer. Due to recurrency, the forward layer encodes the parts (t_1^{k-1}, s_1^k), and the backward layer encodes s_k^K, and together they encode (t_1^{k-1}, s_1^K), which is used to score the output target word t_k. For the sake of comparison to FFNN and count models, we also experiment with a recurrent model that does not include future source information, this is obtained by replacing the term s_1^K with s_1^k in Eq. 5. It will be referred to as the unidirectional recurrent neural network (URNN) model in the experiments.

Note that the JTR source and target sides include jump information, therefore, the RNN model described above explicitly models reordering. In contrast, the models proposed in (Sundermeyer et al., 2014) do not include any jumps, and hence do not provide an explicit way of including word reordering. In addition, the JTR RNN models do not require the use of IBM-1 lexica to resolve multiply-aligned words. As discussed in Section 3, these cases are resolved by aligning the multiply-aligned word to the first word on the opposite side.

The integration of the NNs into the decoder is not trivial, due to the dependence on the target context. In the case of RNNs, the context is unbounded, which would affect state recombination, and lead to less variety in the beam used to prune the search space. Therefore, the RNN scores are computed using approximations instead (Auli et al., 2013; Alkhouli et al., 2015). In (Alkhouli et al., 2015), it is shown that approximate RNN integration into the phrase-based decoder has a slight advantage over n-best rescoring. Therefore, we apply RNNs in rescoring in this work, and to allow for a direct comparison between FFNNs and RNNs, we apply FFNNs in rescoring as well.

5 Evaluation

We perform experiments on the large-scale IWSLT 2013[2] (Cettolo et al., 2014) German→English, WMT 2015[3] German→English and the DARPA BOLT Chinese→English tasks. The statistics for the bilingual corpora are shown in Table 2. Word alignments are generated with the GIZA++ toolkit

(Och and Ney, 2003). We use a standard phrase-based translation system (Koehn et al., 2003). The decoding process is implemented as a beam search. All baselines contain phrasal and lexical smoothing models for both directions, word and phrase penalties, a distance-based reordering model, enhanced low frequency features (Chen et al., 2011), a hierarchical reordering model (HRM) (Galley and Manning, 2008), a word class LM (Wuebker et al., 2013) and an *n*-gram LM. The lexical and phrase translation models of all baseline systems are trained on all provided bilingual data. The log-linear feature weights are tuned with minimum error rate training (MERT) (Och, 2003) on BLEU (Papineni et al., 2001). All systems are evaluated with *MultEval* (Clark et al., 2011). The reported BLEU scores are averaged over three MERT optimization runs.

All LMs, OSMs and count-based JTR models are estimated with the KenLM toolkit (Heafield et al., 2013). The OSM and the count-based JTR model are implemented in the phrasal decoder. NNs are used only in rescoring. The 9-gram FFNNs are trained with two hidden layers. The short lists contain the 10k most frequent words, and all remaining words are clusterd into 1000 word classes. The projecton layer has 17×100 nodes, the first hidden layer 1000 and the second 500. The RNNs have LSTM architectures. The URNN has 2 hidden layers while the BRNN has one forward, one backward and one additional hidden layer. All layers have 200 nodes, while the output layer is class-factored using 2000 classes. For the count-based JTR model and OSM we tuned the *n*-gram size on the tuning set of each task. For the full data, 7-grams were used for the IWSLT and WMT tasks, and 8-grams for BOLT. When using in-domain data, smaller *n*-gram sizes were used. All rescoring experiments used 1000-best lists without duplicates.

5.1 Tasks description

The domain of IWSLT consists of lecture-type talks presented at TED conferences which are also available online[4]. All systems are optimized on the `dev2010` corpus, named `dev` here. Some of the OSM and JTR systems are trained on the TED portions of the data containing 138K sentences. To estimate the 4-gram LM, we additionally make use of parts of the Shuffled News, LDC English Gigaword and 10^9-French-English corpora, selected by a cross-entropy difference criterion (Moore and Lewis, 2010). In total, 1.7 billion running words are taken for LM training. The BOLT Chinese→English task is evaluated on the "discussion forum" domain. The 5-gram LM is trained on 2.9 billion running words in total. The in-domain data consists of a subset of 67.8K sentences and we used a set of 1845 sentences for tuning. The evaluation set `test1` contains 1844 and `test2` 1124 sentences. For the WMT task, we used the target side of the bilingual data and all monolingual data to train a pruned 5-gram LM on a total of 4.4 billion running words. We concatenated the `newstest2011` and `newstest2012` corpora for tuning the systems.

5.2 Results

We start with the IWSLT 2013 German→ English task, where we compare between the different JTR and OSM models. The results are shown in Table 3. When comparing the in-domain *n*-gram JTR model trained using Kneser-Ney smoothing (KN) to OSM, we observe that the *n*-gram KN JTR model improves the baseline by 1.4 BLEU on both `test` and `eval11`. The OSM model performs similarly, with a slight disadvantage on `eval11`. In comparison, the FFNN of Eq. (4) improves the baseline by 0.7–0.9 BLEU, compared to the slightly better 0.8–1.1 BLEU achieved by the URNN. The difference between the FFNN and the

Table 4: Results measured in BLEU for the BOLT Chinese→English task.

URNN is that the latter captures the unbounded source and target history that extends until the beginning of the sentences, giving it an advantage over the FFNN. The performance of the URNN can be improved by including the future part of the source sentence, as described in Eq. (5), resulting in the BRNN model. Next, we explore whether the models are additive. When rescoring the *n*-gram KN JTR output with the BRNN, an additional improvement of 0.6 BLEU is obtained. There are two reasons for this: The BRNN includes the future part of the source input when scoring target words. This information is not used by the KN model. Moreover, the BRNN is able to score word combinations unseen in training, while the KN model uses backing off to score unseen events.

When training the KN, FFNN, and OSM models on the full data, we observe less gains in comparison to in-domain data training. However, combining the KN models trained on in-domain and full data gives additional gains, which suggests that although the in-domain model is more adapted to the task, it still can gain from out-of-domain data. Adding the FFNN on top improves the combination. Note here that the FFNN sees the same information as the KN model, but the difference is that the NN operates on the word level rather than the word-pair level. Second, the FFNN is able to handle unseen sequences by design, without the need for the backing off workaround. The BRNN improves the combination more than the FFNN, as the model captures an unbounded source and target history in addition to an unbounded future source context. Combining the KN, FFNN and BRNN JTR models leads to an overall gain of 2.2 BLEU on both dev and test.

Next, we present the BOLT Chinese→English results, shown in Table 4. Comparing *n*-gram KN JTR and OSM trained on the in-domain data shows they perform equally well on test1, improving the baseline by 0.7 BLEU, with a slight advantage for the JTR model on test2. The feed-forward and the recurrent in-domain networks yield the same results in comparison to each other. Training the OSM and JTR models on the full data yields slightly worse results than in-domain training. However, combining the two types of training improves the results. This is shown when adding the in-domain KN JTR model on top of the model trained on full data, improving it by up to 0.4 BLEU. Rescoring with the feed-forward and the recurrent network improves this even further, supporting the previous observation that the *n*-gram KN JTR and NNs complement each other. The combination of the 4 models yields an overall improvement of 1.2–1.4 BLEU.

Finally, we compare KN JTR and OSM models on the WMT German→English task in Table 5. The two models perform almost similar to each other. The JTR model improves the baseline by up to 0.7 BLEU. Rescoring the KN JTR with the FFNN improves it by up to 0.3 BLEU leading to an overall improvement between 0.5 and 1.0 BLEU.

5.3 Analysis

To investigate the effect of including jump information in the JTR sequence, we trained a BRNN using jump classes and another excluding them. The BRNNs were used in rescoring. Below, we demonstrate the difference between the systems:

source: wir kommen später noch auf diese Leute zurück .
reference: We'll come back to these people later .
Hypothesis 1:
JTR source: wir kommen δ zurück δ später noch auf diese Leute δ .
JTR target: we come $\curvearrowright$ back $\curvearrowleft$ later σ to these people $\curvearrowright$.
Hypothesis 2:
JTR source: wir kommen später noch auf diese Leute zurück .
JTR target: we come later σ on these guys back .

Note the German verb "zurückkommen", which is split into "kommen" and "zurück". German places "kommen" at the second position and "zurück" towards the end of the sentence. Unlike German, the corresponding English phrase "come back" has the words adjacent to each other. We found that the system including jumps prefers the correct translation of the verb, as shown in Hypothesis 1 above. The system translates "kommen" to "come", jumps forward to "zurück", translates it to "back", then jumps back to continue translating the word "später". In contrast, the system that excludes jump classes is blind to this separation of words. It favors Hypothesis 2 which is a strictly monotone translation of the German sentence. This is also reflected by the BLEU scores, where we found the system including jump classes outperforming the one without by up to 0.8 BLEU.

6 Conclusion

We introduced a method that converts bilingual sentence pairs and their word alignments into joint translation and reordering (JTR) sequences. They combine interdepending lexical and alignment dependencies into a single framework. A main advantage of JTR sequences is that a variety of models can be trained on them. Here, we have estimated *n*-gram models with modified Kneser-Ney smoothing, FFNN and RNN architectures on JTR sequences.

We compared our count-based JTR model to the OSM, both used in phrase-based decoding, and showed that the JTR model performed at least as good as OSM, with a slight advantage for JTR. In comparison to the OSM, the JTR model operates on words, leading to a smaller vocabulary size. Moreover, it utilizes simpler reordering structures without gaps and only requires one log-linear feature to be tuned, whereas the OSM needs 5. Due to the flexibility of JTR sequences, we can apply them also to FFNNs and RNNs. Utilizing two count models and applying both networks in rescoring gains the overall highest improvement over the phrase-based system by up to 2.2 BLEU, on the German→English IWSLT task. The combination outperforms OSM by up to 1.2 BLEU on the BOLT Chinese→English tasks.

The JTR models are not dependent on the phrase-based framework, and one of the long-term goals is to perform standalone decoding with the JTR models independently of phrase-based systems. Without the limitations introduced by phrases, we believe that JTR models could perform even better. In addition, we aim to use JTR models to obtain the alignment, which would then be used to train the JTR models in an iterative manner, achieving consistency and hoping for improved models.

Effective Approaches to Attention-based Neural Machine Translation

Minh-Thang Luong **Hieu Pham** **Christopher D. Manning**
Computer Science Department, Stanford University, Stanford, CA 94305
{lmthang,hyhieu,manning}@stanford.edu

Abstract

An attentional mechanism has lately been used to improve neural machine translation (NMT) by selectively focusing on parts of the source sentence during translation. However, there has been little work exploring useful architectures for attention-based NMT. This paper examines two simple and effective classes of attentional mechanism: a *global* approach which always attends to all source words and a *local* one that only looks at a subset of source words at a time. We demonstrate the effectiveness of both approaches on the WMT translation tasks between English and German in both directions. With local attention, we achieve a significant gain of 5.0 BLEU points over non-attentional systems that already incorporate known techniques such as dropout. Our ensemble model using different attention architectures yields a new state-of-the-art result in the WMT'15 English to German translation task with 25.9 BLEU points, an improvement of 1.0 BLEU points over the existing best system backed by NMT and an n-gram reranker.[1]

1 Introduction

Neural Machine Translation (NMT) achieved state-of-the-art performances in large-scale translation tasks such as from English to French (Luong et al., 2015) and English to German (Jean et al., 2015). NMT is appealing since it requires minimal domain knowledge and is conceptually simple. The model by Luong et al. (2015) reads through all the source words until the end-of-sentence symbol <eos> is reached. It then starts emitting one target word at a time, as illustrated in Figure 1. NMT

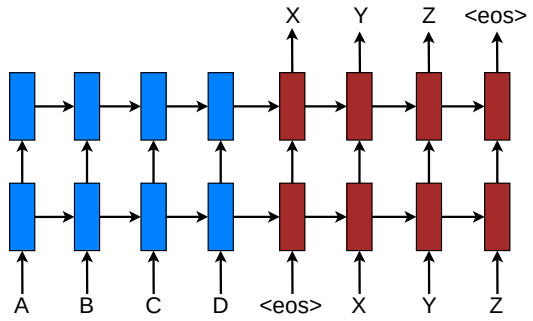

Figure 1: **Neural machine translation** – a stacking recurrent architecture for translating a source sequence A B C D into a target sequence X Y Z. Here, <eos> marks the end of a sentence.

is often a large neural network that is trained in an end-to-end fashion and has the ability to generalize well to very long word sequences. This means the model does not have to explicitly store gigantic phrase tables and language models as in the case of standard MT; hence, NMT has a small memory footprint. Lastly, implementing NMT decoders is easy unlike the highly intricate decoders in standard MT (Koehn et al., 2003).

In parallel, the concept of "attention" has gained popularity recently in training neural networks, allowing models to learn alignments between different modalities, e.g., between image objects and agent actions in the dynamic control problem (Mnih et al., 2014), between speech frames and text in the speech recognition task (Chorowski et al., 2014), or between visual features of a picture and its text description in the image caption generation task (Xu et al., 2015). In the context of NMT, Bahdanau et al. (2015) has successfully applied such attentional mechanism to jointly translate and align words. To the best of our knowledge, there has not been any other work exploring the use of attention-based architectures for NMT.

In this work, we design, with simplicity and effectiveness in mind, two novel types of attention-

[1] All our code and models are publicly available at http://nlp.stanford.edu/projects/nmt.

Proceedings of the 2015 Conference on Empirical Methods in Natural Language Processing, pages 1412–1421,
Lisbon, Portugal, 17-21 September 2015.

based models: a *global* approach in which all source words are attended and a *local* one whereby only a subset of source words are considered at a time. The former approach resembles the model of (Bahdanau et al., 2015) but is simpler architecturally. The latter can be viewed as an interesting blend between the *hard* and *soft* attention models proposed in (Xu et al., 2015): it is computationally less expensive than the global model or the soft attention; at the same time, unlike the hard attention, the local attention is differentiable, making it easier to implement and train.[2] Besides, we also examine various alignment functions for our attention-based models.

Experimentally, we demonstrate that both of our approaches are effective in the WMT translation tasks between English and German in both directions. Our attentional models yield a boost of up to 5.0 BLEU over non-attentional systems which already incorporate known techniques such as dropout. For English to German translation, we achieve new state-of-the-art (SOTA) results for both WMT'14 and WMT'15, outperforming previous SOTA systems, backed by NMT models and n-gram LM rerankers, by more than 1.0 BLEU. We conduct extensive analysis to evaluate our models in terms of learning, the ability to handle long sentences, choices of attentional architectures, alignment quality, and translation outputs.

2 Neural Machine Translation

A neural machine translation system is a neural network that directly models the conditional probability $p(y|x)$ of translating a source sentence, $x_1, \ldots, x_n$, to a target sentence, $y_1, \ldots, y_m$.[3] A basic form of NMT consists of two components: (a) an *encoder* which computes a representation $\boldsymbol{s}$ for each source sentence and (b) a *decoder* which generates one target word at a time and hence decomposes the conditional probability as:

$$\log p(y|x) = \sum_{j=1}^{m} \log p\left(y_j|y_{<j}, \boldsymbol{s}\right) \quad (1)$$

A natural choice to model such a decomposition in the decoder is to use a recurrent neural network (RNN) architecture, which most of the recent NMT work such as (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Cho et al., 2014; Bahdanau et al., 2015; Luong et al., 2015; Jean et al., 2015) have in common. They, however, differ in terms of which RNN architectures are used for the decoder and how the encoder computes the source sentence representation $\boldsymbol{s}$.

Kalchbrenner and Blunsom (2013) used an RNN with the standard hidden unit for the decoder and a convolutional neural network for encoding the source sentence representation. On the other hand, both Sutskever et al. (2014) and Luong et al. (2015) stacked multiple layers of an RNN with a Long Short-Term Memory (LSTM) hidden unit for both the encoder and the decoder. Cho et al. (2014), Bahdanau et al. (2015), and Jean et al. (2015) all adopted a different version of the RNN with an LSTM-inspired hidden unit, the gated recurrent unit (GRU), for both components.[4]

In more detail, one can parameterize the probability of decoding each word y_j as:

$$p\left(y_j|y_{<j}, \boldsymbol{s}\right) = \mathrm{softmax}\left(g\left(\boldsymbol{h}_j\right)\right) \quad (2)$$

with g being the transformation function that outputs a vocabulary-sized vector.[5] Here, $\boldsymbol{h}_j$ is the RNN hidden unit, abstractly computed as:

$$\boldsymbol{h}_j = f(\boldsymbol{h}_{j-1}, \boldsymbol{s}), \quad (3)$$

where f computes the current hidden state given the previous hidden state and can be either a vanilla RNN unit, a GRU, or an LSTM unit. In (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Cho et al., 2014; Luong et al., 2015), the source representation $\boldsymbol{s}$ is only used once to initialize the decoder hidden state. On the other hand, in (Bahdanau et al., 2015; Jean et al., 2015) and this work, $\boldsymbol{s}$, in fact, implies a set of source hidden states which are consulted throughout the entire course of the translation process. Such an approach is referred to as an attention mechanism, which we will discuss next.

In this work, following (Sutskever et al., 2014; Luong et al., 2015), we use the stacking LSTM architecture for our NMT systems, as illustrated in Figure 1. We use the LSTM unit defined in (Zaremba et al., 2015). Our training objective is formulated as follows:

$$J_t = \sum_{(x,y)\in D} -\log p(y|x) \quad (4)$$

[2] There is a recent work by Gregor et al. (2015), which is very similar to our local attention and applied to the image generation task. However, as we detail later, our model is much simpler and can achieve good performance for NMT.

[3] All sentences are assumed to terminate with a special "end-of-sentence" token <eos>.

[4] They all used a single RNN layer except for the latter two works which utilized a bidirectional RNN for the encoder.

[5] One can provide g with other inputs such as the currently predicted word y_j as in (Bahdanau et al., 2015).

with D being our parallel training corpus.

3 Attention-based Models

Our various attention-based models are classifed into two broad categories, *global* and *local*. These classes differ in terms of whether the "attention" is placed on all source positions or on only a few source positions. We illustrate these two model types in Figure 2 and 3 respectively.

Common to these two types of models is the fact that at each time step t in the decoding phase, both approaches first take as input the hidden state $\boldsymbol{h}_t$ at the top layer of a stacking LSTM. The goal is then to derive a context vector $\boldsymbol{c}_t$ that captures relevant source-side information to help predict the current target word y_t. While these models differ in how the context vector $\boldsymbol{c}_t$ is derived, they share the same subsequent steps.

Specifically, given the target hidden state $\boldsymbol{h}_t$ and the source-side context vector $\boldsymbol{c}_t$, we employ a simple concatenation layer to combine the information from both vectors to produce an attentional hidden state as follows:

$$\tilde{\boldsymbol{h}}_t = \tanh(\boldsymbol{W_c}[\boldsymbol{c}_t; \boldsymbol{h}_t]) \tag{5}$$

The attentional vector $\tilde{\boldsymbol{h}}_t$ is then fed through the softmax layer to produce the predictive distribution formulated as:

$$p(y_t|y_{<t}, x) = \text{softmax}(\boldsymbol{W_s}\tilde{\boldsymbol{h}}_t) \tag{6}$$

We now detail how each model type computes the source-side context vector $\boldsymbol{c}_t$.

3.1 Global Attention

The idea of a global attentional model is to consider all the hidden states of the encoder when deriving the context vector c_t. In this model type, a variable-length alignment vector $\boldsymbol{a}_t$, whose size equals the number of time steps on the source side, is derived by comparing the current target hidden state $\boldsymbol{h}_t$ with each source hidden state $\bar{\boldsymbol{h}}_s$:

$$\begin{aligned}\boldsymbol{a}_t(s) &= \text{align}(\boldsymbol{h}_t, \bar{\boldsymbol{h}}_s) \\ &= \frac{\exp\left(\text{score}(\boldsymbol{h}_t, \bar{\boldsymbol{h}}_s)\right)}{\sum_{s'} \exp\left(\text{score}(\boldsymbol{h}_t, \bar{\boldsymbol{h}}_{s'})\right)}\end{aligned} \tag{7}$$

Here, score is referred as a *content-based* function for which we consider three different alternatives:

$$\text{score}(\boldsymbol{h}_t, \bar{\boldsymbol{h}}_s) = \begin{cases} \boldsymbol{h}_t^\top \bar{\boldsymbol{h}}_s & \textit{dot} \\ \boldsymbol{h}_t^\top \boldsymbol{W_a} \bar{\boldsymbol{h}}_s & \textit{general} \\ \boldsymbol{W_a}[\boldsymbol{h}_t; \bar{\boldsymbol{h}}_s] & \textit{concat} \end{cases} \tag{8}$$

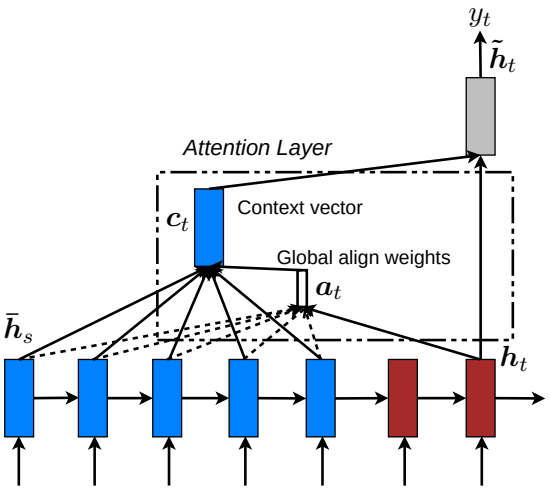

Figure 2: **Global attentional model** – at each time step t, the model infers a *variable-length* alignment weight vector $\boldsymbol{a}_t$ based on the current target state $\boldsymbol{h}_t$ and all source states $\bar{\boldsymbol{h}}_s$. A global context vector $\boldsymbol{c}_t$ is then computed as the weighted average, according to $\boldsymbol{a}_t$, over all the source states.

Besides, in our early attempts to build attention-based models, we use a *location-based* function in which the alignment scores are computed from solely the target hidden state $\boldsymbol{h}_t$ as follows:

$$\boldsymbol{a}_t = \text{softmax}(\boldsymbol{W_a}\boldsymbol{h}_t) \qquad \textit{location} \tag{9}$$

Given the alignment vector as weights, the context vector c_t is computed as the weighted average over all the source hidden states.[6]

Comparison to (Bahdanau et al., 2015) – While our global attention approach is similar in spirit to the model proposed by Bahdanau et al. (2015), there are several key differences which reflect how we have both simplified and generalized from the original model. First, we simply use hidden states at the top LSTM layers in both the encoder and decoder as illustrated in Figure 2. Bahdanau et al. (2015), on the other hand, use the concatenation of the forward and backward source hidden states in the bi-directional encoder and target hidden states in their non-stacking uni-directional decoder. Second, our computation path is simpler; we go from $\boldsymbol{h}_t \rightarrow \boldsymbol{a}_t \rightarrow \boldsymbol{c}_t \rightarrow \tilde{\boldsymbol{h}}_t$ then make a prediction as detailed in Eq. (5), Eq. (6), and Figure 2. On the other hand, at any time t, Bahdanau et al. (2015) build from the previous hidden state $\boldsymbol{h}_{t-1} \rightarrow \boldsymbol{a}_t \rightarrow \boldsymbol{c}_t \rightarrow \boldsymbol{h}_t$, which, in turn,

[6] Eq. (9) implies that all alignment vectors $\boldsymbol{a}_t$ are of the same length. For short sentences, we only use the top part of $\boldsymbol{a}_t$ and for long sentences, we ignore words near the end.

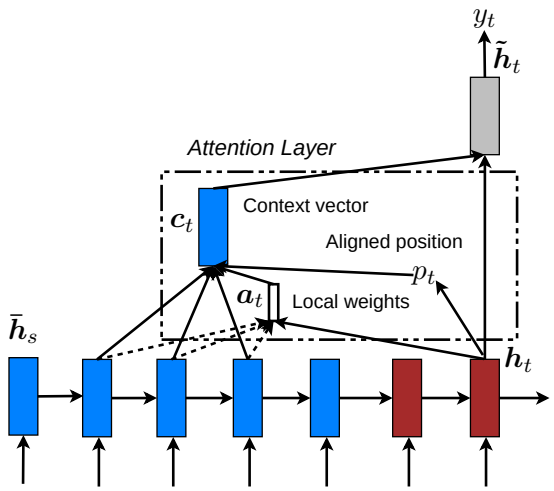

Figure 3: **Local attention model** – the model first predicts a single aligned position p_t for the current target word. A window centered around the source position p_t is then used to compute a context vector $\boldsymbol{c}_t$, a weighted average of the source hidden states in the window. The weights $\boldsymbol{a_t}$ are inferred from the current target state $\boldsymbol{h}_t$ and those source states $\bar{\boldsymbol{h}}_s$ in the window.

goes through a deep-output and a maxout layer before making predictions.[7] Lastly, Bahdanau et al. (2015) only experimented with one alignment function, the *concat* product; whereas we show later that the other alternatives are better.

3.2 Local Attention

The global attention has a drawback that it has to attend to all words on the source side for each target word, which is expensive and can potentially render it impractical to translate longer sequences, e.g., paragraphs or documents. To address this deficiency, we propose a *local* attentional mechanism that chooses to focus only on a small subset of the source positions per target word.

This model takes inspiration from the tradeoff between the *soft* and *hard* attentional models proposed by Xu et al. (2015) to tackle the image caption generation task. In their work, soft attention refers to the global attention approach in which weights are placed "softly" over all patches in the source image. The hard attention, on the other hand, selects one patch of the image to attend to at a time. While less expensive at inference time, the hard attention model is non-differentiable and requires more complicated techniques such as variance reduction or reinforcement learning to train.

[7] We will refer to this difference again in Section 3.3.

Our local attention mechanism selectively focuses on a small window of context and is differentiable. This approach has an advantage of avoiding the expensive computation incurred in the soft attention and at the same time, is easier to train than the hard attention approach. In concrete details, the model first generates an aligned position p_t for each target word at time t. The context vector $\boldsymbol{c}_t$ is then derived as a weighted average over the set of source hidden states within the window $[p_t - D, p_t + D]$; D is empirically selected.[8] Unlike the global approach, the local alignment vector $\boldsymbol{a}_t$ is now fixed-dimensional, i.e., $\in \mathbb{R}^{2D+1}$. We consider two variants of the model as below.

Monotonic alignment (**local-m**) – we simply set $p_t = t$ assuming that source and target sequences are roughly monotonically aligned. The alignment vector $\boldsymbol{a}_t$ is defined according to Eq. (7).[9]

Predictive alignment (**local-p**) – instead of assuming monotonic alignments, our model predicts an aligned position as follows:

$$p_t = S \cdot \text{sigmoid}(\boldsymbol{v}_p^\top \tanh(\boldsymbol{W_p h}_t)), \qquad (10)$$

$\boldsymbol{W_p}$ and $\boldsymbol{v}_p$ are the model parameters which will be learned to predict positions. S is the source sentence length. As a result of sigmoid, $p_t \in [0, S]$. To favor alignment points near p_t, we place a Gaussian distribution centered around p_t . Specifically, our alignment weights are now defined as:

$$\boldsymbol{a}_t(s) = \text{align}(\boldsymbol{h}_t, \bar{\boldsymbol{h}}_s) \exp\left(-\frac{(s - p_t)^2}{2\sigma^2}\right) \qquad (11)$$

We use the same align function as in Eq. (7) and the standard deviation is empirically set as $\sigma = \frac{D}{2}$. It is important to note that p_t is a *real* nummber; whereas s is an *integer* within the window centered at p_t.[10]

Comparison to (Gregor et al., 2015) – have proposed a *selective attention* mechanism, very similar to our local attention, for the image generation task. Their approach allows the model to select an image patch of varying location and zoom. We, instead, use the same "zoom" for all target positions, which greatly simplifies the formulation and still achieves good performance.

[8] If the window crosses the sentence boundaries, we simply ignore the outside part and consider words in the window.

[9] *local-m* is the same as the global model except that the vector $\boldsymbol{a}_t$ is fixed-length and shorter.

[10] *local-p* is similar to the local-m model except that we dynamically compute p_t and use a Gaussian distribution to modify the original alignment weights $\text{align}(\boldsymbol{h}_t, \bar{\boldsymbol{h}}_s)$ as shown in Eq. (11). By utilizing p_t to derive $\boldsymbol{a}_t$, we can compute backprop gradients for $\boldsymbol{W_p}$ and $\boldsymbol{v}_p$.

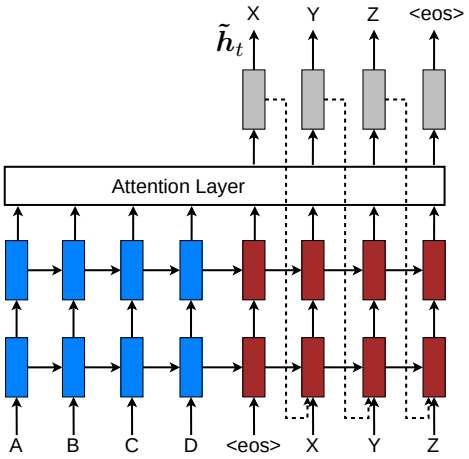

Figure 4: **Input-feeding approach** – Attentional vectors $\tilde{\boldsymbol{h}}_t$ are fed as inputs to the next time steps to inform the model about past alignment decisions.

3.3 Input-feeding Approach

In our proposed global and local approaches, the attentional decisions are made independently, which is suboptimal. Whereas, in standard MT, a *coverage* set is often maintained during the translation process to keep track of which source words have been translated. Likewise, in attentional NMTs, alignment decisions should be made jointly taking into account past alignment information. To address that, we propose an *input-feeding* approach in which attentional vectors $\tilde{\boldsymbol{h}}_t$ are concatenated with inputs at the next time steps as illustrated in Figure 4.[11] The effects of having such connections are two-fold: (a) we hope to make the model fully aware of previous alignment choices and (b) we create a very deep network spanning both horizontally and vertically.

Comparison to other work – Bahdanau et al. (2015) use context vectors, similar to our $\boldsymbol{c}_t$, in building subsequent hidden states, which can also achieve the "coverage" effect. However, there has not been any analysis of whether such connections are useful as done in this work. Also, our approach is more general; as illustrated in Figure 4, it can be applied to general stacking recurrent architectures, including non-attentional models.

Xu et al. (2015) propose a *doubly attentional* approach with an additional constraint added to the training objective to make sure the model pays equal attention to all parts of the image during the caption generation process. Such a constraint can also be useful to capture the coverage set effect in NMT that we mentioned earlier. However, we chose to use the input-feeding approach since it provides flexibility for the model to decide on any attentional constraints it deems suitable.

[11] If n is the number of LSTM cells, the input size of the first LSTM layer is $2n$; those of subsequent layers are n.

4 Experiments

We evaluate the effectiveness of our models on the WMT translation tasks between English and German in both directions. newstest2013 (3000 sentences) is used as a development set to select our hyperparameters. Translation performances are reported in case-sensitive BLEU (Papineni et al., 2002) on newstest2014 (2737 sentences) and newstest2015 (2169 sentences). Following (Luong et al., 2015), we report translation quality using two types of BLEU: (a) *tokenized*[12] BLEU to be comparable with existing NMT work and (b) *NIST*[13] BLEU to be comparable with WMT results.

4.1 Training Details

All our models are trained on the WMT'14 training data consisting of 4.5M sentences pairs (116M English words, 110M German words). Similar to (Jean et al., 2015), we limit our vocabularies to be the top 50K most frequent words for both languages. Words not in these shortlisted vocabularies are converted into a universal token `<unk>`.

When training our NMT systems, following (Bahdanau et al., 2015; Jean et al., 2015), we filter out sentence pairs whose lengths exceed 50 words and shuffle mini-batches as we proceed. Our stacking LSTM models have 4 layers, each with 1000 cells, and 1000-dimensional embeddings. We follow (Sutskever et al., 2014; Luong et al., 2015) in training NMT with similar settings: (a) our parameters are uniformly initialized in $[-0.1, 0.1]$, (b) we train for 10 epochs using plain SGD, (c) a simple learning rate schedule is employed – we start with a learning rate of 1; after 5 epochs, we begin to halve the learning rate every epoch, (d) our mini-batch size is 128, and (e) the normalized gradient is rescaled whenever its norm exceeds 5. Additionally, we also use dropout for our LSTMs as suggested by (Zaremba et al., 2015). For dropout models, we train for 12 epochs and start halving the learning rate after 8 epochs.

Our code is implemented in MATLAB. When

[12] All texts are tokenized with `tokenizer.perl` and BLEU scores are computed with `multi-bleu.perl`.

[13] With the `mteval-v13a` script as per WMT guideline.

Table 1: **WMT'14 English-German results** – shown are the perplexities (ppl) and the *tokenized* BLEU scores of various systems on newstest2014. We highlight the **best** system in bold and give *progressive* improvements in italic between consecutive systems. *local-p* referes to the local attention with predictive alignments. We indicate for each attention model the alignment score function used in pararentheses.

running on a single GPU device Tesla K40, we achieve a speed of 1K *target* words per second. It takes 7–10 days to completely train a model.

4.2 English-German Results

We compare our NMT systems in the English-German task with various other systems. These include the winning system in WMT'14 (Buck et al., 2014), a phrase-based system whose language models were trained on a huge monolingual text, the Common Crawl corpus. For end-to-end neural machine translation systems, to the best of our knowledge, (Jean et al., 2015) is the only work experimenting with this language pair and currently the SOTA system. We only present results for some of our attention models and will later analyze the rest in Section 5.

As shown in Table 1, we achieve progressive improvements when (a) reversing the source sentence, +1.3 BLEU, as proposed in (Sutskever et al., 2014) and (b) using dropout, +1.4 BLEU. On top of that, (c) the global attention approach gives a significant boost of +2.8 BLEU, making our model slightly better than the base attentional system of Bahdanau et al. (2015) (row *RNNSearch*). When (d) using the *input-feeding* approach, we seize another notable gain of +1.3 BLEU and outperform their system. The local attention model with predictive alignments (row *local-p*) proves to be even better, giving us a further improvement of +0.9 BLEU on top of the global attention model. It is interesting to observe the trend previously reported in (Luong et al., 2015) that perplexity strongly correlates with translation quality. In total, we achieve a significant gain of 5.0 BLEU points over the non-attentional baseline, which already includes known techniques such as source reversing and dropout.

The unknown replacement technique proposed in (Luong et al., 2015; Jean et al., 2015) yields another nice gain of +1.9 BLEU, demonstrating that our attentional models do learn useful alignments for unknown works. Finally, by ensembling 8 different models of various settings, e.g., using different attention approaches, with and without dropout etc., we were able to achieve a *new SOTA* result of 23.0 BLEU, outperforming the existing best system (Jean et al., 2015) by +1.4 BLEU.

tablishes a *new SOTA* performance of 25.9 BLEU, outperforming the existing best system backed by NMT and a 5-gram LM reranker by +1.0 BLEU.

4.3 German-English Results

We carry out a similar set of experiments for the WMT'15 translation task from German to English. While our systems have not yet matched the performance of the SOTA system, we nevertheless show the effectiveness of our approaches with large and progressive gains in terms of BLEU as illustrated in Table 3. The *attentional* mechanism gives us +2.2 BLEU gain and on top of that, we obtain another boost of up to +1.0 BLEU from the *input-feeding* approach. Using a better alignment function, the content-based *dot* product one, together with *dropout* yields another gain of +2.7 BLEU. Lastly, when applying the unknown word replacement technique, we seize an additional +2.1 BLEU, demonstrating the usefulness of attention in aligning rare words.

5 Analysis

We conduct extensive analysis to better understand our models in terms of learning, the ability to handle long sentences, choices of attentional architectures, and alignment quality. All models considered here are English-German NMT systems tested on newstest2014.

5.1 Learning curves

We compare models built on top of one another as listed in Table 1. It is pleasant to observe in Figure 5 a clear separation between non-attentional and attentional models. The input-feeding approach and the local attention model also demonstrate their abilities in driving the test costs lower. The non-attentional model with dropout (the blue + curve) learns slower than other non-dropout models, but as time goes by, it becomes more robust in terms of minimizing test errors.

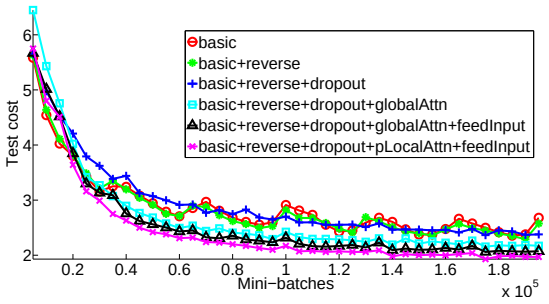

Figure 5: **Learning curves** – test cost (ln perplexity) on newstest2014 for English-German NMTs as training progresses.

5.2 Effects of Translating Long Sentences

We follow (Bahdanau et al., 2015) to group sentences of similar lengths together and compute a BLEU score per group. As demonstrated in Figure 6, our attentional models are more effective than the other non-attentional model in handling long sentences: the translation quality does not degrade as sentences become longer. Our best model (the blue + curve) outperforms all other systems in all length buckets.

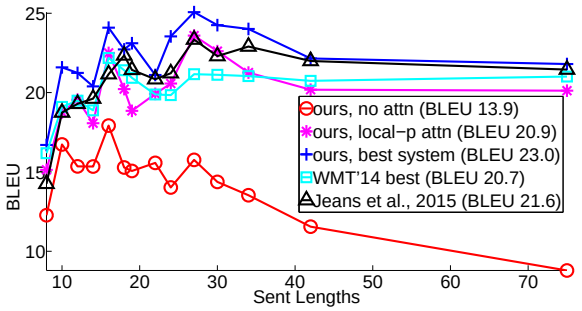

Figure 6: **Length Analysis** – translation qualities of different systems as sentences become longer.

5.3 Choices of Attentional Architectures

We examine different attention models (*global, local-m, local-p*) and different alignment functions (*location, dot, general, concat*) as described in Section 3. Due to limited resources, we cannot run all the possible combinations. However,

System	Ppl	BLEU	
		Before	After unk
global (location)	6.4	18.1	19.3 (+1.2)
global (dot)	6.1	18.6	20.5 (+1.9)
global (general)	6.1	17.3	19.1 (+1.8)
local-m (dot)	>7.0	x	x
local-m (general)	6.2	18.6	20.4 (+1.8)
local-p (dot)	6.6	18.0	19.6 (+1.9)
local-p (general)	**5.9**	**19**	**20.9 (+1.9)**

Table 4: **Attentional Architectures** – performances of different attentional models. We trained two local-m (dot) models; both have ppl > 7.0.

Method	AER
global (location)	0.39
local-m (general)	0.34
local-p (general)	0.36
ensemble	0.34
Berkeley Aligner	0.32

Table 6: **AER scores** – results of various models on the RWTH English-German alignment data.

results in Table 4 do give us some idea about different choices. The *location-based* function does not learn good alignments: the *global (location)* model can only obtain a small gain when performing unknown word replacement compared to using other alignment functions.[14] For *content-based* functions, our implementation of *concat* does not yield good performances and more analysis should be done to understand the reason.[15] It is interesting to observe that *dot* works well for the global attention and *general* is better for the local attention. Among the different models, the local attention model with predictive alignments (*local-p*) is best, both in terms of perplexities and BLEU.

5.4 Alignment Quality

A by-product of attentional models are word alignments. While (Bahdanau et al., 2015) visualized alignments for some sample sentences and observed gains in translation quality as an indication of a working attention model, no work has assessed the alignments learned as a whole. In contrast, we set out to evaluate the alignment quality using the alignment error rate (AER) metric.

Given the gold alignment data provided by RWTH for 508 English-German Europarl sentences, we "force" decode our attentional models to produce translations that match the references. We extract only one-to-one alignments by selecting the source word with the highest alignment weight per target word. Nevertheless, as shown in Table 6, we were able to achieve AER scores comparable to the one-to-many alignments obtained by the Berkeley aligner (Liang et al., 2006).[16]

We also found that the alignments produced by local attention models achieve lower AERs than those of the global one. The AER obtained by the ensemble, while good, is not better than the local-m AER, suggesting the well-known observation that AER and translation scores are not well correlated (Fraser and Marcu, 2007). Due to space constraint, we can only show alignment visualizations in the arXiv version of our paper.[17]

5.5 Sample Translations

We show in Table 5 sample translations in both directions. It it appealing to observe the effect of attentional models in correctly translating names such as "Miranda Kerr" and "Roger Dow". Non-attentional models, while producing sensible names from a language model perspective, lack the direct connections from the source side to make correct translations.

We also observed an interesting case in the second English-German example, which requires translating the *doubly-negated* phrase, "not incompatible". The attentional model correctly produces "nicht ... unvereinbar"; whereas the non-attentional model generates "nicht vereinbar", meaning "not compatible".[18] The attentional model also demonstrates its superiority in translating long sentences as in the last example.

6 Conclusion

In this paper, we propose two simple and effective attentional mechanisms for neural machine

[14]There is a subtle difference in how we retrieve alignments for the different alignment functions. At time step t in which we receive y_{t-1} as input and then compute $\boldsymbol{h}_t, \boldsymbol{a}_t, \boldsymbol{c}_t$, and $\tilde{\boldsymbol{h}}_t$ before predicting y_t, the alignment vector $\boldsymbol{a}_t$ is used as alignment weights for (a) the predicted word y_t in the *location-based* alignment functions and (b) the input word y_{t-1} in the *content-based* functions.

[15]With *concat*, the perplexities achieved by different models are 6.7 (global), 7.1 (local-m), and 7.1 (local-p).

[16]We concatenate the 508 sentence pairs with 1M sentence pairs from WMT and run the Berkeley aligner.

[17]http://arxiv.org/abs/1508.04025

[18]The reference uses a more fancy translation of "incompatible", which is "im Widerspruch zu etwas stehen". Both models, however, failed to translate "passenger experience".

translation: the *global* approach which always looks at all source positions and the *local* one that only attends to a subset of source positions at a time. We test the effectiveness of our models in the WMT translation tasks between English and German in both directions. Our local attention yields large gains of up to 5.0 BLEU over non-attentional models that already incorporate known techniques such as dropout. For the English to German translation direction, our ensemble model has established new state-of-the-art results for both WMT'14 and WMT'15.

We have compared various alignment functions and shed light on which functions are best for which attentional models. Our analysis shows that attention-based NMT models are superior to non-attentional ones in many cases, for example in translating names and handling long sentences.

Acknowledgment

We gratefully acknowledge support from a gift from Bloomberg L.P. and the support of NVIDIA Corporation with the donation of Tesla K40 GPUs. We thank Andrew Ng and his group as well as the Stanford Research Computing for letting us use their computing resources. We thank Russell Stewart for helpful discussions on the models. Lastly, we thank Quoc Le, Ilya Sutskever, Oriol Vinyals, Richard Socher, Michael Kayser, Jiwei Li, Panupong Pasupat, Kelvin Gu, members of the Stanford NLP Group and the annonymous reviewers for their valuable comments and feedback.

Document Modeling with Gated Recurrent Neural Network for Sentiment Classification

Duyu Tang, Bing Qin*, Ting Liu
Harbin Institute of Technology, Harbin, China
{dytang, qinb, tliu}@ir.hit.edu.cn

Abstract

Document level sentiment classification remains a challenge: encoding the intrinsic relations between sentences in the semantic meaning of a document. To address this, we introduce a neural network model to learn vector-based document representation in a unified, bottom-up fashion. The model first learns sentence representation with convolutional neural network or long short-term memory. Afterwards, semantics of sentences and their relations are adaptively encoded in document representation with gated recurrent neural network. We conduct document level sentiment classification on four large-scale review datasets from IMDB and Yelp Dataset Challenge. Experimental results show that: (1) our neural model shows superior performances over several state-of-the-art algorithms; (2) gated recurrent neural network dramatically outperforms standard recurrent neural network in document modeling for sentiment classification.[1]

1 Introduction

Document level sentiment classification is a fundamental task in sentiment analysis, and is crucial to understand user generated content in social networks or product reviews (Manning and Schütze, 1999; Jurafsky and Martin, 2000; Pang and Lee, 2008; Liu, 2012). The task calls for identifying the overall sentiment polarity (e.g. *thumbs up* or *thumbs down*, 1-5 stars on review sites) of a document. In literature, dominant approaches follow (Pang et al., 2002) and exploit machine learning algorithm to build sentiment classifier. Many of them focus on designing hand-crafted features (Qu et al., 2010; Paltoglou and Thelwall, 2010) or learning discriminate features from data, since the performance of a machine learner is heavily dependent on the choice of data representation (Bengio et al., 2015).

Document level sentiment classification remains a significant challenge: how to encode the intrinsic (semantic or syntactic) relations between sentences in the semantic meaning of document. This is crucial for sentiment classification because relations like "contrast" and "cause" have great influences on determining the meaning and the overall polarity of a document. However, existing studies typically fail to effectively capture such information. For example, Pang et al. (2002) and Wang and Manning (2012) represent documents with bag-of-ngrams features and build SVM classifier upon that. Although such feature-driven SVM is an extremely strong performer and hardly to be transcended, its "sparse" and "discrete" characteristics make it clumsy in taking into account of side information like relations between sentences. Recently, Le and Mikolov (2014) exploit neural networks to learn continuous document representation from data. Essentially, they use local ngram information and do not capture semantic relations between sentences. Furthermore, a person asked to do this task will naturally carry it out in a sequential, bottom-up fashion, analyze the meanings of sentences before considering semantic relations between them. This motivates us to develop an end-to-end and bottom-up algorithm to effectively model document representation.

In this paper, we introduce a neural network approach to learn continuous document representation for sentiment classification. The method is on the basis of the principle of compositionality (Frege, 1892), which states that the meaning of a longer expression (e.g. a sentence or a docu-

Lisbon, Portugal, 17-21 September 2015.

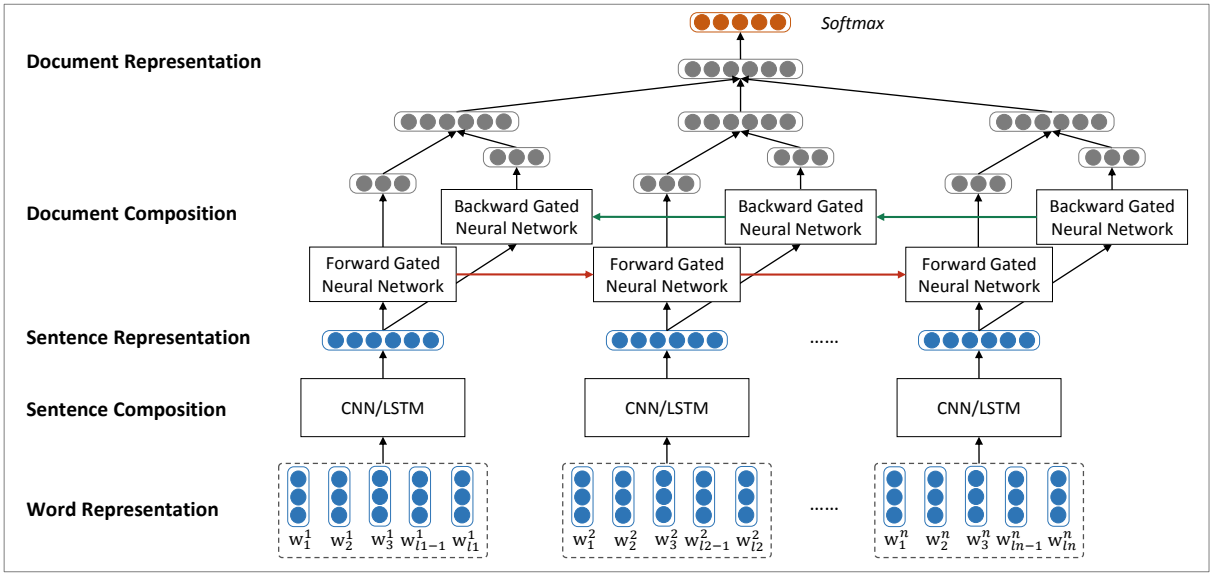

Figure 1: The neural network model for document level sentiment classification. w_i^n stands for the i-th word in the n-th sentence, l_n is sentence length.

ment) depends on the meanings of its constituents. Specifically, the approach models document representation in two steps. In the first step, it uses convolutional neural network (CNN) or long short-term memory (LSTM) to produce sentence representations from word representations. Afterwards, gated recurrent neural network is exploited to adaptively encode semantics of sentences and their inherent relations in document representations. These representations are naturally used as features to classify the sentiment label of each document. The entire model is trained end-to-end with stochastic gradient descent, where the loss function is the cross-entropy error of supervised sentiment classification[2].

We conduct document level sentiment classification on four large-scale review datasets from IMDB[3] and Yelp Dataset Challenge[4]. We compare to neural network models such as paragraph vector (Le and Mikolov, 2014), convolutional neural network, and baselines such as feature-based SVM (Pang et al., 2002), recommendation algorithm JMARS (Diao et al., 2014). Experimental results show that: (1) the proposed neural model shows superior performances over all baseline algorithms; (2) gated recurrent neural network dramatically outperforms standard recurrent neural network in document modeling. The main contributions of this work are as follows:

- We present a neural network approach to encode relations between sentences in document representation for sentiment classification.
- We report empirical results on four large-scale datasets, and show that the approach outperforms state-of-the-art methods for document level sentiment classification.
- We report empirical results that traditional recurrent neural network is weak in modeling document composition, while adding neural gates dramatically improves the classification performance.

2 The Approach

We introduce the proposed neural model in this section, which computes continuous vector representations for documents of variable length. These representations are further used as features to classify the sentiment label of each document. An overview of the approach is displayed in Figure 1.

Our approach models document semantics based on the principle of compositionality (Frege, 1892), which states that the meaning of a longer expression (e.g. a sentence or a document) comes from the meanings of its constituents and the rules used to combine them. Since a document consists of a list of sentences and each sentence is made up of a list of words, the approach models document representation in two stages. It first produces continuous sentence vectors from word represen-

[2]A similar work can be found at: http://deeplearning.net/tutorial/lstm.html

[3]http://www.imdb.com/

[4]http://www.yelp.com/dataset_challenge

tations with sentence composition (Section 2.1). Afterwards, sentence vectors are treated as inputs of document composition to get document representation (Section 2.2). Document representations are then used as features for document level sentiment classification (Section 2.3).

2.1 Sentence Composition

We first describe word vector representation, before presenting a convolutional neural network with multiple filters for sentence composition.

Each word is represented as a low dimensional, continuous and real-valued vector, also known as word embedding (Bengio et al., 2003). All the word vectors are stacked in a word embedding matrix $L_w \in \mathbb{R}^{d \times |V|}$, where d is the dimension of word vector and $|V|$ is vocabulary size. These word vectors can be randomly initialized from a uniform distribution (Socher et al., 2013b), or be pre-trained from text corpus with embedding learning algorithms (Mikolov et al., 2013; Pennington et al., 2014; Tang et al., 2014). We adopt the latter strategy to make better use of semantic and grammatical associations of words.

We use convolutional neural network (CNN) and long short-term memory (LSTM) to compute continuous representations of sentences with semantic composition. CNN and LSTM are state-of-the-art semantic composition models for sentiment classification (Kim, 2014; Kalchbrenner et al., 2014; Johnson and Zhang, 2015; Li et al., 2015a). They learn fixed-length vectors for sentences of varying length, captures words order in a sentence and does not depend on external dependency or constituency parse results. One could also use tree-based composition method such as Recursive Neural Tensor Network (Socher et al., 2013b) or Tree-Structured LSTM (Tai et al., 2015; Zhu et al., 2015) as alternatives.

Specifically, we try CNN with multiple convolutional filters of different widths (Tang et al., 2015) to produce sentence representation. Figure 2 displays the method. We use multiple convolutional filters in order to capture local semantics of n-grams of various granularities, which have been proven effective for sentiment classification. For example, a convolutional filter with a width of 2 essentially captures the semantics of bigrams in a sentence. In this work, we use three convolutional filters whose widths are 1, 2 and 3 to encode the semantics of unigrams, bigrams and trigrams in a sentence. Each filter consists of a list of linear layers with shared parameters. Formally, let us denote a sentence consisting of n words as $\{w_1, w_2, ...w_i, ...w_n\}$, let l_c be the width of a convolutional filter, and let W_c, b_c be the shared parameters of linear layers in the filter. Each word w_i is mapped to its embedding representation $e_i \in \mathbb{R}^d$. The input of a linear layer is the concatenation of word embeddings in a fixed-length window size l_c, which is denoted as $I_c = [e_i; e_{i+1}; ...; e_{i+l_c-1}] \in \mathbb{R}^{d \cdot l_c}$. The output of a linear layer is calculated as

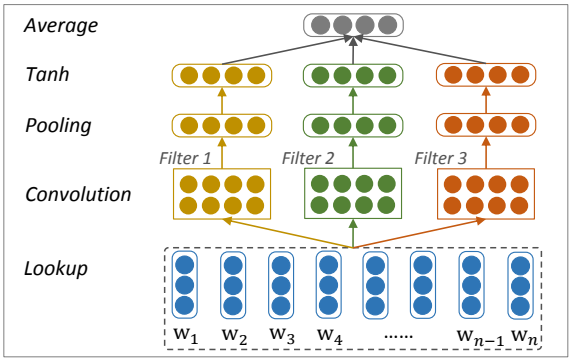

Figure 2: Sentence composition with convolutional neural network.

$$O_c = W_c \cdot I_c + b_c \tag{1}$$

where $W_c \in \mathbb{R}^{l_{oc} \times d \cdot l_c}$, $b_c \in \mathbb{R}^{l_{oc}}$, l_{oc} is the output length of linear layer. To capture global semantics of a sentence, we feed the outputs of linear layers to an *average* pooling layer, resulting in an output vector with fixed-length. We further add hyperbolic tangent ($tanh$) to incorporate pointwise nonlinearity, and *average* the outputs of multiple filters to get sentence representation.

We also try lstm as the sentence level semantic calculator, the performance comparison between these two variations is given in Section 3.

2.2 Document Composition with Gated Recurrent Neural Network

The obtained sentence vectors are fed to a document composition component to calculate the document representation. We present a gated recurrent neural network approach for document composition in this part.

Given the vectors of sentences of variable length as input, document composition produces a fixed-length document vector as output. To this end, a simple strategy is ignoring the order of sen-

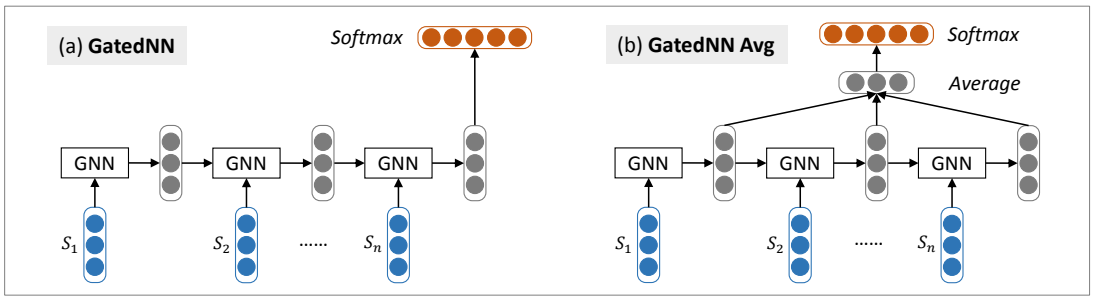

Figure 3: Document modeling with gated recurrent neural network. GNN stands for the basic computational unit of gated recurrent neural network.

tences and averaging sentence vectors as document vector. Despite its computational efficiency, it fails to capture complex linguistic relations (e.g. "cause" and "contrast") between sentences. Convolutional neural network (Denil et al., 2014) is an alternative for document composition, which models local sentence relations with shared parameters of linear layers.

Standard recurrent neural network (RNN) can map vectors of sentences of variable length to a fixed-length vector by recursively transforming current sentence vector s_t with the output vector of the previous step h_{t-1}. The transition function is typically a linear layer followed by pointwise non-linearity layer such as $tanh$.

$$h_t = tanh(W_r \cdot [h_{t-1}; s_t] + b_r) \quad (2)$$

where $W_r \in \mathbb{R}^{l_h \times (l_h + l_{oc})}$, $b_r \in \mathbb{R}^{l_h}$, l_h and l_{oc} are dimensions of hidden vector and sentence vector, respectively. Unfortunately, standard RNN suffers the problem of gradient vanishing or exploding (Bengio et al., 1994; Hochreiter and Schmidhuber, 1997), where gradients may grow or decay exponentially over long sequences. This makes it difficult to model long-distance correlations in a sequence. To address this problem, we develop a gated recurrent neural network for document composition, which works in a sequential way and adaptively encodes sentence semantics in document representations. The approach is analogous to the recently emerged LSTM (Graves et al., 2013; Zaremba and Sutskever, 2014; Sutskever et al., 2014; Xu et al., 2015) and gated neural network (Cho et al., 2014; Chung et al., 2015). Specifically, the transition function of the gated RNN used in this work is calculated as follows.

$$i_t = sigmoid(W_i \cdot [h_{t-1}; s_t] + b_i) \quad (3)$$

$$f_t = sigmoid(W_f \cdot [h_{t-1}; s_t] + b_f) \quad (4)$$

$$g_t = tanh(W_r \cdot [h_{t-1}; s_t] + b_r) \quad (5)$$

$$h_t = tanh(i_t \odot g_t + f_t \odot h_{t-1}) \quad (6)$$

where $\odot$ stands for element-wise multiplication, W_i, W_f, b_i, b_f adaptively select and remove history vector and input vector for semantic composition. The model can be viewed as a LSTM whose output gate is alway on, since we prefer not to discarding any part of the semantics of sentences to get a better document representation. Figure 3 (a) displays a standard sequential way where the last hidden vector is regarded as the document representation for sentiment classification. We can make further extensions such as averaging hidden vectors as document representation, which takes considerations of a hierarchy of historical semantics with different granularities. The method is illustrated in Figure 3 (b), which shares some characteristics with (Zhao et al., 2015). We can go one step further to use preceding histories and following evidences in the same way, and exploit bidirectional (Graves et al., 2013) gated RNN as the calculator. The model is embedded in Figure 1.

2.3 Sentiment Classification

The composed document representations can be naturally regarded as features of documents for sentiment classification without feature engineering. Specifically, we first add a linear layer to transform document vector to real-valued vector whose length is class number C. Afterwards, we add a $softmax$ layer to convert real values to conditional probabilities, which is calculated as follows.

$$P_i = \frac{exp(x_i)}{\sum_{i'=1}^{C} exp(x_{i'})} \quad (7)$$

We conduct experiments in a supervised learning setting, where each document in the training data is accompanied with its gold sentiment label.

Corpus	#docs	#s/d	#w/d	$\|V\|$	#class	Class Distribution
Yelp 2013	335,018	8.90	151.6	211,245	5	.09/.09/.14/.33/.36
Yelp 2014	1,125,457	9.22	156.9	476,191	5	.10/.09/.15/.30/.36
Yelp 2015	1,569,264	8.97	151.9	612,636	5	.10/.09/.14/.30/.37
IMDB	348,415	14.02	325.6	115,831	10	.07/.04/.05/.05/.08/.11/.15/.17/.12/.18

Table 1: Statistical information of Yelp 2013/2014/2015 and IMDB datasets. #docs is the number of documents, #s/d and #w/d represent average number of sentences and average number of words contained in per document, $|V|$ is the vocabulary size of words, #class is the number of classes.

For model training, we use the cross-entropy error between gold sentiment distribution $P^g(d)$ and predicted sentiment distribution $P(d)$ as the loss function.

$$loss = -\sum_{d \in T} \sum_{i=1}^{C} P_i^g(d) \cdot log(P_i(d)) \quad (8)$$

where T is the training data, C is the number of classes, d represents a document. $P^g(d)$ has a *1-of-K* coding scheme, which has the same dimension as the number of classes, and only the dimension corresponding to the ground truth is 1, with all others being 0. We take the derivative of loss function through back-propagation with respect to the whole set of parameters $\theta = [W_c; b_c; W_i; b_i; W_f; b_f; W_r; b_r; W_{softmax}, b_{softmax}]$, and update parameters with stochastic gradient descent. We set the widths of three convolutional filters as 1, 2 and 3, output length of convolutional filter as 50. We learn 200-dimensional word embeddings with SkipGram (Mikolov et al., 2013) on each dataset separately, randomly initialize other parameters from a uniform distribution $U(-0.01, 0.01)$, and set learning rate as 0.03.

3 Experiment

We conduct experiments to empirically evaluate our method by applying it to document level sentiment classification. We describe experimental settings and report empirical results in this section.

3.1 Experimental Setting

We conduct experiments on large-scale datasets consisting of document reviews. Specifically, we use one movie review dataset from IMDB (Diao et al., 2014) and three restaurant review datasets from Yelp Dataset Challenge in 2013, 2014 and 2015. Human labeled review ratings are regarded as gold standard sentiment labels, so that we do not need to manually annotate sentiment labels of documents. We do not consider the cases that rating does not match with review texts (Zhang et al., 2014).

Statistical information of these datasets are given in Table 1. We use the same dataset split as in (Diao et al., 2014) on IMDB dataset, and split Yelp datasets into training, development and testing sets with 80/10/10. We run tokenization and sentence splitting with Stanford CoreNLP (Manning et al., 2014) on all these datasets. We use *accuracy* (Manning and Schütze, 1999; Jurafsky and Martin, 2000) and MSE (Diao et al., 2014) as evaluation metrics, where *accuracy* is a standard metric to measure the overall sentiment classification performance. We use *MSE* to measure the divergences between predicted sentiment labels and ground truth sentiment labels because review labels reflect sentiment strengths (e.g. one star means strong negative and five star means strong positive).

$$MSE = \frac{\sum_i^N (gold_i - predicted_i)^2}{N} \quad (9)$$

3.2 Baseline Methods

We compare our methods (Conv-GRNN and LSTM-GRNN) with the following baseline methods for document level sentiment classification.

(1) *Majority* is a heuristic baseline, which assigns the majority sentiment label in training set to each document in test set.

(2) In *SVM+Ngrams*, we use bag-of-unigrams and bag-of-bigrams as features and train SVM classifier with LibLinear (Fan et al., 2008)[5].

(3) In *TextFeatures*, we implement sophisticated features (Kiritchenko et al., 2014) including word ngrams, character ngrams, sentiment lexicon features, cluster features, et al.

[5]We also try discretized regression (Pang and Lee, 2005) with fixed decision thresholds (e.g. 0.5, 1.5, 2.5, ...). However, its performance is obviously worse than SVM classifier.

	Yelp 2013		Yelp 2014		Yelp 2015		IMDB	
	Accuracy	MSE	Accuracy	MSE	Accuracy	MSE	Accuracy	MSE
Majority	0.356	3.06	0.361	3.28	0.369	3.30	0.179	17.46
SVM + Unigrams	0.589	0.79	0.600	0.78	0.611	0.75	0.399	4.23
SVM + Bigrams	0.576	0.75	0.616	0.65	0.624	0.63	0.409	3.74
SVM + TextFeatures	0.598	0.68	0.618	0.63	0.624	0.60	0.405	3.56
SVM + AverageSG	0.543	1.11	0.557	1.08	0.568	1.04	0.319	5.57
SVM + SSWE	0.535	1.12	0.543	1.13	0.554	1.11	0.262	9.16
JMARS	N/A	–	N/A	–	N/A	–	N/A	4.97
Paragraph Vector	0.577	0.86	0.592	0.70	0.605	0.61	0.341	4.69
Convolutional NN	0.597	0.76	0.610	0.68	0.615	0.68	0.376	3.30
Conv-GRNN	0.637	0.56	0.655	0.51	0.660	0.50	0.425	**2.71**
LSTM-GRNN	**0.651**	**0.50**	**0.671**	**0.48**	**0.676**	**0.49**	**0.453**	3.00

Table 2: Sentiment classification on Yelp 2013/2014/2015 and IMDB datasets. Evaluation metrics are accuracy (higher is better) and MSE (lower is better). The best method in each setting is in **bold**.

(4) In *AverageSG*, we learn 200-dimensional word vectors with *word2vec*[6] (Mikolov et al., 2013), average word embeddings to get document representation, and train a SVM classifier.

(5) We learn sentiment-specific word embeddings (SSWE), and use max/min/average pooling (Tang et al., 2014) to get document representation.

(6) We compare with a state-of-the-art recommendation algorithm JMARS (Diao et al., 2014), which utilizes user and aspects of a review with collaborative filtering and topic modeling.

(7) We implement a convolutional neural network (CNN) baseline as it is a state-of-the-art semantic composition method for sentiment analysis (Kim, 2014; Denil et al., 2014).

(8) We implement a state-of-the-art neural network baseline Paragraph Vector (Le and Mikolov, 2014) because its codes are not officially provided. Window size is tuned on the development set.

3.3 Comparison to Other Methods

Experimental results are given in Table 2. We evaluate each dataset with two metrics, namely accuracy (higher is better) and MSE (lower is better). The best method in each dataset and each evaluation metric is in bold.

From Table 2, we can see that majority is the worst method because it does not capture any textual semantics. SVM classifiers with unigram and bigram features (Pang et al., 2002) are extremely strong, which are almost the strongest performers among all baseline methods. Designing complex features are also effective for document level sentiment classification, however, it does not surpass the bag-of-ngram features significantly as on Twitter corpora (Kiritchenko et al., 2014). Furthermore, the aforementioned bag-of-features are discrete and sparse. For example, the feature dimension of bigrams and TextFeatures on Yelp 2015 dataset are 899K and 4.81M after we filter out low frequent features. Based on them, we try to concatenate several discourse-driven features, but the classification performances remain unchanged.

AverageSG is a straight forward way to compose document representation without feature engineering. Unfortunately, we can see that it does not work in this scenario, which appeals for powerful semantic composition models for document level sentiment classification. We try to make better use of the sentiment information to learn a better SSWE (Tang et al., 2014), e.g. setting a large window size. However, its performance is still worse than context-based word embedding. This stems from the fact that there are many sentiment shifters (e.g. negation or contrast words) in document level reviews, while Tang et al. (2014) learn SSWE by assigning sentiment label of a text to each phrase it contains. How to learn SSWE effectively with document level sentiment supervision remains as an interesting future work.

Since JMARS outputs real-valued outputs, we only evaluate it in terms of MSE. We can see that sophisticated baseline methods such as JMARS, paragraph vector and convolutional NN obtain significant performance boosts over AverageSG by

[6]We use Skipgram as it performs slightly better than CBOW in the experiment. We also try off-the-shell word embeddings from Glove, but its performance is slightly worse than tailored word embedding from each corpus.

	Yelp 2013		Yelp 2014		Yelp 2015		IMDB	
	Accuracy	MSE	Accuracy	MSE	Accuracy	MSE	Accuracy	MSE
Average	0.598	0.65	0.605	0.75	0.614	0.67	0.366	3.91
Recurrent	0.377	1.37	0.306	1.75	0.383	1.67	0.176	12.29
Recurrent Avg	0.582	0.69	0.591	0.70	0.597	0.74	0.344	3.71
Bi Recurrent Avg	0.587	0.73	0.597	0.73	0.577	0.82	0.372	3.32
GatedNN	0.636	0.58	0.656	0.52	0.651	0.51	**0.430**	2.95
GatedNN Avg	0.635	0.57	**0.659**	0.52	0.657	0.56	0.416	2.78
Bi GatedNN Avg	**0.637**	**0.56**	0.655	**0.51**	**0.660**	**0.50**	0.425	**2.71**

Table 3: Sentiment classification on IMDB, Yelp 2013/2014/2015 datasets. Evaluation metrics are accuracy (higher is better) and MSE (lower is better). The best method in each setting is in **bold**.

capturing deeper semantics of texts. Comparing between CNN and AverageSG, we can conclude that deep semantic compositionality is crucial for understanding the semantics and the sentiment of documents. However, it is somewhat disappointing that these models do not significantly outperform discrete bag-of-ngrams and bag-of-features. The reason might lie in that semantic meanings of documents, e.g. relations between sentences, are not well captured. We can see that the proposed method Conv-GRNN and LSTM-GRNN yield the best performance on all four datasets in two evaluation metrics. Compared with CNN, Conv-GRNN shows its superior power in document composition component, which encodes semantics of sentences and their relations in document representation with gated recurrent neural network. We also find that LSTM (almost) consistently performs better than CNN in modeling the sentence representation.

3.4 Model Analysis

As discussed before, document composition contributes a lot to the superior performance of Conv-GRNN and LSTM-GRNN. Therefore, we take Conv-GRNN as an example and compare different neural models for document composition in this part. Specifically, after obtaining sentence vectors with convolutional neural network as described in Section 2.1, we carry out experiments in following settings.

(1) *Average*. Sentence vectors are averaged to get the document vector.

(2) *Recurrent* / *GatedNN*. Sentence vectors are fed to standard (or gated) recurrent neural network in a sequential way from the beginning of the input document. The last hidden vector is regarded as document representation.

(3) *Recurrent Avg* / *GatedNN Avg*. We extend setting (2) by averaging hidden vectors of recurrent neural network as document vector.

(4) *Bi Recurrent Avg* / *Bi GatedNN Avg*. We extend setting (3) by calculating hidden vectors from both preceding histories and following contexts. Bi-directional hidden vectors are averaged as document representation.

Table 3 shows the experimental results. We can see that standard recurrent neural network (RNN) is the worst method, even worse than the simple vector average. This is because RNN suffers from the vanishing gradient problem, stating that the influence of a given input on the hidden layer decays exponentially over time on the network output. In this paper, it means that document representation encodes rare semantics of the beginning sentences. This is further justified by the great improvement of *Recurrent Avg* over *Recurrent*. *Bi Recurrent Avg* and *Recurrent Avg* perform comparably, but disappointingly both of them fail to transcend *Average*. After adding neural gates, *GatedNN* obtains dramatic accuracy improvements over *Recurrent* and significantly outperforms previous settings. The results indicate that *Gated RNN* is capable of handling the vanishing gradient problem to some extend, and it is practical to adaptively model sentence semantics in document representation. *GatedNN Avg* and *Bi GatedNN Avg* obtains comparable performances with *GatedNN*.

4 Related Work

Document level sentiment classification is a fundamental problem in sentiment analysis (Pang and Lee, 2008; Liu, 2012), which aims at identifying the sentiment label of a document (Pang et al., 2002; Turney, 2002). Pang and Lee (2002; 2005)

cast this problem as a classification task, and use machine learning method in a supervised learning framework. Turney (2002) introduces an unsupervised approach by using sentiment words/phrases extracted from syntactic patterns to determine the document polarity. Goldberg and Zhu (2006) place this task in a semi-supervised setting, and use unlabelled reviews with graph-based method. Dominant studies in literature follow Pang et al. (2002) and work on designing effective features for building a powerful sentiment classifier. Representative features include word ngrams (Wang and Manning, 2012), text topic (Ganu et al., 2009), bag-of-opinions (Qu et al., 2010), syntactic relations (Xia and Zong, 2010), sentiment lexicon features (Kiritchenko et al., 2014).

Despite the effectiveness of feature engineering, it is labor intensive and unable to extract and organize the discriminative information from data (Bengio et al., 2015). Recently, neural network emerges as an effective way to learn continuous text representation for sentiment classification. Existing studies in this direction can be divided into two groups. One line of research focuses on learning continuous word embedding. Traditional embedding learning algorithms typically leverage contexts of words in a context-prediction way (Bengio et al., 2003; Mikolov et al., 2013; Baroni et al., 2014). Since these methods typically map words with similar contexts but opposite polarity (e.g. "good" and "bad") to neighboring vectors, several studies (Maas et al., 2011; Labutov and Lipson, 2013; Tang et al., 2014) learn sentiment-specific word embeddings by taking sentiment of texts into account. Another line of research concentrates on semantic composition (Mitchell and Lapata, 2010). Yessenalina and Cardie (2011) represent each word as a matrix and use iterated matrix multiplication as phrase-level composition function. Socher et al. (2013b) introduce a family of recursive neural networks for sentence-level semantic composition. Recursive neural network is extended with global feedbackward (Paulus et al., 2014), feature weight tuning (Li, 2014), deep recursive layer (Irsoy and Cardie, 2014), adaptive composition functions (Dong et al., 2014), combined with Combinatory Categorial Grammar (Hermann and Blunsom, 2013), and used for opinion relation detection (Xu et al., 2014). Glorot et al. (2011) use stacked denoising autoencoder. Convolutional neural networks are widely used for semantic composition (Kim, 2014; Kalchbrenner et al., 2014; Denil et al., 2014; Johnson and Zhang, 2015) by automatically capturing local and global semantics. Le and Mikolov (2014) introduce Paragraph Vector to learn document representation from semantics of words. Sequential model like recurrent neural network or long short-term memory (LSTM) are also verified as strong approaches for semantic composition (Li et al., 2015a).

In this work, we represent document with convolutional-gated recurrent neural network, which adaptively encodes semantics of sentences and their relations. A recent work in (Li et al., 2015b) also investigate LSTM to model document meaning. They verify the effectiveness of LSTM in text generation task.

5 Conclusion
