A Datasets

GENIA (Ohta et al., 2002) is an English biology nested named entity dataset and contains 5 entity types, including `DNA`, `RNA`, `protein`, `cell line`, and `cell type` categories. Follow Yu et al. (2020), we use 90%/10% train/test split and evaluate the model on the last epoch.

ACE04 and ACE05 (Doddington et al., 2004; Walker et al., 2006) are two English nested datasets, each of them contains 7 entity categories. We follow the same setup as previous work Katiyar and Cardie (2018); Lin et al. (2019).

KBP17 (Ji et al., 2017) has 5 entity categories, including `GPE`, `ORG`, `PER`, `LOC`, and `FAC`. We follow Lin et al. (2019) to split all documents into 866/20/167 documents for train/dev/test set.

NNE (Ringland et al., 2019) is a English nested NER dataset with 114 fine-grained entity types. Follow Wang et al. (2020a), we keep the original dataset split and pre-processing.

FewNERD (Ding et al., 2021) is a large-scale English flat NER dataset with 66 fine-grained entity types. Follow Ding et al. (2021), we adopt a standard supervised setting.

CoNLL03 (Tjong Kim Sang and De Meulder, 2003) is an English dataset with 4 types of named entities: `LOC`, `ORG`, `PER` and `MISC`. Follow Yan et al. (2021); Yu et al. (2020), we train our model on the train and development sets.

OntoNotes (Pradhan et al., 2013) is an English dataset with 18 types of named entity, consisting of 11 types and 7 values. We use the same train, development, test splits as Li et al. (2020b).

Chinese MSRA (Levow, 2006) is a Chinese dataset with 3 named entity types, including `ORG`, `PER`, `LOC`. We keep the original dataset split and pre-processing.

In Table 6 and Table 7, we report the number of sentences, the number of sentences containing nested entities, the average sentence length, the total number of entities, the number of nested entities, the nesting ratio, the maximum and the average number of entities in a sentence on all datasets.

B Implementation Details

In default setting, we set the number of instance queries $M = 60$, and the total assignable quantity $Q = M \times 0.75 = 45$. To ensure that the assignable quantities of different entities are balanced, we randomly divide Q to different entities and adjust each division to be larger than Q/G, where G is the number of the ground-truth entities. When the number of entities is more than the total assignable quantity, we specify $Q = G$. We have also tried other configurations that will be discussed in Appendix D.3. We set L word-level transformer layers after BERT and set auxiliary losses in each layer. In the default setting L equals 5. We compare the effect of different auxiliary layers on the model performance, which will be discussed in Appendix D.1. Since the instance queries are randomly initialized and do not have query semantics at the initial stage of training, we first fix the parameters of BERT and train the model for 5 epochs, allowing the instance queries to initially learn the query semantics. When decoding entities, we filter out the predictions with localization probability and classification probability less than the threshold 0.6 and 0.8, respectively.

C Baselines

We compare PIQN with the following baselines:

- **ARN** (Lin et al., 2019) designs a sequence-to-nuggets architecture for nested mention detection, which first identifies anchor words and then recognizes the mention boundaries.
- **HIT** (Wang et al., 2020b) designs a head-tail detector and a token interaction tagger, which can leverage the head-tail pair and token interaction to express the nested structure.
- **Pyramid** (Wang et al., 2020a) presents a layered neural model for nested entity recognition, consisting of a stack of inter-connected layers.
- **Biaffine** (Yu et al., 2020) formulates NER as a structured prediction task and adopts a dependency parsing approach for NER.
- **BiFlaG** (Luo and Zhao, 2020) designs a bipartite flat-graph network with two subgraph modules for outermost and inner entities.
- **BERT-MRC** (Li et al., 2020b) formulates the NER task as a question answering task. They construct type-specific queries using semantic prior information for entity categories.

- **BARTNER** (Yan et al., 2021) formulates NER as an entity span sequence generation problem and uses a unified Seq2Seq model with the pointer mechanism to tackle flat, nested, and discontinuous NER tasks.

- **Seq2Set** (Tan et al., 2021) formulates NER as an entity set prediction task. Different from Straková et al. (2019), they utilize a non-autoregressive decoder to predict entity set.

- **Locate&Label** (Shen et al., 2021a) treats NER as a joint task of boundary regression and span classification and proposed a two-stage identifier of locating entities first and labeling them later.

For a fair comparison, we did not compare with Sun et al. (2020); Li et al. (2020a); Meng et al. (2019) on Chinese MSRA because they either used glyphs or an external lexicon or a larger pre-trained language model. In addition, some works (Wang et al., 2021, 2022b) used search engines to retrieve input-related contexts to introduce external information, and we did not compare with them as well.

D Analysis

D.1 Analysis of Auxiliary Loss

Many works (Al-Rfou et al., 2019; Carion et al., 2020) have demonstrated that the auxiliary loss in the middle layer introduces supervised signals in advance and can improve model performance. We compared the effect of the different number of auxiliary-loss layers on the model performance (F1-score on ACE04). Overall, the model performs better as the number of auxiliary-loss layers increases. The model achieves the best results when the number of layers equals 5.

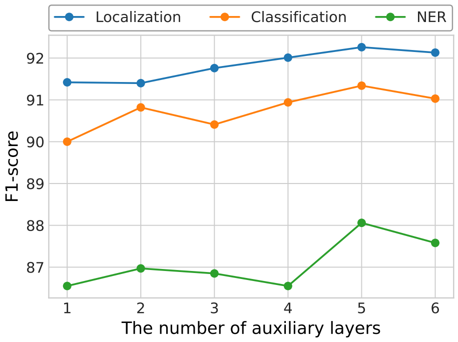

Figure 5: Analysis of Auxiliary Loss

D.2 Analysis of Two Subtasks

We compare the model performance on entity localization and entity classification subtasks on the ACE04 dataset, as shown in Table 8. Compared with the previous state-of-the-art models (Tan et al., 2021; Shen et al., 2021a), our model achieves better performance on both entity localization and entity classification subtasks. This illustrates that the instance queries can automatically learn their query semantics about location and type of entities, which is consistent with our analysis in 5.3.

Model	Localization		
	Pr.	Rec.	F1
Tan et al. (2021)	92.75	90.24	91.48
Shen et al. (2021a)	92.28	90.97	91.62
PIQN	92.56	**91.89**	**92.23**

Model	Classification		
	Pr.	Rec.	F1
Tan et al. (2021)	95.36	86.03	90.46
Shen et al. (2021a)	95.40	86.75	90.87
PIQN	**95.59**	**87.81**	**91.53**

Table 8: Localization and Classification Performance on ACE04

D.3 Analysis of Label Assignment

(M, Q)	Loc. F1	Cls. F1	Pr.	Rec.	F1
(60, 15)	91.05	90.15	87.57	85.67	86.61
(60, 30)	91.76	90.37	88.23	86.16	87.18

(60, 30)	91.76	90.37	88.23	86.16	87.18
(90, 45)	**91.88**	**90.56**	**88.23**	**86.46**	**87.34**
(120, 60)	91.75	90.45	87.19	86.56	86.87

Table 9: Analysis on Dynamic Label Assignment for different combinations of the number M of instance queries and the total assignable quantity Q of labels.

We analyze the impact of dynamic label assignment on model performance for different combinations of the number M of instance queries and the total assignable quantity Q of labels. From Table 9, we observe that (1) there is a tradeoff between M and Q, and the model achieves the best performance with a ratio of 4:3. With this setting, the ratio of positive to negative instances of instance queries is 3:1. (2) The number of instance queries and the total assignable quantity is not as large as possible, and an excessive number may degrade the model performance. In our experiments $(M, Q) = (60, 45)$ is the best combination.

ProphetChat: Enhancing Dialogue Generation with Simulation of Future Conversation

Abstract

Typical generative dialogue models utilize the dialogue history to generate the response. However, since one dialogue utterance can often be appropriately answered by multiple distinct responses, generating a desired response solely based on the historical information is not easy. Intuitively, if the chatbot can foresee in advance what the user would talk about (i.e., the dialogue future) after receiving its response, it could possibly provide a more informative response. Accordingly, we propose a novel dialogue generation framework named ProphetChat that utilizes the simulated dialogue futures in the inference phase to enhance response generation. To enable the chatbot to foresee the dialogue future, we design a beam-search-like roll-out strategy for dialogue future simulation using a typical dialogue generation model and a dialogue selector. With the simulated futures, we then utilize the ensemble of a history-to-response generator and a future-to-response generator to jointly generate a more informative response. Experiments on two popular open-domain dialogue datasets demonstrate that ProphetChat can generate better responses over strong baselines, which validates the advantages of incorporating the simulated dialogue futures.

1 Introduction

Recent years have witnessed a surge of interest in building open-domain chatbots using generative approaches (Shang et al., 2015; Zhao et al., 2017; Tao et al., 2018; Zhang et al., 2020). These prevailing methods typically utilize dialogue histories as the dialogue context to generate the response via maximum likelihood estimation. Different from directed text generation tasks like machine translation where the target sentences are strictly constrained by the source sentence (Holtzman et al., 2019), the dialogue history and the response in chit-chat conversations are loosely coupled (Feng et al., 2020a). In other words, open-domain chatbots often have more "freedom" to decide what to respond since there often exists multiple distinct responses that can appropriately answer the given utterance. However, we argue that such excessive "freedom" also reveals that the dialogue history only may not contain enough information to generate a desired response that is informative and easy to reply to. If provided with enriched dialogue contexts that contain more useful dialogue cues, it could be easier for the model to chat with a human. So here comes the questions: what kind of dialogue cues is complementary to dialogue histories, and how to obtain and use them.

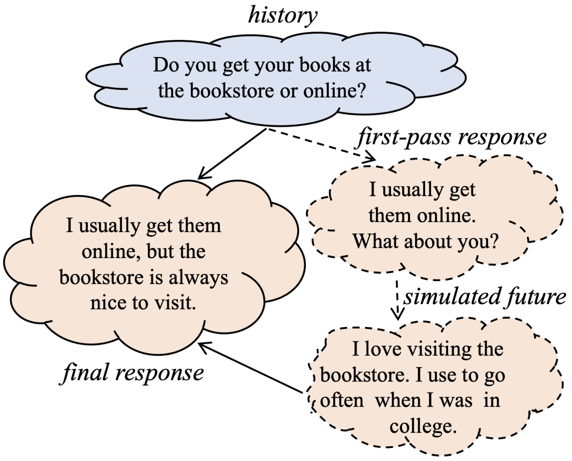

Figure 1: A generation case of ProphetChat. It first simulates the dialogue future then generates the response conditioned on both the history and the future.

Recent studies in representation learning have demonstrated that when representing a token in a sentence, considering the tokens on its right side in addition to its left side can bring significant improvement (Devlin et al., 2019; Yang et al., 2019). Similar findings also appear in directed text generation where the future tokens on the right side can be beneficial to generate the current token (Serdyuk et al., 2017; Zhang et al., 2018c; Chen et al., 2020; Qi et al., 2020). Sharing the same spirit, we pursue to use the "right side" information, which is the dialogue future in our task, as the complementary dialogue cue to enhance the generation of the current response. Intuitively, if the chatbot can be told in advance what the user would probably talk about (i.e., the dialogue future) after receiving its response, it only needs to provide a response that can smoothly connect the history and the future. To verify whether the dialogue future can act as the complementary dialogue cue, we conduct empirical studies. We find that using a dialogue generation model to learn the reverse dialogue flow (i.e., using the future to generate the response) is quite effective. Furthermore, when utilizing the ensemble of the history-to-response generation model and the future-to-response generation model to generate the response conditioned on both the history and the gold future, the quality of the generated response surely improves. Though effective, the ground truth dialogue future is inaccessible in the inference phase. Therefore, all existing works in this line choose to leverage the dialogue future only in the training phase (Shen et al., 2018; Feng et al., 2020a,b), leaving the inference phase unchanged.

We argue that explicitly providing the possible dialogue futures in the inference phase can offer more direct help for the generation of the current response. To enable the incorporation of dialogue futures into response generation in the inference phase, we propose a response generation framework namely ProphetChat by answering two questions: how to acquire the future and how to use it. Figure 1 shows the generation process of ProphetChat. It consists of a history-to-response model (denoted as the forward model), a future-to-response model (denoted as the backward model), an ensemble gate, and a dialogue selector. Given a dialogue history, we first utilize an effective beam-search-like roll-out strategy to simulate possible dialogue futures. Concretely, the forward model first generates a batch of n possible responses based on the dialogue history. The dialogue selection model then comes to pick up the k-best responses. We further generate n possible futures for each of the picked responses, resulting in $k \cdot n$ futures. The selection model again picks up the k-best futures which are of higher quality compared with randomly sampled ones. Next, conditioned on both the history and the simulated future, we employ the forward model and the backward model to jointly generate the response by summing the per-step output probability distributions of the two models using a calculated weight. The weight is obtained by a trainable gate that learns to balance the trade-off between history and future information. Finally, we gather the k responses generated solely based on the history and the $k \cdot n$ responses generated based on both the history and the future, and use the selector to choose the top-ranked one as the final response. Since the ensemble generation model relies on the selector to sequentially select the response and the future, and the ensemble generation model also needs to learn how to balance the history and the future information given the selected future, we jointly train the whole model to make each module better collaborate with others to fulfill the ultimate goal: to maximize the likelihood of the gold response estimated by the ensemble generation model given the history and the selected future. We train the ensemble generation model directly using MLE objective while adopting reinforcement learning to tune the selector.

Our contributions in this paper are three folds:

- We propose a novel dialogue generation framework named ProphetChat which leverages the simulated dialogue future to enhance response generation through the ensemble of the history-to-response generator and the future-to-response generator. To the best of our knowledge, we are the first to utilize the dialogue futures for response generation in the inference phase.

- To acquire better dialogue futures in the inference phase, we propose an effective beam-search-like roll-out strategy for dialogue future simulation with the help of a dialogue selector.

- We conduct comprehensive experiments on two popular open-domain dialogue datasets and the results verify the advantages of incorporating the simulated dialogue futures.

2 Related Work

Dialogue System. Open-domain response generation has long been the research hot spot. Recently, various efforts have been made to generate informative and diverse responses by introducing effective architectures and learning objectives and by incorporating external knowledge. Zhao et al. (2017); Gu et al. (2018) applied CVAE to model the variability of responses. Li et al. (2016b); Zhang et al. (2018a); Saleh et al. (2020) adopted reinforcement learning to encourage the model to generate desired responses through carefully designed reward functions. Zhang et al. (2018b); Chan et al. (2019); Zheng et al. (2020); Li et al. (2021) exploited persona information to improve the coherence of the response. Zhou et al. (2018); Song et al. (2019); Shen and Feng (2020) considered emotions when generating the response. Dinan et al. (2018); Lian et al. (2019); Zhao et al. (2020a,b); Li et al. (2020) conditioned the response generation model with knowledge. Different from the above works that aimed to design specific history-to-response generation models, we propose a response generation framework where possible dialogue futures are utilized in the inference phase with the help of an effective future simulation strategy.

Future Modeling. There are various scenarios where considering future information is useful. In text generation, Serdyuk et al. (2017) proposed a twin network to regularize the hidden states of the left-to-right decoder with the future-aware right-to-left decoder. Zhang et al. (2018c) used the target-side hidden states generated by the right-to-left decoder to help the right-to-left decoder during translation so that the target-side future information can help avoid under-translation. Different from these works that consider the right side tokens as the future for the current token, we define "future" as the next dialogue utterance of the current response in a dialogue session. In response generation, Feng et al. (2020a) proposed to use gold futures as the conditions of two discriminators and adopted adversarial training to encourage diversity. Feng et al. (2020b) employed gold dialogue futures to learn a future-aware teacher model and transferred the knowledge to a history-to-response student model via imitation learning. These works only use the future information in the training phase, while we utilize the simulated dialogue future in the inference phase to provide the history-to-response generation model with direct help.

3 Preliminaries

In this section, we introduce the major off-the-shelf components in our framework.

DialoGPT (Zhang et al., 2020) is a GPT-based response generation model pre-trained on large-scale open-domain dialogue corpus by maximizing the likelihood of the successive dialogue utterances (i.e., the forward dialogue flow) given the initial dialogue history. While trained on the same corpus with the same architecture, DialoGPT-MMI is trained on the backward dialogue flow where the order of the utterances in a dialogue are reversed. We adopt DialoGPT as the forward generator and DialoGPT-MMI as the backward generator.

GRADE (Huang et al., 2020) is a graph-enhanced dialogue evaluation model that uses both utterance-level contextualized representations and topic-level graph representations to evaluate the response. As it is one of the SOTA dialogue evaluation models, we choose it as our dialogue selector.

4 Method

4.1 Overview

Our framework consists of a forward generator G_F that models the history-response-future dialogue flow, a backward generator G_B that models the reversed dialogue flow, a dialogue selector S that ranks the sampled utterances conditioned on the dialogue context, and a gate g that dynamically balance the ensemble weights between G_F and G_B. Given a history h, we first use G_F to sequentially sample the response r and the future f with the help of S. We then employ the ensemble of G_F and G_B using g to generate the response based on both h and f. The firstly generated responses together with the future-aware second-pass responses are finally re-ranked by S to produce the final response. Figure 2 illustrates our proposed framework.

4.2 Future Simulation

Given a dialogue history h, we first use G_F to generate n responses $\{r^i\}_{i=1}^n$ using top-k sampling (Fan et al., 2018). We denote these responses as the *first-pass responses*. Then the selector S calculates the quality scores $\boldsymbol{s_r} \in \mathbb{R}^n$ for all history-response pairs. The quality scores naturally form a propability distribution $\boldsymbol{p_r} \in \mathbb{R}^n$ over the sampled responses by using a softmax operation. We here consider the response selection procedure as sampling from such a distribution. Considering

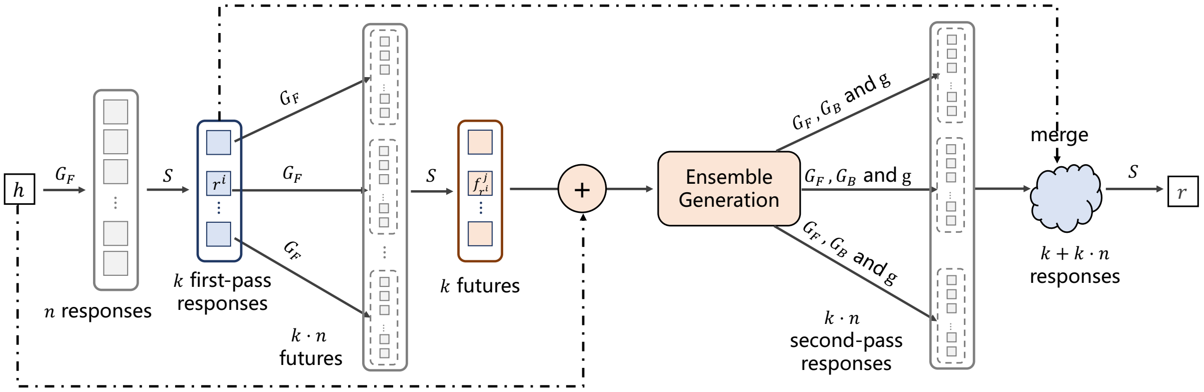

Figure 2: The overall framework of ProphetChat.

that the responses in open-domain dialogue are often diverse and hard to evaluate by any automatic evaluation metric, only using the response with the highest quality score or probability to further simulate the future is suboptimal. Meanwhile, generating futures conditioned on all the n sampled responses is too time-consuming. Therefore, borrowing the idea from beam search (Sutskever et al., 2014) where the k-best sentence prefixes are maintained during decoding to balance the searching performance and speed, we propose to keep the k-best responses at hand while discarding the others. For each of the selected response r^i, we concatenate it with h and use G_F to again sample n dialogue futures $\{f^j_{r^i}\}^n_{j=1}$, where $f^j_{r^i}$ denotes the j-th future simulated from h and r^i.

Up to now, we obtain $k \cdot n$ history-response-future dialogue triplets for the same dialogue history h by simulation. We again resort to the selector S to calculate the quality scores of all the generated futures conditioned on h and their corresponding ancestral responses as $\{\boldsymbol{s}_{\boldsymbol{f}_{\boldsymbol{r}^1}}, \ldots, \boldsymbol{s}_{\boldsymbol{f}_{\boldsymbol{r}^i}}, \ldots, \boldsymbol{s}_{\boldsymbol{f}_{\boldsymbol{r}^k}}\}$. We consider all the generated futures in the same sampling space (i.e., the future space of the given history) and directly perform softmax over the $k \cdot n$ quality scores to get the future distribution. Considering that the responses used to generate the futures are not equal in quality, we additionally multiply each probability of the simulated future $f^j_{r^i}$ with the probability of its ancestral response p_{r^i} to get the final ranking scores based on which we select k-best dialogue futures.

4.3 Ensemble Generation

Now with the history h and k plausible dialogue futures at hand, we pursue to generate the second-pass response conditioned on both the history and the future information. Given that the simulated futures contain noise derived from error accumulation in the simulation phase, it is necessary to balance the weights between the history-conditioned G_F and the future-conditioned G_B when they collaboratively generate the response. Hereby we introduce a trainable gate g which takes the last hidden states from G_F and G_B as inputs and calculates an ensemble weighting score w using an MLP with sigmoid activation. We then generate the response $\hat{r}$ using the per-step weighted ensemble of G_F and G_B conditioned on h and f:

$$\begin{aligned} P(\hat{r}_t|h, f, \hat{r}_{<t}; \theta_F, \theta_B, \theta_g) &= w \cdot P(\hat{r}_t|h, \hat{r}_{<t}; \theta_F) \\ &+ (1-w) \cdot P(\hat{r}_t|f, \hat{r}_{<t}; \theta_B), \end{aligned} \tag{1}$$

where the subscript t denotes the t-th token in $\hat{r}$ and θ_F, θ_B and θ_g denote the parameters of G_F, G_B and g respectively. Specifically, we sample n responses for the ensemble generation of h and each of the k futures, resulting in $k \cdot n$ future-aware responses. We denote these responses as the *second-pass responses*. To make full use of the k-best first-pass responses, we finally re-rank the $k + k \cdot n$ responses with S and consider the top-ranked response as our system outputs.

4.4 Training

Recall that there are several components G_F, G_B, S, and g in our framework. Although some of them can directly be used without post-training, this might be suboptimal. For one thing, post-training the models on domain-specific data with the same objective often brings better performance (Gururangan et al., 2020). For another, the original loss functions may not be thoroughly in accord with the ultimate goal in our framework. Thereby we propose a customized joint training algorithm.

For G_F and G_B, we adopt a similar training objective used by Zhang et al. (2020). Take G_F for example, we consider every consecutive three utterances in a dialogue session as a history-response-future triplet and fine-tune the models by minimizing the negative log likelihood of the response and the future conditioned on the history. G_B is fine-tuned in a similar manner with the reversed inputs. After fine-tuning, G_F and G_B are fixed.

For g, we can directly minimize the negative log-likelihood of the gold response r^*:

$$\mathcal{L}_1(\theta_g) = -\sum_t \log P(r^*_t | h, f, r^*_{<t}; \theta_F, \theta_B, \theta_g), \tag{2}$$

where f is simulated from either the gold response (denoted as the teacher-forcing mode) or a sampled response (denoted as the free-running mode).

While for S, considering that the original objective used in Huang et al. (2020) is not customized for selecting better responses and futures, it is better to perform task-specific post-training. Therefore, we propose to directly optimize S to our ultimate goal which is to maximize the log-likelihood of the gold response given the history and the selected simulated future. Since the sampling operation is non-differentiable, we use REINFORCE (Williams, 1992) with a self-critic (Rennie et al., 2017) baseline to estimate the gradient. We consider the future simulation process as sequential sampling from the score distributions of the responses and the futures respectively. Given the n responses generated by G_F conditioned on h, we sample a response r^i from $\boldsymbol{p}_r$. Then we generate n futures conditioned on h and r^i using G_F and again sample a future $f^j_{r^i}$ from them. We feed this sampled future and the gold history into our ensemble generation model and calculate the log-likelihood of the gold response, which is the opposite number of Equation 2, as the reward R. To reduce the variance of gradient estimation, we introduce a self-critic baseline. Concretely, we sequentially select the response and the future with the highest scores in each sampling step and calculate the reward of using the greedy future as the baseline reward R_b. The gradients are then estimated as follows:

$$\begin{aligned}\nabla_{\theta_S}\mathcal{L}_2(\theta_S) \approx -(R - R_b)\nabla_{\theta_S}[\log P(r^i | h; \theta_S) \\ + \log P(f^j_{r^i} | r^i, h; \theta_S)].\end{aligned} \tag{3}$$

Intuitively, directly forcing the model to learn in a fully free-running mode may be burdensome as the futures generated from the sampled responses may contain much noise. A better choice is to allow the model to gradually learn from easy to hard. We create a curriculum schedule (Bengio et al., 2015) that gradually switches from the teacher-forcing mode to the free-running mode. Specifically, let η denote the proportion of teacher-forcing mode, we gradually decrease η from β to α with cosine annealing schedule, where $0 \leq \alpha < \beta \leq 1$.

For the overall training, we first train g using Equation 2 and set $\eta = \beta$. Then we tune S using Equation 3 with the help of the above curriculum learning schedule. Finally, we jointly tune g and S with a fixed $\eta = \alpha$.

5 Experimental Setup

5.1 Datasets

To verify the effectiveness of our proposed response generation framework, we experiment on two popular dialogue datasets, **DailyDialog** (Li et al., 2017) and **PersonaChat** (Zhang et al., 2018b). We follow the original train/dev/test division and reconstruct the datasets by treating each consecutive three utterances as a triplet that represents history-response-future, resulting in approximately 65k/6k/6k examples in DailyDialog and 114k/14k/13k examples in PersonaChat.

5.2 Comparison Methods

5.2.1 Baselines

Posterior-GAN (Feng et al., 2020a) and **RegDG** (Feng et al., 2020b) are two non-GPT-based response generation models that use dialogue futures in the training time through either adversarial training or knowledge distillation.

DialoGPT$_F$ denotes the fine-tuned DialoGPT $_{medium}$ (Zhang et al., 2020) on two downstream datasets. **DialoGPT**$_{F,rerank}$ is its enhanced version which is equipped with the dialogue evaluation model (i.e., GRADE (Huang et al., 2020)) to select the top-ranked response.

5.2.2 Variants of ProphetChat

ProphetChat$_{k=?}$ denotes the model with the same model parameters but different beam sizes when simulating the futures.

ProphetChat$_{first}$ and **ProphetChat**$_{second}$ are used to denote the settings where only the first-pass or the second-pass responses are used in the final re-ranking process.

Table 1: Response generation results on DailyDialog (the upper) and PersonaChat (the lower) datasets. Within each table, the upper block lists baseline results, the middle block presents the performance of ProphetChat and its variants, and the lower block gives the ablation results. The lines with gray backgound are our main model.

5.2.3 Ablations of ProphetChat

ProphetChat *w/o* history means we utilize the top-ranked simulated future to generate the response without the help of the history.

ProphetChat *w/o* selector denotes the model where we sequentially sample the responses and the futures randomly without using the selector.

ProphetChat *w/o* train means we directly utilize the fine-tuned G_F, G_B and the fixed S without post-training. We manually choose a fixed ensemble weight for the ensemble generation process instead of using a trainable gate.

ProphetChat *w/* gold future denotes the model that utilizes the history and the gold future, which is **inaccessible** in the inference phase, to generate the response.

5.3 Implementation Details

Our implementation is based on the open-source toolkit Transformers (Wolf et al., 2020). For the generator G_F and G_B, we initialize them with the publicly released DialoGPT$_{medium}$ and DialoGPT-MMI$_{medium}$[1]. For the dialogue selector, we use the pre-trained GRADE[2] as initialization. We firstly use AdamW (Loshchilov and Hutter, 2017) with learning rate 3e-5 to fine-tune G_F and G_B. Then, we jointly train the ensemble gate g and the top non-transformer layers of the selector S with learning rate 2e-5, while keeping other parameters (i.e., G_F, G_B and most of the parameters of S except for its top layers) fixed. We set the curriculum hyperparameters (α, β) as (0.0, 1.0) on both datasets. We fix the sample number n of both the response and the future as 10 and vary the simulation beam size $k \in \{1, 2, 3, 5\}$. We choose k=5 on DailyDialog and k=3 on PersonaChat. We use top-k sampling (Fan et al., 2018) to generate the first-pass responses, the futures, and the second-pass responses with the temperature as 0.7 and k as 40. All the hyperparameters are chosen depending on

their performance on the development set.

5.4 Evaluation Metrics

Automatic Metrics. We use **BLEU** (Papineni et al., 2002) to measure the word overlap between the ground truth responses and the generated ones. For simplification, we use B-n to denote the n-gram overlap scores. We employ **Distinct 1-4** (Li et al., 2016a) to measure the diversity of the generated responses, where Distinct-n (abbreviated as D-n) represents the ratio of distinct n-grams in responses. We adopt the embedding-based metrics (i.e., **Average**, **Extrema**, and **Greedy**) (Liu et al., 2016) to measure the semantic relevance between the ground truth responses and the generated ones.

Human Evaluation. We ask three well-educated annotators to score 150 randomly selected responses generated by ProphetChat and other baselines. The annotators are asked to evaluate the human-likeness of the responses from three perspectives: readability, sensibleness and specificity. For readability, we ask annotators whether the response is grammatically correct and easy to read. For sensibleness and specificity, we follow Adiwardana et al. (2020) to conduct the evaluation. For all three metrics, the annotators are asked to give 0-1 labels. We provide the averaged scores and further calculate the Fleiss's kappa (Fleiss, 1971) to measure the inter-annotator agreement.

6 Experimental Results

6.1 Overall Performance

Table 1 presents the overall performance of our proposed method as well as its variants and ablations. Table 2 shows the human evaluation results. Compared with the two non-GPT baselines, GPT-based models generally achieve superior performance, especially in Distinct and human evaluation. ProphetChat outperforms all the baseline methods by a large margin on both datasets in almost all automatic metrics and all human evaluation metrics. For human evaluation results, the Fleiss's kappa scores are mainly distributed in [0.4, 0.6], which means annotators achieved moderate agreement.

6.2 Discussion of Model Variants

With the same model parameters, we have several model variants by using different hyperparameters or computation flow in the inference phase. Here we mainly discuss two types of model variants: (1) the model with different simulation beam size k, (2) the final re-ranking among the first-pass responses or the second-pass responses.

The simulation beam size. When simulating the dialogue future, we can choose different beam sizes to balance the computation cost and the performance. We test $k \in \{1, 2, 3, 5\}$ on both datasets and find $k = 5$ is better than others on DailyDialog, while $k = 3$ is enough on PersonaChat. It can be seen that when k is small, increasing k can boost the performance. With the appropriate choice of the simulation beam size, ProphetChat can be deployed to various scenarios with different computation resources. We further directly test the future simulation performance by comparing the futures generated by our method and generated using the gold responses. The results are listed in Table 3. It can be observed that on DailyDialog, with the increase of k, our future simulation method gradually catches up with the teacher forcing counterpart in BLEU and Distinct, while still lagging behind in embedding-based metrics. On PersonaChat, our method even outperforms TF_{rerank} in several metrics. These findings proves that we are able to obtain dialogue futures of good quality solely based on the history through our effectiveness future simulation algorithm.

Re-ranking among the first pass or the second pass responses. Recall that in our main framework, we finally gather the k first-pass responses and the $k \cdot n$ second-pass responses together and finally re-rank them with the selector conditioned on both the history and the corresponding future. From Table 1 we can find that on both datasets, re-ranking using both groups of responses yield better performance in most of the metrics than only using one of them. When comparing their individual performance, it can be observed that on DailyDialog, $\text{ProphetChat}_{second}$ is superior to $\text{ProphetChat}_{first}$ in BLEU and Distinct, while $\text{ProphetChat}_{first}$ wins in embedding-based metrics. On PersonaChat, $\text{ProphetChat}_{second}$ wins all metrics except BLEU. There exist some cases where the simulated futures are meaningless or include irrelevant information. When this happens, the final re-ranking process comes as the remedy. We find that the proportions of the test cases where the final responses are picked from the second-pass responses are 40.4% on DailyDialog and 36.6% on PersonaChat, which are less than the proportions of the second-pass responses involved in re-ranking. This finding indicates that re-ranking plays a vital role to select the appropriate responses from the two groups of candidate responses of various qualities.

6.3 Ablation Study

We make ablation study from several perspectives including the effect of the history, the selector and the training algorithm. Table 1 shows that although only using the simulated future (i.e., ProphetChat *w/o* history) can generate plausible responses, the performance is largely inferior to the full model. Also, we observe that ProphetChat *w/o* selector underperforms the full model, demonstrating the effectiveness of the selector which helps simulate better futures. When considering the training objective, we find that ProphetChat *w/o* train already achieves good performance, but jointly training the whole model further makes our model perform better. Finally, when provided with the gold future, ProphetChat *w/* gold future outperforms ProphetChat in terms of embedding-based metrics on both datasets, and BLEU on PersonaChat, while underperforming on other metrics. In other words, with the simulated futures, ProphetChat can achieve comparable performance with the model that "cheats" to see the gold future, which also demonstrates the effectiveness of our method.

6.4 Case Study

Figure 3 presents two cases sampled from the two datasets. For ProphetChat, in addition to its final response, we provide its corresponding first-pass response, and the simulated future of the response. From the two cases we can observe that by taking the simulated future into consideration, ProphetChat generates more informative responses than baselines. Specifically, in case 1, when a two-choice query is issued in the history, the first-pass response chooses “online" as the answer and meanwhile poses another question. ProphetChat then uses the history and this first-pass response to simulate the future where the other possible choice (i.e., the bookstore) is talked about. Given the history and the simulated future, ProphetChat finally obtains its response which not only answers the query

Case 1

History: That is cool. Do you get your books at the bookstore or online?
Gold Response: I usually try to use the library, but otherwise I get them online.
Gold Future: Are you going for elementary education or high school or college?

PropherChat: I usually get them online, but the bookstore is always nice to visit.
PropherChat First-Pass Response: I usually get them online. What about you?
Simulated Future: I love visiting the bookstore. I use to go often when I was in college.

DialoGPT$_F$: I usually get them online. You?
Posterior-GAN: I get them on line.
RegDG: I like to go to the bookstore.

Case 2

History: Well, I'm a bit out of shape. I'm thinking about getting some exercises to keep fit.
Gold Response: Oh, that's good news for us.
Gold Future: So what do you provide?

PropherChat: That's a good idea! What kind of exercise do you like to do?
PropherChat First-Pass Response: What kind of exercise?
Simulated Future: Well, I'm thinking of doing some kind of body weight exercises. I don't know if that will help me lose weight, though.

DialoGPT$_F$: What kind of exercise?
Posterior-GAN: Yes, you need exercise.
RegDG: I'd like to do some exercise too.

Figure 3: Generation cases from the two datasets. Case 1 is sampled from PersonaChat and Case 2 is sampled from DailyDialog.

in the history but also incorporates the cues in the future. This response becomes more informative than the previous one. A similar phenomenon can also be found in case 2 where the final response is more comprehensive that connects the history and the future smoothly.

7 Conclusion

We propose a novel response generation framework that utilizes the simulated dialogue futures in the inference phase to enhance response generation. To acquire the dialogue futures, we design an effective beam-search-like roll-out strategy using a history-to-response dialogue generation model and a dialogue selector. To make use of the simulated future, we use the dynamic ensemble of the history-to-response and the future-to-response generation model. Experiment results demonstrate the effectiveness of our proposed method on two popular datasets. In the future, we plan to enable our future simulation method to simulate multiple turns of dialogue futures.

Ethical Statement

This paper proposes a new dialogue generation framework that utilizes the simulated dialogue futures in the inference phase to enhance the generation of the response. Generative approaches are widely used in a wide range of dialogue applications. The proposed method improves the quality of the generated responses, which could be beneficial to research and real-world applications. The research will not pose ethical issues. This paper doesn't involve any data collection and release thus there are no privacy issues. All the datasets used in this paper are publicly available and are widely adopted by researchers to test the performance of open-domain response generation models. This paper conducts human evaluation to evaluate the quality of the generated responses. Three part-time research assistants were recruited to do human evaluation with clearly demonstrated evaluation rules. They worked with the pay 100 CNY/hour during their evaluation.

Abstract

Fusion-in-decoder (FID) (Izacard and Grave, 2021) is a generative question answering (QA) model that leverages passage retrieval with a pre-trained transformer and pushed the state of the art on single-hop QA. However, the complexity of multi-hop QA hinders the effectiveness of the generative QA approach. In this work, we propose a simple generative approach (PATHFID) that extends the task beyond just answer generation by explicitly modeling the reasoning process to resolve the answer for multi-hop questions. By linearizing the *hierarchical reasoning path* of supporting passages, their key sentences, and finally the factoid answer, we cast the problem as a single sequence prediction task. To facilitate complex reasoning with multiple clues, we further extend the unified flat representation of multiple input documents by encoding cross-passage interactions. Our extensive experiments demonstrate that PATHFID leads to strong performance gains on two multi-hop QA datasets: HotpotQA and IIRC. Besides the performance gains, PATHFID is more interpretable, which in turn yields answers that are more faithfully grounded to the supporting passages and facts compared to the baseline FID model.

1 Introduction

Leveraging knowledge to make complex reasoning has been a fundamental problem of artificial intelligence. Open-domain question answering (QA) (Voorhees, 1999) is an integral part of such a line of research with impactful applications (Esteva et al., 2020; Zhang et al., 2020), where the task is to answer general domain questions by gathering evidence from a large collection of documents. While super-human level performance has been achieved on single-passage reading comprehension dataset like SQuAD (Rajpurkar et al., 2016), open-domain QA still has a long way to go, especially for questions requiring more complex reasoning. The main challenge in the task of complex QA, namely *multi-hop QA*, is that it requires a QA system to combine multiple pieces of evidence from multiple documents (Welbl et al., 2018; Talmor and Berant, 2018; Yang et al., 2018). Even for single-hop QA, it has been shown challenging for extractive QA models to effectively aggregate evidence from the combined pool of multiple passages, which has been the focus of recent work (Clark and Gardner, 2018; Min et al., 2019; Guu et al., 2020).

Recent work (Lewis et al., 2020b; Min et al., 2020) has demonstrated the promise of a generative approach at combining evidences from multiple passages for answer generation. Thanks to large pre-trained transformers like T5 (Raffel et al., 2020), Izacard and Grave (2021) introduced *fusion-in-decoder* (FID) that leverages passage retrieval with generative models for open-domain QA, achieving state-of-the-art scores across several single-hop QA benchmarks. However, we observe that the success of the FID model does not extend to multi-hop QA, which is corroborated by the findings in (Xiong et al., 2021). Further, the FID model is a rather opaque model in terms of interpretation of the answer generation process. This capability becomes especially important for multi-hop QA, which requires sequential reasoning across multiple evidences from the pool of retrieved passages.

In this work, we propose PATHFID, a generative QA model that learns to generate an answer along with a *reasoning path* to improve its capability of multi-hop reasoning. PATHFID extends multi-hop QA beyond just answer generation by explicitly modeling the full reasoning path to resolve the answer with a generative sequence-to-sequence model. To this end, we cast the problem as a single sequence prediction task that simultaneously models reasoning path consisting of supporting passages and facts, and eventually the factoid answer. Furthermore, we extend PATHFID to allow for cross-passage interactions between the

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 974 - 990
May 22-27, 2022

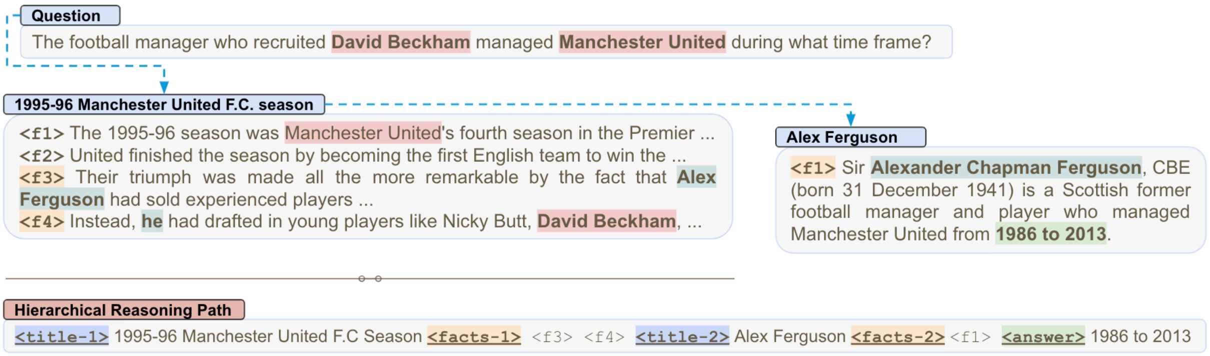

Figure 1: An example of multi-hop question from HotpotQA dataset. It requires fusing multiple evidences (supporting facts) from multiple passages in a certain order to arrive at the correct answer. We formulate the entire problem as a single sequence prediction of the linearized hierarchical path ending with the answer.

retrieved passages to obtain more expressive representations from the encoder to facilitate modeling a complex reasoning chain by the decoder. Figure 1 shows an example of our task formulation, and Figure 2 shows an overview of our approach. We evaluate our proposed approach on two multi-hop QA datasets: HotpotQA (Yang et al., 2018) and IIRC (Ferguson et al., 2020). Our extensive experiments demonstrate that (i) PathFiD leads to significant performance gains over FiD on answer generation, (ii) PathFiD is the first generative model unlocking the possibility of generating the reasoning path jointly with the answer while achieving competitive performance on supporting fact extraction metric as well. Besides the performance gains, PathFiD is able to expose the underlying reasoning process behind the answer generation, which allows us to conduct a much finer-grained qualitative and quantitative analysis on the model's behavior, providing insights into further improving and better understanding generative models for multi-hop QA.

2 Problem Setup and Background

In this section, we formally introduce the problem setup and establish the necessary background.

2.1 Multi-hop Question Answering

We first describe the multi-hop QA task in a general way. We assume that a collection of K passages are given for a question q: $D_q = \{p_1, p_2, \dots, p_K\}$, where D_q can be a pre-defined set, or it can also be an output from a text retrieval system (e.g., DPR (Karpukhin et al., 2020) and MDR (Xiong et al., 2021)) in an open-domain QA setting. That is, in the case of the open-domain setting, D_q is a subset of a large collection of passages, such as Wikipedia. The task is to generate an answer string a given q and D_q. In addition, we aim at identifying which passages provide evidence, and which sentences in them are describing the evidence. Figure 1 shows a comprehensive example of the task definition, where we can see that some sentences (called *supporting facts*) in the two paragraphs are crucial to answer the question. Moreover, there is a reasoning flow: the question → the first paragraph → the second paragraph, which is called a *reasoning path* in previous work (Asai et al., 2020). The overall task is then to predict the reasoning path along with the supporting facts, and the answer.

2.2 Fusion-in-Decoder Model (FiD)

Fusion-in-Decoder (FiD) is a generative reader based on a sequence-to-sequence architecture, initialized from pre-trained models such as T5 (Raffel et al., 2020) or BART (Lewis et al., 2020a). It consists of an encoder (**Enc**) and a decoder (**Dec**). First, it constructs a single block of text $b_n := \texttt{question:}\ q\ \texttt{title:}\ t_n\ \texttt{context:}\ p_n$ of concatenated evidence from each passage-title pair (p_n, t_n) together with the question (q). Then, each of the resulting evidence block b_n is independently encoded into $|b_n| \times d$-dimensional output representations, which are then concatenated to form a unified input representation

$$\mathbf{X} = [\mathbf{Enc}(b_1); \mathbf{Enc}(b_2); \dots, \mathbf{Enc}(b_N)] \quad (1)$$

of dimension $(\sum_n |b_n|) \times d$ where $|b_n|$ denotes the length of the n-th block b_n in number of tokens. Note that, the motivation behind this strategy is to avoid the expensive quadratic self-attention computation on the encoder-side, effectively reducing the complexity from $\mathcal{O}((\sum |b_n|)^2)$ to $\mathcal{O}(\sum |b_n|^2)$. Then, the overall answer generation is modeled as a conditional generation $p_\theta(a|\mathbf{X})$ given $\mathbf{X}$ consuming the unified input representation $\mathbf{X}$, where θ represents the set of all model parameters. The model is trained to minimize the cross-entropy loss for generating answer tokens on the decoder side. At inference time, FiD first computes $\mathbf{X}$ based on the retrieved passages, and then decodes the answer token by token following $p_\theta(a_i|a_{<i}, \mathbf{X})$ with the learned model parameters θ.

3 PathFiD Reader for Multi-hop QA

In this section, we introduce a generative reader (PathFiD) for K-hop QA that jointly generates an alternating sequence of *passage-level* and *fact-level* clues on the reasoning path by more explicit fusion of evidence from the pool of input passages to arrive at the correct answer.

3.1 Overview of PathFiD

As illustrated in Figure 2, PathFiD employs a single sequence-to-sequence architecture that independently encodes the input passages after inserting special fact markers ($<f_i>$) before the i-th sentence of each passage. Conditioning on the concatenation of token-level input representations per passage, its decoder then generates the linearized hierarchical reasoning path obtained by concatenating the sequence of passage titles and their corresponding supporting fact pointers followed by the answer. Each segment on the reasoning path is separated by special markers in a way that makes it possible to uniquely recover the individual segment predictions after decoding in the inference time.

3.2 Extending Multi-hop QA beyond Answer Generation

The opaqueness of the FiD model, which makes understanding of the reasoning process more difficult, motivated our approach and its emphasis on exposing the reasoning path. Instead of only modeling answer generation, we propose to jointly model it with the full *reasoning path* in an *hierarchical fashion* to derive the answer in a unified way using *multi-task maximum likelihood training*.

3.2.1 Global Input Representation

We utilize the core input encoding architecture from FiD approach (Section 2.2) by introducing a new passage representation that will facilitate supporting fact generation on the reasoning path as illustrated in Figure 2. To this end, we independently encode each input passage-title pair (p_n, t_n) along with the question q as a separate block $b_n^{\text{path}} := \texttt{question: } q \texttt{ title: } t_n \texttt{ context: } p_n^{\text{path}}$ where we redefine the context representation by inserting special tokens ($<f_i>$) before each sentence of the passage as

$$p_n^{\text{path}} := \ <f_1>\ s_n^{(1)}\ <f_2>\ s_n^{(2)}\ \cdots\ <f_{l_n}>\ s_n^{(l_n)} \quad (2)$$

where $s_n^{(i)}$ denotes the i-th sentence of passage p_n, and l_n is the number sentences it contains. Having redefined the input blocks (b_n^{path}) per passage, we then compute the global input representation similar to Eq. 1 by

$$\mathbf{X}_q^{\text{path}} = [\mathbf{Enc}(b_1^{\text{path}}); \mathbf{Enc}(b_2^{\text{path}}); \ldots; \mathbf{Enc}(b_N^{\text{path}})] \quad (3)$$

Note that sentence indicators ($<f_i>$) are shared across all passages, encouraging a more hierarchical passage representation by explicitly breaking them down into sentence-level sub-blocks using the same indicator tokens.

3.2.2 Hierarchical Reasoning Path as a Sequence

The hierarchical design of reasoning path is inspired by the human reasoning process for multi-hop QA task. More precisely, if a question q requires K-hop reasoning, then we process these K passages in a sequential order alternating between their passage-level and sentence-level evidence until we reach the answer. To this end, let $R_q = \{p_{r_1}, p_{r_2}, \ldots, p_{r_K}\}$ with $r_i \in [1, N]$ denote the sequence of passages from the larger pool D_q reflecting this reasoning process for locating the answer a for question q. As shown in Figure 2, we define the hierarchical reasoning path as a linearized sequence of blocks of passage titles and supporting facts followed by the answer block

$$\mathbf{Y}_q^{\text{path}} := [T_{r_1}; E_{r_1}; T_{r_2}; E_{r_2}; \cdots; T_K; E_{r_K}; A] \quad (4)$$

where T_{r_i} represents the i-th title block obtained by inserting a special token (`<title-i>`) before the title t_{r_j} and A denotes the answer block derived by prepending a special token (`<answer>`) to the answer a as illustrated in Figure 2. On the other hand, i-th supporting fact block is defined as the sequence of fact indicators following `<facts-i>` token by

$$E_{r_i} := \texttt{<facts-i>}\ <f_{j_1}>\ <f_{j_2}> \cdots\ <f_{j_{m_i}}> \quad (5)$$

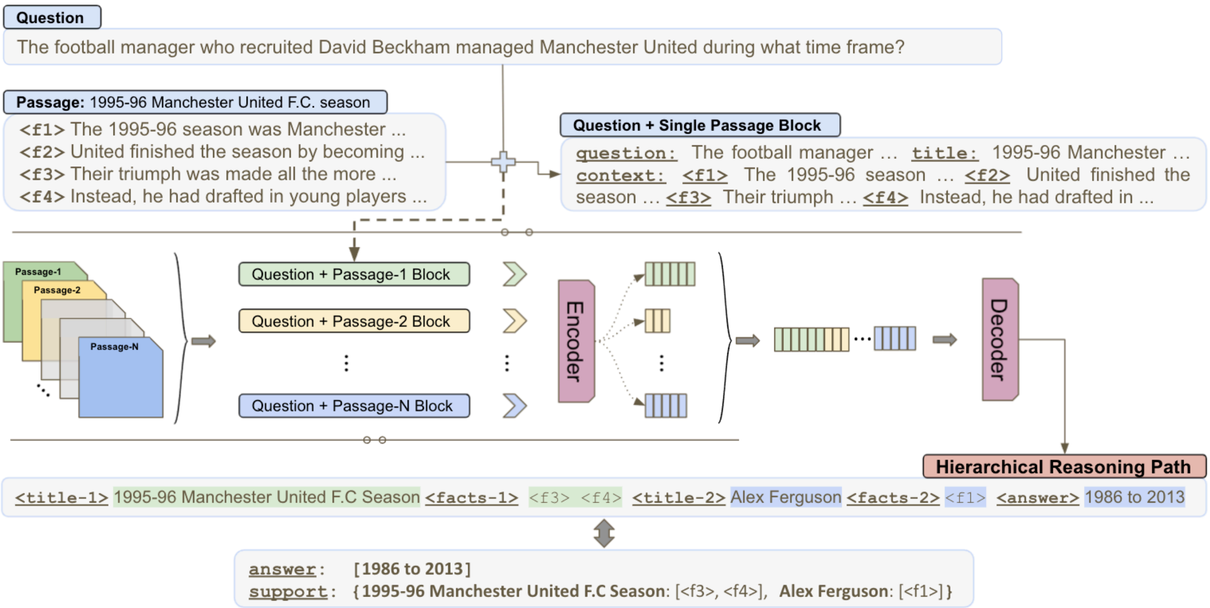

Figure 2: PATHFID model overview. Each question+passage block is encoded in parallel, which are then concatenated in to a long flat sequence of vector representations. The decoder then consumes this long sequence and generates the full reasoning path, which is then uniquely parsed into the final answer along with the supporting facts exposing the underlying reasoning.

where $\{j_1, j_2, \ldots, j_{m_i}\}$ denote the indices of key sentences to leverage from passage p_{r_i} to transition to the next evidence on the reasoning process R_q for question q, and $1 \leq m_i \leq l_{r_i}$ denotes the number of supporting facts. Note that fact indicators $<f_i>$ are shared between the contexts p^{path}_n of input blocks (Eq. 2) and supporting fact blocks (Eq. 5) on the target reasoning path to allow the decoder to follow along the sequential reasoning R_q by pointing to the facts E_{r_i} of passage p_{r_i}.

3.3 Encoding Cross-Passage Interactions (PATHFID+)

PATHFID enables more explicit evidence fusion through the reasoning path to guide the model to towards correct answer in a structured way. However, it still relies on the decoder to combine all the clues together, which might still struggle due to lack of cross-passage interactions as input blocks are encoded independently. To address this potential limitation, we propose PATHFID+, where we further extend PATHFID in a way that enables cross-passage interaction by redefining the input block consisting of a pair of passages (p_{n_1}, p_{n_2}) as

$$\begin{aligned} b^{\text{path+}}_{n_1,n_2} := {} & \texttt{question:}\ q \\ & \texttt{<title-1>}\ t_{n_1}\ \texttt{<context-1>}\ p^{\text{path}}_{n_1} \\ & \texttt{<title-2>}\ t_{n_2}\ \texttt{<context-2>}\ p^{\text{path}}_{n_2} \end{aligned}$$

assuming that a set of passage pairs (p_{n_1}, p_{n_2}) are available for model to consume. In particular, we derive a set of pairs of passages from the initial set D_q by $D^+_q = \{(p^*, p_1), (p^*, p_2), \ldots, (p^*, p_N)\}$ where p^* corresponds to the first passage that is possible to immediately hop to from question q, which may be determined by another model, or by executing the original PATHFID on D_q in our case. Global input representation $\mathbf{X}^{\text{path+}}_q$ is obtained similarly (Eq. 3) by except encoding the new blocks $b^{\text{path+}}_{n_1,n_2}$ allowing for cross-passage interactions, while the target reasoning path $\mathbf{Y}^{\text{path+}}_q$ remains the same as $\mathbf{Y}^{\text{path}}_q$. Note that `<title-i>` special markers are shared between new input block $b^{\text{path+}}_{n_1,n_2}$ and target reasoning path $\mathbf{Y}^{\text{path+}}_q$ to provide the model with additional clue regarding the first passage on the reasoning path while still relaying the complete evidence fusion to the decoder via information redundancy encoded in $\mathbf{X}^{\text{path+}}_q$.

3.4 Training and Inference

Having defined global input representation $\mathbf{X}^{\text{path}}_q$, the decoder autoregressively generates the reasoning path $\mathbf{Y}^{\text{path}}_q$ per token at each step by following self-attention, cross-attention on the entire $\mathbf{X}^{\text{path}}_q$, and feed-forward modules. So, the overall reasoning path generation is modeled as conditional generation $p_{\theta^{\text{path}}}(\mathbf{Y}^{\text{path}}_q | \mathbf{X}^{\text{path}}_q)$. The model then is trained to minimize $J(\theta^{\text{path}}) = -\sum_{i=1}^{|\mathbf{Y}^{\text{path}}_q|} \log p_\theta(y_i | y_{<i}, \mathbf{X}^{\text{path}}_q)$ with teacher forcing over a training set of $\{(q, a, D_q)\}$.

In the inference, the decoder consumes the input representation $\mathbf{X}_q^{\text{path}}$ computed by encoder, and generates the full reasoning path token by token. We then post-process the decoded sequence using the answer indicator (`<answer>`) to first obtain the answer, followed by recursively parsing the remaining sequence using the special separator tokens (`<title-k>`, `<facts-k>`) to reconstruct the title and retrieve its relevant sentences at each hop k. As illustrated in Figure 2, the final result of the inference can be summarized into a dictionary which maps each generated passage title to the list of sentence pointers as well as the final answer.

4 Experiments

4.1 Datasets and General Setup

We conduct experiments on two multi-hop question answering datasets: *HotpotQA* and *IIRC*.

HotpotQA (Yang et al., 2018) is a large-scale human-annotated dataset including 113K multi-hop questions. It focuses on using documents from Wikipedia as the source of information for answering questions rather than knowledge bases as in other multi-hop QA datasets (Welbl et al., 2018; Talmor and Berant, 2018). The questions in HotpotQA are not constrained by the fixed knowledge-base schema, hence they can cover more diverse topics. The answer for each question in HotpotQA is extracted from 10 paragraphs in the *distractor* setting, while it is allowed to use the entire Wikipedia for the *full wiki* setting. There are two main question types *bridge* (80%) and *comparison* (20%) in the corpus, where each question is designed in a way that extracting the correct answer requires reasoning over multiple evidence distributed across two passages. While comparison questions do not require the these passages to be processed in a particular order, *bridge* questions often require identifying the bridge entity in the first passage to correctly hop to the second one that contains the answer. Each question is also provided with the annotation of 2 supporting passages and up to 5 corresponding relevant sentences as their supporting facts. Since our proposed approach is a reader model that reasons over a given set of evidence documents, we primarily focus our experiments on the *distractor* setting[1].

IIRC (Ferguson et al., 2020) is a dataset of more than 13K human-written questions over paragraphs from English Wikipedia, where crowdworkers had access only to initial paragraph and list of hyperlinks to other relevant Wikipedia articles, with the missing information occurring in one or more linked documents. This annotation design encouraged less lexical overlap between the questions and the contexts that actually contain the answer. This dataset presents unique challenges compared to HotpotQA because (1) it additionally requires discrete/numerical reasoning and identification of unanswerable questions, which adds up to 4 different possible answer types (span, binary, numerical, unanswerable), and (2) about 30% of questions require reasoning over more than 2 passages including the main passage.

Evaluation Metrics. We use standard metrics exact-match (EM) and F_1 scores for measuring the quality of predicted answers. For HotpotQA experiments, we are also able to evaluate PATHFID on supporting fact predictions using the official metrics (Support-EM, Support-F_1), which measures the performance of the reader model in correctly identifying the supporting facts from the relevant passages. Note that this metric implicitly requires correctly identifying relevant passages among the distractors as well. For our experiments on IIRC dataset, similar to the baseline model constructed in the original work (Ferguson et al., 2020), we follow the evaluation methods used by DROP (Dua et al., 2019).

Implementation Details. We use pre-trained T5-large encoder-decoder (Raffel et al., 2020) to initialize the models in our experiments. We train the model with batch size of 64 with constant learning rate of 1e-4 for 10 epochs. We use maximum length of 256 (resp. 512) tokens for input blocks of PATHFID (resp. PATHFID+), while the maximum target sequence length is set to be 64. However, the sequence truncation is performed on the reasoning path excluding answer part for sequences of length longer than 64 tokens. All the experiments are conducted on a machine with 4 or 8 many 40GB A100 GPUs. Our code is based on Huggingface Transformers (Wolf et al., 2019). Please see Appendix for further details on the hyperparameter settings.

4.2 Main Experiments: HotpotQA

4.2.1 Overall Results

We present our main results on the HotpotQA distractor setting in Table 1. We report results on the HotpotQA development set in comparison with the

Table 2: How faithfully grounded are the gold/predicted answers in gold/predicted supporting facts?

previous published methods. PATHFID reader provides 1.4% absolute gain on answer EM score in comparison to FID model. Moreover, it achieves competitive supporting fact predictions of 59.3% support-EM and 85.7% support-F$_1$ as a result of path generation compared to strong extractive models such as (Asai et al., 2020). In summary, PATHFID establishes the usefulness of modeling the full reasoning path along with answer generation for multi-hop QA. More notably, PATHFID+ achieves a quite significant performance gain across all the central evaluation metrics, demonstrating the importance of cross-passage interactions. Overall results validate the effectiveness of the two central modeling contributions of our proposed method. Next, we present further analysis and discussion on the unique advantages of PATHFID approach under a few central questions which motivated our research at the first place.

4.2.2 Analysis

How faithfully grounded are the generated answers on supporting facts? In Table 2, we present a detailed analysis comparing different models in terms of the faithfulness of their generated answers on both gold and predicted supporting facts. The first row focuses on the passage-level answer grounding computed by the percentage of the answers found in one of the gold supporting passages, while the second row reports the same analysis on sentence-level. We can observe that PATHFID models significantly improves on how faithfully the generated answers are grounded on the supporting facts both at passage-level and sentence-level granularities. The next two rows provide further insight into the quality of the generated supporting facts by PATHFID models by measuring how often the gold answer can be found in them. This analysis shows that the generated supporting facts are of quite high-quality including the gold answer for more than 95.3% and 96.2% at sentence-level and passage-level, respectively. The last two rows measure the faithfulness of the generated answers on the model generated supporting facts, which is not applicable to FID model as it does not perform supporting fact prediction. We observe that the generated answers are quite faithfully grounded on the predicted supporting facts, showing the path generation not only improves the answer EM performance but also successfully grounds them on the evidence it generates as part of the full reasoning path.

It is important emphasize here that extractive reader models can be guaranteed to output perfectly grounded answers simply by locating the answer in their predicted supporting facts. On the other hand, it is difficult for generative models to ensure 100% answer grounding simply due to its generative na-

	Answer-EM				**Support-EM**			
	Comparison		**Bridge**		**Comparison**		**Bridge**	
# Supp Facts	FiD	PathFiD	FiD	PathFiD	FiD	PathFiD	FiD	PathFiD
2	70.4	71.8	63.3	64.6	-	86.7	-	70.0
3	66.1	68.2	62.7	63.1	-	43.4	-	30.7
4	62.2	63.8	64.3	66.5	-	5.4	-	26.2
>=5	83.3	87.5	60.0	65.0	-	0.0	-	3.8

Table 3: Performance breakdown on Answer-EM and Support-EM by question type and the number of gold supporting facts (rows). Since FiD does not generate supporting facts, corresponding columns are left empty.

ture. However, we are able to provide additional evidence validating the answers generated by PathFiD are significantly grounded in the supporting facts it generates, which might implicitly indicate that the generated reasoning path tightly aligns with the model's underlying process for answer generation. Although this is a strong evidence, it is still quite implicit in exposing the model's prediction process, so we see our approach as a step in the right direction rather than a complete solution.

Performance breakdown by the number of supporting facts and question types. In Table 3, we compare the performance of models by breaking them down based on the number of gold supporting sentences and the question type (e.g., bridge and comparison). Our first observation is that PathFiD provides consistent improvement on answer-EM score over FiD across both the question types and different number of supporting facts required to answer the question. The high variance in the answer-EM score on *comparison* questions can be attributed to the strictness of exact-match metric as well as the imbalanced nature of the dataset where only 5% of the comparison questions have more than 3 supporting facts. Surprisingly, both FiD and PathFiD models perform considerably well on the *comparison* questions even when it requires at least 5 supporting facts.

A more important motivation behind the performance breakdown analysis was to understand how the supporting fact prediction of PathFiD would change as the number of gold supporting facts grows. Although it starts degrading on examples with more than 2 supporting facts, it still achieves more than 25% Support-EM for *bridge* questions with up to 4 supporting facts. Recalling the average performance on the whole dataset is less than 60%, we conclude this result might be satisfactory enough, especially for a fully generative model on a very strict evaluation metric.

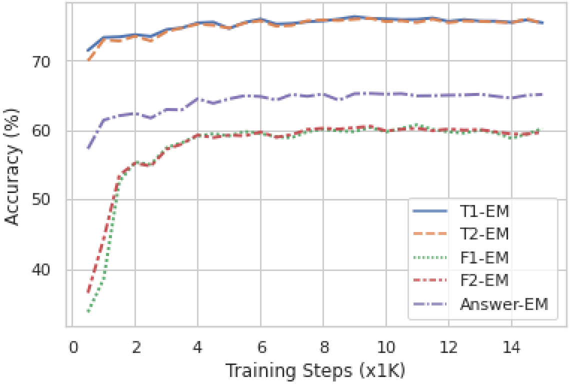

Figure 3: PathFiD model evolution on the HotpotQA Dev set during training. T1-EM, T2-EM, indicate the model's accuracy on predicting the title-1 and title-2 on the reasoning path. Similarly F1-EM, and F2-EM denote the model's accuracy on predicting set of supporting facts in passage-1 and passage-2.

Analyzing the evolution of sub-tasks during joint training with PathFiD. In Figure 3, we present the evolution of PathFiD model on the HotpotQA development set at every 500 training steps. We observe that while the model more quickly picks up the patterns for title generation, it takes much longer for it to reach to a reasonable level of fact prediction. As one would expect, the general trend in the evolution of different segments (title-1, facts-1, title-2, facts-2, answer) of the reasoning path mostly follows the difficulty of the corresponding sub-task although all the sub-tasks are jointly formulated and trained in an end-to-end fashion. On the other hand, it seems counter-intuitive for model to reach to a better accuracy on predicting the facts of the second passage (F2-EM) on the reasoning path earlier despite having a better accuracy on (T1-EM). However, one can also interpret it as a result of stronger feedback provided by the answer segment of the reasoning path as most of the ground-truth answers are contained in the facts of the second passage.

Reasoning Path	Generated-Title EM Passage-1	Passage-2	Passage-Chain	Reconstructed-Title EM Passage-1	Passage-2	Passage-Chain
[t1-t2]	74.3	74.8	71.6	75.4	75.4	72.9
[t1-t2-answer]	74.8	75.0	71.8	75.8	**75.8**	**73.3**
[t1-f1-t2-f2-answer]	**75.0**	**75.1**	**71.9**	**76.0**	75.6	**73.3**

Table 4: The effect of joint training as a case study on title prediction performance of PATHFID variants trained with different target reasoning paths. **Generated-Title** column corresponds to ordered passage chain prediction performance in exact-match (EM), while **Reconstructed-Title** version is computed after applying title reconstruction post-processing described in Section D.

Methods	Answer EM	F1
IIRC* (Ferguson et al., 2020)	63.9	69.2
FID** (Izacard and Grave, 2021)	63.4	69.1
This Work		
PATHFID	65.2	70.5
PATHFID+	68.1	72.9

Table 5: Experimental results on IIRC dataset in model-free retrieval setting comparing the proposed method against two baselines. * indicates that the result is taken directly from the original paper (Ferguson et al., 2020) (see their Table-3), while ** indicates that we obtain the result of FID with our implementation.

4.3 Experiments: IIRC

In addition to our main experiments presented in greater detail, we also conduct experiments on IIRC dataset to verify the generalization of the proposed approach. To this end, we closely follow the authors' model-free retrieval setting (referred to as Oracle L+C in Table-3) because the model checkpoints for the baseline retrieval model are not available in the public release. We use a python script[2] provided in the open-sourced repository to replicate the same setting for a fair comparison.

In Table 5, we present the results on the development set for our proposed PATHFID and PATHFID+ in comparison with the baseline reported in the original paper (Ferguson et al., 2020) and our implementation of the FiD (Izacard and Grave, 2021) baseline. FID model obtains a comparable F1 with IIRC baseline with a slightly worse exact-match performance. However, the proposed PATHFID approach is able to provide 1.3% and 1.4% improvement in F1 score over the two baselines. Furthermore, PATHFID+ extension leads to the best performance achieving 4.7% and 4.2% EM score improvement in absolute value over the FID baseline and IIRC baseline, respectively. Our experimental results validate the benefit of the proposed approach on the IIRC dataset, suggesting strong evidence for the generalizability of our approach.

4.4 Analyzing the Benefit of Joint Training

In Table 4, we present the results of a case study where we analyze the benefit of multi-task training on the passage chain prediction. The first row of the table shows the results for training PATHFID only to predict the sequence of titles for the gold passages (i.e., **[t1-t2]**), which is just a subsequence of the full reasoning path obtained by discarding facts and the answer. The second row is another variant, where we add the answer back to the linearized target sequence while still excluding the segments corresponding to the facts. The last row correspond to the full reasoning path generation, which is corresponding to the original formulation of PATHFID as described in Section 3 and illustrated in Figure 2. Comparing first two rows in Table 4, we can immediately observe that including answer segment in the target reasoning path (i.e., **[t1-t2-answer]**) boosts the performance across the board although in principle it makes the task more complicated while utilizing the same underlying model capacity. Further including segments corresponding to FACTS (sentences within supporting passages) in addition to answer segment (i.e., **[t1-f1-t2-f2-answer]** – full reasoning path) boosts the title-EM even further, especially before applying title reconstruction post-processing step. Although the objective of the first task (i.e., **[t1-t2]**) is perfectly aligned with the evaluation metric used in Table 4, the performance of the resulting model remains inferior compared to jointly modeling the same task with the answer (and/or supporting facts) prediction. These two observations elicit a compelling evidence regarding the benefit of jointly modeling the sub-tasks of multi-hop QA as single sequence capturing the full reasoning path.

5 Related Work

Multi-hop question answering. Research on multi-hop QA aims to tackle complex questions that require reasoning across multiple pieces of evidence in multiple documents (Welbl et al., 2018; Yang et al., 2018; Ferguson et al., 2020). In particular, the HotpotQA dataset (Yang et al., 2018) provides both the closed and open-domain settings to evaluate multi-hop reading comprehension models. Compared to single-hop QA, such complex questions pose additional challenges for both reader and retriever models since they are required to capture relationships between documents, instead of independently processing each document. This is challenging because the number of document combinations exponentially grows due to the sequential nature of the process. Two recent works (Nie et al., 2019; Asai et al., 2020) have tackled this challenge by leveraging hyperlink structure in the underlying Wikipedia corpus, while Xiong et al. (2021) has taken a recursive approach to extend the dense retrieval process to handle sequential search. Most of the reading comprehension (RC) models in existing work (Xiong et al., 2019; Chen et al., 2019; Nishida et al., 2019; Qi et al., 2021; Li et al., 2020; Xiong et al., 2021) follow an extractive architecture (Devlin et al., 2019) for selection of the answer spans and their corresponding supporting evidence with minor modifications such as initializing the backbone model from a stronger or larger pre-trained models (Clark et al., 2020). On the other hand, some recent works (Inoue et al., 2021) take a more abstractive approach and generate question-focused summaries of input paragraphs as concise explanations to be fed to the RC module.

Generative question answering. Especially after the emergence of the SQuAD dataset (Rajpurkar et al., 2016), neural extractive QA models have been widely studied. An underlying assumption is that we can extract a short text span (or a phrase) as an answer, but it is not always the case in reality. Motivated by this, the generative QA approach has also been investigated (Hewlett et al., 2017; Fan et al., 2019). Recent advances on pre-trained transformers have pushed this direction; for example, Lewis et al. (2020a) jointly trained a generative QA model along with a text retrieval model, and Roberts et al. (2020) explored an ambitious approach to directly generate an answer without any evidence documents. We focused on the fusion-in-decoder model (Izacard and Grave, 2021); they claimed that the decoder might be good at aggregating information across multiple documents. However, we have shown that it is not trivial in the multi-hop reasoning task, and pushed the model's ability to jointly learn to predict reasoning paths. Besides question answering, jointly learning multiple intrinsic capabilities required by the final objective with a generative approach has been shown useful in modeling other NLP tasks such as task-oriented dialogues (Neelakantan et al., 2019; Hosseini-Asl et al., 2020; Peng et al., 2021).

Open-domain question answering. Open-domain QA (Voorhees, 1999) is practically important, which requires a system to retrieve relevant documents to answer a given question. The task is recently gaining much attention, thanks to the development of large-scale datasets like HotpotQA, SQuAD Open (Chen et al., 2017), Natural Questions Open (Kwiatkowski et al., 2019; Lee et al., 2019), etc. Pre-trained transformer models like BERT (Devlin et al., 2019) have accelerated the development of neural text retrievers (Lee et al., 2019; Karpukhin et al., 2020; Asai et al., 2020; Xiong et al., 2021; Liu et al., 2021) in the retriever-reader framework (Chen et al., 2017). We have investigated the effectiveness of our method in the multi-hop open-domain QA task (see Appendix B) using an existing external retriever component.

6 Conclusion

In this work, we propose a generative question answering (QA) approach that models multi-hop QA as a single sequence prediction task. It learns to generate an answer along with a reasoning path to improve its capability of multi-hop reasoning. Our experiments on prominent multi-hop QA benchmarks, HotpotQA and IIRC, validate the promise and effectiveness of our proposed method PATHFID and its extension PATHFID+. Future work will explore (1) our PATHFID approach more closely with text retrieval models in open-domain QA scenarios and (2) more explicit grounding on the input information to make our approach even more interpretable and controllable.

A Visualizing the Correlation between Evidence and Answer

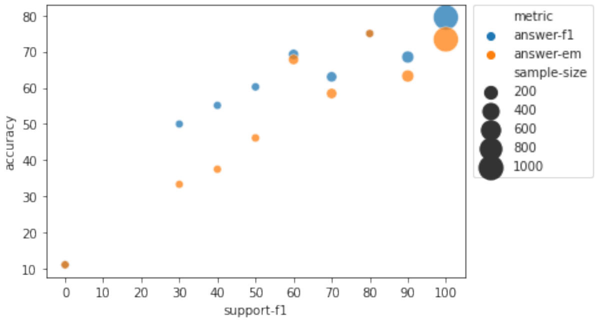

Figure 4: Visualizing the correlation between evidence and answer prediction for COMPARISON questions.

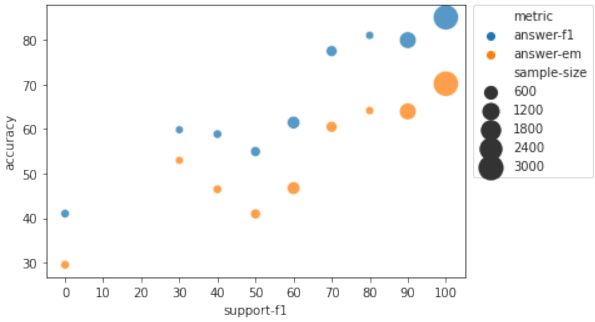

Figure 5: Visualizing the correlation between evidence and answer prediction for BRIDGE questions.

In Figure 4 and 5, we visualize the correlation between supporting evidence and answer prediction performances for *comparison* and *bridge* question types, respectively. To obtain these plots, we first split the examples into 10 buckets where n-th bucket contains the examples with support-F1 score in $(10 * (n-1), 10 * n]$ percentile for $n = \{1, 2, \ldots, 10\}$. Then, we take the average answer prediction accuracy (both EM and F1) over these examples for each bucket, and report this number on the y-axis of the plot at the corresponding support-F1 bucket on the x-axis, while dropping the empty buckets. Note that $x = 0$ corresponds to examples with support-F1 score of 0. Also note that the size of a data point on the figure reflects the number of examples in the corresponding bucket as also indicated by the legend. From Figures 4 and 5, we can observe that the accuracy of the generated answers is significantly lower, 30% for *bridge* and 10% for *comparison*, for the first bucket with zero support-F1 compared to buckets with positive support-F1 score. This suggests that the model has a difficult time figuring out the answer when the supporting evidence prediction is poor. Another observation that holds for both categories is the general trend of increased answer quality as the supporting fact prediction improves. Combining these two points provide additional evidence (in addition to Table 2 in the main paper) implicitly supporting the answer generation process of PATHFID being grounded on the generated supporting facts, which is generated as the prefix of the answer segment in the full decoded reasoning path sequence during inference.

B Case Study: Full-Wiki Setting with Multi-hop Dense Retriever

In this subsection, we evaluate PATHFID in open domain setting of HotpotQA leveraging a recently proposed multi-hop dense retriever (MDR) (Xiong et al., 2021) for passage retrieval. Unlike distractor setting, MDR returns a set of passage pairs $D_q^{\text{MDR}} = \{(p_1^{(1)}, p_1^{(2)}), (p_2^{(1)}, p_2^{(2)}), \ldots, (p_N^{(1)}, p_N^{(2)})\}$ for question q, where each passage $p_n^{(i)}$ comes with a title $t_n^{(i)}$, being retrieved from Wikipedia corpus. This setting naturally fits into how we formulate PATHFID+, which operates on the pairs of input passages as introduced in Section 3.3, where we simply set $D_q^+ = D_q^{\text{MDR}}$. For experiments with FID and PATHFID, which operate on set of single input passages, we simply split the pairs into single passages, ending up with $2K$ passages when using top-K retrieved paths from MDR. We present our results for this setting in Table 6. Similar to our observation in distractor setting, PATHFID provides a significant (%1.8) answer EM score improvement over FID, while also achieving a quite competitive performance on the supporting fact prediction compared to strong discriminative models (Asai et al., 2020; Li et al., 2020) optimized for better retrieval performance. Most notably, PATHFID+ provides significant gains over PATHFID, achieving 59.8% answer-EM and 52.8% supporting fact EM score, showing the importance of encoding cross-passage interactions. It is important to note here that our results with PATHFID+ is not directly comparable to the reader results from MDR (Xiong et al., 2021) because we are able to only use top-25 retrieved paths due to hardware limitations. Finally, we also evaluate the same PATHFID+ model on Dev* obtained by adding the pair of gold passages in D_q^{MDR}, where we aim to isolate the error propagation from the

T5-LARGE	Top-25	59.8	72.4	52.8	76.6

Table 7: Full-wiki results with PathFiD+ comparing two different T5 model sizes.

underlying retriever. Table 6 shows that both the answer and supporting fact prediction performance improves quite significantly, showing the potential impact that developments on retriever side of the problem can also make.

C The Effect of Model Size for Future Reference

As discussed in Section D, fine-tuning PathFiD+ with T5-large initialization might require significant resources and non-trivial memory efficient optimization (e.g., gradient checkpointing). To provide a baseline with a smaller model for future research, here we include the results of PathFiD+ with T5-base initialization using the same setting reported in Table 6 in the main paper. As presented in Table 7, although the performance difference on the supporting fact prediction is relatively small (1%), answer prediction performance drops significantly (by 3.2%) when we switch from T5-large to T5-base. However, working with T5-base is much more efficient in terms of resources and iteration time for building baselines, trying out new ideas and thought experiments. So, we hope this baseline will be helpful for future research.

D More on Training and Implementation Details

Hop ordering. HotpotQA benchmark provides annotation only for *unordered* gold passages, without explicitly specifying which passage corresponds to the k-th hop (e.g., first-hop, second-hop, etc.) on the reasoning path. In our implementation, we combine the heuristic strategies applied by GRR (Asai et al., 2020) and MDR (Xiong et al., 2021). More precisely, if only one of the gold passages contains the answer, then we take the passage that includes the answer span as the final passage. If the answer span is included in both passages, we break the tie by falling back to the hyperlink-based ordering strategy proposed by GRR (Asai et al., 2020).

Post-processing for passage title reconstruction. Note that PathFiD generates the titles of the passages on the reasoning path token by token including the separator tokens. However, the decoder might fall into some minor errors during the generation process, which may cause the resulting titles to end up slightly different from the original ones. To account for such minor errors, we leverage the set of titles coming from the input passages and find the most similar among them to our generated passage titles based on token-level F1-score. We call this process *title reconstruction* and apply it while reporting the performance for supporting fact predictions. Table 4 shows the benefit of *title reconstruction* for mitigating such minor generation errors. On the other hand, the small performance boost suggests that titles PATHFID already generates quite faithful title predictions.

Model selection. For all the models reported in this work, we perform evaluation at every 500 steps during training by decoding the whole development set on a separate machine in a non-blocking fashion. We then select the best model based on the answer exact-match score performance. However, since PATHFID variants generate more than just the answer, it can be leveraged to optimize for a more holistic metric including the supporting fact prediction performance, offering further control on model selection. We leave further exploration of this phenomenon to future work.

Scaling to larger evidence pools for full-wiki setting. As briefly noted in Appendix B, we report results in full-wiki setting using only top-25 paths returned by MDR (Xiong et al., 2021) due to hardware constraints. More precisely, a single training example becomes impossible to fit into GPU memory (40GB) even for top-25 paths for PATHFID+ model with T5-large initialization. To make the training feasible, we resort to gradient checkpointing[3] which trades off GPU memory with speed. However, in this case, even with 25 retrieved paths, training PATHFID+ for 10K steps with batch size of 64 using gradient accumulation takes 19 hours on 8 A100 GPUs with 40GB memory each, which is one of the most prominent limitations hurdling the progress for this line of research. Further research on making generative approaches with large pretrained models more efficient without losing on the performance side holds a great potential impact to accelerate the progress of fully generative models for question answering.

E Hyperparameter Settings

In Tables 9, 8 and 10, we provide the full set of important hyperparameters used for the models reported both in the main paper (HotpotQA-distractor and IIRC) and in the Appendix B (HotpotQA-fullwiki), respectively.

parameter	FID	PATHFID	PATHFID+
initialization	t5-large	t5-large	t5-large
learning rate	1e-4	1e-4	1e-4
learning rate schedule	constant	constant	constant
batch size	64	64	64
gradient checkpointing	no	no	no
maximum input length	256	256	512
maximum output length	32	64	64
warmup ratio	0	0	0
gradient clipping norm	1.0	1.0	1.0
training epoch	10	10	10
weight decay	0	0	0

Table 8: Hyperparameters for experiments on HotpotQA Distractor setting.

parameter	FID	PATHFID	PATHFID+
initialization	t5-large	t5-large	t5-large

weight decay	0	0	0
top-K path retrieval	25	25	25

Table 10: Hyperparameters for experiments on HotpotQA Full-wiki setting.

F Qualitative Analysis

In this section, we provide examples comparing the predictions of FID and PATHFID over *bridge* and *comparison* question types. Each of the example Table 11, 12, 13 in the next pages follows a similar structure, where we include gold answer, FID answer prediction, PATHFID answer (and full path) prediction, and 5 supporting passages (out of 10) for the brevity of presentation. Among the input passages, the first two correspond to gold passages, for which we include the full content as well as highlighting the key supporting facts/sentences with orange color. The following three passages are presented as a subset of the distractors, for each of which we include a one-line content unless it plays a crucial role in distracting at least one of the models in making a wrong prediction. In this case, we also add the content of this particular passage as well as highlighting the specific distractor span/sentence causing the failure of either FID or PATHFID.

Question	The Memphis Hustle are based in a suburb of a city with a population of what in 2010?
Input Passages	1. Memphis Hustle: <f1> The Memphis Hustle are an American professional basketball team of the NBA G League announced to begin play for the 2017–18 season as an affiliate of the Memphis Grizzlies of the National Basketball Association (NBA). <f2> Based in the Memphis suburb of Southaven, Mississippi, the team will play their home games at the Landers Center. 2. Southaven, Mississippi: <f1> Southaven is a city in DeSoto County, Mississippi, United States. <f2> It is a suburb of Memphis, Tennessee, and a principal city in the Memphis metropolitan area. <f3> The 2010 census reported a population of 48,982, making Southaven the third largest city in Mississippi. <f4> Southaven is traversed from north to south by the I-55/I-69 freeway. <f5> The city's name derives from the fact that Southaven is located south of Whitehaven, a neighborhood in Memphis. 3. Lakeland, Tennessee: Lakeland is a city in Shelby County, Tennessee, and a suburb of Memphis. The population was 12,430 at the 2010 census. 4. Marion, Arkansas: Marion is a city in and the county seat of Crittenden County, Arkansas ... 5. West Memphis, Arkansas: West Memphis is the largest city in Crittenden County, Arkansas ... ...
Gold Answer	**48,982**
FID Answer	12,430
PATHFID Answer	48,982
PATHFID Output	<title-1> Memphis Hustle <facts-1> <f1> <f2> <title-2> Southaven, Mississippi <facts-2> <f1> <f2> <f3> <answer> 48,982

Table 11: BRIDGE-type question example, where **PATHFID predicts the correct answer while FID fails to do so.** The third passage is the **distractor causing FID to make a wrong prediction** due to the highlighted sentence in red.

Question	What government position was held by the woman who portrayed Corliss Archer in the film Kiss and Tell?
Input Passages	1. Kiss and Tell (1945 film): <f1> Kiss and Tell is a 1945 American comedy film starring then 17-year-old Shirley Temple as Corliss Archer. <f2> In the film, two teenage girls cause their respective parents much concern when they start to become interested in boys. <f3> The parents' bickering about which girl is the worse influence causes more problems than it solves. 2. Shirley Temple: <f1> Shirley Temple Black (April 23, 1928 – February 10, 2014) was an American actress, singer, dancer, businesswoman, and diplomat who was Hollywood's number one box-office draw as a child actress from 1935 to 1938. <f2> As an adult, she was named United States ambassador to Ghana and to Czechoslovakia and also served as Chief of Protocol of the United States. 3. Meet Corliss Archer (TV series): Meet Corliss Archer is an American television sitcom that ... 4. Meet Corliss Archer: Meet Corliss Archer, a program from radio's Golden Age, ran from ... 5. Charles Craft: Charles Craft (May 9, 1902 – September 19, 1968) was an English-born ... ...
Gold Answer	**Chief of Protocol**
FiD Answer	United States ambassador
PathFiD Answer	Chief of Protocol of the United States
PathFiD Output	<title-1> Kiss and Tell (1945 film) <facts-1> <f1> <title-2> Shirley Temple <facts-2> <f2> <answer> Chief of Protocol of the United States

Table 12: BRIDGE-type question example, where both **PathFiD and FiD fail to predict the exact gold answer.** Although the generated answers are wrong, they can both be acceptable by humans. On the other hand, both answers fail in EM accuracy, but PathFiD manages to perfectly generate the reasoning path starting from the right sentence of the correct first passage, then jumping to correct second-hop passage, followed by identifying its key sentence (<f2>), then finally locating answer in the right part of this evidence, but only failing in getting the span perfectly, which still rewards it with a reasonable F1 score. However, this example is also important in showing the possible ambiguities in questions and strictness of the exact-match accuracy metric.

Question	Which band, Letters to Cleo or Screaming Trees, had more members?
Input Passages	1. Screaming Trees: <f1> Screaming Trees was an American rock band formed in Ellensburg, Washington in 1985 by vocalist Mark Lanegan, guitarist Gary Lee Conner, bass player Van Conner and drummer Mark Pickerel. <f2> Pickerel had been replaced by Barrett Martin by the time the band reached its most successful period. <f3> Although widely associated with grunge, the band's sound incorporated hard rock and psychedelic elements. <f4> During Screaming Trees' existence the band released seven studio albums, five EPs, and three compilations. 2. Letters to Cleo: <f1> Letters to Cleo are an alternative rock band from Boston, Massachusetts, best known for the 1994 single, "Here & Now", from their full-length debut album, "Aurora Gory Alice". <f2> The band's members are Kay Hanley, Greg McKenna, Michael Eisenstein, Stacy Jones, Scott Riebling, and later, Tom Polce. 3. Change Has Come: Change Has Come was the only recording the Screaming Trees released ... 4. Jamboree (Beat Happening album): Jamboree is the second album by Beat Happening, released ... 5. Abstract

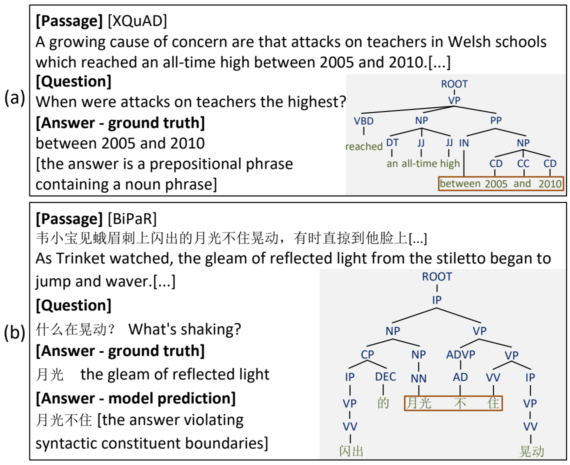
Multilingual pre-trained models are able to zero-shot transfer knowledge from rich-resource to low-resource languages in machine reading comprehension (MRC). However, inherent linguistic discrepancies in different languages could make answer spans predicted by zero-shot transfer violate syntactic constraints of the target language. In this paper, we propose a novel multilingual MRC framework equipped with a Siamese Semantic Disentanglement Model (S^{2}DM) to disassociate semantics from syntax in representations learned by multilingual pre-trained models. To explicitly transfer only semantic knowledge to the target language, we propose two groups of losses tailored for semantic and syntactic encoding and disentanglement. Experimental results on three multilingual MRC datasets (i.e., XQuAD, MLQA, and TyDi QA) demonstrate the effectiveness of our proposed approach over models based on mBERT and XLM-100.



(a)
[Passage] [XQuAD]
A growing cause of concern are that attacks on teachers in Welsh schools which reached an all-time high between 2005 and 2010.[...]
[Question]
When were attacks on teachers the highest?
[Answer - ground truth]
between 2005 and 2010
[the answer is a prepositional phrase containing a noun phrase]

(b)
[Passage] [BiPaR]
韦小宝见蛾眉刺上闪出的月光不住晃动，有时直掠到他脸上[...]
As Trinket watched, the gleam of reflected light from the stiletto began to jump and waver.[...]
[Question]
什么在晃动？ What's shaking?
[Answer - ground truth]
月光 the gleam of reflected light
[Answer - model prediction]
月光不住 [the answer violating syntactic constituent boundaries]

Figure 1: Relations between answer spans and syntactic constituents. (a) An example from XQuAD (Artetxe et al., 2020) where the ground-truth answer is a syntactic constituent. (b) A case from BiPaR (Jing et al., 2019) where the answer predicted by a model transferred from English to Chinese violates syntactic constituent boundaries in the target language.

1 Introduction

Multilingual pre-trained language models (PLMs) (Devlin et al., 2019; Conneau and Lample, 2019; Conneau et al., 2020) have been widely explored in cross-lingual understanding tasks. However, zero-shot transfer method based on multilingual PLMs does not work well for low-resource language MRC. Such multilingual MRC models could roughly detect answer spans but may fail to predict the precise boundaries of answers (Yuan et al., 2020).

In order to address this issue, existing methods mainly resort to external resources. Based on the finding that 70% of answer spans are language-specific phrases (e.g., named entities, noun phrases) in MLQA (Lewis et al., 2020), Yuan et al. (2020) propose an additional language-specific knowledge phrase masking (LAKM) task to enhance boundary detection for low-resource languages. Liang et al. (2021) present a boundary calibration model stacked over a base sequence labeling module, introducing a phrase boundary recovery task to pretrain the calibration module on large-scale multilingual datasets synthesized from Wikipedia documents. These two methods rely on external resources, which are not always easily available.

As illustrated in Figure 1(b), the transfer model may violate syntactic constraints for answer spans in the target language (e.g., the predicted answer "月光不住" crossing the boundaries of two subtrees). An intuitive assumption is that the majority of answer spans respect syntactic constituency boundaries (i.e., syntactic constraint, illustrated by the case in Figure 1(a)). On four multilingual MRC datasets, we use Stanford CoreNLP[1] to collect syn-

tax parse trees and calculate the percentages of ground-truth answers that respect syntactic constituent boundaries. As shown in Table 1, over 87% of answer spans respect the syntactic constraint.

On the bilingual parallel MRC corpus BiPaR (Jing et al., 2019), we have compared two MRC models: a monolingual MRC model trained on the Chinese data of BiPaR vs. an mBERT-based MRC model trained on the English data of BiPaR and adapted to Chinese via zero-shot transfer. For questions where the monolingual model correctly predicts the answer and respect syntactic constraint, 23.15% of them are incorrectly predicted by the transfer model, and the predicted answers violate the syntactic constraint, illustrated by the case in Figure 1(b). This suggests that the source language syntax may have a negative impact on the answer boundary detection in the target language during zero-shot transfer, due to the linguistic discrepancies between the two languages.

However, linguistic discrepancies are diverse and it is difficult to learn them. We hence propose to decouple semantics from syntax in pre-trained models for multilingual MRC, transforming the learning of linguistic discrepancies into universal semantic information. Specifically, we propose a Siamese Semantic Disentanglement Model (S^{2}DM) that utilises two latent variables to learn semantic and syntactic vectors in multilingual pre-trained representations. As shown in Figure 2(a), stacking a linear output layer for MRC over the disentangled semantic representation layer, we can fine-tune the multilingual PLMs on the rich-resource source language and transfer only disentangled semantic knowledge into the target language MRC. Our model aims to reduce the negative impact of the source language syntax on answer boundary detection in the target language.

To disassociate semantic and syntactic information in PLMs well, we introduce objective functions of learning cross-lingual reconstruction and semantic discrimination together with losses of incorporating word order information and syntax structure information (Part-of-Speech tags and syntax parse trees). We use a publicly available multilingual sentence-level parallel corpus with syntactic labels to train S^{2}DM.

To summarize, our main contributions are as follows.

- We propose a multilingual MRC framework that explicitly transfers semantic knowledge of the source language to the target language to reduce the negative impact of source syntax on answer span detection in the target language MRC.

- We propose a siamese semantic disentanglement model that can effectively separate semantic from syntactic information of multilingual PLMs with semantics/syntax-oriented losses.

- Experimental results on three multilingual MRC datasets (XQuAD, MLQA, and TyDi QA) demonstrate that our model can achieve significant improvements of 3.13 and 2.53 EM points over two strong baselines, respectively.

2 Related Work

Cross-lingual/Multilingual Machine Reading Comprehension Recent advances in multilingual MRC evaluation datasets (Artetxe et al., 2020; Lewis et al., 2020; Clark et al., 2020) trigger research interests in multilingual and cross-lingual MRC (Hsu et al., 2019; Cui et al., 2019; Yuan et al., 2020; Liu et al., 2020; Huang et al., 2021; Wu et al., 2021). Hsu et al. (2019) investigate cross-lingual transfer capability of multilingual BERT (mBERT) on MRC tasks and find that zero-shot learning based on PLM is feasible, even between distant languages, such as English and Chinese. Various approaches have been proposed on top of multilingual MRC based on PLMs. Cui et al. (2019) propose a method that combines multilingual BERT and back-translation for cross-lingual MRC. In order to effectively leverage translation data and reduce the impact of noise in translations, Liu et al. (2020) propose a cross-lingual training approach based on knowledge distillation for multilingual MRC. Yuan et al. (2020) present two auxiliary tasks: mixMRC and LAKM to introduce additional phrase boundary supervision into the fine-tuning stage. Liang et al. (2021) propose a pre-trained boundary calibration module based on the output

Figure 2: Diagram of the proposed zero-shot cross-lingual transfer framework for multilingual MRC. (a) The overview of our multilingual MRC framework. (b) The architecture of S^{2}DM that is composed of two siamese networks with shared parameters for the source and target language. Once trained, only the output of source language MLP network is fed into the linear output layer. The subscripts s and t in (b) represent the source and target language respectively. CRL: cross-lingual reconstruction loss. SDL: semantic discrimination loss. WPL: word position loss. POS: Part-of-Speech loss. STL: syntax tree loss.

of a base zero-shot transfer model, refining the boundaries of initial answers.

Different from the above studies, we mainly consider the impact of syntactic divergences between the source and target language in zero-shot cross-lingual transfer based on multilingual PLMs, and attempt to disassociate semantics from syntax and only transfer semantics to the target language.

Disentangled Representation Learning Recently, there has been a growing amount of work on learning disentangled latent representations in NLP tasks (Zhang et al., 2019; Hu et al., 2017; Yin et al., 2018). In this aspect, the most related work to our syntax-semantics decoupling method is the vMF-Gaussian Variational Autoencoder (VGVAE) model proposed by Chen et al. (2019). It is a generative model using two latent variables to represent semantics and syntax of the sentence, developed for monolingual setting and trained with paraphrases. It uses paraphrase reconstruction loss and a discriminative paraphrase loss to learn semantic representations and word order information for syntactic representations. We adapt this model to multilingual syntax-semantics disentanglement. We use bilingual sentence pairs to train our model with a cross-lingual reconstruction loss and semantic discrimination loss. To better disentangle semantics from complex and diverse syntax in multilingual PLMs, we introduce two additional syntax-related losses for incorporating POS tags and syntax trees.

3 Approach

Figure 2 shows the architecture of our multilingual MRC framework with the proposed siamese semantic disentanglement model.

3.1 Multilingual MRC Framework

Our multilingual MRC framework consists of three essential components: the multilingual PLM layer, the siamese semantic disentanglement module, and the linear output layer. The output representations from the multilingual PLM are fed into S^{2}DM to disassociate semantic and syntactic information. Only the disentangled semantic representations are input to the linear output layer for predicting answer spans in passages.

In order to facilitate the zero-shot cross-lingual transfer of only semantic knowledge from the rich-resource source language to the low-resource target language, we take a two-stage training strategy. First, we pre-train S^{2}DM with parallel data (see Section 3.2) while the parameters of the multilingual PLM are frozen. Once S^{2}DM is trained, only the output of source language MLP network is fed into the linear output layer for MRC. In the second step, we freeze the parameters of the S^{2}DM and fine-tune the entire multilingual MRC framework on MRC data of the source language.

3.2 Siamese Semantic Disentanglement Model

In S^{2}DM, we assume that a sentence x is generated by a semantic and syntactic variable, i.e., y and z, independently. We follow VGVAE Chen et al.

(2019) to use the von Mises-Fisher (vMF) distribution for the semantic variable and the Gaussian distribution for the syntactic variable. Formally, the joint probability of the sentence and its two latent variables can be factorized as:

$$p_\theta(x, y, z) = p_\theta(y)p_\theta(z)p_\theta(x|y, z) \tag{1}$$

where $p_\theta(x|y, z)$ is a generative model consisting of bag-of-words decoder.

The variational inference process of VGVAE uses a factorized approximated posterior $q_\phi(y|x)q_\phi(z|x) = q_\phi(y, z|x)$ with the objective function that maximizes a lower bound of the marginal log-likelihood:

$$\begin{aligned} L_{VGVAE} = L_{RL} &+ \mathrm{KL}(q_\phi(z|x)||p_\theta(z)) \\ &+ \mathrm{KL}(q_\phi(y|x)||p_\theta(y)), \end{aligned} \tag{2}$$

$$L_{RL} = \mathbb{E}_{\substack{y\sim q_\phi(y|x)\\ z\sim q_\phi(z|x)}}\big[-\log p_\theta(x|y, z)\big] \tag{3}$$

where $q_\phi(y|x)$ is subject to $\mathrm{vMF}(\mu_\alpha(x), \kappa_\alpha(x))$ while $q_\phi(z|x)$ follows $N(\mu_\beta(x), diag(\kappa_\beta(x)))$. The prior $p_\theta(y)$ and $p_\theta(z)$ follows the uniform distribution $\mathrm{vMF}(\cdot, 0)$ and a standard Gaussian distribution respectively. Eq.(3) is the **reconstruction loss (RL)** of the generator. In our model, we adopt a multilayer perceptron (MLP) network to learn the mean (μ) and variance (κ) of two distributions. As pre-trained representations are contextually-encoded token vectors, latent variable vectors obtained by sampling from the distributions need to be averaged so as to output sentence-level semantic and syntactic vector.

Since S^{2}DM uses a Siamese network for both the source and target language, the disentanglement between semantics and syntax is conducted for the two languages simultaneously with two parameter-shared subnetworks, as shown in Figure 2(b).

We attempt to extract rich semantic information from multilingual representations which is universal for multiple languages and contains less syntactic information. Except for the conventional reconstruction loss, we propose two additional losses on parallel data to encourage the latent variable y to capture semantic information: a **Cross-lingual Reconstruction Loss (CRL)** and **Semantic Discrimination Loss (SDL)**. The former estimates the cross-entropy loss when we use the semantic representation y_t of the target language to reconstruct the source input and use the source semantic representation y_s for target reconstruction. The latter is used to force the learned source semantic representation y_s to be as close as possible to the target semantic representation y_t since the semantic meanings of the parallel source and target sentence is equivalent to each other. The two losses are estimated as follows:

$$\begin{aligned} L_{CRL} = &\,\mathbb{E}_{\substack{y_t\sim q_\phi(y|x_t)\\ z_s\sim q_\phi(z|x_s)}}\big[-\log p_\theta(x_s|y_t, z_s)\big] \\ &+ \mathbb{E}_{\substack{y_s\sim q_\phi(y|x_s)\\ z_t\sim q_\phi(z|x_t)}}\big[-\log p_\theta(x_t|y_s, z_t)\big], \end{aligned} \tag{4}$$

$$\begin{aligned} L_{SDL} = &\max\big\{0, \delta - \mathrm{sim}(y_s, y_t) + \mathrm{sim}(y_s, n_t)\big\} \\ &+ \max\big\{0, \delta - \mathrm{sim}(y_s, y_t) + \mathrm{sim}(n_s, y_t)\big\} \end{aligned} \tag{5}$$

where $\mathrm{sim}(\cdot, \cdot)$ is a cosine similarity score function. The margin δ is a hyperparameter to control the gap between parallel sentence pair (y_s, y_t) and two non-parallel sentence pairs (y_s, n_t) and (n_s, y_t). n_s is the semantic vector of a negative sample, which has the highest cosine similarity to y_s. Specially, as partial sentences in our corpus are parallel in more than two languages, we limit the data range of negative sampling to only 2-way parallel pairs. n_t are obtained in the similar way to n_s.

In order to guide S^{2}DM to disassociate syntactic information into the syntactic latent variable z, we also define three losses tailored for capturing different types of syntactic information. First, we employ **Word Position Loss (WPL)** , defined as follows:

$$L_{WPL} = \mathbb{E}_{z\sim q_\phi(z|x)}\big[-\sum_i \log \mathrm{softmax}(f(h_i))_i\big], \tag{6}$$

where $\mathrm{softmax}(\cdot)_i$ indicates the probability of the ith word at position i, and $f(\cdot)$ is a three-layer feedforward neural network with input $h_i = [e_i; z]$ that is the concatenation of the syntactic variable z and the embedding vector e_i of the multilingual PLM for the ith token in the input sentence.

In addition, we define a Part-of-Speech and syntax tree loss to encourage S^{2}DM to isolate deeper syntactic information from pre-trained representations. POS tagging is a sequence labeling task, which can be regarded as a multi-class classification problem for each token in a sentence. Hence, we define **Part-of-Speech (POS) Loss** as a cross-entropy style loss as follows:

$$L_{POS} = \sum_i \Big[\sum_{j=1}^{m} -\log \mathrm{softmax}(g(h_i))_{j=class}\Big] \tag{7}$$

where $g(\cdot)$ is a linear layer, $\mathrm{softmax}(\cdot)_{j=class}$ estimates the probability of gold POS tag $class$, m is the number of different POS tags.

For learning structural information, we design **Syntax Tree Loss (STL)**. Many studies have found that PLMs can encode syntactic structures of sentences (Hewitt and Manning (2019); Chi et al. (2020)). Inspired by Hewitt and Manning (2019), we formulate syntactic parsing from pre-trained word representations as two independent tasks: depth prediction of a word and distance prediction of two words in the parse tree. Given a matrix $B \in \mathbb{R}^{k \times m}$ as a linear transformation, the losses of these two subtasks are defined as:

$$L_{depth} = \sum_i (\|w_i\| - \|Bh_i\|_2^2), \tag{8}$$

$$L_{distance} = \sum_{i,j} \left| \mathrm{d}_T(w_i, w_j) - \mathrm{d}_B(h_i, h_j) \right| \tag{9}$$

where $\|w_i\|$ is the parse depth of a word defined as the number of edges from the root of the parse tree to w_i, and $\|Bh_i\|_2$ is the tree depth L2 norm of the vector space under the linear transformation. $\mathrm{d}_T(w_i, w_j)$ is the number of edges in the path between the ith and jth word in the parse tree T. As for $\mathrm{d}_B(h_i, h_j)$, it can be defined as the squared L_2 distance after transformation by B:

$$\mathrm{d}_B(h_i, h_j) = (B(h_i - h_j))^T (B(h_i - h_j)) \tag{10}$$

To induce parse trees, we minimize the summation of the above two losses L_{depth} and $L_{distance}$, and L_{STL} is defined as:

$$L_{STL} = L_{depth} + L_{distance} \tag{11}$$

According to the different syntactic tasks, we train two S^{2}DM variants: S^{2}DM_POS and S^{2}DM_SP (SP for syntactic parsing), where their training objectives are defined as follows:

$$L_1 = L_{VGVAE} + L_{CRL} + L_{SDL} + L_{WPL} + L_{POS},$$

$$L_2 = L_{VGVAE} + L_{CRL} + L_{SDL} + L_{WPL} + L_{STL}$$

3.3 Generalization Analysis

In this section, we analyze the generalization of our decoupling-based multilingual MRC model.

By two reconstruction losses Eq.(3) and Eq.(4), we will prove that the syntactic and semantic vectors obtained by S^{2}DM are language-agnostic. Since the mathematic structures of Eq.(3) and Eq.(4) are the same, we take one part of Eq.(4) for analysis. Due to z_s and y_t are independent of each other, $p_\theta(x_s, z_s|y_t) = p_\theta(x_s, z_s)$. We obtain:

$$\begin{aligned}
&\mathbb{E}_{\substack{y_t \sim q_\phi(y|x_t) \\ z_s \sim q_\phi(z|x_s)}} \left[-\log p_\theta(x_s|y_t, z_s) \right] \\
&= \mathbb{E}_{y_t \sim q_\phi(y|x_t)} \Big(\sum_{z_s \sim q_\phi(z|x_s)} p_\theta(z_s) \log \frac{p_\theta(z_s)}{p_\theta(x_s, z_s|y_t)} \Big) \\
&= \mathrm{KL}(p_\theta(z_s) || p_\theta(x_s, z_s))
\end{aligned}$$

Similarly,

$$\mathbb{E}_{\substack{y_s \sim q_\phi(y|x_s) \\ z_t \sim q_\phi(z|x_t)}} [-\log p_\theta(x_t|y_s, z_t)] = \mathrm{KL}(p_\theta(z_t) || p_\theta(x_t, z_t))$$

$$L_{RL} = \mathrm{KL}(p_\theta(y_s) || p_\theta(x_s, y_s)) + \mathrm{KL}(p_\theta(y_t) || p_\theta(x_t, y_t))$$

Minimizing $\mathrm{KL}(q_\phi(z|x) || p_\theta(z))$ and $\mathrm{KL}(q_\phi(y|x) || p_\theta(y))$ will eventually fit both $p_\theta(x_s, z_s)$ and $p_\theta(x_t, z_t)$ into the same distribution. In the same way, both $p_\theta(x_s, y_s)$ and $p_\theta(x_t, y_t)$ also fit to the same distribution, no matter what the target language is. This is consistent with our motivation to use the siamese network.

Furthermore, the semantic discrimination loss in Eq.(5) guarantees that the semantic vectors of the source language and the target language are similar to each other. Minimizing Eq.(5) can be equivalent to:

$$\begin{cases} \mathrm{sim}(y_s, y_t) > \mathrm{sim}(y_s, n_t) + \delta \\ \mathrm{sim}(y_s, y_t) > \mathrm{sim}(n_s, y_t) + \delta \end{cases}$$

which is to maximize $\mathrm{sim}(y_s, y_t)$ to encourages the target semantic vector to approach parallel source semantic vector.

In summary, S^{2}DM can obtain language-agnostic semantic and syntactic vectors. Therefore, our multilingual MRC model is suitable even for low-resource languages without training data for the decoupling model.

4 Experiment

4.1 Datasets

To verify the effectiveness of our multilingual MRC model, we conducted experiments on three multilingual question answering benchmarks:

XQuAD (Artetxe et al., 2020) consists of 11 datasets of different languages translated from the SQuAD v1.1 (Rajpurkar et al., 2016) development set, including Spanish (es), German (de), Greek (el), Russian (ru), Turkish (tr), Arabic (ar), Vietnamese (vi), Thai (th), Chinese (zh), Hindi (hi), and Romanian (ro).

MLQA (Lewis et al., 2020) consists of over 5K extractive MRC instances in 7 languages: English (en), Arabic (ar), German (de), Spanish (es), Hindi (hi), Vietnamese (vi) and Chinese (zh). MLQA is also highly parallel, with MRC instances parallel across 4 different languages on average.

TyDi QA-GoldP is the gold passage task in TyDi QA (Clark et al., 2020) covering 9 typologically diverse languages: Arabic (ar), Bengali (bg), English (en), Finnish (fi), Indonesian (id), Korean (ko), Russian (ru), Swahili (sw), Telugu (te). It is a more challenging MRC benchmark as questions have been written without seeing the answers, leading to 3 and 2 times less lexical overlap than XQuAD and MLQA, respectively (Hu et al., 2020).

4.2 Baseline Models

We used the following two multilingual PLMs to build our MRC model to conduct experiments:

mBERT is the multilingual version of BERT Devlin et al. (2019), with 177M parameters, is pre-trained on the Wikipedia of 104 languages to optimize the masked language modeling objective.

XLM-100 uses a pre-training objective similar to that of mBERT but with a larger number of parameters (578M) and a larger shared vocabulary than mBERT, and is trained on the same Wikipedia data covering 100 languages as mBERT.

Furthermore, we compared with a strong baseline that uses external knowledge to enhance cross-lingual MRC:

LAKM is a pre-trained task proposed in (Yuan et al., 2020) by introducing external sources for phrase-level masked language modeling task. The external corpus contain 363.5k passages and 534k knowledge phrases in four languages: English (en), French (fr), German (de), and Spanish (es).

4.3 Setup

For S^{2}DM, we collected approximately 26k labelled parallel sentence pairs from the Universal Dependencies (UD 2.7) Corpus (Zeman et al., 2020) as the training set. The training set covers 20 languages and overlap with 13 languages of three MRC datasets. We used Universal POS tags and HEAD tags in UD 2.7 for the POS tagging and syntactic parsing task. We chose data from the Chinese semantic textual similarity (STS) task (Tang et al., 2016) as the development set. For hyper-parameters in S^{2}DM, the learning rate was set to 5e-5, the margin δ was 0.4, and the latent variable dimensions was 200.

For our multilingual MRC models and two baseline models, we fine-tuned them on the SQuAD v1.1 (Rajpurkar et al., 2016) and evaluated them on the test data of the three multilingual MRC datasets. For models based on mBERT, we fine-tuned them for 3 epochs with a training batch size of 32 and a learning rate of 2e-5. We fine-tuned models based on XLM-100 for 2 epochs with a training batch size of 16 and a learning rate of 3e-5.

Table 2: The average experimental results on XQuAD, MLQA and TyDi QA dataset.

4.4 Experiment Results

The overall experimental results are shown in Table 2. All our tests were conducted under the conditions of zero-shot transfer. Our models (S^{2}DM_POS, S^{2}DM_SP combined with XLM-100 or mBERT) significantly outperform both XLM-100 and mBERT baselines on three datasets. S^{2}DM_SP achieves the best performance, indicating that the learning of deeper syntax information is compelling. Especially, compared with baselines on the TyDi QA-Gold dataset, S^{2}DM_SP based on XLM-100 and mBERT gains 4.1%, 4.2% EM improvements on average across 9 languages, respectively.

The results of 12 languages in XQuAD and MLQA are shown in Table 3. For cross-lingual transfer performance, our models are better than the two baselines in terms of either EM or F1 on all 11 low-resource target languages. On the MLQA dataset, LAKM uses a larger extra corpus to train a better backbone language model, while our method with less external data can still achieve similar performance in German (de) and Spanish (es).

The TyDi QA-GoldP dataset is more challenging than XQuAD and MLQA. The results of TyDi QA-GoldP are shown in Table 4, and our models are superior to the baselines in terms of either EM or F1 for all 8 low-resource target languages. Significantly, XLM+S^{2}DM_SP outperforms the XLM-100 baselines by 8.4%, 9.5% in EM for Finnish (fi), Russian(ru), respectively. The language families of these two languages are different from that of English. The evaluation results on these three datasets verify the effectiveness of our proposed method.

In Section 3.3, we theoretically analyze the generalization of our model. The results on the three datasets show the effectiveness on five languages not included in the training target languages for S^{2}DM. The five languages are Romanian (ro), Vietnamese (vi) in XQuAD and Bengali (bg), Swahili (sw), Telugu (te) in TyDi QA-GoldP, which are resource-scarce and have differ-

5 Analysis

5.1 Ablation Study

We further conducted an ablation study based on the mBERT and VGVAE model with different combinations of losses (introduced in the Section.3.2). The results are shown in Figure 3. Our mBERT+S^{2}DM_SP MRC model achieves the strongest performance among all variants, surpassing the model w/ all losses. According to the results shown in Figure 3, we can summarize that each loss is essential and suitable to our model.

The results without POS and STL loss (e.g., w/ CRL+SDL+WPL) on the MLQA dataset validate the effectiveness of our losses (POS or STL loss) tailored for capturing syntactic information. The performance of models that only contain two losses in CRL, SDL, and WPL drops significantly compared with the w/ CRL+SDL+WPL model. The results of models that only contain one of the losses in CRL, SDL drop slightly, but the EM of the model with only WPL is better than w/ CRL+WPL and w/ SDL+WPL, which further demonstrates the importance of the syntax-oriented loss. All ablation models do not exceed our best model, illustrating the importance of all proposed losses.

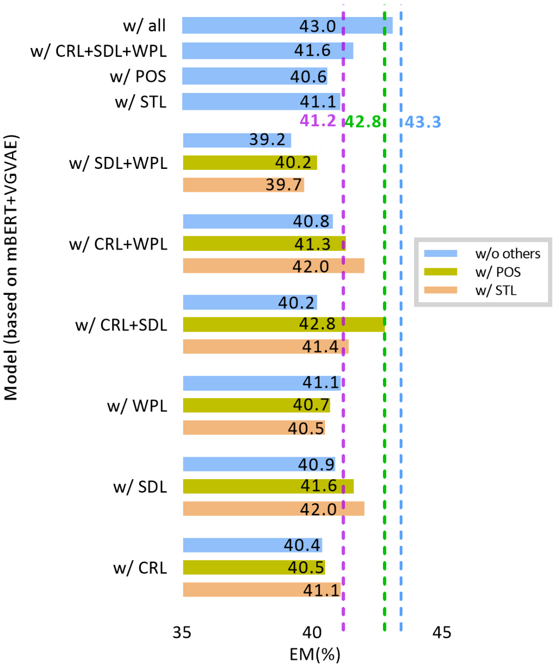

Figure 3: The ablation study results on the MLQA dataset. The three dotted lines indicate the results of baseline mBERT, S^{2}DM_POS, and S^{2}DM_SP from left to right, respectively.

5.2 Why Use a Siamese Network in S^{2}DM?

In order to separate semantic information from PLMs, an alternative way is to train a single network based on the VGVAE model as shown in Figure 4. Compared with S^{2}DM, the single-network model does not use the CRL and SDL loss and only requires labeled monolingual data. Corresponding to S^{2}DM, there are also two single-network variants: S^{2}DM_single_POS and S^{2}DM_single_SP. Since there is no explicit semantics learning across the source and target language, we conjecture that the single-network S^{2}DM will affect the quality of learned semantic vectors and the degree of semantics-syntax decoupling. As shown in Table 5, the performance of the single-network S^{2}DM is worse than the siamese-network model.

5.3 Why the S^{2}DM Works?

Our method mainly aims to reduce the potential negative impact of syntactic differences of languages in the zero-shot transfer process by explicitly isolating semantics from syntax in representations from multilingual pre-trained models. Therefore, we hope to obtain multilingual semantic representations with rich semantic information to guide the machine to read and understand texts. In order to examine (1) whether semantic vectors y in S^{2}DM encode rich semantic information, and (2) whether semantics is sufficiently separated from syntax, and (3) whether semantic disentanglement can improve predicted answer spans in matching syntactic structures of the target language, we conducted additional experiments and analyses.

Here we used three datasets of cross-lingual semantic textual similarity (STS) in SemEval-2017[2] to evaluate the quality of semantic vectors learned by S^{2}DM. The three datasets are for Arabic to English (ar-en), Spanish to English (es-en), and Turkish to English (tr-en) cross-lingual STS. We report the results of our models in Figure 5 based on mBERT. We also evaluated learned syntactic vectors in cross-lingual STS, hoping that the performance gap between semantic vectors (i.e., y in S^{2}DM) and syntactic vectors (i.e., z in S^{2}DM) is as large as possible. As shown in Figure 5, disentangled semantic representations significantly improve Pearson correlation over the baseline in ar-en, es-en, and tr-en by 11.46%, 3.40%, 4.98%, respectively. Additionally, disentangled syntactic representations are negatively correlated to STS in most cases. These results suggest that disentangled semantic vectors indeed learn rich universal semantic information.

We visualize hidden representations of the last layer of mBERT and semantic representations of mBERT+S^{2}DM_POS and mBERT+S^{2}DM_SP in Figure 6, in which the parallel sentences are from

---

[2] `https://alt.qcri.org/semeval2017/task1/`

a 15-way parallel corpus (Conneau et al., 2018). It is clear to see that disentangled semantic representations learned by S^{2}DM make parallel sentences in 15 languages (semantically equivalent to each other) closer to one another in space, blending language boundaries clearly seen from mBERT representations (Figure 6(a)). Combined with the negative/positive results of syntactic/semantic vectors in the cross-lingual STS task in SemEval-2017, the visualization demonstrates that S^{2}DM can efficiently disassociate semantics from syntax.

Finally, we evaluated the degree of consistency to syntactic constituents of predicted answer spans. As described in Section 1, 23.15% of the non-transfer predicted correct answers violate syntactic constraint of the target language during the raw zero-shot cross-lingual transfer on BiPaR. By contrast, S^{2}DM_POS and S^{2}DM_SP drop this percentage to 12.98% and 6.60%, respectively. Moreover, on the entire test set of BiPaR (Jing et al., 2019) in Chinese, 93.27% answers predicted by S^{2}DM_SP exactly span syntactic constituents, which is 8.14% higher than the mBERT model.

6 Conclusions

In this paper, we have presented a novel multilingual MRC model for zero-shot cross-lingual transfer, which can disentangle semantic from syntactic representations and explicitly transfer semantic information from rich-resource language to low-resource languages, reducing the influence of syntactic differences between languages on the answer span prediction of the target language. To disassociate semantics from syntax in multilingual pre-trained representations, we propose the siamese semantic disentanglement model that semantics/syntax-oriented losses to guide latent variables to learn corresponding information. For low-resource languages without training data for the decoupling model, our theoretical analysis and experiments verify the generalization of our multilingual MRC model. Further in-depth analyses suggest that the proposed S^{2}DM can efficiently disentangle semantics from syntax and significantly improve syntactic consistency of answer predictions on the target language after zero-shot cross-lingual transfer.

Abstract

Transferring the knowledge to a small model through distillation has raised great interest in recent years. Prevailing methods transfer the knowledge derived from mono-granularity language units (e.g., token-level or sample-level), which is not enough to represent the rich semantics of a text and may lose some vital knowledge. Besides, these methods form the knowledge as individual representations or their simple dependencies, neglecting abundant structural relations among intermediate representations. To overcome the problems, we present a novel knowledge distillation framework that gathers intermediate representations from multiple semantic granularities (e.g., tokens, spans and samples) and forms the knowledge as more sophisticated structural relations specified as the pair-wise interactions and the triplet-wise geometric angles based on multi-granularity representations. Moreover, we propose distilling the well-organized multi-granularity structural knowledge to the student hierarchically across layers. Experimental results on GLUE benchmark demonstrate that our method outperforms advanced distillation methods.

1 Introduction

Recent years have witnessed a surge of pre-trained language models (Devlin et al., 2019; Lewis et al., 2020; Clark et al., 2020; Brown et al., 2020). Building upon the transformer architecture (Vaswani et al., 2017) and pre-trained on large-scale corpora using self-supervised objectives, these PLMs have achieved remarkable success in a wide range of natural language understanding and generation tasks. Despite their high performance, these PLMs usually suffer from high computation and memory costs, which hinders them from being deployed into resource-scarce scenarios, e.g., mobile phones and embedded devices.

Various attempts have been made to compress the huge PLMs into small ones with minimum performance degradation. As one of the main approaches, knowledge distillation (Hinton et al., 2015) utilizes a large and powerful teacher model to transfer the knowledge to a small student model. Based on the teacher-student framework, Jiao et al. (2020); Wang et al. (2020) distilled the token-level representations and attention dependencies to the student, Sanh et al. (2019); Sun et al. (2019) taught the student to mimic the output logits of the teacher, Sun et al. (2020) enforced the student's representation to be closed to the teacher's while pushing negative samples to be far apart. Although proved effective, existing approaches have some flaws. For one thing, these distillation methods only adopted the representations of mono-granularity language units (i.e., token-level or sample-level), while neglecting other granularity. For another, their distillation objectives either matched the corresponding representations between the teacher and the student or aligned the attention dependencies, failing to capture more sophisticated structural relations between the representations.

To address these issues, in this paper we propose a novel knowledge distillation framework named **M**ulti-**G**ranularity **S**tructural **K**nowledge **D**istillation (MGSKD) through answering the three research questions: (1) *which* granularity should the knowledge be, (2) *what* form of knowledge is effective to transfer and (3) *how* to teach the student using the knowledge. For the "*which*" question, given that natural languages have multiple semantic granularities, we consider the intermediate representations in three granularities: tokens, spans and samples. Specifically, we first take the sub-word tokens as the smallest granularity, then

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 1001 - 1011
May 22-27, 2022

select phrases and whole words as spans for they hold complete meanings, and finally treat the whole input texts as samples. We use mean-pooling to obtain the representations of spans and samples based on token representations. For the "*what*" question, we propose to leverage the sophisticated structural relations between the representations as the knowledge. Concretely, instead of aligning the corresponding representations of the teacher and the student, we propose to form the knowledge as the pair-wise interactions and the triplet-wise geometric angels of a group of representations. For the "*how*" question, following the recent findings that the bottom layers capture syntactic features while the upper layers encode semantic features (Jawahar et al., 2019), we conduct hierarchical distillation where the bottom layers of the student are taught token-level and span-level knowledge while the upper layers learn sample-level knowledge.

We conduct comprehensive experiments on standard language understanding benchmark GLUE (Wang et al., 2018). Experimental results demonstrate that our knowledge distillation framework outperforms strong baselines methods. Surprisingly, MGSKD achieves comparable or better performance than $\text{BERT}_{\text{base}}$ on most of the tasks on GLUE, while keeping much smaller and faster. Our contributions in this paper are three folds:

- We are the first to leverage multi-granularity semantic representations in language (i.e., the representations of tokens, spans and samples) for knowledge distillation.
- We propose to form the knowledge as sophisticated structural relations specified as the pair-wise interactions and the triplet-wise geometric angles based on multi-granularity representations.
- We conduct comprehensive experiments on GLUE benchmark and MGSKD achieves superior results over other knowledge distillation baselines.

2 Related Work

Language Model Compression. Pre-trained language models (Devlin et al., 2019; Clark et al., 2020; Brown et al., 2020) perform remarkably well on various applications but at the cost of high computation and memory usage. To deploy these powerful models into resource-scarce scenarios, various attempts have been made to compress the language models into small ones. Quantization methods (Zafrir et al., 2019; Shen et al., 2020; Zhang et al., 2020; Bai et al., 2021) convert the model parameters to lower precision. Pruning approaches identify then remove unimportant individual weights or structures (Michel et al., 2019; Fan et al., 2019; Gordon et al., 2020; Hou et al., 2020). Weight sharing techniques (Dehghani et al., 2018; Lan et al., 2019) allow the model to reuse the transformer layer multiple times to reduce parameters.

Knowledge Distillation. Knowledge distillation (Hinton et al., 2015) is another major line of research to do model compression, which is the main concentration in this paper. Hinton et al. (2015) first proposed to minimize the KL-divergence between the predicted distributions of the teacher and the student. Sanh et al. (2019); Sun et al. (2019); Liang et al. (2020) adopted this objective to teach the student on masked language modeling or text classification tasks. Romero et al. (2014) proposed to directly match the feature activations of the teacher and the student. Jiao et al. (2020) followed the idea and took the intermediate representations in each transformer layer of the teacher as one of the knowledge to be transferred. Tian et al. (2019) proposed a contrastive distillation framework where the teacher's representations were treated as positives to the corresponding student's representations. Sun et al. (2020); Fu et al. (2021) customized this idea to language model compression and proved its effectiveness. Researchers also attempted to use the mutual relations of representations as the knowledge to transfer. In the literature of image classification, Peng et al. (2019); Tung and Mori (2019); Park et al. (2019) pointed out that the relations of the image representations of the teacher should be preserved in the student's feature space, and adopted a series of geometric measurements to model the sample relations. For distilling transformer models, Park et al. (2021) enforced the relations across tokens and layers between the teacher and the student to be consistent. Jiao et al. (2020); Wang et al. (2020, 2021) used the attention dependencies between tokens to teach the student. In this paper, we propose to transfer the multi-granularity knowledge to the student. Different from previous works that only considered a single granularity of representations, we jointly transfer the token-level, span-level and sample-level structural knowledge. And compared with Shao and Chen (2021) which considered the multi-granularity visual features in an image as the knowledge, our method works in a different modality, presents a different definition of granularity,

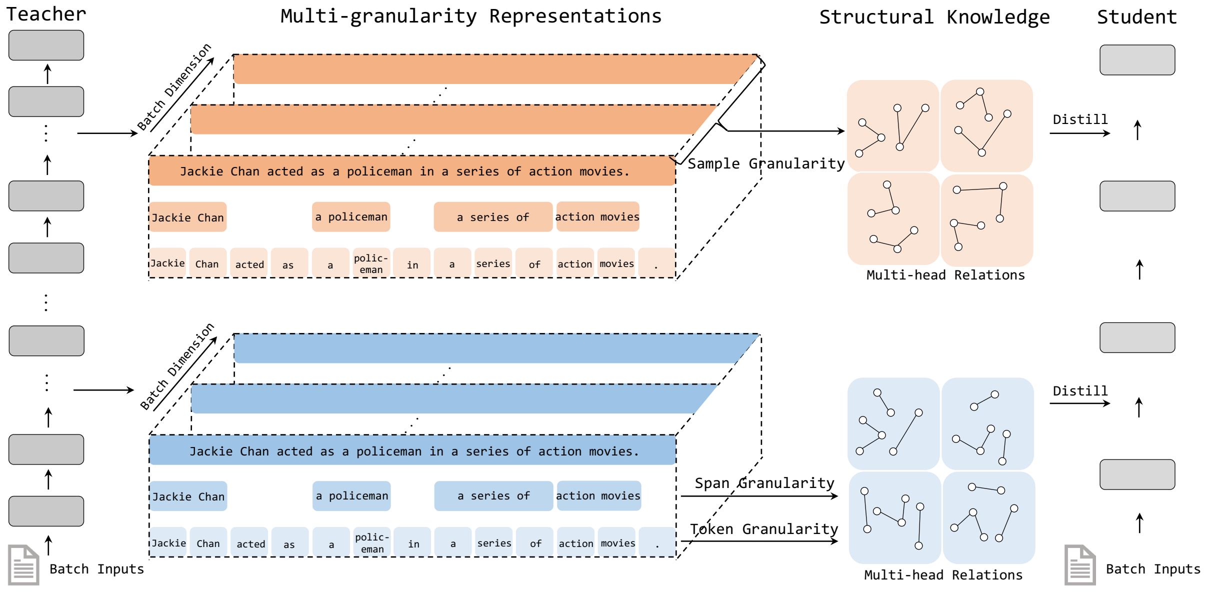

Figure 1: The overall framework of MGSKD.

and prepares the multi-granularity knowledge as the structural relations among representations.

3 Method

We propose **M**ulti-**G**ranularity **S**tructural **K**nowledge **D**istillation, a novel framework to distill the knowledge from a large transformer language model to a small one. Different from previous works that transferred the knowledge derived from either token-level or sample-level outputs, we prepare the knowledge in three semantic granularities: token-level, span-level and sample-level. Given some granularity of representations of the teacher model, we form the knowledge as the structural relations, i.e., the pair-wise interactions and the triplet-wise geometric angles, between the representations. We then distill the well-organized structural knowledge to the student hierarchically across layers, where the token-level and the span-level knowledge are transferred to the bottom layers to provide more syntactic guidance while the sample-level knowledge is transferred to the upper layers to offer more help of semantic understanding. The framework of MGSKD is illustrated in Figure 1.

3.1 Multi-granularity Representation

Natural languages have multiple granularities of conceptual units. In the context of pre-trained transformers (Devlin et al., 2019), the basic unit is the tokens produced by sub-word tokenizers (Wu et al., 2016; Radford et al., 2019). Several consecutive tokens become a text span, and the sample is comprised of all the tokens it contains. Existing knowledge distillation approaches (Jiao et al., 2020; Wang et al., 2020; Sun et al., 2020; Fu et al., 2021) focused on one granularity of representation, neglecting that texts are built upon language units from multiple granularities. Intuitively, incorporating multi-granularity representations in knowledge distillation may provide more guidance since the student can be taught how to compose the semantic concepts from small granularities to larger ones. Therefore, we propose to gather multi-granularity representations for knowledge distillation. We construct three granularities of representations: tokens, spans that hold complete meanings, and samples.

Token Representation. The first granularity is the sub-word token, which is the foundation of high-level granularity. Given an input text, a tokenizer such as WordPiece (Wu et al., 2016) splits it into n tokens $x = [t_1, t_2, \dots, t_n]$. The tokens are converted to a sequence of continuous representations $\boldsymbol{E} = [\boldsymbol{e}_1, \boldsymbol{e}_2, \dots, \boldsymbol{e}_n] \in \mathbb{R}^{n\times d}$ through the embedding layer. For the sake of clarity, we treat the embedding layer as the 0-th layer and set $\boldsymbol{H}^0 = \boldsymbol{E}$. Then the token embeddings $\boldsymbol{H}^0$ are passed to L stacked transformer layers. The l-th layer takes the output representations $\boldsymbol{H}^{l-1}$ of the previous layer as its input, and returns the updated representations $\boldsymbol{H}^l$ using multi-head attention (MHA) and position-wise feed-forward network (FFN). Herein, we obtain $L+1$ layers of token representations $\{\boldsymbol{H}^l\}_{l=0}^{L}$ where $\boldsymbol{H}^l \in \mathbb{R}^{n\times d}$.

Span Representation. The second granularity is the span, which is comprised of several consecutive tokens. Different from SpanBERT (Joshi et al., 2020) that randomly selects token spans whose start positions and lengths are sampled from some distributions for masked language modeling, we propose to extract spans that have complete meanings. Widely adopted sub-word tokenizers in pre-trained transformers split some of the English words into several sub-word tokens. We consider these whole words consisting of multiple sub-word tokens, and phrases, as meaningful spans. Sub-word tokens for whole words are easy to obtain using WordPiece tokenizer (Wu et al., 2016). While for phrase identification, we train a classifier-based English chunker on CoNLL-2000 corpus (Tjong Kim Sang and Buchholz, 2000) following the instructions[1]. We then use the trained chunker to extract noun phrases (NP), verb phrases (VP), and prepositional phrases (PP). These identified phrases are tokenized by WordPiece tokenizer to obtain tokens. Herein, we can obtain n_s token spans $x_{\text{span}} = [s_1, s_2, \ldots, s_{n_s}]$, where $s_i = [t_j, t_{j+1}, \ldots, t_{j+n_{s_i}-1}]$ denotes the i-th span that starts at the j-th token and contains n_{s_i} tokens. We then build span representations based on token representations using mean pooling:

$$\hat{\boldsymbol{h}}_{\boldsymbol{i}}^{\boldsymbol{l}} = \text{Pool}(\boldsymbol{H}^l_{j:j+n_{s_i}}), \tag{1}$$

where $\hat{\boldsymbol{h}}_{\boldsymbol{i}}^{\boldsymbol{l}} \in \mathbb{R}^d$ is the representation of the i-th span in layer l. We obtain $L+1$ layers of span representations as $\{\hat{\boldsymbol{H}}^l\}_{l=0}^{L}$ where $\hat{\boldsymbol{H}}^l \in \mathbb{R}^{n_s\times d}$.

Sample Representation. The third granularity is the input text sample itself. Based on token representations again, we use mean-pooling to aggregate all the token representations in a text sample to form sample representation:

$$\tilde{\boldsymbol{h}}^{\boldsymbol{l}} = \text{Pool}(\boldsymbol{H}^l), \tag{2}$$

Herein, we get $L+1$ layers of sample representations as $\{\tilde{\boldsymbol{h}}^l\}_{l=0}^{L}$ where $\tilde{\boldsymbol{h}}^l \in \mathbb{R}^d$.

3.2 Structural Knowledge Extraction

With multi-granularity representations, we then need to formulate the specific knowledge we aim to transfer from the teacher to the student. Considering that an element holds its meaning only when it is put into a semantic space where it has various relations to other elements, we propose that the knowledge is better specified as the structural relations of the representations in a semantic space, instead of the individual representations themselves. Therefore, instead of directly matching each hidden representation between the teacher and the student, we propose to extract structural relations from multi-granularity representations as the knowledge to teach the student. We first project the representations into multiple sub-spaces, then we extract two types of structural knowledge: pair-wise interactions and triplet-wise geometric angles.

Multi-head Modeling. A recent study by Wang et al. (2021) pointed out that distilling knowledge with multiple relation heads helps the student learn better. Therefore, before extracting structural knowledge for intermediate representations, we first project them into m sub-spaces, which we call multi-head modeling. Specifically, given a set of n representations $\boldsymbol{R} \in \mathbb{R}^{n\times d}$, we linearly project them into m sub-spaces whose dimensions are d/m. [2] We use $\boldsymbol{R}' \in \mathbb{R}^{m\times n\times d/m}$ to denote the multi-head representations which are then used for extracting structural knowledge.

Pair-wise Interaction. Given two vectors $\boldsymbol{r}_i, \boldsymbol{r}_j \in \mathbb{R}^{d/m}$ in a sub-space, we calculate their interaction as their scaled dot product:

$$\varphi(\boldsymbol{r}_i, \boldsymbol{r}_j) = \frac{\boldsymbol{r}_i \cdot \boldsymbol{r}_j^{\intercal}}{\sqrt{d/m}}. \tag{3}$$

Herein, we obtain the multi-head pair-wise interaction features for each pair as $\boldsymbol{P} \in \mathbb{R}^{m\times n\times n}$, where $\boldsymbol{P}_{h,i,j}$ denotes the interaction between the i-th representation and the j-th representation in the sub-space of the h-th relation head. Note that $\boldsymbol{P}$ can be considered as the unnormalized self-attention (Vaswani et al., 2017) scores for the given representations, the difference lies in that in our calculation the queries are identical to the keys.

Triplet-wise Geometric Angle. Pair-wise interaction features only consider two vectors at once, which is not enough to represent the complicated structural relations between representations in the high-dimensional space. Therefore, we propose to model the high-order relations as the geometric angles for triplets of vectors. Specifically, given

---

[1] `https://www.nltk.org/book/ch07.html`

[2] For the student model, its representations are linearly projected into intermediate states whose dimensions are the same as the teacher model's hidden dimensions, so that it can be split into m sub-spaces as the teacher model.

a triplet of representations $\boldsymbol{r}_i, \boldsymbol{r}_j, \boldsymbol{r}_k \in \mathbb{R}^{d/m}$, we calculate their geometric angle as:

$$\begin{gathered} \psi(\boldsymbol{r}_i, \boldsymbol{r}_j, \boldsymbol{r}_k) = cos\angle \boldsymbol{r}_i \boldsymbol{r}_j \boldsymbol{r}_k = \langle \boldsymbol{r}_{ij}, \boldsymbol{r}_{kj} \rangle \\ \boldsymbol{r}_{ij} = \frac{\boldsymbol{r}_i - \boldsymbol{r}_j}{\|\boldsymbol{r}_i - \boldsymbol{r}_j\|_2}, \boldsymbol{r}_{kj} = \frac{\boldsymbol{r}_k - \boldsymbol{r}_j}{\|\boldsymbol{r}_k - \boldsymbol{r}_j\|_2}. \end{gathered} \tag{4}$$

We can calculate the geometric angles for all the triplets, and obtain $\boldsymbol{T} \in \mathbb{R}^{m \times n \times n \times n}$ where $\boldsymbol{T}_{h,i,j,k}$ stands for the angle of $\angle \boldsymbol{r}_i \boldsymbol{r}_j \boldsymbol{r}_k$ in the sub-space of the h-th relation head. As the computation complexity increases cubically with n, such a calculation is infeasible when the number of representations is large. Hereby, we propose a two-stage selection strategy to sequentially select important representations to form angles. Similar to Goyal et al. (2020), we assume that the more attention a representation receives from others, the more important it is. Therefore, we first calculate the self-attention distributions $\boldsymbol{A} \in \mathbb{R}^{m \times n \times n}$ by applying *softmax* function on the last dimension of $\boldsymbol{P}$. Then for the j-th representation, we calculate a global salient score s_j by summing up self-attention distributions across all heads and all queries. Based on the score, we pick the top-k_1 salient representations as vertices. Next, if the i-th representation is selected as vertex, we pick k_2 representations with the highest local salient score to form angles with the vertex. We define the local salient score $s_{i,j}$ as the attention posed by the i-th representation on the j-th representation, The salient scores s_i and $s_{i,j}$ are calculated as follows:

$$s_j = \sum_{h=1}^{m} \sum_{i=1}^{n} \boldsymbol{A}_{h,i,j}, \quad s_{i,j} = \sum_{h=1}^{m} \boldsymbol{A}_{h,i,j}. \tag{5}$$

Therefore, by sequentially selecting salient representations to form angles, we reduce the computation complexity from $\mathcal{O}(mn^3)$ to $\mathcal{O}(mk_1k_2^2)$. By choosing proper k_2 and k_2, we can facilitate the computation of triplet-wise geometric angles for any number of representations.

3.3 Hierarchical Distillation

We utilize the structural knowledge extraction approach described in Sec. 3.2 to prepare knowledge based on three granularities of representations presented in Sec. 3.1 for distillation. Based on the findings that the bottom layers capture syntactic features while the upper layers encode semantic features (Jawahar et al., 2019), we propose to conduct hierarchical distillation for the student where different granularities of knowledge are transferred to different layers. For a teacher model with L_t layers and a student model with L_s layers, we first define a layer mapping function $g(\cdot)$ that maps each student layer to a teacher layer that it learns from. Following previous work (Jiao et al., 2020), we adopt the "uniform strategy" for $g(\cdot)$. Then we transfer token-level and span-level knowledge to the bottom-M layers of the student, while leveraging sample-level knowledge to teach its upper $L_s + 1 - M$ layers.

Token- and Span-level. Specifically, given the token-level and the span-level representations of the teacher $\{\boldsymbol{H}_{\boldsymbol{t}}^l, \hat{\boldsymbol{H}}_{\boldsymbol{t}}^l\}_{l=0}^{L_t}$, we use Eq. 3 and Eq. 4 to calculate the pair-wise interactions and the triplet-wise geometric angles among tokens and spans within a single sample as $\{\boldsymbol{P}_{\boldsymbol{t}}^l, \hat{\boldsymbol{P}}_{\boldsymbol{t}}^l\}_{l=0}^{L_t}$ and $\{\boldsymbol{T}_{\boldsymbol{t}}^l, \hat{\boldsymbol{T}}_{\boldsymbol{t}}^l\}_{l=0}^{L_t}$. Similarly, we can obtain the structural relations of the students: $\{\boldsymbol{P}_{\boldsymbol{s}}^l, \hat{\boldsymbol{P}}_{\boldsymbol{s}}^l\}_{l=0}^{L_s}$ and $\{\boldsymbol{T}_{\boldsymbol{s}}^l, \hat{\boldsymbol{T}}_{\boldsymbol{s}}^l\}_{l=0}^{L_s}$. We then teach the student by minimizing the differences of the structural relations among their representations between the teacher and the student:

$$\begin{aligned} \mathcal{L}_{token} &= \sum_{0 \le l < M} (\ell_1(\boldsymbol{P}_{\boldsymbol{t}}^{g(l)}, \boldsymbol{P}_{\boldsymbol{s}}^l) + \ell_2(\boldsymbol{T}_{\boldsymbol{t}}^{g(l)}, \boldsymbol{T}_{\boldsymbol{s}}^l)) \\ \mathcal{L}_{span} &= \sum_{0 \le l < M} (\ell_1(\hat{\boldsymbol{P}}_{\boldsymbol{t}}^{g(l)}, \hat{\boldsymbol{P}}_{\boldsymbol{s}}^l) + \ell_2(\hat{\boldsymbol{T}}_{\boldsymbol{t}}^{g(l)}, \hat{\boldsymbol{T}}_{\boldsymbol{s}}^l)). \end{aligned} \tag{6}$$

Sample-level. Recall that we obtain $\{\tilde{\boldsymbol{h}}_{\boldsymbol{t}}^{\boldsymbol{l}}\}_{l=0}^{L_t}$ and $\{\tilde{\boldsymbol{h}}_{\boldsymbol{s}}^{\boldsymbol{l}}\}_{l=0}^{L_s}$ for the teacher and the student where $\tilde{\boldsymbol{h}}_{\boldsymbol{t}}^{\boldsymbol{l}}, \tilde{\boldsymbol{h}}_{\boldsymbol{s}}^{\boldsymbol{l}} \in \mathbb{R}^d$. Different from the structural knowledge of tokens and spans which is modeled within a sample, the sample-level structural relations rely on a group of sample representations. Although the choice of samples may make a difference to the overall performance, here we simply gather all the sample representations in a mini-batch to calculate their structural relations as the sample-level knowledge. Specifically, we only focus on the triplet-wise relations $\{\tilde{\boldsymbol{T}}_{\boldsymbol{t}}^{\boldsymbol{l}}\}_{l=0}^{L_t}$ and $\{\tilde{\boldsymbol{T}}_{\boldsymbol{s}}^{\boldsymbol{l}}\}_{l=0}^{L_s}$:

$$\mathcal{L}_{sample} = \sum_{M \le l \le L_s} \ell_2(\tilde{\boldsymbol{T}}_{\boldsymbol{t}}^{g(l)}, \tilde{\boldsymbol{T}}_{\boldsymbol{s}}^l). \tag{7}$$

ℓ_1 and ℓ_2 in Eq. 6 and Eq. 7 are loss functions that measure the distance between the structural relations of the teacher's and the student's representations. We empirically choose MSE for ℓ_1 and Huber loss ($\delta = 1$) for ℓ_2.

Table 1: Evaluation results on the dev set of GLUE benchmark. The results of the models with 66M parameters are taken from published papers. Our results are averaged for 3 runs with different random seeds. The best results of the student models are in-bold. † means the method is implemented with the same distillation setting as ours.

Overall Objectives. The overall distillation objective for multi-granularity structural knowledge distillation is:

$$\mathcal{L}_1 = \lambda_1 \mathcal{L}_{sample} + \lambda_2 \mathcal{L}_{token} + \lambda_3 \mathcal{L}_{span}, \quad (8)$$

where λ_1, λ_2 and λ_3 are weights of loss functions of different granularities.

After this, we also teach the student to match the prediction distributions with the teacher's for text classification tasks:

$$\mathcal{L}_2 = \tau^2 D_{\text{KL}}(\boldsymbol{z}_t/\tau \| \boldsymbol{z}_s/\tau), \quad (9)$$

where $\boldsymbol{z}_t$ and $\boldsymbol{z}_s$ are the predicted probability distributions of the teacher and the student respectively, τ denotes the temperature.

4 Experiments

4.1 Datasets and Metrics

We conduct our experiments on the General Language Understanding Evaluation (GLUE) benchmark (Wang et al., 2018). Sepcifically, there are 2 single-sentence tasks: SST-2 (Socher et al., 2013), CoLA (Warstadt et al., 2019), 3 similarity and paraphrase tasks: MRPC (Dolan and Brockett, 2005), STS-B (Cer et al., 2017), QQP (Chen et al., 2018), and 4 inference tasks: MNLI (Williams et al., 2018), QNLI (Rajpurkar et al., 2016), RTE (Bentivogli et al., 2009), WNLI (Levesque et al., 2012). Following previous work (Jiao et al., 2020; Wang et al., 2021; Park et al., 2021), we evaluate our method on 8 datasets except WNLI. We report accuracy on 5 datasets: SST-2, QQP, MNLI, QNLI and RTE. We report F1 score on MRPC, Matthews correlation coefficient on CoLA, and Spearman's rank correlation coefficient on STS-B.

4.2 Implementation Details

We focus on task-specific distillation. We follow Jiao et al. (2020) to augment the training sets for each of the GLUE tasks using the code[3] they released. We fine-tune ELECTRA$_{\text{base}}$ on the original training sets as the teacher model, and utilize TinyBERT-4-312[4] which is distilled on general corpora as the initialization of our student model. For token-level and span-level distillation, we use 64 relation heads for calculating pair-wise interactions, and 1 relation head for triplet-wise angles due to its huge computation and memory costs. And we set $k_1 = k_2 = 20$ for calculating angles. For sample-level distillation, we use 64 relation heads and set k_1 and k_2 as the batch size. We distill token-level and span-level knowledge to the bottom-2 layers of the student and distill sample-level knowledge to the other layers. For the structural distillation objective, we set $\lambda_1 = 4$, $\lambda_2 = \lambda_3 = 1$ to maintain their gradient norms in the same order of magnitude. We first distill the student model using Eq. 8 for 50 epochs on CoLA and 20 epochs on other tasks. The learning rate is 1e-5 and the batch size is 32. Then we use Eq. 9 to distill the predictions for all tasks except STS-B since we empirically find that directly fine-tuning after distillation using Eq. 8 yields better performance for it. For QQP and CoLA, we adopt the original training set and distill the student for 10 epochs while for other 5 tasks we use the augmented training sets and distill the student for 3 epochs. We set τ as 1.0, the learning

4.3 Comparison Methods

Medium-sized Student Models. Most of the existing knowledge distillation methods are conducted on medium-sized student models which have 6 transformer layers, 768 hidden neurons, 12 attention heads, and overall 66M parameters. We adopt 3 of them as baselines: DistilBERT (Sanh et al., 2019), MiniLMv2 (Wang et al., 2021) and CKD (Park et al., 2021). Notice that these models adopted different distillation settings. DistilBERT and MiniLMv2 were firstly under task-agnostic distillation then directly fine-tuned on GLUE, while CKD was under both task-agnostic and task-specific distillation. The corpora they adopted for task-agnostic distillation were also not exactly the same. Nevertheless, we list the results as they reported on GLUE dev set as baselines, and we implement MiniLMv2 and CKD, two state-of-the-art distillation methods under the same distillation setting as ours for a fair comparison, which is described in the next paragraph.

Small-sized Student Models. For fair comparisons, we implement two state-of-the-art distillation methods: MiniLMv2 (Wang et al., 2021), CKD (Park et al., 2021) under the same distillation setting as ours. All these methods use the same student model as ours which has 4 transformer layers, 312 hidden neurons, 12 attention heads and overall 14M parameters. We adopt the fine-tuned $\text{ELECTRA}_{\text{base}}$ as the teacher, and conduct task-specific distillation using the same distillation schedule and hyperparameters on the same augmented training sets as ours.

4.4 Main Results

We first evaluate the effectiveness of our proposed distillation framework. The main results are shown in Table 1. We calculate #Params by summing up the number of parameters contained in the embedding layer and all the transformer layers. The speed-up ratios are directly taken from previous works (Jiao et al., 2020; Wang et al., 2021). It can be observed that under the same distillation setting (models with † in Table 1), $\text{Student}^{\dagger}_{\text{MGSKD}}$ outperforms strong baseline methods (i.e., $\text{Student}^{\dagger}_{\text{MiniLMv2}}$ and $\text{Student}^{\dagger}_{\text{CKD}}$) on 7 of the 8 GLUE tasks. When compared with medium-sized models from the literature which have more parameters but under different distillation settings (e.g., CKD), our method can still beat them on the majority of the 8 tasks. And surprisingly, with a stronger teacher model and data augmentation technique, our method MGSKD enables a 14M student transformer model to achieve comparable performance with $\text{BERT}_{\text{base}}$ on most of the GLUE tasks, while keeping 9.4 times faster. Also, we observe that although MGSKD performs well on most of the GLUE tasks, it lags behind some baselines on CoLA, where the model is asked to judge the grammatical acceptability of a sentence. One reason might be that CoLA requires the model to focus on syntactic information while paying less attention to the sample-level semantic meanings, thus reducing the need for multi-granularity semantic knowledge that we propose to transfer to the student.

Method	SST-2	MNLI-(m/mm)
MGSKD	93.7	84.7/84.3
MGSKD w/o token	93.0	84.1/83.7
MGSKD w/o span	93.2	84.3/84.0
MGSKD w/o sample	92.8	83.9/83.6
MGSKD w token_{p}	92.1	83.4/82.9
MGSKD w token_{t}	91.7	82.8/82.6
MGSKD w $\text{token}_{\text{p,t}}$	92.5	83.7/83.2
MGSKD w span_{p}	91.8	82.5/82.3
MGSKD w span_{t}	91.8	82.3/82.0
MGSKD w $\text{span}_{\text{p,t}}$	92.2	83.0/82.7
MGSKD w sample_{p}	91.9	82.6/82.5
MGSKD w sample_{t}	92.9	83.9/83.5
MGSKD w $\text{sample}_{\text{p,t}}$	92.8	83.7/83.6

Table 3: Ablation study of knowledge granularity. The subscripts $_{\text{p}}$ and $_{\text{t}}$ denote pair-wise and triplet-wise relations respectively.

4.5 Discussions

The Impact of Relation Heads. Recall that when calculating the structural relations between representations, we project them into m relation heads. We show how the number of relation heads impacts the performance on SST-2 and MNLI. As shown in Table 2, the performance gets better as the

(a) Token-level

(b) Sample-level

Figure 2: The accuracy curve of different k_1, k_2 for calculating angles.

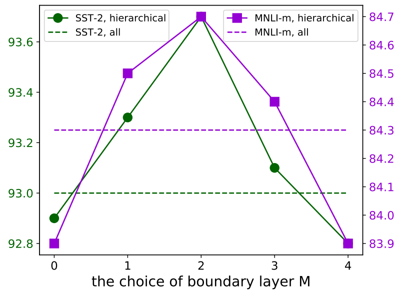

Figure 3: The accuracy curve of different choices of the boundary layer M.

number of relation heads increases, since it eases the trouble for the student to learn the structural relations in the very high-dimensional vector space by providing fine-grained supervision in multiple relatively low-dimensional spaces. We also find that when m is large, continuing to increase m is not worthwhile since the time and memory complexity increase linearly with m. Therefore we choose $m = 64$ in our setting.

Ablation Study of Knowledge Granularity. We transfer the structural knowledge to the student in three granularities: token-level, span-level, and sample-level. We extract pair-wise and triplet-wise structural relations for token- and span-level, while we adopt triplet-wise relations for sample-level. To verify the effectiveness of each granularity of knowledge and each form of structural relations, we conduct ablation studies and present the results in Table 3. (1) We first remove each granularity of knowledge from the objectives of MGSKD individually.[6] We can conclude that the sample-level knowledge is most crucial for the overall performance, the token-level knowledge provides moderate benefit, and the span-level knowledge contributes the least. We assume the reason why span-level knowledge distillation performs a little bit worse than token-level lies in that the average number of meaningful spans per sample on the 8 tasks is 7.19, which is 5.2 times fewer than the average number of tokens. Nevertheless, distillation with span-level knowledge still yields comparable performance. Overall, the results prove that each granularity of knowledge brings a positive effect to the model performance. (2) Then for each granularity, we study the effect of each form of structural knowledge (i.e., pair-wise and triplet-wise relations). In this stage, we distill each granularity of knowledge into all the student layers for a fair comparison. It can be observed that for token-level and span-level knowledge, pair-wise relations are more effective than triplet-wise relations, and the model performs better when jointly utilizing both. While for sample-level knowledge, we find that using triplet-wise relations outperforms using pair-wise relations by a large margin. Moreover, jointly utilizing the sample-level pair-wise and triplet-wise relations can't further improve the model's performance, therefore we only employ triplet-wise relations as sample-level knowledge.

The Impact of k_1 and k_2 for Calculating Angles. To ease the computation and memory complexity, we propose to sequentially select important representations to form angles, leading to the hyperparameters k_1 and k_2. We test different choices of k_1 and k_2 by adopting token-level and sample-level triplet-wise relations to teach the student respectively. To reduce the search space, we simply set $k_1 = k_2$. We draw the accuracy curve for different choices of k_1, k_2, as shown in Fig. 2. For token-level objectives, we find that increasing k_1, k_2 improves the accuracy when they are small and when $k_1, k_2 \geq 20$, the curves begin to vibrate. Therefore we choose $k_1 = k_2 = 20$ for token-level angle calculation. While for the triplet-wise relations of sample-level features, we observe that the accuracy increases monotonically with k_1, k_2. Therefore we just set k_1, k_2 as the batch size.

The Choice of the Boundary Layer M. We propose the hierarchical distillation strategy where we distill the token- and span-level knowledge into the bottom-M layers of the student and transfer the sample-level knowledge to the upper layers. To verify the effectiveness as well as to find the best choice of the boundary layer M, we conduct exper-

---

[6] When the sample-level objective is removed, we use the remaining objectives for all the student layers instead of only the bottom layers, as this setting yields better performance.

iments and show the results in Fig. 3. The dashed lines represent the setting dubbed as "*all*", where we distill token-, span- and sample-level knowledge into all the student layers. And the solid lines denote our hierarchical distillation setting with different choices of the boundary layer M. When $M = 0$ and $M = 4$, the student learns sample-level knowledge or token- and span-level knowledge for all layers. Without the help of other knowledge granularities, the student yields relatively poor performance on both tasks. As M increases from 0 to 4, we find the model's performance curves surpass the dashed lines, which verifies the effectiveness of our proposed hierarchical distillation strategy which transfers the knowledge to the proper positions of the student. We find the model achieves the highest accuracy when $M = 2$, i.e., the middle layer, indicating that both the syntactic knowledge transferred by token- and span-level features and the semantic knowledge derived from sample-level features are indispensable.

5 Conclusion

In this paper, we propose a novel knowledge distillation framework named MGSKD. We leverage intermediate representations of multi-granularity language units (i.e., tokens, spans and samples), and form the knowledge as the sophisticated structural relations between the representations rather than the individual representations themselves. The well-organized structural knowledge is then distilled into the student hierarchically across layers. Evaluation results on GLUE benchmark verify the effectiveness of our method. In the future, we plan to explore more forms of structural knowledge.

Ethical Statement

This paper proposes a knowledge distillation framework that leverages multi-granularity structural knowledge to compress a large and powerful language model into a small one with minimum performance degradation, which is beneficial to energy-efficient NLP applications. The research will not pose ethical problems or negative social consequences. The datasets used in this paper are all publicly available and are widely adopted by researchers as the general testbed for natural language understanding evaluation. The proposed method doesn't introduce ethical/social bias or aggravate the potential bias in the data.

Abstract

Human-like biases and undesired social stereotypes exist in large pretrained language models. Given the wide adoption of these models in real-world applications, mitigating such biases has become an emerging and important task. In this paper, we propose an automatic method to mitigate the biases in pretrained language models. Different from previous debiasing work that uses external corpora to fine-tune the pretrained models, we instead directly probe the biases encoded in pretrained models through prompts. Specifically, we propose a variant of the beam search method to automatically search for *biased prompts* such that the cloze-style completions are the most different with respect to different demographic groups. Given the identified biased prompts, we then propose a distribution alignment loss to mitigate the biases. Experiment results on standard datasets and metrics show that our proposed **Auto-Debias** approach can significantly reduce biases, including gender and racial bias, in pretrained language models such as BERT, RoBERTa and ALBERT. Moreover, the improvement in fairness does not decrease the language models' understanding abilities, as shown using the GLUE benchmark.

1 Introduction

Pretrained language models (PLMs), such as masked language models (MLMs), have achieved remarkable success in many natural language processing (NLP) tasks (Devlin et al., 2019; Liu et al., 2019; Lan et al., 2020; Brown et al.). Unfortunately, pretrained language models, which are trained on large human-written corpora, also inherit human-like biases and undesired social stereotypes (Caliskan et al., 2017; Bolukbasi et al., 2016; Blodgett et al., 2020). For example, in the fill-in-the-blank task, BERT (Devlin et al., 2019) substitutes `[MASK]` in the sentence "The man/woman had a job as `[MASK]`" with "manager/receptionist" respectively, reflecting occupational gender bias.

The human-like biases and stereotypes encoded in PLMs are worrisome as they can be propagated or even amplified in downstream NLP tasks such as sentiment classification (Kiritchenko and Mohammad, 2018), co-reference resolution (Zhao et al., 2019; Rudinger et al., 2018), clinical text classification (Zhang et al., 2020) and psychometric analysis (Abbasi et al., 2021; Ahmad et al., 2020).

However, although it is important to mitigate biases in PLMs, debiasing masked language models such as BERT is still challenging, because the biases encoded in the contextualized models are hard to identify. To address this challenge, previous efforts seek to use additional corpora to retrieve the contextualized embeddings or locate the biases and then debias accordingly. For example, Liang et al. (2020); Kaneko and Bollegala (2021); Garimella et al. (2021) use external corpora to locate sentences containing the demographic-specific words (e.g., man and women) or stereotype words (e.g., manager and receptionist) and then use different debiasing losses to mitigate the biases.

Using external corpora to debias PLMs heavily relies on the quality of the corpora. Empirical results show that different corpora have various effects on the debiasing results: some external corpora do mitigate the bias, while others introduce new biases to the PLMs (Garimella et al., 2021; Liang et al., 2020). This is because the corpora used for debiasing may not have enough coverage of the biases encoded in the PLMs. Nevertheless, our understanding of how to quantitatively assess the level of biases in a corpus remains limited (Blodgett et al., 2020).

Mitigating biases in PLMs without external corpora is an open research gap. Recent work in language model prompting shows that through cloze-style prompts, one can probe and analyze the knowledge (Petroni et al., 2019), biases (May et al., 2019) or toxic content (Ousidhoum et al., 2021) in PLMs. Motivated by this, instead of refer-

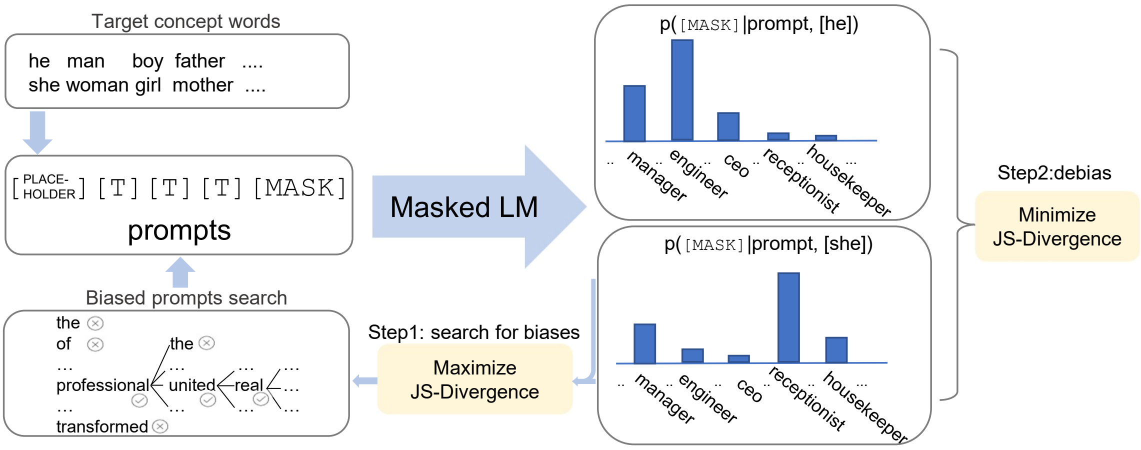

Figure 1: The Auto-Debias framework. In the first stage, our approach searches for the *biased prompts* such that the cloze-style completions (i.e., masked token prediction) have the highest disagreement in generating stereotype words. In the second stage, the language model is fine-tuned by minimizing the disagreement between the distributions of the cloze-style completions.

ring to any external corpus, we directly use cloze-style prompts to probe and identify the biases in PLMs. But what are the biases in a PLM? Our idea is motivated by the assumption that a fair NLP system should produce scores that are independent to the choice of identities mentioned in the text (Prabhakaran et al., 2019). In our context, we propose automatically searching for "discriminative" prompts such that the cloze-style completions have the highest disagreement in generating stereotype words (e.g., manager/receptionist) with respect to demographic words (e.g., man/woman). The automatic *biased prompt* search also minimizes human effort.

After we obtain the biased prompts, we probe the biased content with such prompts and then correct the model bias. We propose an equalizing loss to align the distributions between the `[MASK]` tokens predictions, conditioned on the corresponding demographic words. In other words, while the automatically crafted biased prompts maximize the disagreement between the predicted `[MASK]` token distributions, the equalizing loss minimizes such disagreement. Combining the automatic prompts generation and the distribution alignment fine-tuning, our novel method, **Auto-Debias** can debias the PLMs without using any external corpus. Auto-Debias is illustrated in Figure 1.

In the experiments, we evaluate the performance of Auto-Debias in mitigating gender and racial biases in three popular masked language models: BERT, ALBERT, and RoBERTa. Moreover, to alleviate the concern that model debiasing may worsen a model's performance on natural language understanding (NLU) tasks (Meade et al., 2021), we also evaluate the debiased models on GLUE tasks. The results show that our proposed Auto-Debias approach can effectively mitigate the biases while maintaining the capability of language models. We have released the Auto-Debias implementation, debiased models, and evaluation scripts at `https://github.com/Irenehere/Auto-Debias`.

2 Related Works

As NLP models are prevalent in real-world applications, a burgeoning body of literature has investigated human-like biases in NLP models. Bias in NLP systems can stem from training data (Dixon et al., 2018), pre-trained word embeddings or can be amplified by the machine learning models. Most existing work focuses on the bias in pre-trained word embeddings due to their universal nature (Dawkins, 2021). Prior work has found that traditional static word embeddings contain human-like biases and stereotypes (Caliskan et al., 2017; Bolukbasi et al., 2016; Garg et al., 2018; Manzini et al., 2019; Gonen and Goldberg, 2019). Debiasing strategies to mitigate static word embeddings have been proposed accordingly (Bolukbasi et al., 2016; Zhao et al., 2018; Kaneko and Bollegala, 2019; Ravfogel et al., 2020).

Contextualized embeddings such as BERT have been replacing the traditional static word embeddings. Researchers have also reported similar human-like biases and stereotypes in contextual embedding PLMs (May et al., 2019; Kurita et al., 2019; Tan and Celis, 2019; Hutchinson et al., 2020; Guo and Caliskan, 2021; Wolfe and Caliskan, 2021) or in the text generation tasks (Schick et al., 2021; Sheng et al., 2019). Compared to static word embeddings, mitigating the biases in contextualized PLMs is more challenging since the representation of a word usually depends on the word's context. Garimella et al. (2021) propose to augment the pretraining corpus with demographic-balanced sentences. Liang et al. (2020); Cheng et al. (2021) suggest removing the demographic-direction from sentence representations in a post-hoc fashion. However, augmenting the pretraining corpus is costly and post-hoc debiasing does not mitigate the intrinsic biases encoded in PLMs. Therefore, recent work has proposed to fine-tune the PLMs to mitigate biases by designing different debiasing objectives (Kaneko and Bollegala, 2021; Garimella et al., 2021; Lauscher et al., 2021). They rely on external corpora, and the debiasing results based on these external corpora vary significantly (Garimella et al., 2021). Moreover, Garimella et al. (2021) find that existing debiasing methods are generally ineffective: first, they do not generalize well beyond gender bias; second, they tend to worsen a model's language modeling ability and its performance on NLU tasks. In this work, we propose a debiasing method that does not necessitate referring to any external corpus. Our debiased models are evaluated on both gender and racial biases, and we also evaluate their performance on NLU tasks.

3 Auto-Debias: Probing and Debiasing using Prompts

We propose Auto-Debias, a debiasing technique for masked language models that does not entail referencing external corpora. Auto-Debias contains two stages: First, we automatically craft the *biased prompts*, such that the cloze-style completions have the highest disagreement in generating stereotype words with respect to demographic groups. Second, after we obtain the biased prompts, we debias the language model by a distribution alignment loss, with the motivation that the prompt completion results should be independent to the choice of different demographic-specific words.

3.1 Task Formulation

Let $\mathcal{M}$ be a Masked Language Model (MLM), and $\mathcal{V}$ be its vocabulary. The language model pre-trained with human-generated corpus contains social bias towards certain demographic groups. To mitigate the bias, we have two types of words: *target concepts* which are the paired tokens related to demographic groups (e.g., he/she, man/woman), and *attribute words* which are the stereotype tokens with respect to the target concepts (e.g., manager, receptionist). We denote the target concepts as a set of m-tuples of words $\mathcal{C} = \{(c_1^{(1)}, c_2^{(1)}, .., c_m^{(1)}), (c_1^{(2)}, c_2^{(2)}, .., c_m^{(2)}), ...\}$. For example, in the two-gender debiasing task, the target concepts are {(he,she), (man,woman),...}. In the three-religion debiasing task, the target concepts are {(judaism,christianity,islam), (jew, christian,muslim), ...}. We omit the superscript of $\mathcal{C}$ if without ambiguity. We denote the set of attribute words as $\mathcal{W}$.

An MLM can be probed by cloze-style prompts. Formally, a prompt $x_{\text{prompt}} \in \mathcal{V}^*$ is a sequence of words with one masked token `[MASK]` and one placeholder token. We use $x_{\text{prompt}}(c)$ to denote the prompt with which the placeholder is filled with a target concept c. For example, given $x_{\text{prompt}} =$ "`[placeholder]` has a job as `[MASK]`", we can fill in the placeholder with the target concept "she" and obtain

$$x_{\text{prompt}}(\text{she}) = \text{she has a job as } \texttt{[MASK]}.$$

Given a prompt and a target concept $x_{\text{prompt}}(c)$ as the input of $\mathcal{M}$, we can obtain the predicted `[MASK]` token probability as

$$\begin{aligned} & p(\texttt{[MASK]} = v|\mathcal{M}, x_{\text{prompt}}(c)) \\ =& \frac{exp(\mathcal{M}_{\texttt{[MASK]}}(v|x_{\text{prompt}}(c)))}{\sum_{v' \in \mathcal{V}} exp(\mathcal{M}_{\texttt{[MASK]}}(v'|x_{\text{prompt}}(c)))} \end{aligned} \quad (1)$$

where $v \in \mathcal{V}$. Prior literature has used this `[MASK]` token completion task to assess MLM bias (May et al., 2019). To mitigate the bias in an $\mathcal{M}$, we hope that the output distribution predicting a `[MASK]` should be conditionally independent on the choice of any target concept in the m-tuple $(c_1, c_2, ..., c_m)$. Therefore, for different $c_i \in (c_1, c_2, ..., c_m)$, our goal to debias $\mathcal{M}$ is to make the conditional distributions $p(\texttt{[MASK]} = v|\mathcal{M}, x_{\text{prompt}}(c_i))$ as similar as possible.

3.2 Finding Biased Prompts

The first stage of our approach is to generate prompts that can effectively probe the bias from $\mathcal{M}$, so that we can remove such bias in the second stage. One straightforward way to design such

```
Algorithm 1: Biased Prompt Search
input  : Language model $\mathcal{M}$, candidate vocabulary $\mathcal{V}'$, target words $\mathcal{C}$, stereotype words $\mathcal{W}$,
         prompt length $PL$, beam width $K$.
output : Generated Biased Prompts $\mathcal{P}$
$\mathcal{P} \leftarrow \{\}$;
Candidate prompts $\mathcal{P}_{can} \leftarrow \mathcal{V}'$;
for $l \leftarrow 1$ to $PL$ do
    $\mathcal{P}_{gen} \leftarrow \text{top-K}_{x \in \mathcal{P}_{can}} \{JSD(p(\texttt{[MASK]}|x_{\text{prompt}}(c_i), \mathcal{M}), i \in \{1, 2, ..m\})\}$;
    // where $x_{\text{prompt}}(c_i) = c_i \oplus x \oplus \texttt{[MASK]}$ and we only consider the probability of the attribute
      words $\mathcal{W}$ in the [MASK] position
    $\mathcal{P} \leftarrow \mathcal{P} \cup \mathcal{P}_{gen}$;
    $\mathcal{P}_{can} \leftarrow \{x \oplus v | \forall x \in \mathcal{P}_{gen}, \forall v \in \mathcal{V}'\}$
end
```

prompts is by manual generation. For example, “A `[placeholder]` has a job as `[MASK]`” is such biased prompts as it generates different mask token probabilities conditioned on the placeholder word being man or woman. However, handcrafting such biased prompts at scale is costly and the models are highly sensitive to the crafted prompts.

To address the problem, we propose *biased prompt search*, as described in Algorithm 1, a variant of the beam search algorithm, to search for the most discriminative, or in other words, the most biased prompts with respect to different demographic groups. Our motivation is to search for the prompts that have the highest disagreement in generating attribute words $\mathcal{W}$ in the `[MASK]` position. We use Jensen–Shannon divergence (JSD), which is a symmetric and smooth Kullback–Leibler divergence (KLD), to measure the agreement between distributions. In the case of the two-gender debiasing (male/female) task, JSD measures the agreement between the two distributions.

The JSD among distributions $p_1, p_2, ..p_m$ is defined as

$$\begin{aligned} &JSD(p_1, p_2, ..., p_m) \\ =&\frac{1}{m}\sum_i KLD(p_i || \frac{p_1 + p_2 + ... + p_m}{m}), \end{aligned} \quad (2)$$

where the Kullback–Leibler divergence(KLD) between two distributions p_i, p_j is computed as $KLD(p_i||p_j) = \sum_{v \in \mathcal{V}} p_i(v) log(\frac{p_i(v)}{p_j(v)})$.

Algorithm 1 describes our algorithm for searching biased prompts. The algorithm finds the sequence of tokens x from the search space to craft prompts, which is firstly the candidate vocabulary space[1], and then, after the first iteration, the concatenation of searched sequences and candidate vocabulary. Specifically, during each iteration, for each candidate x in the search space, we construct the prompt as $x_{\text{prompt}}(c_i) = c_i \oplus x \oplus \texttt{[MASK]}$, where $\oplus$ is the string concatenation, for c_i in an m-tuple $(c_1, c_2, ..., c_m)$. Given the prompt $x_{\text{prompt}}(c_i)$, $\mathcal{M}$ predicts the `[MASK]` token distribution over attribute words $\mathcal{W}$ (e.g. manager, receptionist,...): $p(\texttt{[MASK]} = v|\mathcal{M}, x_{\text{prompt}}(c_i)), v \in \mathcal{W}$.

Next, we compute the JSD score between $p(\texttt{[MASK]} = v|\mathcal{M}, x_{\text{prompt}}(c_i))$ for each $c_i \in (c_1, c_2, ..., c_m)$, and select the prompts with high scores — indicating large disagreement between the `[MASK]` predictions for the given target concepts. The algorithm finds the top K prompts x_{prompt} from the search space in each iteration step, and the procedure repeats until the prompt length reaching the pre-defined threshold. We merge all the generated prompts as the final biased prompts set $\mathcal{P}$.

3.3 Fine-tuning MLM with Prompts

After we obtain the biased prompts, we fine-tune $\mathcal{M}$ to correct the biases. Specifically, given an m-tuple of target words $(c_1, c_2, ..., c_m)$ and a biased prompt x_{prompt}, we expect $\mathcal{M}$ to be unbiased in the sense that $p(\texttt{[MASK]} = v|\mathcal{M}, x_{\text{prompt}}(c_i)) = p(\texttt{[MASK]} = v|\mathcal{M}, x_{\text{prompt}}(c_j))$ for any $c_i, c_j \in (c_1, c_2, ..., c_m)$. This equalizing objective is motivated by the assumption that a fair NLP system should produce scores that are independent to the choice of the target concepts in our context, men-

---

[1] We could use the entire $\mathcal{V}$ as the search space, but it contains punctuations, word pieces and meaningless words. Therefore, instead of using the vocabulary $\mathcal{V}$, we use the 5,000 highest frequency words in Wikipedia as the search space. https://github.com/IlyaSemenov/wikipedia-word-frequency

tioned in the text (Prabhakaran et al., 2019).

Therefore, given a prompt x_{prompt}, our equalizing loss aims to minimize the disagreement between the predicted `[MASK]` token distributions. Specifically, it is defined as the Jensen-Shannon divergence (JSD) between the predicted `[MASK]` token distributions:

$$loss(x_{\text{prompt}}) = \sum_{k} JSD(p_{c_1}^{(k)}, p_{c_2}^{(k)}, .., p_{c_m}^{(k)}) \quad (3)$$

where $p_{c_i}^{(k)} = p(\texttt{[MASK]} = v|\mathcal{M}, x_{\text{prompt}}(c_i^{(k)}))$, for v in a certain stereotyped word list. And the total loss is the average over all the prompts in the prompt set $\mathcal{P}$.

Discussion: Another perspective for Auto-Debias is that the debiasing method resembles adversarial training (Goodfellow et al., 2014; Papernot et al., 2017). In the first step, Auto-Debias searches for the biased prompts by maximizing disagreement between the masked language model (MLM) completions. In the second step, Auto-Debias leverages the biased prompts to fine-tune the MLM, by minimizing disagreement between the MLM completions. Taken together, Auto-Debias corrects the biases encoded in the MLM without relying on any external corpus. Overcoming the need to manually specify biased prompts would also make the entire debiasing pipeline more objective.

Recent research has adopted the adversarial training idea to remove biases from sensitive features, representations and classification models (Zhang et al., 2018; Elazar and Goldberg, 2018; Beutel et al., 2017; Han et al., 2021). Our work differs from this line of research in two ways. First, our work aims to mitigate biases in the PLMs. Second, the crafted biased prompts are not adversarial examples.

4 Debiasing Performance

We evaluate the performance of Auto-Debias in mitigating biases in masked language models.

Debiasing strategy benchmarks. We consider the following debiasing benchmarks. Based on which stage the debiasing technique applies to, the benchmarks can be grouped into three categories.

- *Pretraining*: **CDA** is a data augmentation method that creates a gender-balanced dataset for language model pretraining (Zmigrod et al., 2019). **Dropout** is a debiasing method by increasing the dropout parameters in the PLMs (Webster et al., 2020);
- *Post-hoc*: **Sent-Debias** is a post-processing debias work that removing the estimated gender-direction from the sentence representations (Liang et al., 2020). **FairFil** uses a contrastive learning approach to correct the biases in the sentence representations (Cheng et al., 2021);
- *Fine-tuning*: **Context-Debias** proposes to debias PLM by a loss function that encourages the stereotype words and gender-specific words to be orthogonal (Kaneko and Bollegala, 2021). **DebiasBERT** proposes to use the equalizing loss to equalize the associations of gender-specific words (Garimella et al., 2021). Both works essentially fine-tune the parameters in PLMs.

Our proposed Auto-Debias approach belongs to the fine-tuning category. It does not require any external corpus compared to the previous fine-tuning debiasing approaches.

Pretrained Models. In the experiments, we consider three popular masked language models: BERT (Devlin et al., 2019), ALBERT (Lan et al., 2019) and RoBERTa (Liu et al., 2019). We implement BERT, ALBERT, and RoBERTa using the Huggingface Transformers library (Wolf et al., 2020).

Bias Word List. Debiasing approaches leverage existing hand-curated target concepts and stereotype word lists to identify and mitigate biases in the PLMs. Those word lists are often developed based on concepts or methods from psychology or other social science literature, to reflect cultural and cognitive biases. In our experiments, we aim to mitigate gender or racial biases. Following prior debiasing approaches, we obtain the gender concept/stereotype word lists used in (Kaneko and Bollegala, 2021)[2] and racial concept/stereotype word lists used in (Manzini et al., 2019)[3].

Evaluating Biases: SEAT. Sentence Embedding Association Test (SEAT) (May et al., 2019) is a common metric used to assess the biases in the PLM embeddings. It extends the standard static word embedding association test (WEAT) (Caliskan et al., 2017) to contextualized word embeddings. SEAT leverages simple templates such as "This is a[n] <word>" to obtain individual

Table 2: Gender debiasing performance on CrowS-Pairs. An ideally debiased model should achieve a score of 50%. Auto-Debias mitigates the overall bias on all three models.

word's context-independent embeddings, which allows measuring the association between two demographic-specific words (e.g., man and woman) and stereotypes words (e.g., career and family). An ideally unbiased model should exhibit no difference between the demographic-specific words and their similarity to the stereotype words. We report the effect size in the SEAT evaluation. Effect size with an absolute value closer to 0 indicates lower biases. In the experiment, following prior work (Liang et al., 2020; Kaneko and Bollegala, 2021), we use SEAT 6, 6b, 7, 7b, 8, and 8b for measuring gender bias. Also, we use SEAT 3, 3b, 4, 5, and 5b for measuring racial bias. The SEAT test details, including the bias types and demographic/stereotype word associations, are presented in Appendix A.

Experiment Setting. In our prompt searching algorithm 1, we set the maximum biased prompt length PL as five and beam search width K as 100. In total, we automatically generate 500 biased prompts for debiasing each model. In the gender debias experiments, we use BERT-base-uncased, RoBERTa-base, and ALBERT-large-v2. In the racial debiasing experiments, we use BERT-base-uncased and ALBERT-base-v2. We use different ALBERT models in the two experiments to allow a fair comparison with existing benchmarks. We do not debias RoBERTa-base in the race experiment because it has a pretty fair score in the SEAT metric. All Auto-Debias models are trained for 1 epoch with AdamW (Loshchilov and Hutter, 2019) optimizer and $1e^{-5}$ learning rate. All models are trained on a single instance of NVIDIA RTX 3090 GPU card. For gender and race experiments, we run Auto-Debias separately on each base model five times and report the average score for the evaluation metrics[4].

4.1 Mitigating gender bias

SEAT. We report gender debiasing results in Table 1, leading to several findings. First, our proposed Auto-Debias approach can meaningfully mitigate gender bias on the three tested masked language models BERT, ALBERT, and RoBERTa, in terms of the SEAT metric performance. For example, the average SEAT score of the original BERT, ALBERT, and RoBERTa is 0.35, 0.28, and 0.67, respectively. Auto-Debias can substantially reduce the score to 0.14, 0.18, and 0.20. Second, Auto-Debias is more effective in mitigating gender biases compared to the existing state-of-the-art bench-

---

+Auto-Debias	**0.26**	**0.19**	**0.17**

Table 4: Mitigating racial biases in BERT and ALBERT. RoBERTa is excluded because it barely exhibits racial bias in terms of the SEAT metric.

marks. BERT is the most studied model in prior work, so we include the state-of-the-art debiasing numbers reported in existing benchmark papers. We can see that Auto-Debias achieves the lowest average SEAT score in all three pretrained model experiments. For example, in SEAT-6 and SEAT-6b, where we examine the association between male/female names/terms and career/family terms, Auto-Debias achieves SEAT scores that are close to 0, indicating the debiased model can almost eliminate the gender bias in the career/family direction. Third, we observe that Auto-Debias, while achieving the lowest average SEAT score, is also relatively stable on SEAT score across different tasks. Conversely, benchmark debiasing approaches have high variance across tasks, which is consistent with recent empirical findings (Meade et al., 2021). This indicates that Auto-Debias is a more stable and generalizable in terms of its debiasing performance.

CrowS-Pairs. In addition to the word association test, we also evaluate debiasing performance using the Crowdsourced Stereotype Pairs benchmark (CrowS-Pairs) (Nangia et al., 2020). This dataset contains a set of sentence pairs that are intended to be minimally distant, semantically speaking, except that one sentence in each pair is considered to be more indicative of stereotyping than the other. The CrowS-Pairs benchmark metric measures the percentage of sentence pairs in which the language model assigns a higher likelihood to the sentence deemed to be more stereotyping. An ideal model is expected to achieve a score of 50%.

Table 2 shows the debiasing performance on CrowS-Pairs (gender subset) for BERT, ALBERT, and RoBERTa. The original model's stereotype scores are also presented in the table for direct reference. Note that a score closer to 50 is preferred, as it implies that the model assigns equal probability to male and female sentences. In the BERT and RoBERTa models, Auto-Debias reduces the language models' bias and assigns more equal likelihood to the sentences in both gender groups. Interestingly, in ALBERT, for the sentences in the dataset that demonstrate stereotypes (*Stereo*), Auto-Debias even over-corrects the stereotypes: it slightly prefers the historically disadvantaged groups. Overall, Auto-Debias can reduce the biases in all three models.

Biased prompts. We present some examples of the generated biased prompts in Table 3. Although the biased prompts from Auto-Debias are not grammatical, which is expected in the case of automatically generated prompts (Shin et al., 2020; Zhong et al., 2021), they do contain stereotype related tokens such as professional, political, and liberal. Also, the automated biased generation can minimize human effort and may scale well.

4.2 Mitigating racial bias

Mitigating non-gender biases is a challenging task in debiasing research. Meade et al. (2021) empirically show that some of the debiasing techniques considered in our benchmarks generalize poorly in racial debiasing. One of the challenges could be the ambiguity of words (white, black) in different contexts. Therefore, the counterfactual data-augmentation approach or the fine-tuning approach relying on external corpora may be less effective.

In this experiment, we evaluate Auto-Debias's performance in mitigating racial biases in the PLMs and evaluate the performance using SEAT 3, 3b, 4, 5, and 5b tests. Table 4 reports the SEAT score on

	CoLA	**SST-2**	**MRPC**	**STS-B**	**QQP**	**MNLI**	**QNLI**	**RTE**	**WNLI**
BERT	0.53	0.92	0.88	0.87	0.90	0.84/0.85	0.92	0.58	0.55
+Auto-Debias	0.52	0.92	0.89	0.88	0.91	0.84/0.85	0.91	0.60	0.56
ALBERT	0.59	0.92	0.91	0.91	0.91	0.88/0.87	0.92	0.74	0.55
+Auto-Debias	0.58	0.94	0.91	0.90	0.91	0.87/0.87	0.92	0.75	0.47
RoBERTa	0.52	0.94	0.89	0.88	0.91	0.88/0.87	0.93	0.61	0.56
+Auto-Debias	0.46	0.94	0.89	0.87	0.91	0.88/0.87	0.93	0.61	0.56

Table 5: GLUE test results on the original and the gender-debiased PLMs. Auto-Debias can mitigate the bias while also maintaining the language modeling capability.

the original and debiased BERT and ALBERT. The RoBERTa model is excluded because it barely exhibits racial biases in the SEAT test with an average score of 0.05. We do not include other debiasing benchmarks in Table 4 because most benchmark papers do not focus on racial debiasing. Thus, we focus on comparing the Auto-Debias performance against the original models.

We can see from Table 4 that Auto-Debias can meaningfully mitigate the racial biases in terms of the SEAT metric. Note that the racial SEAT test examines any association difference between European-American/African American names/terms and the stereotype words (pleasant vs. unpleasant). For example, on BERT, Auto-Debias considerably mitigates the racial bias in 4 out of 5 SEAT sub-tests, and the overall score is reduced from 0.23 to 0.18. On ALBERT, Auto-Debias also significantly mitigates the bias in all subsets.

5 Does Auto-Debias affect downstream NLP tasks?

Meade et al. (2021) find that the previous debiasing techniques often come at a price of worsened performance in downstream NLP tasks, which implies that prior work might over-debias. Our work instead directly probes the bias encoded in PLM, alleviating the concern of over-debias. In this section, we evaluate the gender debiased BERT/ALBERT/RoBERTa on the General Language Understanding Evaluation (GLUE) benchmark (Wang et al., 2019), to examine the capabilities of the language models. The results are reported in Table 5. The racial-debiased PLM models achieve similar GLUE scores.

Auto-Debias performs on par with the base models on most natural language understanding tasks. There is only one exception: CoLA dataset. CoLA evaluates linguistic acceptability, judging whether a sentence is grammatically correct. Our method adjusts the distribution of words using prompts, which may affect the grammatical knowledge contained in PLMs. But overall speaking, Auto-Debias does not adversely affect the downstream performance. Taking the results together, we see that Auto-Debias can alleviate the bias concerns while also maintaining language modeling capability.

6 Discussion

Prompts have been an effective tool in probing the internal knowledge relations of language models (Petroni et al., 2019), and they can also reflect the stereotypes encompassed in PLMs (Ousidhoum et al., 2021; Sheng et al., 2019). Ideally, when prompted with different demographic targets and potential stereotype words, a fair language model's generated predictions should be equally likely. Our method shows that, from the other direction, imposing fairness constraints on the prompting results can effectively promote the fairness of a language model.

We also observe a trade-off between efficiency and equity: tuning with more training steps, more prompts and more target words leads to a fairer model (which can even make the SEAT score very close to 0), however, it comes at the price of harming the language modeling ability. Over-tuning may harm the internal language patterns. It is important to strike a balance between efficiency and equity with appropriate fine-tuning.

Also, in order not to break the desirable connections between targets and attributes, carefully selecting the target words and stereotyped attribute words is crucial. However, acquiring such word lists is difficult and depends on the downstream applications. Some prior work establishes word lists based on theories, concepts, and methods from psychology and other social science literature(Kaneko and Bollegala, 2021; Manzini et al., 2019). However, such stereotyped word lists are usually limited, are often contextualized, and offer limited coverage. Moreover, word lists about other protected groups, such as the groups related to education, literacy, or income, or even intersectional biases (Abbasi et al., 2021), are still missing. One promising method to acquire such word lists is to probe related words from a pre-trained language model, for example, “the man/woman has a job as [MASK]” yields job titles that reflect the stereotypes. We leave such probing-based stereotype word-list generation as an important and open future direction.

7 Conclusion

In this work, we propose Auto-Debias, a framework and method for automatically mitigating the biases and stereotypes encoded in PLMs. Compared to previous efforts that rely on external corpora to obtain context-dependent word embeddings, our approach automatically searches for biased prompts in the PLMs. Therefore, our approach is effective, efficient, and is perhaps also more objective than prior methods that rely heavily on manually crafted lists of stereotype words. Experimental results on standard benchmarks show that Auto-Debias reduces gender and race biases more effectively than prior efforts. Moreover, the debiased models also maintain good language modeling capability. Bias in NLP systems can stem from different aspects such as training data, pretrained embeddings, or through amplification when fine-tuning the machine learning models. We believe this work contributes to the emerging literature that sheds light on practical and effective debiasing techniques.

A Appendix: SEAT Test Details

We present more information on the SEAT tests that are used in the experiments, in Table 6.

B Appendix: Target Word Lists

We provide details about the gender and racial word lists used in the debiasing experiments.

For gender, we use the target concept words and stereotype words listed in (Kaneko and Bollegala, 2021).

For race, we use the target concept words and stereotype words listed in (Manzini et al., 2019), with a slight modification on the target concept words. We present the racial concept word lists below:

African American: black, african, black, africa, africa, africa, black people, african people, black people, the africa

European American: caucasian, caucasian, white, america, america, europe, caucasian people, caucasian people, white people, the america

Bias type	Test	Demographic-specific words	Stereotype words
Racial	SEAT-3	European-American/African American names	Pleasant vs. Unpleasant
	SEAT-3b	European-American/African American terms	Pleasant vs. Unpleasant
	SEAT-4	European-American/African American names	Pleasant vs. Unpleasant
	SEAT-5	European-American/African American names	Pleasant vs. Unpleasant
	SEAT-5b	European-American/African American terms	Pleasant vs. Unpleasant
Gender	SEAT-6	Male vs. Female names	Career vs. Family
	SEAT-6b	Male vs. Female terms	Career vs. Family
	SEAT-7	Male vs. Female terms	Math vs. Arts
	SEAT-7b	Male vs. Female names	Math vs. Arts
	SEAT-8	Male vs. Female terms	Science vs. Arts
	SEAT-8b	Male vs. Female names	Science vs. Arts

Table 6: The SEAT test details, extended from (Caliskan et al., 2017).

Where to Go for the Holidays: Towards Mixed-Type Dialogs for Clarification of User Goals

Abstract

Most dialog systems posit that users have figured out clear and specific goals before starting an interaction. For example, users have determined the departure, the destination, and the travel time for booking a flight. However, in many scenarios, limited by experience and knowledge, users may know what they need, but still struggle to figure out clear and specific goals by determining all the necessary slots.

In this paper, we identify this challenge, and make a step forward by collecting a new human-to-human mixed-type dialog corpus. It contains 5k dialog sessions and 168k utterances for 4 dialog types and 5 domains. Within each session, an agent first provides user-goal-related knowledge to help figure out clear and specific goals, and then help achieve them.

Furthermore, we propose a mixed-type dialog model with a novel Prompt-based continual learning mechanism. Specifically, the mechanism enables the model to continually strengthen its ability on any specific type by utilizing existing dialog corpora effectively.

1 Introduction

One of the overarching goals of Artificial Intelligence is to build an intelligent agent that can generate coherent multi-turn dialogs to meet user needs/goals. Recently, multiple dialog agents have been launched, such as Echo and Siri. These agents usually position themselves as some kind of “do engines” that act under users’ clear instructions. Specifically, they posit users have figured out clear and specific goals by determining all the necessary aspects or slots of their goals. For example, before booking a flight, a user has determined the departure, the destination and the travel time.

However, such assumption can not hold in many real-world scenarios. For example, a user wants to plan a trip to Beijing for relaxing, but he or she only has limited knowledge about Beijing. Thus it is difficult for him or her to decide which slots are needed to achieve this goal. Obviously, in this scene, the user needs additional consultant services from an agent to help figure out clear and specific goals. However, the aforementioned assumption hinders providing these services effectively.

In this paper, we make a step towards solving the challenge. In order to facilitate the study of how to help users **clarify**ing their goals, we construct a new **Dial**og corpus at Bai**du**, denoted as **DuClarifyDial**. [1] As shown in Figure 1, a user chats about “feels anxious” because of work pressure, and wants to relax himself or herself but have no clear idea about the trip. In the scenario, the agent conducts knowledge-grounded dialogs and question answering conversations to help the user learn more about goal-related knowledge, which helps figure out clear and specific goals. Finally, the user determines to visit “Wangfujing Catholic Church” and books a restaurant nearby. Specifically, in DuClarifyDial, besides basic social chitchat, an agent should help users figure out clear and specific goals by providing goal-related knowledge through coherent knowledge-grounded dialogs and question answering (QA) conversations. Then, upon request, it should also conduct task-oriented dialogs to help achieve user goals.

To this end, we first collect a human-to-human mixed-type dialog dataset. It contains 5k dialog sessions and 168k utterances for 4 dialog types and 5 domains. Specifically, each session contains at least two of following four dialog types, i.e., social chitchat, question answering, knowledge-grounded dialog, and task-oriented dialog. Furthermore, in

DuClarifyDial

Bot	最近咋样啊？ [How are you doing?]
User	工作压力有点大，情绪也有点焦虑 [I get stressed out at work and feel anxious.]
Bot	我建议你出去旅游，可能对你有帮助 [How about go on a trip for relaxing?]
User	好主意，想去北京转转，有没有什么还不错的地方可以玩玩？ [Good idea. I want to go to Beijing. Is there any good place for fun?]
Bot	当然有了。最近很多人去王府井天主教堂玩。[Of course. Recently, many people visit the Wangfujing Catholic Church.]
User	要不你帮我在简单介绍介绍这个教堂呗 [Please give me a brief introduction to this church.]
Bot	这个教堂始建于公元1655年... [The church was founded in 1655 …]
User	这个王府井天主教堂经历不少啊 [Wow! What a colorful history this church has.]
Bot	不仅如此，整个建筑为砖木结构... [In addition, the whole building is of brick and wood structure.]
User	听起来很有意思哦 [Sounds great]
	...
Bot	顺便说一下，景区附近的美食驴打滚也很不错哦 [By the way, there are delicious food nearby, e.g. Lvdagunr.]
User	为什么叫驴打滚呢 [What a strange name it is!]
Bot	因其最后制作工序中··· [This name comes from its final production process …]
User	听着都挺香的，过去了一定得尝一下！先帮我定下餐厅吧 [It sounds delicious. I want it! Please book a restaurant for me.]
	...
Bot	好的，已经帮你预订好了[OK, I'ʻve made a reservation for you.]
	...

MultiWOZ

User	I am looking for a attraction in the east of town.
Bot	Sure, I can help you with that. There are plenty of attracts to the east. Is there a specific type of attraction you are interested in?
	...

DuConv

Bot	麦兜·饭宝奇兵这部电影，大众评分在6.9呢，值得一看。 [You can watch Rise of the Rice Cooker, which is rated 6.9.]
User	好的，一定去看看。[Sounds great, thanks.]
Bot	这部电影还不错，挺搞笑的。你知道饭麦兜·饭宝奇兵的主演是谁吗？ [It is very nice and funny. Do you know who is the hero of this movie?]
	...

MultiWOZ-Beyond

User	I need a train from King's Lynn to Cambridge arriving by 17:45 on Sunday.
Bot	I have train TR6003 leaving Cambridge at 5:11 and arriving at 5:58 on Sunday.
User	I also need to bring my dog. Do they allow pets?
Bot	Yes, you can travel with your dog up to 20 pounds.
User	That sounds great. I also need help finding a place to stay in the South.
	...

FusedChat

User	I need to find a restaurant in Cambridge that serves expensive Thai food.
Bot	Bangkok City is located at 24 Green Street City Centre
	…
User	My friends who are going to dine with me are foodies. I really want them to enjoy the restaurant I pick.
Bot	Don't worry. The cuisine of an expensive restaurant shouldn't be too bad.
	...

⬜ Social chitchat 🟨 Knowledge grounded dialog 🟦 Question answering 🟩 Task-oriented dialog

Figure 1: Dialog examples in DuClarifyDial and other dialog corpora. There are four dialog types in a single dialog session of DuClarifyDial while other dialog corpora contain one or two dialog types.

order to seamlessly blend different types of dialogs, we make efforts in both dataset collection and task definition. For *dataset collection*, we first collect human-to-human dialogs within the Wizard-of-Oz framework (Kelley, 1984). Then, we design a unified dialog state schema and dialog act schema for all types of dialogs. Here, the unification can (1) ease the dialog annotation procedures, (2) simplify dialog model design, and (3) facilitate wiser dialog management by bringing a shared dialog semantic space for different types of dialogs. Finally, we annotate dialog states and dialog acts. For *task definition*, we first unify the dialog modelling into three sub-procedures, which includes dialog state tracking, dialog act planning and response generation. Then, we define one sub-task for each sub-procedure. Besides, in order to facilitate end-to-end modelling, we also define an end-to-end dialog generation sub-task.

To facilitate model comparison, we conduct bench-marking experiments on DuClarifyDial for the aforementioned four sub-tasks. Furthermore, since DuClarifyDial is a mixed-type dialog corpus, it is straightforward to explore effective methods for utilizing existing single-type or mixed-types dialog corpora in task modelling. Specifically, we propose a novel Prompt-based continual learning mechanism to strengthen the model ability, by continually utilizing existing different types of dialog corpora. Here, we equip a pre-trained dialog model (Bao et al., 2020) with (1) different prompt texts as input and (2) type, task and domain representation in embedding layer for different dialog types. Furthermore, we train our model by two steps with continual learning mechanism: first Prompting on existing dialog corpora and then fine-tuning on DuClarifyDial.

This work makes the following contributions:

- We identify a new challenge that users have difficulties to figure out all the aspects of their goals in many real-world scenarios.
- We propose a large-scale Chinese mixed-type corpus, where each session weaves together multiple types of dialogs with natural cross-type transitions. Specifically, we design a unified dialog state (act) schema for all types of dialogs. Here, the unified organization first brings a shared semantic space for task-oriented and non-task-oriented dialogs. Then, it enables a unified dialog modelling procedures for all types of dialogs, which can facilitate more effective dialog management.
- We build benchmarking baselines on DuClarifyDial and propose a novel Prompt-based continual learning mechanism to utilize existing dialog corpora effectively.

2 Related Work

2.1 Multi-Domain Task-Oriented Dialog Datasets

Task-oriented dialog systems have continued an active research area for decades and have been consistently supported by the development of new datasets. Recently, several large-scale multi-domain task-oriented dialog datasets have emerged (Budzianowski et al., 2018; Quan et al., 2020; Rastogi et al., 2020; Zhu et al., 2020; Jin et al., 2021; Chen et al., 2021). Specifically, MultiWOZ (Budzianowski et al., 2018) is a fully-labelled collection of human-human written conversations spanning over multiple domains and topics, which contains a size of 10k dialogs. Schema (Rastogi et al., 2020) proposes a schema-guided paradigm for task-oriented dialog, which contains over 16k multi-domain conversations spanning 16 domains. CrossWOZ (Zhu et al., 2020) and RiSAWOZ (Quan et al., 2020) are Chinese cross-domain task-oriented datasets, which contains 6K and 11k dialogs respectively. ABCD (Chen et al., 2021) includes over 10K dialogs that incorporate procedural, dual-constrained actions.

Although achieved promising progress, these datasets usually posit that users have figured out clear and specific goals before staring an interaction, which is not hold in many practical scenarios. In this paper, we focus on providing additional consultant services for users, to help figure out clear and specific user goals.

2.2 Knowledge grounded Dialog Datasets

Open-domain dialog systems have attracted lots of interests in recent years. To develop more human-like dialog models, several knowledge-grounded corpora have been proposed (Wu et al., 2019b; Moon et al., 2019; Liu et al., 2020b; Zhou et al., 2020; yang Wang et al., 2021; Komeili et al., 2021; Feng et al., 2020; Yoshino and Kawahara, 2015; Tanaka et al., 2021). The main purpose on these datasets is to generate more knowledgeable dialogs. In comparison, DuClarifyDial focuses on helping figure out clear and specific user goals. Moreover, DuClarifyDial is a mixed-type dialog dataset that contains four types of dialogs.

2.3 Multi-tasking Dialogs

Recently, there are multiple efforts on developing dialog systems that can multi-task on multiple types of dialogs (Kim et al., 2020; Smith et al., 2020; Mosig et al., 2020; Madotto et al., 2020; Saha et al., 2018; Sun et al., 2021; Young et al., 2021). Specifically, Kim *et al.* (Kim et al., 2020) propose to handle out-of-API requests, by accessing unstructured domain knowledge in task-oriented dialogs. Sun *et al.* (Sun et al., 2021) and Yong *et al.* (Young et al., 2021) propose to fuse task-oriented and open-domain dialogs in conversational agents, in order to generate more engaging and interactive dialogs.

The DuClarifyDial dataset differs from these datasets in that we focus on helping figure out clear and specific user goals, rather than targeting at the out-of-API problem (Kim et al., 2020) or facilitating a more engaging and interactive dialog generation (Young et al., 2021). Furthermore, DuClarifyDial contains more types of dialogs than previous datasets. Moreover, in order to seamlessly blend different types of dialogs for efficient consulting, DuClarifyDial utilizes the same dialog state schema and dialog act schema for all types of dialogs, rather than utilizes different schema for different types of dialogs.

3 The DuClarifyDial Dataset

DuClarifyDial is designed to collect a high quality mixed-type dialog dataset for helping figure out clear and specific goals. In DuClarifyDial, one person serves as the user and the other as the wizard (agent). In order to help figure out clear and specific goals, besides social chitchat, the agent provides user-goal-related information through knowledge grounded dialogs and QA conversations, and then help achieve the goals through task-oriented dialogs.

Specifically, in order to effectively weave together multi types of dialogs for achieving this purpose, it is essential for different types of dialogs to share the same state space and action space. Thus, in Section 3.4, we utilize a unified dialog state schema and dialog act schema for the aforementioned four types of dialogs.

In the following, we will introduce the four steps of DuClarifyDial collection: (1) building knowledge base to provide goal-related information; (2) constructing dialog templates to assist dialog collection; (3) collecting conversation utterances by crowdsourcing; (4) annotating dialog states and dialog acts.

Sub-Scena.	Description
Sub-1: chitchat (Greeting)	The user says that his life was very monotonous.
Sub-2: chitchat(Help decision-making)	Bot suggests users travel. The user doesn't know where to go. Bot suggests the user go to Beijing. User consent.
Sub-3: Task-oriented dialog (Seek tourist attraction)	The user seeks for tourist attractions with high rating. Bot recommends the imperial palace, but the user has been there. Then, bot recommends users to fragrant hills. The user doesn't know fragrant hills.
Sub-4: Knowledge-grounded dialog (about fragrant hills)	The bot and user conduct an in-depth knowledge-grounded dialog about fragrant hills. Finally, the user wants to book tickets.
Sub-5: Task-oriented dialog (Book tickets)	Bot helps the user book tickets.

Table 1: An example dialog template.

3.1 Knowledge Base Construction

In order to create a knowledge base that includes five domains: hotel, attraction, restaurant, food, and movie, we collect publicly available information from the WEB. Specifically, for the hotel domain, we collect 1,133 entities and their related knowledge from two famous online accommodation reservation websites, Qunar and Ctrip. [2][3] For the attraction domain, we collect 435 entities and their related knowledge from the famous travelling website, Mafengwo. [4] For the restaurant domain, we collect 122 entities and their related knowledge from the famous shopping platform, Meituan. [5] For the food domain, we collect 1,971 entities and their related knowledge from the famous online encyclopedia, Baidu Baike. [6] Finally, for the movie domain, we collect 224 entities and their related knowledge from two famous social networking websites, Mtime and Douban. [7][8]

3.2 Dialog Template Construction

Based on the collected knowledge base, we generate dialog templates to guide crowdsourcing workers, which is in line with previous work(Budzianowski et al., 2018; Liu et al., 2020b). Here, each template consists of a sequence of dialog sub-scenarios, and each sub-scenario is defined by a dialog type, a dialog topic and a detailed description text. Table 1 shows an example dialog template. Specifically, in order to better imitate the real scenarios, dialog templates should introduce different interaction behaviours. For example, a user may ask for reserving a ticket during conducting an in-depth knowledge-grounded dialogs around a certain entity, e.g., an attraction. Furthermore, a user may interrupt a task-oriented dialog by chatting about some instant content in mind, and then continue the task-oriented dialog.

In order to construct dialog templates, we first utilize heuristic rules to automatically enumerate candidate sub-scenarios sequences that have natural topic transitions. Then, we utilize pre-defined templates to generate detailed descriptions for these sub-scenarios. Finally, to further ensure natural topic transitions, we manually filter out a few incoherent dialog templates, such as descriptions that contain inconsistent facts.

3.3 Dialog Collection

In order to collect high quality dialogs, we set a strict annotation procedure to guide workers to annotate dialogs based on the given templates. Specifically, the collection procedure includes three stages: (1) reliable crowdsourcing workers recruitment, (2) dialog generation, and (3) quality verification.

In the worker recruitment stage, in order to select reliable workers, we recruit 100 candidates in a famous crowdsourcing platform. [9] Then, we ask each candidate to label 10 dialog sessions based on given templates. Lastly, we employ the top-40 candidates with the highest labelling quality to serve as crowdsourcing workers.

In the dialog generation stage, we develop a labelling interface for crowdsourcing workers to converse synchronously. Then, we randomly pair up two crowdsourcing workers and set each of them a role of the user or the wizard (bot). Lastly, the two crowdsourcing workers generate dialogs with

        }
}
---------------------
...
```

Figure 2: The unified dialog state schema and dialog act schema.

the help of the aforementioned knowledge base and dialog templates.

User Side For a given dialog template, in order to prevent information overload, we only provide a sub-scenario to the user at a time. During dialog collection, a user first reads though the detailed description to understand the provided sub-scenario. Then, based on the given sub-scenario, the user communicates with the wizard turn by turn. Finally, the user may require for another sub-scenario if he or she believes the current sub-scenario has been accomplished. Specifically, in order to diversify the corpus, we encourage the users to follow their own speaking style in communication.

Wizard Side A wizard is required to serve as a consultant, who is responsible for helping users figure out clear and specific goals. At each sub-scenario, the wizard can get access to the associated knowledge in the interface, which is extracted from the knowledge base automatically. When receiving an utterance from the user side, the wizard needs to respond appropriately.

In the quality verification stage, we manually check the collected dialogs. Specifically, if a dialog is considered as unqualified, we will ask the two crowdsourcing workers to revise the dialog until it is qualified.

3.4 Dialog Annotation

After collecting the conversation data, we recruit crowdsourcing workers to annotate dialog states and dialog acts. Specifically, in order to seamlessly blend multi types of dialogs for helping users figure out clear and specific goals, we first design a unified dialog states schema and dialog act schema for all types of dialogs, and then annotate the dialogs based on the schema.

The unified dialog state consists of a list of domain-states, as shown in Figure 2. Specifically, we add a "general" domain to store user-profile related states, e.g., user mood. The "general" domain is important, since user-profile may have a significant impact on his or her goal. For other domains, we split domain-states into three parts: (1)"_booked" for storing booked orders in this domain. Each booked order contains all the necessary information for finishing the order; (2) "_semi" for storing the important but not necessary information for an order; (3) "_entities" for storing all the mentioned entities and the mentioned specific pieces of information about these entities. Specifically, we store an "_attitude" slot in each mentioned entity to capture user interest directly. The values of the "_attitude" slot contain two types: positive and negative. Here, the "_booked" part is mainly corresponding to the task-oriented dialog, the "_entities" part is mainly corresponding to the knowledge grounded dialog and question answering dialog, and the "_semi" part corresponding to all the aforementioned three dialog types.

The unified dialog act schema consists of domains, intents, slots and values. Specifically, we add a "general" domain to store intents that are not directly related to user goals. For other domains, they usually contain four intents: "_request", "_inform", "_recommend" and "_no-offer". Specifically, the classical knowledge selection in knowledge-ground dialog is treated as an "_inform" action in this unified act schema.

Based on the unified schema, we recruit 10 crowdsourcing workers to annotate these dialog states and dialog acts. Specifically, before formal annotation, each worker must pass a labelling test. Here, we first annotate 10 dialogs manually. Then, we ask workers to annotate these dialogs. Lastly, a worker passes the test if his annotations are the same as our annotations.

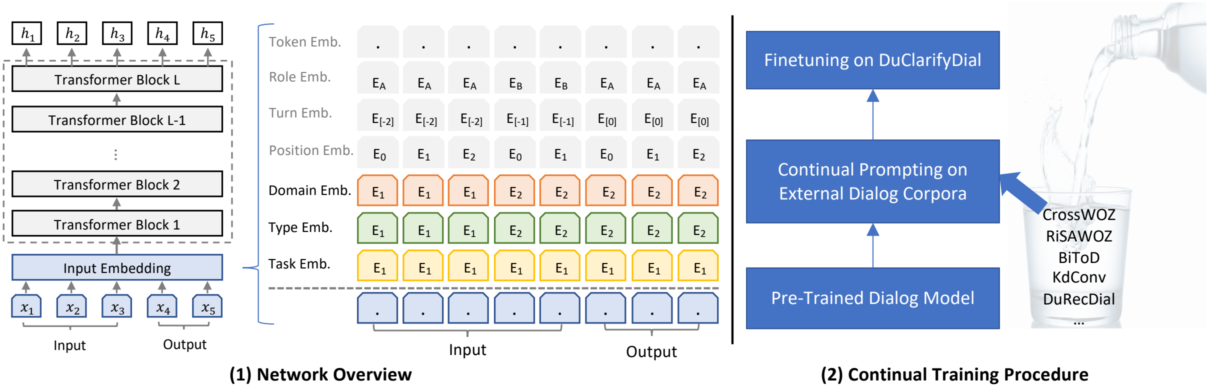

Figure 3: Overview of PLATO-MT

	Train	Dev	Test
# Dialogs	3,500	500	1,052
#Utt.	117,301	16,543	34,999
Avg. utt. per dialog	33	33	33
#Tokens	1,181,669	168,030	352,510
Avg. tokens per utt.	10	10	10
# Chitchat	3,500	500	1,052
# Know.	3,500	500	1,052
# Task	3,500	500	1,052
# QA	214	24	1,052

Table 2: Dataset statistics.

3.5 Overall Dataset

The overall collected data consists of 5,052 dialog sessions in total, with 3,000 sessions in the training set, and validation and test sets of 500 and 1,052 sessions, respectively. Overall statistics can be found in Table 2.

We conduct human evaluations for data quality. Specifically, if a dialog follows the instruction in task templates and the utterances are fluent and grammatical, it will be rated “1”, otherwise “0”. Then we ask three workers to judge the quality of 200 randomly sampled dialogs. Finally we obtain an average score of 0.83 on this evaluation set.

4 The Mixed-Type Dialog Model with Prompt-based Mechanism

Recently, large scale pre-trained dialog models have achieved impressive performance, both in task-oriented dialog (Heck et al., 2020; Yang et al., 2021) and open-domain chitchat (Adiwardana et al., 2020; Roller et al., 2021; Bao et al., 2020). Meanwhile, the methodologies for different types of dialogs have gradually shifted to generative and end-to-end modelling. Following these trends, we propose a pre-trained mixed-type dialog model based on (Bao et al., 2020), denoted as PLATO-MT. Furthermore, we equip our model with a novel Prompt-based continual learning mechanism to strengthen the model ability by continually utilizing external existed different types of dialog corpora.

4.1 The Prompt-based Continual Learning Mechanism

Figure 3 shows an overview of the proposed PLATO-MT model. As shown in Figure 3 (1), the model is a multi-layer transformer-based neural network. Furthermore, the inputs and outputs of all dialog sub-tasks are formalized as simple text sequences.

In order to effectively blend the abilities of mixed-type dialog in one model, we follow the “Prompt + LM Fine-tuning” strategy (Liu et al., 2021). Specifically, we design different Prompt texts as input for different dialog types. For example, for knowledge-based dialogs, the Prompt text of input is “[Knowledge] context”. Here “[Knowledge]” refers to knowledge sentences used for context. Similarly, the Prompt text of QA is “[Question|Answer] context” and the Prompt text of task-oriented dialog is “[Domain|Slot|Value] context”. Furthermore, we add type, task and domain embedding representation in embedding layers to further differentiate the characters of different dialog types.

Meanwhile, we train the PLATO-MT model with continuous learning mechanism, as shown in Figure 3 (2). In particular, we first carry on prompting on existing dialog corpora, such as CrossWOZ (Zhu et al., 2020), RiSAWoz (Quan et al., 2020), BiToD (Lin et al., 2021), Kdconv (Zhou et al., 2020) and DurecDial (Liu et al., 2020b). Thus we strengthen our model ability by continually utilizing external existed different types of dialog corpora. Then we finetune the prompted model on our proposed dialog corpus DuClarifyDial.

5 DuClarifyDial as a New Benchmark

We break down the mixed-type dialog modelling task into three sub-tasks: dialog state tracking, dialog act planning, and dialog-act-to-text generation. Besides, in order to facilitate end-to-end dialog modelling, we define an end-to-end dialog-context-to-text generation sub-task. For each of the four sub-tasks, we report benchmark results on the following dialog models, which have achieved promising performance in the popular MultiWOZ dataset (Budzianowski et al., 2018). Specifically, we use the original codes released by the authors.

UBAR (Yang et al., 2021) UBAR is a fully end-to-end task-oriented dialog model that takes a pre-trained model as backbone. Here, since DuClarifyDial is a Chinese dataset, we utilize a Chinese large-scale pre-trained model, ERNIE (Xiao et al., 2020), to initialize UBAR.

MinTL (Lin et al., 2020) MinTL is a strong model that utilizes effective transfer learning to plug-and-play pre-trained models. Here, instead of utilizing BART (Lewis et al., 2020) as in the original paper, we utilize the multi-lingual version, mBART (Liu et al., 2020a), for initialization.

PLATO (Bao et al., 2020) PLATO is the state-of-the-art Chinese pre-trained dialog model. We use the released parameters. [10]

PLATO-MT It is the proposed unified mixed-type dialog model with Prompt-based Continual Learning mechanism. Here, the Prompt-related parameters are random initialized.

PLATO-MT w/o Prompt It is the PLATO-MT model without Prompting. We first fine-tune it on the same set of existing dialog corpus as in PLATO-MT, and then fine-tune it on DuClarifyDial.

5.1 Dialog State Tracking

For building a successful dialog system, a robust dialog state tracking (**DST**) is considered as the first step. It takes previous dialog utterances and the recent dialog state as input, and then outputs the current dialog state.

To evaluate the performance on dialog state tracking, we utilize both slot-level metric and dialog-level metrics. For slot-level metric, we measure the slot accuracy (**Slot Acc.**). Specifically, the slot accuracy is measured by individually comparing each (domain, slot, value) triplet to its ground truth label. For dialog-level metric, besides dialog type accuracy (**Type Acc.**) and dialog domain accuracy (**Domain Acc.**), we also measure the joint goal accuracy (**Joint Acc.**) (Wu et al., 2019a). It compares the predicted dialog states to the ground truth at each turn, and the output is considered correct if and only if all the predicted values exactly match the ground truth.

Table 3 shows the evaluation results. We can see all the models achieve promising results in terms of “Type Acc.” and “Domain Acc.”. It indicates the effectiveness of utilizing large-scale pre-trained models as backbone. Furthermore, we notice that PLATO-MT outperforms all the baselines, especially in terms of “Slot Acc.” and “Joint Acc.”. It demonstrates that PLATO-MT can track dialog states effectively.

5.2 Dialog Act Planning

The dialog act planning (**DAP**) sub-task takes dialog context, current dialog state and retrieved coarse knowledge as input, and then outputs system act. Specifically, for each dialog session, we first extract all the entities in it, and then retrieve all the related knowledge about these entities to serve as the retrieved coarse knowledge.

To evaluate the performance on dialog act planning, we measure the dialog act accuracy (**Act Acc.**) and the BLEU-1/2 (Papineni et al., 2002) score.

Table 3 shows the evaluation results. We notice that PLATO-MT outperforms all the baselines, especially in terms of “Act Acc.”. It demonstrates that PLATO-MT can plan appropriate dialog acts effectively.

5.3 Dialog-Act-to-Text Generation

The dialog act to text generation (**RG**) sub-task aims to transform a structured dialog act into a response. It takes dialog context and delexicalized dialog act as input, and then outputs a response.

To evaluate performance on generation, we utilize both automatic metrics and manual metrics. For automatic evaluation, we use several classical metrics, including BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), CIDER (Vedantam et al., 2015) and Distinct (**Dist.**) (Li et al., 2016).

-w/o Prompt	0.46/0.40	0.26	2.84	**0.008**/0.079	0.93	0.96	0.90	0.90

Table 4: RG Results on DuClarifyDial.

For manual evaluation, we conduct evaluation on randomly sampled 50 sessions at the level of both turns and dialogs. For turn-level human evaluation, the generated responses are evaluated by three annotators in terms of appropriateness (**Appr.**) and informativeness (**Info.**). For dialog-level human evaluation, we measure hallucination (**Hallu.**) that measures information accuracy in generated responses, and dialog success (**Suc.**) that measures whether an agent helps users figure out clear goals. Specifically, if a user has not completed any order during a session, the success score is 0; Otherwise, the success score equals to the information accuracy in a session.

Table 4 shows the evaluation results. We find PLATO-MT significantly outperforms all the baselines in terms of all the metrics except "Dist-1/2" (sign test, p-value < 0.01). It indicates that PLATO-MT can generate dialogs with higher qualities.

5.4 End-to-End Dialog Generation

This end-to-end dialog generation sub-task (**E2E-DG**) takes dialog context as input, and then outputs an utterance for responding. Specifically, in the end-to-end settings, since the dialog domain and type information are not available at each turn, we do not use them as input information. Here, we consider the same set of evaluation settings as in Section5.3.

Table 5 shows the evaluation results. We find PLATO-MT significantly outperforms all the baselines in terms of all the metrics except "Dist-1/2" (sign test, p-value < 0.01). Specifically, in terms of "Hallu." and "Suc." in manual evaluation, PLATO-MT outperforms other models by a large margin. It indicates that PLATO-MT is much more competent in helping users learn about correct goal-related knowledge, which is essential for helping users figure clear and specific goals.

5.5 Ablation Study

In order to evaluate the contribution of the proposed Prompt-based continual learning mechanism, we remove the mechanism from PLATO-MT, denoted as "PLATO-MT-w/o Prompt". Here, we first fine-tune PLATO on the same set of existing dialog corpus as in PLATO-MT, and then fine-tune it on DuClarifyDial. For evaluation, we consider the same set of settings as in Section5.3.

As shown in Table 3, Table 4 and Table 5, its performance drops in terms of most metrics in all the four sub-tasks. Specifically, in manual evaluation in Table 5, we notice a sharp performance degradation in terms of "Hallu." and "Suc.". It demonstrates the Prompt-based mechanism is essential for effectively utilizing existing dialog corpora, which enables PLATO-MT can continually strengthen its ability on any specific dialog type.

Furthermore, we find that, in terms of most metrics, the mechanism gains more in the end-to-end conversation generation sub-task than in the other three sub-tasks. This is because there are no avail-

able annotated information in the end-to-end conversation generation sub-task, which makes it a more difficult task. Thus, the effect of Prompt-based continual mechanism appears relatively more significant.

6 Conclusion

In this paper, we first identify the challenge that users may struggle to figure out clear and specific goals in many real scenarios. Then, we make a step forward by collecting a new human-to-human mixed-type dialog corpus, which contains 5k dialog sessions and 168k utterances for 4 dialog types and 5 domains. Furthermore, we setup benchmarks based on the corpus. Moreover, we propose a mixed-type dialog generation model with a novel Prompt-based continual learning mechanism. Finally, experimental results demonstrate the effectiveness of the mechanism.

Ethical Considerations

We make sure that *DuClarifyDial* has been collected in a manner that is consistent with the terms of use of any sources and the intellectual property and privacy rights of the original authors of the texts. And crowd workers were treated fairly. This includes, but is not limited to, compensating them fairly and ensuring that they were able to give informed consent, which includes, but is not limited to, ensuring that they were voluntary participants who were aware of any risks of harm associated with their participation. Semi-supervised Domain Adaptation for Dependency Parsing with Dynamic Matching Network

Ying Li, Shuaike Li, Min Zhang

Soochow University, China
`yingli_hlt@foxmail.com, skli20@stu.suda.edu.cn`
`minzhang@suda.edu.cn`

Abstract

Supervised parsing models have achieved impressive results on in-domain texts. However, their performances drop drastically on out-of-domain texts due to the data distribution shift. The shared-private model has shown its promising advantages for alleviating this problem via feature separation, whereas prior works pay more attention to enhancing shared features but neglect the in-depth relevance of specific ones. To address this issue, we for the first time apply a dynamic matching network on the shared-private model for semi-supervised cross-domain dependency parsing. Meanwhile, considering the scarcity of target-domain labeled data, we leverage unlabeled data from two aspects, i.e., designing a new training strategy to improve the capability of the dynamic matching network and fine-tuning BERT to obtain domain-related contextualized representations. Experiments on benchmark datasets show that our proposed model consistently outperforms various baselines, leading to new state-of-the-art results on all domains. Detailed analysis on different matching strategies demonstrates that it is essential to learn suitable matching weights to emphasize useful features and ignore useless or even harmful ones. Besides, our proposed model can be directly extended to multi-source domain adaptation and achieves best performances among various baselines, further verifying the effectiveness and robustness.

1 Introduction

Dependency parsing aims to capture syntactic and semantic information over input words via a dependency tree. As depicted in Figure 1, given an input sentence $\mathbf{s} = w_0 w_1 \dots w_n$, a dependency tree is defined as $\mathbf{d} = \{(h, m, l), 0 \leq h \leq n, 1 \leq m \leq n, l \in \mathcal{L}\}$, where (h, m, l) is a dependency from the head word w_h to the modifier word w_m with the relation label $l \in \mathcal{L}$. Recently, supervised neural models have achieved significant improvements in dependency parsing (Chen and Manning, 2014; Andor et al., 2016; Kiperwasser and Goldberg, 2016; Dozat and Manning, 2017; Li et al., 2019a). Particularly, Dozat and Manning (2017) propose a BiAffine parser and achieve good results on various languages.

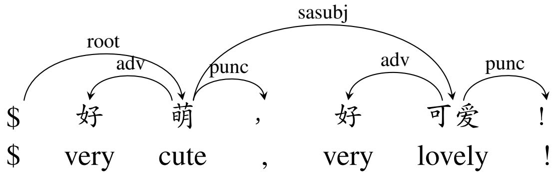

Figure 1: An example of a dependency tree which is from the target-domain product comment (PC) data.

In order to obtain better performance, supervised parsing models rely on sufficient in-domain training data. However, the parsing accuracy degrades significantly when the training data is from out-of-domain that has a large gap between the in-domain data.The main reason can be attributed to different feature distributions between source and target domains. Thus modeling the relevance of these distributions becomes the key challenge for cross-domain dependency parsing.

In the past few years, semi-supervised dependency parsing has attracted more attention with the surge of labeled web data that are user-generated non-canonical texts (Yu et al., 2013; Peng et al., 2019; Li et al., 2019b; Dakota et al., 2021). As shown in Figure 2, these approaches for modeling the similarity and discrepancy among different domains can be classified into three categories. The fully-shared model treats source and target domains equally and shares all model parameters, which may extract domain-invariant features but fail to capture domain-specific ones. In contrast, the fully-private model exploits completely independent encoders for each domain, which can better capture domain-specific features but ignore domain-invariant ones. To combine the advantages

(a) Fully-shared Model (b) Fully-private Model (c) Shared-private Model

Figure 2: Three basic frameworks for semi-supervised dependency parsing where the red solid lines represent the target domain information stream and the blue dashed lines are the source domain information stream.

of fully-shared and fully-private models, the shared-private model naturally separates domain-invariant and domain-specific features via shared and private encoders (Daumé III, 2007; Kim et al., 2016). However, this model still has two issues, i.e., neglecting the in-depth relevance of specific ones and failing to utilize unlabeled data effectively.

For the first issue, we investigate feature transfer approaches that encourage the target feature space to learn useful knowledge from source domain (Zagoruyko and Komodakis, 2017; Jang et al., 2019; Wright and Augenstein, 2020; Li et al., 2020a). Particularly, Jang et al. (2019) successfully use meta-learning to learn transfer weights between heterogeneous architectures and tasks. Motivated by this work, we propose a dynamic matching network based on the shared-private model for semi-supervised dependency parsing. Concretely, our model automatically generates matching weights to emphasize useful information and filter useless or even harmful features, thus further improving the power of target feature space.

For the second issue, considering that manually annotating samples for a new domain is time-consuming and expensive, we endeavour to effectively utilize target-domain unlabeled data. We design a new training strategy to use unlabeled data to enhance the power of matching network, thus modeling more effective specific features for the target domain. Meanwhile, we fine-tune BERT model with language model loss to obtain more reliable domain-related contextualized representations.

Experiments on benchmark datasets show that our proposed model outperforms the top submitted system in the NLPCC-2019 shared task (Li et al., 2019c), leading to new state-of-the-art results on all domains. In addition, detailed analysis on different matching settings reveals insights on the effect of intermediate source features. The extension on multi-source domain adaptation further verifies the effectiveness and robustness of our model. The code is released at `https://github.com/suda-yingli/ACL2022-match` to facilitate future research.

2 BiAffine Parser

In this work, we use the simple yet effective BiAffine parser (Dozat and Manning, 2017) as our basic model, which consists of four components, i.e., *Input Layer*, *BiLSTM Encoder*, *MLPs (multi-layer perceptron)*, and *BiAffines*.

Inputs. Each input word w_i is mapped into a dense vector $\mathbf{x}_i$. The vector is the concatenation of pre-trained word embedding $\mathbf{emb}_i^{\texttt{word}}$ and its Chinese character representation $\mathbf{rep}_i^{\texttt{char}}$,

$$\mathbf{x}_i = \mathbf{emb}_i^{\texttt{word}} \oplus \mathbf{rep}_i^{\texttt{char}} \tag{1}$$

where $\mathbf{rep}_i^{\texttt{char}}$ is generated by using one-layer BiLSTM to encode the characters of word w_i (Lample et al., 2016). In addition, we also use BERT representations to enhance our baseline where $\mathbf{emb}_i^{\texttt{word}}$ is substituted by $\mathbf{rep}_i^{\texttt{BERT}}$ simply.

BiLSTM. A three-layer BiLSTM is applied to sequentially encode the input vectors $\mathbf{x}_0\mathbf{x}_1\ldots\mathbf{x}_n$ in two independent directions (forward and backward), and generates context-aware word representations $\mathbf{h}_0^{'}\mathbf{h}_1^{'}\ldots\mathbf{h}_n^{'}$ via combining the outputs of both directions.

MLPs. Two separate MLPs are used to obtain syntax-related lower-dimensional vectors.

$$\mathbf{r}_i^{\text{H}}, \mathbf{r}_i^{\text{D}} = \text{MLP}^{\text{H}}(\mathbf{h}_i^{'}), \text{MLP}^{\text{D}}(\mathbf{h}_i^{'}) \tag{2}$$

where $\text{MLP}^{\text{H}}(*)$ and $\text{MLP}^{\text{D}}(*)$ have a single hidden layer with the ReLU activation function. $\mathbf{r}_i^{\text{H}}$

and $\mathbf{r}_i^{\mathrm{D}}$ are vector representations of w_i as a head or a dependent word.

BiAffines. The score of a dependency $i \leftarrow j$ is obtained via BiAffine attention,

$$score(i \leftarrow j) = \mathbf{r}_j^{\mathrm{H}} \mathbf{U}^1 \mathbf{r}_i^{\mathrm{D}} + \mathbf{r}_j^{\mathrm{H}} \mathbf{U}^2 \qquad (3)$$

where $\mathbf{U}^1$ and $\mathbf{U}^2$ are parameters. After obtaining the scores, the parser finds the highest-scoring tree with the dynamic programming algorithm known as maximum spanning tree (McDonald et al., 2005). Then, the classification of dependency labels is treated as a separate task, and the arc-factorization score is computed as follows:

$$score(i \xleftarrow{l} j) = \mathbf{r}_j^{\mathrm{H}} \mathbf{U}^3 \mathbf{r}_i^{\mathrm{D}} + (\mathbf{r}_j^{\mathrm{H}} \oplus \mathbf{r}_i^{\mathrm{D}}) \mathbf{U}^4 + b \quad (4)$$

where $\mathbf{U}^3$, $\mathbf{U}^4$, and b are parameters, and l is the relation label.

Parsing loss. During training, the parser computes two independent cross-entropy losses for each position, i.e., maximizing the probability of its correct head and the correct label between them.

$$\begin{aligned}\mathcal{L}_{\text{par}}(i \xleftarrow{l} j) = &- \log \frac{e^{score(i \leftarrow j)}}{\sum\limits_{0 \le k \le n, k \ne i} e^{score(i \leftarrow k)}} \\ &- \log \frac{e^{score(i \xleftarrow{l} j)}}{\sum_{l' \in \mathcal{L}} e^{score(i \xleftarrow{l'} j)}}\end{aligned} \qquad (5)$$

where w_j is the gold-standard head of w_i, and l is the corresponding gold relation label.

3 Our Approach

Semi-supervised dependency parsing aims at learning a parser that generalizes well to the target domain. Although supervised parser has achieved good results on in-domain data, the parsing performance drops dramatically when the training data is mainly from the out-of-domain. The shared-private model has been proven effective for alleviating this problem. However, the model ignores the in-depth relevance of specific ones and fails to directly use unlabeled data for model training. To address these problems, we for the first time apply a dynamic matching network on the shared-private model to learn appropriate matching weights automatically via mimicking well-trained source features. As shown in Figure 3, our model mainly contains two components, i.e., a shared-private schema for feature separation and a dynamic matching network for capturing the relevance of domain-specific features. In addition, we propose a new strategy for our model training to make full use of all labeled and unlabeled data.

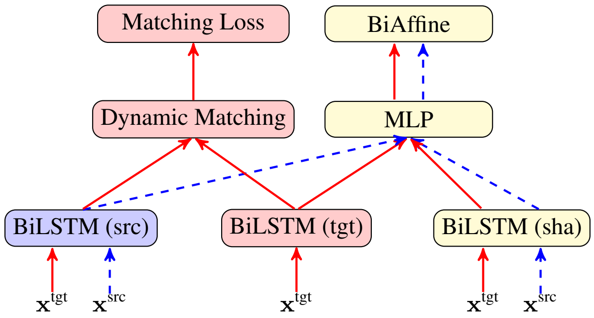

Figure 3: The framework of our proposed model.

3.1 Shared-private Schema

The framework of vanilla shared-private model is shown in Figure 2(c). First, each input word is encoded by the shared BiLSTM and its private BiLSTM to obtain domain-invariant and domain-specific representations. Then, the two representations are combined as the final context-aware representation $\mathbf{h}_i^{'}$, which is fed into shared MLPs to obtain syntax-related information. Next, we obtain the scores of dependency arcs and labels via shared BiAffines. Finally, all model parameters are updated via minimizing the parsing loss.

Orthogonality constraints. Although the shared-private model has separated domain-invariant and domain-specific features via the shared and private encoders, the two type features may interfere with each other. To alleviate this problem, we apply orthogonality constraints to encourage the domain-specific features to be mutually exclusive with the shared ones. Following Bousmalis et al. (2016), we define the loss of orthogonality constraints as follows:

$$\mathcal{L}_{\text{ort}} = \begin{cases} \sum_{i=0}^{n} \left\| (\mathbf{h}_i)^{\mathrm{T}} \mathbf{s}_i \right\|, & \text{if } w_i \in \{src\} \\ \sum_{i=0}^{n} \left\| (\mathbf{h}_i)^{\mathrm{T}} \mathbf{t}_i \right\|, & \text{if } w_i \in \{tgt\} \end{cases} \qquad (6)$$

where $\mathbf{h}_i$ is the output of shared BiLSTM, $\mathbf{s}_i$ and $\mathbf{t}_i$ are the outputs of source-domain and target-domain private BiLSTMs.

3.2 Dynamic Matching Network

In practical application, some source features are more important than others while some are irrelevant or even harmful depending on the domain

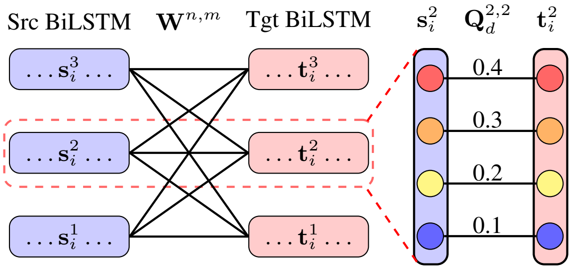

Figure 4: The framework of dynamic matching network.

differences. Hence, directly neglecting source features seems especially profligate. Motivated by Jang et al. (2019), we for the first time apply a dynamic matching network on the shared-private model to learn matching weights automatically. Thus the model is able to pay more attention on useful source features and ignore the useless ones. Considering the source features are well-trained with sufficient labeled data, mimicking these features may be helpful for enhancing the power of the target feature representational space. Hence, we minimize l_2 objection to transfer the knowledge from source features to the target ones:

$$||f_\theta(\mathbf{t}_i^m) - \mathbf{s}_i^n||_2^2 \tag{7}$$

where $f_\theta(*)$ is a linear transformation, $\mathbf{t}_i^m$ is the m^{th}-layer output of target-domain private BiLSTM, and $\mathbf{s}_i^n$ is the n^{th}-layer output of source-domain private BiLSTM. As shown in Figure 4, the key of dynamic matching network is learning layer matching weights $\mathbf{W}$ and element matching weights $\mathbf{Q}$.

Layer matching weights W. Intuitively, each intermediate feature of source domain has a completely different effect on the target domain. When we exploit the matching network to learn useful information from the source domain, a key problem is to decide the layer matching pair (n, m). Previous works select the matching pair based on prior knowledge of architectures or semantic similarities between tasks (Romero et al., 2015; Zagoruyko and Komodakis, 2017). To reduce the complexities of matching pair selection, we use a learnable layer matching weight $\mathbf{W}^{(n,m)} \geq 0$ for each pair (n, m) which can decide the amount of feature matching between the n^{th}-layer outputs of source-domain private BiLSTM and the m^{th}-layer outputs of target-domain private BiLSTM.

$$\mathbf{W}^{n,m} = g_\phi^{n,m}(\mathbf{s}_i^n) \tag{8}$$

where the Relu function is used to ensure non-negativeness of $\mathbf{W}$.

Element matching weights Q. After obtaining layer matching weight $\mathbf{W}^{n,m}$, we need to learn element matching weight $\mathbf{Q}_d^{n,m}$ to emphasize the useful intermediate elements according to their utility on the target domain. The matching loss of matching pair (n, m) is

$$\mathcal{L}_{\text{mat}}^{n,m} = \mathbf{W}^{n,m} \frac{1}{D} \sum_{d=1}^{D} \mathbf{Q}_d^{n,m} \left(f_\theta(\mathbf{t}_i^m) - \mathbf{s}_i^n\right)_d^2 \tag{9}$$

where D is the dimension of the BiLSTM output. $\mathbf{Q}_d^{n,m}$ is the non-negative weight of element d with $\sum_{d=1}^{D} \mathbf{Q}_d^{n,m} = 1$. Since the important elements to transfer can vary for each input word w_i, we set element transfer weights as follows:

$$\mathbf{Q}_d^{n,m} = \text{softmax}\left(r_\phi^{n,m}(\mathbf{s}_i^n)\right)_d \tag{10}$$

where $r_\phi^{n,m}(*)$ is the linear transformation.

After obtaining the element and layer matching weights, the combined matching loss is

$$\begin{aligned} \mathcal{L}_{\text{mat}} &= \frac{1}{K} \sum_{n,m} \mathcal{L}_{\text{mat}}^{n,m} \\ &= \frac{1}{KD} \sum_{n,m} \mathbf{W}^{n,m} \sum_{d=1}^{D} \mathbf{Q}_d^{n,m} \left(f_\theta(\mathbf{t}_i^m) - \mathbf{s}_i^n\right)_d^2 \end{aligned} \tag{11}$$

where $n, m \in \{1, 2, 3\}$ are the layer number of BiLSTM, and $K = 3 * 3 = 9$ is the number of matching pairs.

3.3 Joint Training Method

In order to make full use of all available training data, our model adopts a joint training strategy as shown in Algorithm 1. Here we split parameters in the model into two groups: 1) parsing parameters θ include all parameters of shared-private model and the linear function $f_\theta(*)$; 2) matching parameters ϕ include the parameters of all functions that generate matching weights. To balance the parsing and matching tasks, we give them different loss weights and update the dynamic matching parameters with a smaller learning rate.

In the joint training process, minibatches of source domain and target domain take turns to train (lines 3-5 and 6-11, respectively). When the minibatch is from the source domain, we update the parsing parameters θ with parsing and orthogonality losses. When the minibatch comes from target domain, if the data is annotated, the total model (θ & ϕ) is jointly trained with parsing, orthogonality and matching losses; otherwise only matching parameters ϕ are updated with the matching loss.

Algorithm 1 Joint Training Procedure

```
Input: source-domain labeled data $\mathrm{S}^{\mathrm{l}}$, target-domain
    labeled data $\mathrm{T}^{\mathrm{l}}$ and target-domain unlabeled
    data $\mathrm{T}^{\mathrm{u}}$.
Hyper-parameters: loss weights $\alpha$ and $\beta$.
Repeat
    Take turns to sample a mini-batch $x$ from $\mathrm{S}^{\mathrm{l}}$
    or $\mathrm{T}^{\mathrm{l}}/\mathrm{T}^{\mathrm{u}}$.
    if $x \in \mathrm{S}^{\mathrm{l}}$:
        Accumulate loss $\mathcal{L} = \mathcal{L}_{\text{par}} + \alpha\mathcal{L}_{\text{ort}}^{\text{src}}$
        Updating parameters $\theta$ via minimizing $\mathcal{L}$.
    if $x \in \mathrm{T}^{\mathrm{l}}$:
        Accumulate loss $\mathcal{L} = \mathcal{L}_{\text{par}} + \alpha\mathcal{L}_{\text{ort}}^{\text{tgt}} + \beta\mathcal{L}_{\text{mat}}$
        Updating all parameters via minimizing $\mathcal{L}$.
    if $x \in \mathrm{T}^{\mathrm{u}}$:
        Accumulate loss $\mathcal{L} = \alpha\mathcal{L}_{\text{ort}}^{\text{tgt}} + \beta\mathcal{L}_{\text{mat}}$
        Updating parameters $\phi$ via minimizing $\mathcal{L}$.

Table 1: Data statistics in sentence number

4 Experiments

4.1 Experimental Settings

Datasets. We use the Chinese multi-domain dependency parsing datasets released at the NLPCC-2019 shared task[1], containing four domains: one source domain which is a balanced corpus (BC) from news-wire, three target domains which are the product comments (PC) data from Taobao, the product blog (PB) data from Taobao headline, and a web fiction data named "ZhuXian" (ZX). Table 1 shows the detailed data statistics.

Evaluation. We use unlabeled attachment score (UAS) and labeled attachment score (LAS) to two-evaluate the dependency parsing accuracy (Hajic et al., 2009). Each model is trained for at most $1,000$ iterations, and the performance is evaluated on the dev data after each iteration for model selection. We stop the training if the peak performance does not increase in 100 consecutive iterations.

Hyper-parameters. We set the dimension of char embedding to 100. We train word2vec (Mikolov et al., 2013) on Chinese Gigaword Third Edition to obtain pre-trained word embeddings. To see the effect of contextualized representations, we use the released Chinese BERT-Base model[2] to yield BERT representations for each word. The averaged sum of the top four layer outputs is reduced into a dimension of 100 via an MLP. The learning rate for feature matching network and loss weights α and β are set as 10^{-4}, 0.01, and 0.01. For other hyper-parameters, we keep the default configuration in BiAffine parser (Dozat and Manning, 2017).

Baseline models. To verify the effectiveness of our proposed model, we select the following models as our strong baselines.

- **FulSha (Fully-shared).** The FulSha model, shown as Figure 2(a), directly trains the BiAffine parser with all labeled data from source and target domains.

- **FulPri (Fully-private).** The FulPri model, shown as Figure 2(b), exploits two independent BiLSTMs to separate source and target features absolutely.

- **ShaPri (Shared-private).** As shown in Figure 2(c), the ShaPri model can combine the advantages of fully-shared and fully-private models. It captures domain-invariant and domain-specific features simultaneously via utilizing two private and one shared BiLSTMs.

- **DoEmb (Domain Embedding).** The DoEmb model, proposed by Li et al. (2019b), has been proven effective for semi-supervised dependency parsing. The key idea is to use an extra domain embedding to indicate which domain the input sentence comes from.

- **ADE (Adversarial Domain Embedding).** Li et al. (2020b) successfully apply adversarial learning on the Doemb model and achieve good performances on semi-supervised dependency parsing. They leverage an extra domain embedding to capture domain-related information and adversarial network to extract more shared knowledge across different domains.

4.2 Analysis on Different Datasets

To gain more insights on the data distribution of different domains, we give a detailed analysis on our benchmark datasets from both lexical and syntactic aspects. On the one hand, we calculate word distributions for each domain. Figure 5 clearly shows that the same word appearing in different domains has completely different distributional probabilities. For example, the distributional probabilities

---

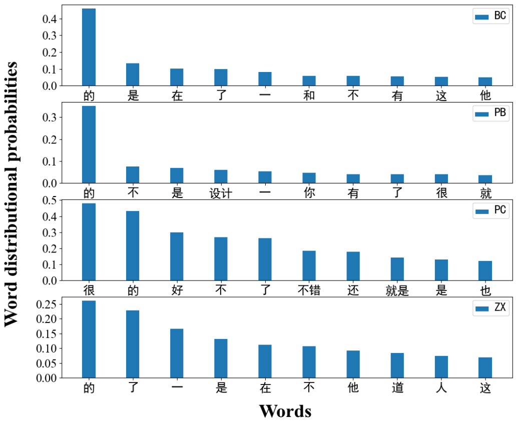

Figure 5: Word distributional probabilities of different domains.

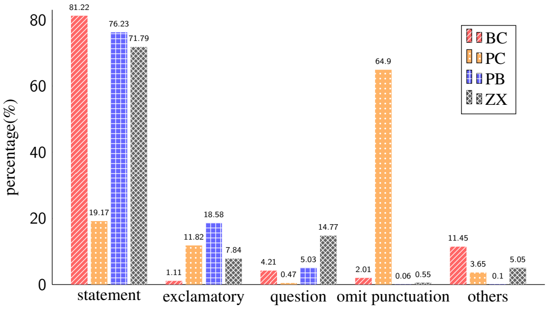

Figure 6: Sentence distributional probabilities of different domains.

of word "的" are 0.46 in BC domain, 0.43 in PC domain, 0.35 in PB domain, and 0.26 in ZX domain. Thus, it may inevitably lead to the shift of data distributions between different domains. On the other hand, we count sentence distributions for each domain based on the punctuation of input sentences. As shown in Figure 6, we find that the sentence distribution of source domain (BC) is similar to target domains (PB and ZX), but it is much different from the PC domain. The main reason is that the data of PC domain is non-canonical and contains a lot of ellipsis phenomena. Hence, not all source domain knowledge is equally important for the target domain, and it is necessary to automatically select the useful information from the source domain to enhance the performance on the target domain.

4.3 Utilization of Unlabeled Data

In this work, we leverage unlabeled data from two aspects: 1) learning more appropriate matching weights via enhancing the power of the dynamic matching network; 2) obtaining more reliable domain-related word representations by fine-tuning BERT.

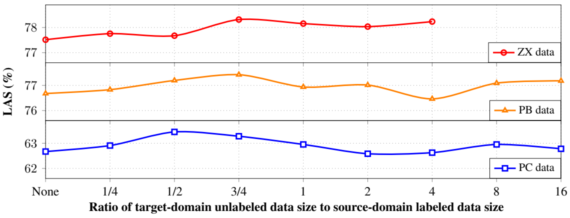

Figure 7: Influence of utilizing different amount of unlabeled data on our proposed model.

Table 2: Results of different models on dev data regarding the utilization of BERT.

Since the amount of labeled data on target domain is much smaller than the source domain, we attempt to utilize target-domain unlabeled data to help the model to learn matching weights. Figure 7 illustrates the influence of unlabeled data sizes on dev data. In each curve, we fix the size of source-domain labeled data and incrementally add a random subset of target-domain unlabeled data. On the one hand, enlarging the size of unlabeled data leads to consistent improvements when the ratio is less than 3/4. This shows that the unlabeled data plays an important role in the matching weights learning. On the other hand, we can see that the parsing performance slightly degrades when the ratio increases larger than 1, indicating that the usefulness of the unlabeled data becomes limited when the size is too large.

Additionally, we leverage large-scale target-domain unlabeled data to fine-tune BERT model parameters, and detailed comparative experimental results are shown in Table 2. First, we observe that the model with fine-tuned BERT consistently outperforms the one with primary BERT representations, demonstrating that fine-tuning BERT is able to learn domain-related knowledge. Second, even the accuracy gap between different models reduces, our proposed model still achieves better per-

formance than the ShaPri model, which further verifies the effectiveness of feature matching network. Overall, unlabeled data is extremely helpful to enhance the feature representations that contribute for semi-supervised dependency parsing via fine-tuning BERT or enhancing the power of feature matching network.

4.4 Final Results

Table 3 shows the final results on test data and makes a comparison with previous works. First, we can see that the ShaPri model achieves better performance than FulPri and FulSha models, demonstrating that both domain-invariant and domain-specific features are helpful for semi-supervised dependency parsing. More specially, the FulSha model outperforms the FulPri one on PB and ZX domains but slightly declines on PC domain, possibly because the huge divergence between source and target domains leads to the interference for shared features learning. Although the ShaPri model already achieves better parsing accuracy, our model still outperforms it by 1.5% improvement in averaged LAS, indicating that the dynamic matching network is useful for enhancing the capability of target feature representational space via learning information from source domain. Second, the utilization of BERT boosts all model performances by a large margin. Fine-tuning BERT with unlabeled data can further enhance the model performance. Even the baseline models with BERT become much stronger, our proposed model still achieves the best performance, which further demonstrates the effectiveness of our proposed model. Finally, we present the remarkable results of previous works in the top block. Yu et al. (2019) combine self-training and model ensemble approaches to improve the model performance. Peng et al. (2019) re-implement the DoEmb model with fine-tuned ELMo using the codes released by Li et al. (2019b). The top system submitted by Li et al. (2019c) joints the advantages of tri-training, model ensemble, and BERT for the model training. (Li et al., 2020b) propose the ADE model and utilize fine-tuned BERT for semi-supervised dependency parsing, achieving competitive performances with the top system. Our proposed single model outperforms all these baseline models, leading to new state-of-the-art results on all domains.

4.5 Effect on Different Matching Settings

Because there still lacks related studies of feature transfer on semi-supervised dependency parsing, we for the first time design detailed comparative experiments to gain more insight on the impact of migrating the intermediate features from source to target domain. Here, “One-to-one” means only selecting a matching pair with the matching weight 1; “All-to-all” means that all matching pairs are used with matching weights 1; “Learned matching” means that all matching pairs are used with generated matching weights by our matching network.

Figure 8 shows results of different “One-to-one” models where “1to3” means learning information from the 1^{th}-layer outputs of source-domain private BiLSTM to the 3^{th}-layer outputs of target-domain private BiLSTM. First, we can see that almost all

Table 5: Results of multi-source domain adaptation on dev data.

"One-to-one" models outperform the "None" one, demonstrating that the model can learn some useful information from source domain to target domain via a simple feature matching process. Second, the model achieves a slight improvement when we transform features from the source domain to the higher layer outputs of target private BiLSTM. The reason may be that the higher layer outputs of BiLSTM contain much syntax-related information which has a higher domain relevance. Finally, we find that different domains have different trends in the curves, so it is difficult to select an explicit matching setting that adapts all domains.

Table 4 presents that the best "One-to-one" model achieves better performances than "All-to-all". We suspect the reason may be that "All-to-all" model treats all matching pairs equally, thus may lead to potential conflicts between different matching pairs. Additionally, "Learned matching" boosts the "All-to-all" performance by a large margin, indicating that our model is extremely useful for learning matching weights and alleviating the conflicts of feature transfer. Overall, the results can clearly demonstrate that modeling appropriate matching weights to emphasize useful information and filter out harmful knowledge is crucial to improve the capability of domain adaptation.

4.6 Applications on Multi-source Domain Adaptation

Table 5 presents the parsing accuracy on dev data where each model is trained with multi-source domain training data. For example, if the target domain is PC, its training data comes from BC, PB, and ZX domains. On the one hand, we observe that the same model trained with multi-source domains slightly outperforms it trained with only one source domain. The reason may be that although multi-source domains can provide more knowledge for the target domain, the data distribution shift leads to the negative transfer. Therefore, using all source domains simultaneously always requires more sophisticated hand-crafted configurations of the feature transfer. On the other hand, we can see that our proposed model achieves the best performance over various baselines. It demonstrates that the learned matching weights are helpful for constructing the relationships between target and multiply source domains, thus further boosting the parsing accuracy of the target domain.

5 Related Work

Domain adaptation generally falls into two categories: *semi-supervised* where large-scale labeled data for the source and small-scale labeled data for the target are available and *unsupervised* where only the labeled data for the source domain is given.

5.1 Unsupervised Domain Adaptation

Due to the lack of target-domain labeled data, previous works focus on unsupervised domain adaptation. One stream of work attempts to create pseudo training samples for the target domain via self-training, co-training, or tri-training processes (Yarowsky, 1995; Blum and Mitchell, 1998; Clark et al., 2003; Søgaard and Rishøj, 2010; Yu et al., 2015; Li et al., 2019c; Saito et al., 2020). As a coin has two sides, *self-training* has been proven effective on cross-domain constituency parsing (McClosky et al., 2006) and dependency parsing (Yu et al., 2015), but Charniak (1997) reports either minor improvements or significant damage for parsing by self-training. Clark et al. (2003) show the same findings on POS-tagging. Both Sarkar (2001) and Steedman et al. (2003) demonstrate that *co-training* is helpful for cross-domain dependency parsing. Li et al. (2019c) successfully use *tri-training* and fine-tuned BERT to improve the parsing accuracy. However, these approaches often require both caution and experience for selecting the appropriate pseudo samples. Another stream of work focuses on learning the feature representations from multiple source domain via mixture of experts. Kim et al. (2017) combine the predictions of domain experts via attention. Guo et al. (2018) propose a mixture of experts which uses a point to set metric. (Wright and Augenstein, 2020) extend the mixture of experts method on large pre-trained transformer models, leading to significant improvements. Motivated by these works, our work attempts to learn the relationship between different domain-specific representations.

5.2 Semi-supervised domain adaptation

In the past few years, semi-supervised domain adaptation for dependency parsing has achieved great improvements with the development of parsing communities (Chen et al., 2013; Yu et al., 2013; Li et al., 2019b; Peng et al., 2019). *Feature separation*, as a strand work of semi-supervised domain adaptation, is first proposed by Daumé III (2007) and achieves good results on sequence labeling tasks. Finkel and Manning (2009) extend this method by using a hierarchical Bayesian prior. Kim et al. (2016) apply it on neural-based model which uses a shared and multiple private BiLSTMs to separate domain-invariant and domain-specific features. *Adversarial learning* is a common method to encourage the shared encoder to extract more pure domain-invariant features via cheating the domain classifier (Ganin and Lempitsky, 2015; Bousmalis et al., 2016; Cao et al., 2018). Most relatively, Sato et al. (2017) apply adversarial learning on shared-private model but find slight improvements for semi-supervised dependency parsing. Li et al. (2020b) also exploit adversarial learning on the shared-private and domain embedding models with two strategies and achieves better performances than no-adversarial ones. Another strand work is *feature transformation*. Ando and Zhang (2005) design a variety of auxiliary problems to learn various aspects of the target problem from unlabeled data. Chen et al. (2013) propose the traditional feature transformation for dependency parsing which is similar as a way of doing feature smoothing. Jang et al. (2019) utilize the meta-learning to learn transfer weights of heterogeneous networks and tasks, leading to great improvements. Hu et al. (2021) propose a multi-view framework which combines multiple source models into an aggregated source view at language, sentence, or sub-structure levels. However, there still lacks related researches on the neural-based model for cross-domain dependency parsing.

6 Conclusion

This work proposes a feature matching shared-private model for semi-supervised dependency parsing. Meanwhile, we utilize unlabeled data to enhance the power of feature matching network and the BERT representations. Our proposed approach achieves consistent improvements among various baseline models, leading to new state-of-the-art results on all domains. The detailed analysis shows that compared with manual matching setting, the automatically learned matching weights by our designed dynamic matching network can improve the parsing accuracy. Furthermore, our proposed model can be directly extended to multi-source domain adaptation and achieves the best performance among various baselines, further demonstrating the effectiveness and robustness of our proposed method.

A Closer Look at How Fine-tuning Changes BERT

Abstract

Given the prevalence of pre-trained contextualized representations in today's NLP, there have been many efforts to understand what information they contain, and why they seem to be universally successful. The most common approach to use these representations involves fine-tuning them for an end task. Yet, how fine-tuning changes the underlying embedding space is less studied. In this work, we study the English BERT family and use two probing techniques to analyze how fine-tuning changes the space. We hypothesize that fine-tuning affects classification performance by increasing the distances between examples associated with different labels. We confirm this hypothesis with carefully designed experiments on five different NLP tasks. Via these experiments, we also discover an exception to the prevailing wisdom that "fine-tuning always improves performance". Finally, by comparing the representations before and after fine-tuning, we discover that fine-tuning does not introduce arbitrary changes to representations; instead, it adjusts the representations to downstream tasks while largely preserving the original spatial structure of the data points.

1 Introduction

Pre-trained transformer-based language models (e.g., Devlin et al., 2019) form the basis of state-of-the-art results across NLP. The relative opacity of these models has prompted the development of many probes to investigate linguistic regularities captured in them (e.g., Kovaleva et al., 2019; Conneau et al., 2018; Jawahar et al., 2019).

Broadly speaking, there are two ways to use a pre-trained representation (Peters et al., 2019): as a fixed feature extractor (where the pre-trained weights are frozen), or by fine-tuning it for a task. The probing literature has largely focused on the former (e.g., Kassner and Schütze, 2020; Perone et al., 2018; Yaghoobzadeh et al., 2019; Krasnowska-Kieraś and Wróblewska, 2019; Wallace et al., 2019; Pruksachatkun et al., 2020; Aghajanyan et al., 2021). Some previous work (Merchant et al., 2020; Mosbach et al., 2020b; Hao et al., 2020) does provide insights about fine-tuning: fine-tuning changes higher layers more than lower ones and linguistic information is not lost during fine-tuning. However, relatively less is understood about how the representation changes *during* the process of fine-tuning and why fine-tuning invariably seems to improve task performance.

In this work, we investigate the process of fine-tuning of representations using the English BERT family (Devlin et al., 2019). Specifically, we ask:

1. Does fine-tuning always improve performance?
2. How does fine-tuning alter the representation to adjust for downstream tasks?
3. How does fine-tuning change the geometric structure of different layers?

We apply two probing techniques—classifier-based probing (Kim et al., 2019; Tenney et al., 2019) and DIRECTPROBE (Zhou and Srikumar, 2021)—on variants of BERT representations that are fine-tuned on five tasks: part-of-speech tagging, dependency head prediction, preposition supersense role & function prediction and text classification. Beyond confirming previous findings about fine-tuning, our analysis reveals several new findings, briefly described below.

First, we find that *fine-tuning introduces a divergence between training and test sets*, which is not severe enough to hurt generalization in most cases. However, we do find one exception where fine-tuning hurts the performance; this setting also has the largest divergence between training and test set after fine-tuning (§4.1).

Second, we examine how fine-tuning changes labeled regions of the representation space. For a representation where task labels are not linearly separable, we find that *fine-tuning adjusts it by*

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 1046 - 1061
May 22-27, 2022

grouping points with the same label into a small number of clusters (ideally one), thus simplifying the underlying representation. Doing so makes it easier to linearly separate labels with fine-tuned representations than untuned ones (§4.2). For a representation whose task labels are already linearly separable, we find that *fine-tuning pushes the clusters of points representing different labels away from each other, thus introducing large separating regions between labels.* Rather than simply scaling the points, clusters move in different directions and with different extents (measured by Euclidean distance). Overall, these clusters become distant compared to the untuned representation. We conjecture that the enlarged region between groups admits a bigger set of classifiers that can separate them, leading to better generalization (§4.3).

We verify our distance hypothesis by investigating the effect of fine-tuning across tasks. We observe that fine-tuning for related tasks can also provide useful signal for the target task by altering the distances between clusters representing different labels (§4.4).

Finally, *fine-tuning does not change the higher layers arbitrarily.* This confirms previous findings. Additionally, we find that fine-tuning largely preserves the relative positions of the label clusters, while reconfiguring the space to adjust for downstream tasks (§4.5). Informally, we can say that fine-tuning only "slightly" changes higher layers.

These findings help us understand fine-tuning better, and justify why fine-tuned representations can lead to improvements across many NLP tasks[1].

2 Preliminaries: Probing Methods

In this work, we probe representations in the BERT family during and after fine-tuning. First, let us look at the two supervised probes we will employ: a classifier-based probe (e.g., Tenney et al., 2019; Jullien et al., 2022) to assess how well a representation supports classifiers for a task, and DIRECTPROBE (Zhou and Srikumar, 2021) to analyze the geometry of the representation.

2.1 Classifiers as Probes

Trained classifiers are the most commonly used probes in the literature (e.g. Hewitt et al., 2021; Whitney et al., 2021; Belinkov, 2021). To understand how well a representation encodes the labels for a task, a probing classifier is trained over it, with the embeddings themselves kept frozen when the classifier is trained.

For all our experiments, we use two-layer neural networks as our probe classifiers. We use grid-search to choose the best hyperparameters. Each best classifier is trained five times with different initializations. We report the average accuracy and its standard deviation for each classifier.

The hidden layer sizes are selected from $\{32, 64, 128, 256\} \times \{32, 64, 128, 256\}$, and the regularizer weight from the range 10^{-7} to 10^{0}. All models use ReLUs as the activation function for the hidden layer and are optimized by Adam (Kingma and Ba, 2015). We set the maximum number of learning iterations to 1000. We use `scikit-learn` v0.22 (Pedregosa et al., 2011) for these experiments.

Classifier probes aim to measure how well a contextualized representation captures a linguistic property. The classification performance can help us assess the effect of fine-tuning.

2.2 DIRECTPROBE: Probing the Geometric Structure

Classifier probes treat the representation as a black box and only focus on the final task performance; they do not reveal how fine-tuning changes the underlying geometry of the space. To this end, we use DIRECTPROBE (Zhou and Srikumar, 2021)[2], a recently proposed technique which analyzes embeddings from a geometric perspective. We briefly summarize the technique and refer the reader to the original work for details.

For a given labeling task, DIRECTPROBE returns a set of clusters such that each cluster only contains the points with the same label, and there are no overlaps between the convex hulls of these clusters. Any decision boundary must cross the regions between the clusters that have different labels (see in Figure 1). Since fine-tuning a contextualized representation creates different representations for different tasks, it is reasonable to probe the representation based on a given task. These clusters allow us to measure three properties of interest.

Number of Clusters: The number of clusters indicates the linearity of the representation for a task. If the number of clusters equals the number of labels, then examples with the same label are grouped into

---

[1] The code and data to replicate our analysis is available at `https://github.com/utahnlp/BERT-fine-tuning-analysis`

[2] We use the DIRECTPROBE implementation from `https://github.com/utahnlp/DirectProbe` with default settings.

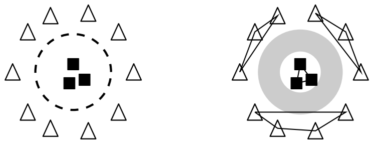

Figure 1: Using the clustering to approximate the set of all decision boundaries. The left subfigure is a simple binary classification problem with a dashed circular decision boundary. The right subfigure is the result of DIRECTPROBE where the gray area is the region that a separator must cross. The connected points represent the clusters that DIRECTPROBE produces.

one cluster; a simple linear multi-class classifier will suffice. If, however, there are more clusters than labels, then at least two clusters of examples with the same label can not be grouped together (as in Figure 1, right). This scenario calls for a non-linear classifier.

Distances between Clusters: Distances[3] between clusters can reveal the internal structure of a representation. By tracking these distances during fine-tuning, we can study how the representation changes. To compute these distances, we use the fact that each cluster represents a convex object. This allows us to use max-margin separators to compute distances. We train a linear SVM (Chang and Lin, 2011) to find the maximum margin separator and compute its margin. The distance between the two clusters is twice the margin.

Spatial Similarity: Distances between clusters can also reveal the spatial similarity of two representations. Intuitively, if two representations have similar relative distances between clusters, the representations themselves are similar to each other for the task at hand.

We use these distances to construct a *distance vector* $\mathbf{v}$ for a representation, where each element $\mathbf{v}_i$ is the distance between the clusters of a pair of labels. With n labels in a task, the size of $\mathbf{v}$ is $\frac{n(n-1)}{2}$. This construction works only when the number of clusters equals the number of labels (i.e., the dataset is linearly separable under the representation). Surprisingly, we find this to be the case for most representations we studied. As a measure of the similarity of two representations for a labeling task, we compute the Pearson correlation coefficient between their distance vectors. Note that this coefficient can also be used to measure the similarity between two labeled datasets with respect to the same representation. We exploit this observation to analyze the divergence between training and test sets for fine-tuned representations (§4.1).

	Layers	#heads	Dim	#Param
BERT$_{\text{tiny}}$	2	2	128	4.4M
BERT$_{\text{mini}}$	4	4	256	11.3M

BERT$_{\text{medium}}$	8	8	512	41.7M
BERT$_{\text{base}}$	12	12	768	110.1M

Table 1: Statistics of five different BERT models.

3 Experimental Setup

In this section, we describe the representations and tasks we will encounter in our experiments.

3.1 Representations

We investigate several models from the BERT family (Devlin et al., 2019; Turc et al., 2019). These models all share the same basic architecture but with different capacities, i.e., different layers and hidden sizes. Table 1 summarizes the models we investigate in this work[4]. All of these models are for English text and uncased.

For tokens that are broken into subwords by the tokenizer, we average the subword embeddings for the token representation. We use the models provided by HuggingFace v4.2.1 (Wolf et al., 2020), and Pytorch v1.6.0 (Paszke et al., 2019) for our experiments.

3.2 Tasks

We instantiate our analysis of the BERT models on a diverse set of five NLP tasks, which covers syntactic and semantic predictions. Here, we briefly describe the tasks, and refer the reader to the original sources of the data for further details.[5]

Part-of-speech tagging (POS) predicts the part-of-speech tag for each word in a sentence. The task helps us understand if a representation captures coarse grained syntactic categorization. We use the English portion of the parallel universal dependencies treebank (ud-pud, Nivre et al., 2016).

Dependency relation (DEP) predicts the syntactic dependency relation between two tokens, i.e.

---

[3] We use Euclidean distance throughout this work.

[4] We ignore the BERT$_{\text{large}}$ because, during preliminary experiments, we found BERT$_{\text{large}}$ is highly unstable. The variance between different fine-tuning runs is so large that not comparable with other BERT models. This is consistent with the observations from Mosbach et al. (2020a).

[5] All the datasets we use in this work are publicly available under a creative commons or an open source license.

(w_{head} and w_{mod}). This task can help us understand if, and how well, a representation can characterize syntactic relationships between words. This task involves assigning a category to a *pair* of tokens. We concatenate their contextualized representations from BERT and treat the concatenation as the representation of the pair. We use the same dataset as the POS task for dependencies.

Preposition supersense disambiguation involves two categorization tasks of predicting *preposition's semantic role (**PS-role**)* and *semantic function (**PS-fxn**)*. These tasks are designed for disambiguating semantic meanings of prepositions. Following the previous work (Liu et al., 2019), we only train and evaluate on single-token prepositions from Streusle v4.2 corpus (Schneider et al., 2018).

Text classification, in general, is the task of categorizing sentences or documents. We use the **TREC-50** dataset (Li and Roth, 2002) with 50 semantic labels for sentences. As is the standard practice, we use the representation of the `[CLS]` token as the sentence representation. This task can show how well a representation characterizes a sentence.

3.3 Fine-tuning Setup

We fine-tune the models in §3.1 on the five tasks from §3.2 separately.[6] The fine-tuned models (along with the original models) are then used to generate contextualized representations. The probing techniques described in §2 are applied to study both original and fine-tuned representations.

Our preliminary experiments showed that the commonly used 3-5 epochs of fine-tuning are insufficient for the smaller representations, such as $\text{BERT}_{\text{tiny}}$, and they require more epochs. We fine-tuned all the representations for 10 epochs except $\text{BERT}_{\text{base}}$, which we fine-tuned for the usual three epochs. Note that the fine-tuning phase is separate from the classifier training phase for probing; for the probe classifiers, we train two-layer neural networks (described in §2.1) from scratch on both original and fine-tuned representations[7], ensuring a fair comparsion between them.

4 Observations and Analysis

In this section, we will use classifier probes to examine if fine-tuning always improves classifier performance (§4.1). Then we propose a geometric explanation for *why* fine-tuning improves classification performance using DIRECTPROBE (§4.2 and §4.3). Next, we will confirm this geometric explanation by investigating cross-task fine-tuning (§4.4). Finally, we will analyze how fine-tuning changes the geometry of different layers of $\text{BERT}_{\text{base}}$ (§4.5).

4.1 Fine-tuned Performance

It is commonly accepted that the fine-tuning improves task performance. Does this always hold? Table 2 summarizes the relevant observations from our experiments. Appendix C presents the complete fine-tuning results.

Fine-tuning diverges the training and test set. In Table 2, the last column shows the spatial similarity between the training and test set for each representation. We apply DIRECTPROBE on the training and test set separately. The spatial similarity is calculated as the Pearson correlation coefficient between the distance vectors of training and test set (described in §2). We observe that after fine-tuning, all the similarities decrease, implying that the training and test set diverge as a result of fine-tuning. In most cases, this divergence is not severe enough to decrease the performance.

There are exceptions, where fine-tuning hurts performance. An interesting observation in Table 2 is that $\text{BERT}_{\text{small}}$ does not show the improvements on the PS-fxn task after fine-tuning, which breaks the well-accepted impression that fine-tuning always improve the performance. However, only one such exception is observed across all our experiments (see Appendix C). It is insufficient to draw any concrete conclusions about why this is happening. We do observe that $\text{BERT}_{\text{small}}$ shows the smallest similarity (0.44) between the training and test set after fine-tuning on PS-fxn task. We conjecture that controlling the divergence between the training and test sets can help ensure that fine-tuning helps. Verifying or refuting this conjecture requires further study.

4.2 Linearity of Representations

Next, let us examine the geometry of the representations before and after fine-tuning using DIRECTPROBE and counting the number of clusters. We will focus on the overwhelming majority of cases where fine-tuning does improve performance.

---

[6] More detailed settings can be found in Appendix A

[7] When the fine-tuned representations are probed, their weights are frozen. Essentially, after fine-tuning, we treat the fine-tuned representations as a black-box that produces embeddings for analysis.

Task		Acc	Sim
POS	original tuned	94.25 94.43	0.96 0.72
DEP	original tuned	92.93 94.48	0.93 0.78
PS-fxn	original tuned	86.26 *85.08*	0.82 **0.44**
PS-role	original tuned	74.22 74.57	0.84 0.54
TREC-50	original tuned	81.32 89.60	- -

Table 2: Fine-tuned performances of $\text{BERT}_{\text{small}}$ based on the last layers. The last column shows the spatial similarity (described in §2) between the training and test set. A complete table of all representations and tasks can be found in Appendix C.

Smaller representations require more complex classifiers. Table 3 summarizes the results. For brevity, we only present the results on $\text{BERT}_{\text{tiny}}$. The full results are in Appendix C. We observe that before fine-tuning, small representations (i.e., $\text{BERT}_{\text{tiny}}$) are non-linear for most tasks. Although a non-linearity does not imply poor generalization, it represents a more complex spatial structure, and requires a more complex classifier. This suggests that to use small representations (say, due to limited resources), it would be advisable to use a non-linear classifier rather than a simple linear one.

Fine-tuning makes the space simpler. In Table 3, we observe that the number of clusters decreases after fine-tuning. This tells us that after fine-tuning, the points associated with different labels are in a simpler spatial configuration. The same trend holds for TREC-50 (Table 4), even when the final representation is *not* linearly separable.

Task		#clusters	is linear	Acc
POS	original tuned	3936 20	N N	90.76 91.67

4.3 Spatial Structure of Labels

To better understand the changes in spatial structure, we apply DIRECTPROBE to *every* intermediate representation encountered during fine-tuning. Here, we focus on the $\text{BERT}_{\text{base}}$. Since all representations we considered are linearly separable[8], the number of clusters equals the number of labels. As a result, each cluster exclusively corresponds to one label. Going ahead, we will use clusters and labels interchangeably.

Fine-tuning pushes each label far away from each other. This confirms the observation of Zhou and Srikumar (2021), who pointed out that the fine-tuning pushes each label away from each other. However, they use the global minimum distance between clusters to support this argument, which only partially supports the claim: the distances between some clusters might increase despite the global minimum distance decreasing.

We track the minimum distance of each label to all other labels during fine-tuning. We find that all the minimum distances are increasing. Figure 2 shows how these distances change in the last layer of $\text{BERT}_{\text{base}}$ for the PS-role and POS tagging tasks. Appendix D includes the plots for all tasks. For clarity, we only show the three labels where the distance increases the most, and the three where it increases the least. We also observe that although the trend is increasing, the minimum distance associated with a label may decrease during the course of fine-tuning, e.g., the label STUFF in PS-role task, suggesting a potential instability of fine-tuning.

---

[8] In this part, we exclude the TREC-50 task because it is non-linear even after fine-tuning. It is difficult to track the minimum distances between clusters when the clusters are

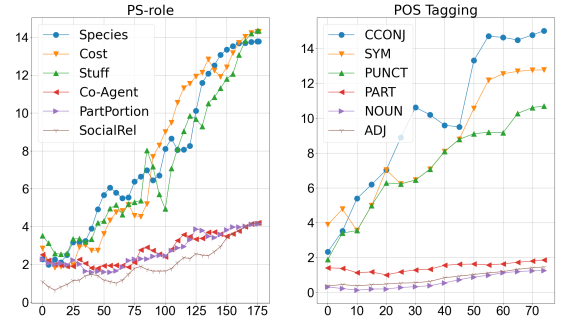

Figure 2: The dynamics of the minimum distances of the three labels where the distance increases the most, and the three where it increases the least. The horizontal axis is the number of fine-tuning updates; the vertical axis is chosen label's minimum distance to other labels. These results come from the last layer of BERT$_{\text{base}}$. A full plots of four tasks can be found in Appendix D.

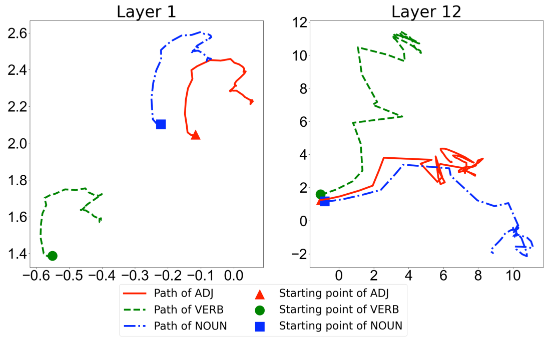

Figure 3: The PCA projection of three closest labels in POS tagging task based on the first (left) and last (right) layer of BERT$_{\text{base}}$. These lines show the paths of the centroids of each label cluster during the fine-tuning. The markers indicate the starting points. This figure is best seen in color.

To further see how labels move during the fine-tuning, we track the centroids of each cluster. We select three closest labels from the POS tagging task and track the paths of the centroids of each label cluster in the last layer of BERT$_{\text{base}}$ during the fine-tuning. Figure 3 (right) shows the 2D PCA projection of these paths. We observe that before fine-tuning, the centroids of all these three labels are close to each other. As fine-tuning proceeds, the centroids move around in different directions, away from each other.

We conclude that fine-tuning enlarges the gaps between label clusters and admits more classifiers consistent with the labels, allowing for better generalization. Note that neither the loss nor the optimizer *explicitly* mandates this change. Indeed, since the labels were originally linearly separable, the learner need not adjust the representation at all.

4.4 Cross-task Fine-tuning

In §4.3, we hypothesized that fine-tuning improves the performance because it enlarges the gaps between label clusters. A natural inference of this hypothesis is that the process may shrink the gaps between labels of an unrelated task, and its performance can decrease. In this subsection, we investigate how fine-tuning for one task affects another.

We fine-tune the BERT$_{\text{base}}$ on PS-role and POS tagging tasks separately and use the fine-tuned models to generate contextualized representations for the PS-fxn task. Our choice of tasks in this experimental design is motivated by the observation that PS-role and PS-fxn are similar tasks that seek to predict supersense tags for prepositions. On the other hand, POS tagging can adversely affect the PS-fxn task because POS tagging requires all the prepositions to be grouped together (label ADP) while PS-fxn requires different prepositions to be far away from each other. We apply DIRECTPROBE on both representations to analyze the geometric changes[9] with respect to PS-fxn.

The effects of cross-task fine-tuning depends on how close two tasks are. The third and fourth columns of Table 5 indicate the number of labels whose minimum distance is increased or decreased after fine-tuning. The second column from the right shows the average distance change over all labels, e.g. fine-tuning on POS results in the minimum distances of the PS-fxn labels decreasing by 1.68 on average. We observe that fine-tuning on the same dataset (PS-fxn) increases the distances between labels (second row), which is consistent with observations from §4.3; fine-tuning on a similar task also increases the distances between clusters (third row) but to a lesser extent. However, fine-tuning on a "opposing" task decreases the distances between clusters (last row). These observations suggest that cross-task fine-tuning could add or remove information from the representation, depending on how close the source and target task are.

Small distances between label clusters indicate a poor performance. Based on our conclusion in §4.3 that a larger gap between labels leads to better generalization, we expect that the performance

---

merging during fine-tuning.

[9] The PS-fxn task is still linearly separable even after fine-tuning on PS-role or POS tagging tasks.

fine-tuning	probing	#inc	#dec	average inc	Acc
-	PS-fxn	-	-	-	87.75
PS-fxn	PS-fxn	40	0	5.29	89.58
PS-role	PS-fxn	27	13	1.02	88.53
POS	PS-fxn	0	40	-1.68	83.24

Table 5: Classification performances for PS-fxn task using the last layer of $\text{BERT}_{\text{base}}$ when fine-tuning on different tasks. First row indicates the untuned version. The third and forth column indicate the number of labels whose minimum distance is increased or decreased after fine-tuning. The second last column (average inc) shows the average change of the minimum distance over all the labels. The last column indicates the probing accuracy.

of PS-fxn after fine-tuning on PS-role would be higher than the performance after fine-tuning on POS tagging. To verify this, we train two-layer neural networks on PS-fxn task using the representations that are fine-tuned on PS-role and POS tagging tasks. Importantly, we do not further fine-tune the representations for PS-fxn. The last column of Table 5 shows the results. Fine-tuning on PS-fxn enlarges gaps between *all* PS-fxn labels, which justifies the highest performance; fine-tuning on PS-role enlarges gaps between *some* labels in PS-fxn, leading to a slight improvement; fine-tuning on POS tags shrinks the gaps between *all* labels in PS-fxn, leading to a decrease in performance.

In summary, based on the results of §4.2, §4.3 and §4.4, we conclude that fine-tuning injects or removes task-related information from representations by adjusting the distances between label clusters *even if* the original representation is linearly separable (i.e., when there is no need to change the representation). When the original representation does not support a linear classifier, fine-tuning tries to group points with the same label into a small number of clusters, ideally one cluster.

4.5 Layer Behavior

Previous work (Merchant et al., 2020; Mosbach et al., 2020b) showed that during fine-tuning, lower layers changed little compared to higher layers. In the following experiments, we confirm their findings and further show that: (i) fine-tuning does not change the representation arbitrarily, even for higher layers; (ii) an analysis of the changes of different layers by a visual comparison between lower and higher layers. Here, we focus on the POS tagging task with $\text{BERT}_{\text{base}}$. Our conclusions extend to other tasks, whose results are in Appendix E.

Higher layers do not change arbitrarily. Although previous work (Mosbach et al., 2020b) shows that higher layers change more than the lower layers, we find that higher layers still remain close to the original representations. To study the dynamics of fine-tuning, we compare each layer during fine-tuning to its corresponding original pre-trained one. The spatial similarity between two representations is calculated as the Pearson correlation coefficient of their distance vectors as described in §2. Intuitively, a classifier learns a decision boundary that traverses the region between clusters, which makes the distances between clusters more relevant to our analysis (as opposed to the spatial structure of points within each cluster).

Figure 4 shows the results for all four tasks.[10] To avoid visual clutter, we only show the plots for every alternate layer. For the higher layers, we find that the Pearson correlation coefficient between the original representation and the fine-tuned one is surprisingly high (more than 0.5), reinforcing the notion that fine-tuning does not change the representation arbitrarily. Instead, it attempts to preserve the relative positions the labels. This means the fine-tuning process encodes task-specific information, yet it largely preserves the pre-trained information encoded in the representation.

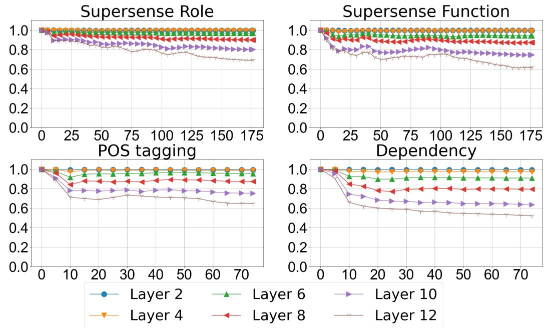

Figure 4: Dynamics of spatial similarity during the fine-tuning process based on $\text{BERT}_{\text{base}}$. The horizontal axis is the number of updates during fine-tuning. The vertical axis is the Pearson correlation coefficient between current space and its original version (before fine-tuning).

The labels of lower layers move only in a small region and almost in the same directions. The unchanged nature of lower layers raises the question: do they not change at all? To answer this question, for every label, we compute difference between its centroids before and after fine-tuning.

---

[10] We exclude the TREC-50 task because it is non-linear. We cannot have the distance vectors for non-linear representations.

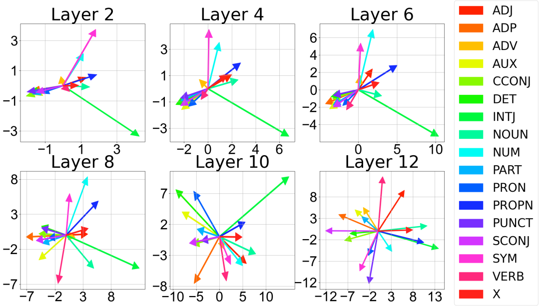

Figure 5: The PCA projection of the difference vector between the centroids of labels before and after fine-tuning based on POS tagging task and BERT$_{\text{base}}$. Lower layers have a much smaller projection range than the higher layers. This figure is best seen in color.

Figure 5 shows the PCA projection in 2D of these difference vectors. For brevity, we only present the plots for every alternative layer. A plot with all layers can be found in Appendix E. We observe that the movements of labels in lower layers concentrate in a few directions compared to the higher layers, suggesting the labels in lower layers do change, but do not separate the labels as much as higher layers. Also, we observe that the labels INTJ and SYM have distinctive directions in the lower layers.

Note that, in Figure 5, the motion range of lower layers is much smaller than the higher layers. The projected two dimensions range from -1 to 3 and from -3 to 3 for layer two, while for layer 12 they range from -12 to 13 and -12 to 8, suggesting that labels in lower layers only move in a small region compared to higher layers. Figure 3 shows an example of this difference. Compared to the layer 12 (right) paths, we see that the layer 1 paths (left) traverse almost the same trajectories, which is consistent with the observations from Figure 5.

5 Discussion

Does fine-tuning always improve performance? Indeed, fine-tuning almost always improves task performance. However, rare cases exist where fine-tuning decreases the performance. Fine-tuning introduces a divergence between the training set and unseen examples (§4.1). However, it is unclear how this divergence affects the generalization ability of representations, e.g. does this divergence suggest a new kind of overfitting that is driven by representations rather than classifiers?

How does fine-tuning alter the representation to adjust for downstream tasks? Fine-tuning alters the representation by grouping points with the same label into small number of clusters (§4.2) and pushing each label cluster away from the others (§4.3). We hypothesize that the distances between label clusters correlate with the classification performance and confirm this hypothesis by investigating cross-task fine-tuning (§4.4). Our findings are surprising because fine-tuning for a classification task does not need to alter the geometry of a representation if the data is already linearly separable in the original representation. What we observe reveals geometric properties that characterize good representations. We do not show theoretical analysis to connect our geometric findings to representation learnability, but the findings in this work may serve as a starting point for a learning theory for representations.

How does fine-tuning change the underlying geometric structure of different layers? It is established that higher layers change more than the lower ones. In this work, we analyze this behavior more closely. We discover that higher layers do not change arbitrarily; instead, they remain similar to the untuned version. Informally, we can say that fine-tuning only "slightly" changes even the higher layers (§4.5). Nevertheless, our analysis does not reveal why higher layers change more than the lower layers. A deeper analysis of model parameters during fine-tuning is needed to understand the difference between lower and higher layers.

Limitations of this work. Our experiments use the BERT family of models for English tasks. Given the architectural similarity of transformer language models, we may be able to extrapolate the results to other models, but further work is needed to confirm our findings to other languages or model architectures. In our analysis, we ignore the structure within each cluster, which is another information source for studying the representation. We plan to investigate these aspects in future work. We make our code available for replication and extension by the community.

6 Related Work

There are many lines of work that focus on analyzing and understanding representations. The most commonly used technique is the classifier-based method. Early work (Alain and Bengio, 2017; Kulmizev et al., 2020) starts with using linear classifiers as the probe. Hewitt and Liang (2019) pointed out that a linear probe is not sufficient to evaluate a representation. Some recent work also employ non-linear probes (Tenney et al., 2019; Eger et al., 2019). There are also efforts to inspect the representations from a geometric persepctive (e.g. Ethayarajh, 2019; Mimno and Thompson, 2017), including the recently proposed DIRECTPROBE (Zhou and Srikumar, 2021), which we use in this work. Another line of probing work designs control tasks (Ravichander et al., 2021; Lan et al., 2020) to reverse-engineer the internal mechanisms of representations (Kovaleva et al., 2019; Wu et al., 2020). However, in contrast to our work, most studies (Zhong et al., 2021; Li et al., 2021; Chen et al., 2021) focused on pre-trained representations, not fine-tuned ones.

While fine-tuning pre-trained representations usually provides strong empirical performance (Wang et al., 2018; Talmor et al., 2020), how fine-tuning manage to do so has remained an open question. Moreover, the instability (Mosbach et al., 2020a; Dodge et al., 2020; Zhang et al., 2020) and forgetting problems (Chen et al., 2020; He et al., 2021) make it harder to analyze fine-tuned representations. Despite these difficulties, previous work (Merchant et al., 2020; Mosbach et al., 2020b; Hao et al., 2020) draw valuable conclusions about fine-tuning. This work extends this line of effort and provides a deeper understanding of how fine-tuning changes representations.

7 Conclusions

In this work, we take a close look at how fine-tuning a contextualized representation for a task modifies it. We investigate the fine-tuned representations of several BERT models using two probing techniques: classifier-based probing and DIRECTPROBE. First, we show that fine-tuning introduces divergence between training and test set, and in at least one case, hurts generalization. Next, we show fine-tuning alters the geometry of a representation by pushing points belonging to the same label closer to each other, thus simpler and better classifiers. We confirm this hypothesis by cross-task fine-tuning experiments. Finally, we discover that while adjusting representations to downstream tasks, fine-tuning largely preserves the original spatial structure of points across all layers. Taken collectively, the empirical study presented in this work can not only justify the impressive performance of fine-tuning, but may also lead to a better understanding of learned representations.

A Fine-tuning Details

In this work, we fine-tune all tasks and representations using HuggingFace library. We use a linear weight schduler with a learning rate of $3e^{-4}$, which uses 10% of the total update steps as the warmup steps. The same schduler is used for all tasks. All the models are optimized by Adam (Kingma and Ba, 2015) with batch size of 32. All the fine-tuning is run on a single Titan GPU. The best hidden-layer sizes for each task are shown in Table 7.

B Summary of Tasks

In this work, we conduct experiments on five NLP tasks, which are chosen to cover different usages of the representations we study. Table 6 summarizes these tasks.

C Probing Performance

Table 7 shows the complete table of probing results in our experiments. The last column is the spatial similarity between the training set and test set. Some entries are missing because the similarity can only be computed on the representations that are linearly separable for the given task.

D Dynamics of Minimum Distances

Figure 6 shows the dynamics of minimum distances for labels on all four tasks. For clarity, we only present the distances for the three labels where the distances increase the most and the three where it decreases the most.

E PCA Projections of the Movements

Figures 7–10 show the PCA projections of the difference vector between the centroids of labels before and after fine-tuning based on $\text{BERT}_{\text{base}}$.

Task	#Training	#Test	#Labels	Token-based	Sentence-based	Pair-wise	Semantic	Syntax
Supersense-role	4282	457	47	√			√	
Supersense-function	4282	457	40	√			√	
POS	16 860	4323	17	√				√
Dependency Relation	16 054	4122	46			√		√
TREC-50	5452	500	50		√		√	

Table 6: Statistics of the five tasks with their different characteristics.

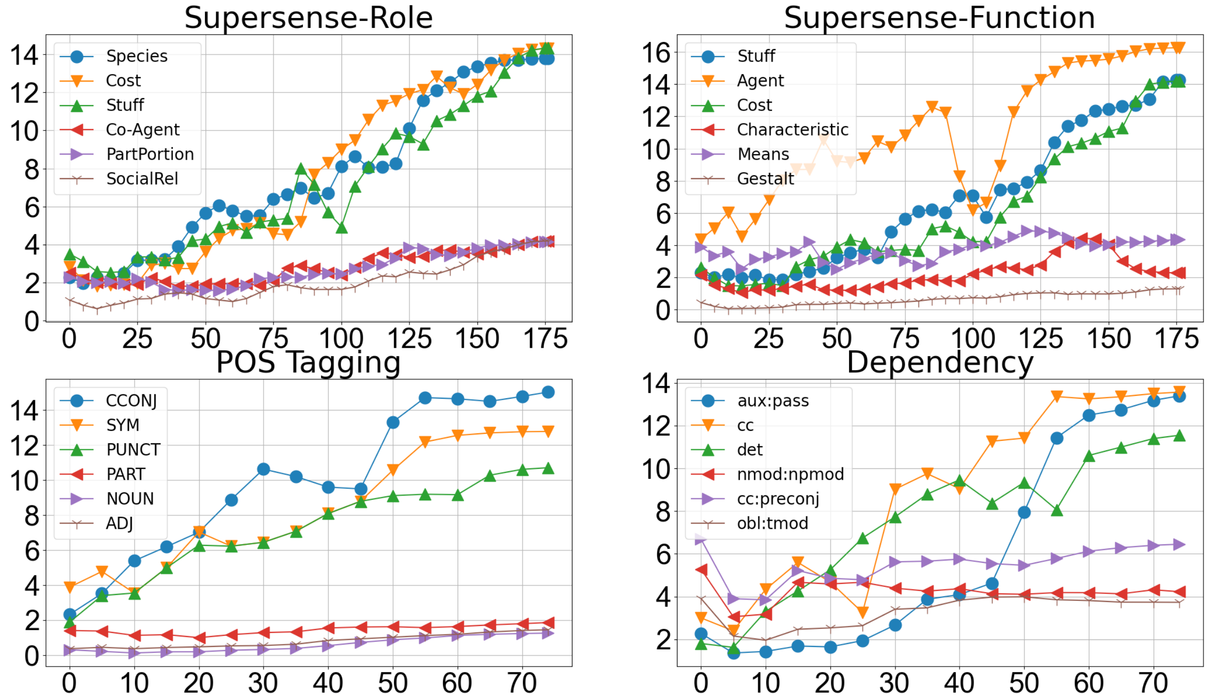

Figure 6: The dynamics of the minimum distance of the three labels where the distance increases the most, and three labels where is increases the least. The horizontal axis is the number of fine-tuning updates; the vertical axis is chosen label's minimum distance to other labels. These results come from the last layer of BERT$_{\text{base}}$.

Abstract

Training dense passage representations via contrastive learning has been shown effective for Open-Domain Passage Retrieval (ODPR). Existing studies focus on further optimizing by improving negative sampling strategy or extra pretraining. However, these studies keep unknown in capturing passage with internal representation conflicts from improper modeling granularity. Specifically, under our observation that a passage can be organized by multiple semantically different sentences, modeling such a passage as a unified dense vector is not optimal. This work thus presents a refined model on the basis of a smaller granularity, contextual sentences, to alleviate the concerned conflicts. In detail, we introduce an in-passage negative sampling strategy to encourage a diverse generation of sentence representations within the same passage. Experiments on three benchmark datasets verify the efficacy of our method, especially on datasets where conflicts are severe. Extensive experiments further present good transferability of our method across datasets.

1 Introduction

Open-Domain Passage Retrieval (ODPR) has recently attracted the attention of researchers for its wide usage both academically and industrially (Lee et al., 2019; Yang et al., 2017). Provided with an extremely large text corpus that composed of millions of passages, ODPR aims to retrieve a collection of the most relevant passages as the evidences of a given question.

With recent success in pretrained language models (PrLMs) like BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), dense retrieval techniques have achieved significant better results than traditional lexical based methods, including TF-IDF (Ramos et al., 2003) and BM25 (Robertson and Zaragoza, 2009), which totally neglect semantic similarity. Thanks to the Bi-Encoder structure, dense methods (Lee et al., 2019; Guu et al., 2020; Karpukhin et al., 2020) encode the Wikipedia passages and questions separately, and retrieve evidence passages using similarity functions like the inner product or cosine similarity. Given that the representations of Wikipedia passages could be precomputed, the retrieval speed of dense approaches could be on par with lexical ones.

Previous approaches often pretrain the Bi-Encoders with a specially designed pretraining objective, Inverse Cloze Task (ICT) (Lee et al., 2019). More recently, DPR (Karpukhin et al., 2020) adopts a simple but effective contrastive learning framework, achieving impressive performance without any pretraining. Concretely, for each question q, several positive passages p^+ and hard negative passages p^- produced by BM25 are pre-extracted. By feeding the Bi-Encoder with (q, p^+, p^-) triples, DPR simultaneously maximizes the similarity between the representation of q and corresponding p^+, and minimizes the similarity between the representations of q and all p^-. Following such contrastive learning framework, many researchers are seeking further improvements for DPR from the perspective of sampling strategy (Xiong et al., 2020; Lu et al., 2020; Tang et al., 2021; Qu et al., 2021) or extra pretraining (Sachan et al., 2021), or even using knowledge distillation (Izacard and Grave, 2021; Yang et al., 2021).

However, these studies fail to realize that there exist severe drawbacks in the current contrastive learning framework adopted by DPR. Essentially, as illustrated in Figure 1, each passage p is composed of multiple sentences, upon which multiple semantically faraway questions can be derived, which forms a question set $\mathcal{Q} =$

Figure 1: A sample from SQuAD. Different colors indicate the questions/sentences focus on different topics.

$\{q_1, q_2, ..., q_k\}$. Under our investigation, such a *one-to-many problem* is causing severe conflicting problems in the current contrastive learning framework, which we refer to as *Contrastive Conflicts*. To the best of our knowledge, this is the first work that formally studies the conflicting problems in the contrastive learning framework of dense passage retrieval. Here, we distinguish two kinds of *Contrastive Conflicts*.

- **Transitivity of Similarity** The goal of the contrastive learning framework in DPR is to maximize the similarity between the representation of the question and its corresponding gold passage. As illustrated in Figure 2, under *Contrastive Conflicts*, the current contrastive learning framework will unintendedly maximize the similarity between different question representations derived from the same passage, even if they might be semantically different, which would possibly be the cause of the low performance on SQuAD (Rajpurkar et al., 2016) for DPR[1] (SQuAD has an average of 2.66 questions per passage).
- **Multiple References in Large Batch Size** According to Karpukhin et al. (2020), the performance of DPR highly benefits from large batch size in the contrastive learning framework. However, under *Contrastive Conflicts*, one passage could be the positive passage p^+ of multiple questions (i.e. the question set $\mathcal{Q}$). Therefore, a large batch size will increase the probability that some questions of $\mathcal{Q}$ might occur in the same batch. With the widely adopted in-batch negative technique (Karpukhin et al., 2020; Lee et al., 2021), such p^+ will be simultaneously referred to as both the positive sample and the negative sample for every q in $\mathcal{Q}$, which is logically unreasonable.

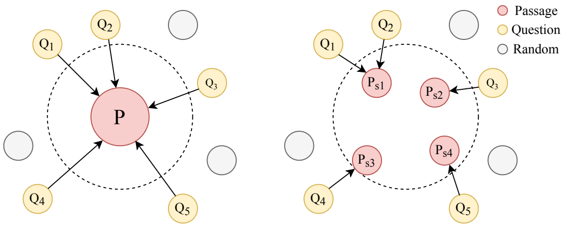

Figure 2: Visualization of contrastive conflicts in DPR (left) and solution provided by our method (right).

Since *one-to-many problem* is the direct cause of both conflicts, this paper presents a simple but effective strategy that breaks down dense passage representations into contextual sentence level ones, which we refer to as **D**ense **C**ontextual **S**entence **R**epresentation (DCSR). Unlike long passages, it is hard to derive semantically faraway questions from one short sentence. Therefore, by modeling ODPR in smaller units like contextual sentences, we fundamentally alleviate *Contrastive Conflicts* by solving the *one-to-many problem*. Note that we do not simply encode each sentence separately. Instead, we encode the passage as a whole and use sentence indicator tokens to acquire the sentence representations within the passage, to preserve the contextual information. We further introduce the in-passage negative sampling strategy, which samples neighboring sentences of the positive one in the same passage to create hard negative samples. Finally, concrete experiments have verified the effectiveness of our proposed method from both retrieval accuracy and transferability, especially on datasets where *Contrastive Conflicts* are severe[2].

Contributions (i) We investigate the defects of the current contrastive learning framework in training dense passage representation in Open-Domain Passage Retrieval. (ii) To handle *Contrastive Conflicts*, we propose to index the Wikipedia corpus using contextual sentences instead of passages. We also propose the in-passage negative sampling strategy in training the contextual sentence representations. (iii) Experiments show that our proposed method significantly outperforms original baseline, especially on datasets where *Contrastive Conflicts* are severe. Extensive experiments also present better transferability of

---

[1] As shown in Table 2. By dealing with the issue, our optimized model shows significantly better performance than DPR on SQuAD dataset.

our DCSR, indicating that our method captures the universality of the concerned task datasets.

2 Related Work

Open-Domain Passage Retrieval Open-Domain Passage Retrieval has been a hot research topic in recent years. It requires a system to extract evidence passages for a specific question from a large passage corpus like Wikipedia, and is challenging as it requires both high retrieval accuracy and specifically low latency for practical usage. Traditional approaches like TF-IDF (Ramos et al., 2003), BM25 (Robertson and Zaragoza, 2009) retrieve the evidence passages based on the lexical match between questions and passages. Although these lexical approaches meet the requirement of low latency, they fail to capture non-lexical semantic similarity, thus performing unsatisfying on retrieval accuracy.

With recent advances of pretrained language models (PrLMs) like BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), a series of neural approaches based on cross-encoders are proposed (Vig and Ramea, 2019; Wolf et al., 2019). Although enjoying satisfying retrieval accuracy, the retrieval latency is often hard to tolerate in practical use. More recently, the Bi-Encoder structure has captured the researchers' attention. With Bi-Encoder, the representations of the corpus at scale can be precomputed, enabling it to meet the requirement of low latency in passage retrieval. Lee et al. (2019) first proposes to pretrain the Bi-Encoder with *Inverse Cloze Task* (ICT). Later, DPR (Karpukhin et al., 2020) introduces a contrastive learning framework to train dense passage representation, and has achieved impressive performance on both retrieval accuracy and latency. Based on DPR, many works make further improvements either by introducing better sampling strategy (Xiong et al., 2020; Lu et al., 2020; Tang et al., 2021; Qu et al., 2021) or extra pretraining (Sachan et al., 2021), or even distilling knowledge from cross-encoders (Izacard and Grave, 2021; Yang et al., 2021).

Our method follows the contrastive learning research line of ODPR. Different from previous works that focus on either improving the quality of negative sampling or using extra pretraining, we make improvements by directly optimizing the modeling granularity with an elaborately designed contrastive learning training strategy.

Contrastive Learning Contrastive learning recently is attracting researchers' attention in all area. After witnessing its superiority in Computer Vision tasks (Chen et al., 2020; He et al., 2020), researchers in NLP are also applying this technique (Wu et al., 2020; Karpukhin et al., 2020; Yan et al., 2021; Giorgi et al., 2021; Gao et al., 2021). For the concern of ODPR, the research lines of contrastive learning can be divided into two types: (i) Improving the sampling strategies for positive samples and hard negative samples. According to (Manmatha et al., 2017), the quality of positive samples and negative samples are of vital importance in the contrastive learning framework. Therefore, many researchers seek better sampling strategies to improve the retrieval performance (Xiong et al., 2020). (ii) Improving the contrastive learning framework. DensePhrase (Lee et al., 2021) uses memory bank like MOCO (He et al., 2020) to increase the number of in-batch negative samples without increasing the GPU memory usage, and models retrieval process on the phrase level but not passage level, achieving impressive performance.

Our proposed method follows the second research line. We investigate a special phenomenon, *Contrastive Conflicts* in the contrastive learning framework, and experimentally verify the effectiveness of mediating such conflicts by modeling ODPR in a smaller granularity. More similar to our work, Akkalyoncu Yilmaz et al. (2019) also proposes to improve dense passage retrieval based on sentence-level evidences, but their work is not in the research line of contrastive learning, and focuses more on passage re-ranking after retrieval but not retrieval itself.

3 Methods

3.1 Contrastive Learning Framework

Existing contrastive learning framework aims to maximize the similarity between the representations of each question and its corresponding gold passages.

Suppose there is a batch of n questions, n corresponding gold passages and in total k hard negative passages. Denote the questions in batch as $q_1, q_2, ..., q_n$, their corresponding gold passages as $gp_1, gp_2, ..., gp_n$, and hard negative passages as $np_1, np_2, ..., np_k$. Two separate PrLMs are first used separately to acquire representations for questions and passages

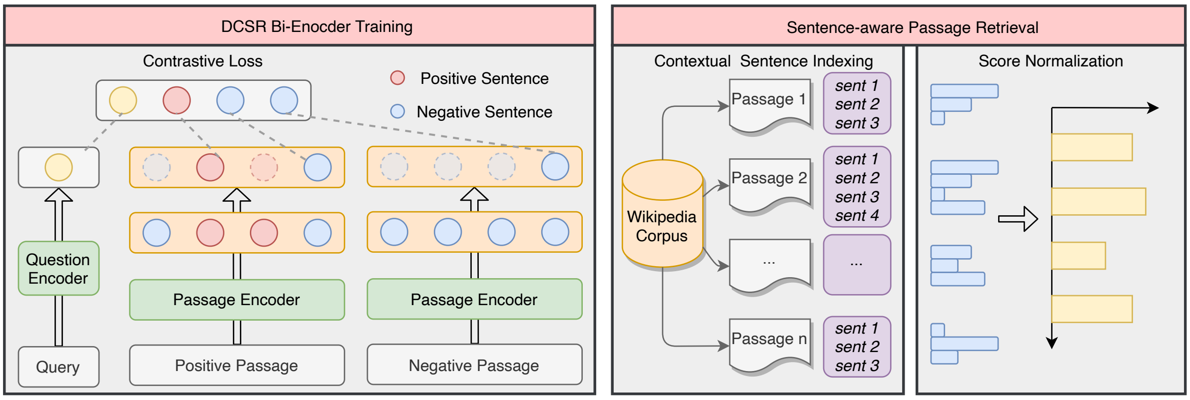

Figure 3: An illustration of our DCSR processing pipeline. The left part shows the contrastive training paradigm of our method, and the right part presents the inference pipeline.

$\{h_{q_1}, h_{q_2}, ...; h_{gp_1}, h_{gp_2}, ...; h_{np_1}, h_{np_2}, ...\}$. The training objective for each question sample q_i of original DPR is shown in Eq (1):

$$\mathcal{L}\left(q_i, gp_1, \cdots, gp_n, np_1, \cdots, np_k\right) = -\log \frac{e^{\operatorname{sim}\left(h_{q_i}, h_{gp_i}\right)}}{\sum_{j=1}^{n} e^{\operatorname{sim}\left(h_{q_i}, h_{gp_j}\right)} + \sum_{j=1}^{k} e^{\operatorname{sim}\left(h_{q_i}, h_{np_j}\right)}} \tag{1}$$

The $\operatorname{sim}(\cdot)$ could be any similarity operator that calculates the similarity between the question representation h_{q_i} and the passage representation h_{p_j}.

Minimizing the objective in Eq (1) is the same as (i) maximizing the similarity between each h_{q_i} and h_{gp_i} pair, and (ii) minimizing the similarity between h_{q_i} and all other h_{gp_j} $(i \neq j)$ and h_{np_k}. As discussed previously, this training paradigm will cause conflicts under current contrastive learning framework due to (i) Transitivity of Similarity, and (ii) Multiple References in Large Batch Size.

3.2 Dense Contextual Sentence Representation

The cause of the *Contrastive Conflicts* lies in *one-to-many problem*, that most of the passages are often organized by multiple sentences, while these sentences may not always stick to the same topic, as depicted in Figure 1. Therefore, we propose to model passage retrieval in a smaller granularity, i.e. contextual sentences, to alleviate the occurrence of *one-to-many problem*.

Since contextual information is also important in passage retrieval, simply breaking down passages into sentences and encoding them independently is infeasible. Instead, following (Beltagy et al., 2020; Lee et al., 2020; Wu et al., 2021), we insert a special <sent> token at the sentence boundaries in each passage, and encode the passage as a whole to preserve the contextual information, which results in the following format of input for each passage:

[CLS] <sent> sent$_1$ <sent> sent$_2$ ... [SEP]

We then use BERT (Devlin et al., 2019) as encoder to get the contextual sentence representations by these indicator <sent> tokens. For convenience of illustration, taking a give query q into consideration, we denote the corresponding positive passage in the training batch as p^+, which consists of several sentences:

$$\mathcal{P} = \{p_{s_1^-}, p_{s_2^-}, ...p_{s_i^+}, ...p_{s_{k-1}^-}, p_{s_k^-}\}$$

Similarly, we denote the corresponding BM25 negative passage as:

$$\mathcal{N} = \{n_{s_1^-}, n_{s_2^-}, ...n_{s_i^-}, ...n_{s_{k-1}^-}, n_{s_k^-}\}$$

Here $(*)^{-/+}$ means whether the sentence or passage contains the gold answer. We refine the original contrastive learning framework by creating sentence-aware positive and negative samples. The whole training pipeline is shown in the left part of Figure 3.

3.2.1 Positives and Easy Negatives

Following Karpukhin et al. (2020), we use BM25 to retrieve hard negative passages for each question. To build a contrastive learning framework based on contextual sentences, we consider the sentence that contains the gold answer as the positive sentence (i.e. $p_{s_i^+}$), and randomly sample several negative sentences (random sentences from $\mathcal{N}$) from a

BM25 random negative passage. Also, following (Karpukhin et al., 2020; Lee et al., 2021), we introduce in-batch negatives as additional easy negatives.

3.2.2 In-Passage Negatives

To handle the circumstance where multiple semantically faraway questions may be derived from one single passage, we hope to encourage the passage encoder to generate contextual sentence representations as diverse as possible for sentences in the same passage. Noticing that not all the sentences in the passage contain the gold answer and stick to the topic related to the given query, we further introduce in-passage negatives to maximize the difference between contextual sentences representations within the same passage. Concretely, we randomly sample one sentence that does not contain the gold answer (i.e. a random sentence from $\mathcal{P}/\{P_{s_i^+}\}$). Note that a positive passage might not contain such sentence. If it does not exist, this in-passage negative sentence is substituted by another easy negative sentence from the corresponding BM25 negative passage (a random sentence from $\mathcal{N}$). These in-passage negatives function as hard negative samples in our contrastive learning framework.

3.3 Retrieval

For retrieval, we first use FAISS (Johnson et al., 2019) to calculate the matching scores between the question and all the contextual sentence indexes. As one passage has multiple keys in the indexes, we retrieve top $100 \times k$ (k is the average number of sentences per passage) contextual sentences for inference. To change these sentence-level scores into passage-level ones, we adopt a probabilistic design for ranking passages, which we refer to as Score Normalization.

Score Normalization After getting the scores for each contextual sentences to each question by FAISS, we first use a Softmax operation to normalize all these similarity scores into probabilities. Suppose one passage $\mathcal{P}$ with several sentences $s_1, s_2, ..., s_n$, and denote the probability for each sentence that contains the answer as $p_{s_1}, p_{s_2}, ..., p_{s_n}$, we can calculate the probability that *the answer is in passage* $\mathcal{P}$ by Equation 2.

$$HasAns(\mathcal{P}) = 1 - \prod_{i=1}^{n}(1 - p_{s_i}) \qquad (2)$$

	1	2	3	≥ 4	Avg
SQuAD	8,482	6,065	5,013	6,754	2.66
Trivia	43,401	5,308	1,206	587	1.20
NQ	32,158	4,971	1,670	1,871	1.45

Table 1: Occurrence of *one-to-many problem* in training sets.

We then re-rank all the retrieved passages by $HasAns(\mathcal{P})$, and select the top 100 passages for evaluation in our following experiments.

4 Experiments

4.1 Datasets

OpenQA Dataset OpenQA (Lee et al., 2019) collects over 21 million 100-token passages from Wikipedia to simulate the open-domain passage corpus. OpenQA also collects question-answer pairs from existing datasets, including SQuAD (Rajpurkar et al., 2016), TriviaQA (Joshi et al., 2017), Natural Questions (Kwiatkowski et al., 2019), WebQuestions (Berant et al., 2013) and TREC (Baudiš and Šedivỳ, 2015).

We experiment our proposed method on SQuAD, TriviaQA and NQ. For the previously concerned *Contrastive Conflicts* problem, we also analyze the existence frequency of the conflicting phenomenon for each dataset. We count the number of questions for each passage, i.e, the times that this passage is referred to as the positive sample. The corresponding results are shown in Table 1. From this table, we can see that of all three datasets we choose, SQuAD is most severely affected by the *Contrastive Conflicts* problem, that many passages occur multiple times as the positive passages for different questions. These statistics are consistent with the fact that DPR performs the worst on SQuAD, while acceptable on Trivia and NQ.

4.2 Training and Implementation Details

Hyperparameters In our main experiments, we follow the hyperparameter setting in DPR (Karpukhin et al., 2020) to acquire comparable performance, i.e. an initial learning rate of 2e-5 for 40 epochs on each dataset. We use 8 Tesla V100 GPUs to train the Bi-Encoder with a batch size of 16 on each GPU.

Extra Cost Although we are modeling passage retrieval in a totally different granularity, our method adds little extra computation overhead

Model	Top-20			Top-100		
	NQ	Trivia	SQuAD	NQ	Trivia	SQuAD
Base Architecture Comparison – Single						
DPR (Karpukhin et al., 2020)	78.4	79.4	52.8†	85.4	85.0	71.0†
DCSR (Ours)	**78.9**(+0.5)	**79.7**(+0.3)	**63.7**(+10.9)	**86.5**(+1.1)	**85.2**(+0.2)	**78.1**(+7.1)
Base Architecture Comparison – Multi						
DPR (Karpukhin et al., 2020)	**79.4**	78.8	51.6	86.0	84.7	67.6
DCSR (Ours)	79.1(-0.3)	**79.6**(+0.8)	**63.8**(+12.2)	**86.6**(+0.6)	**85.2**(+0.5)	**77.6**(+10.0)

Table 2: Retriever Performance Comparison on the test sets. "†": For SQuAD dataset on DPR in the *Single* setting, we are not able to reproduce the original results from the official DPR code[1,2]. Instead, we rerun DPR on SQuAD in the *Single* setting and report its performance based on our reproduction. The parameter settings are shared between our DPR reproduction and DCSR to ensure fairness. Other statistics are taken from Karpukhin et al. (2020).

compared to DPR. For model complexity, our proposed method adopts exactly the same model structure as DPR does, meaning that there are no additional parameters introduced. For training time, the negative sentences in our method are randomly sampled from the negative passage in DPR. Therefore, the extra time burden brought by our method is only caused by the sampling procedure, which is negligible.

Training Settings To have a comprehensive comparison with DPR, we train DCSR under three different settings. (i) *Single*, where each dataset is both trained and evaluated under their own domain. (ii) *Multi*, where we use a combination of the NQ, Trivia and SQuAD datasets to train a universal Bi-Encoder, and evaluate its performance on the test sets of all three datasets. (iii) *Adversarial Training*, which is a simple negative sampling strategy. We first use the original dataset to train a DPR or DCSR checkpoint, and use such checkpoint to acquire semantically hard negative passages from the whole Wikipedia corpus.

4.3 Main Results on Passage Retrieval

Table 2 shows our main results on OpenQA.

For the *Single* setting, (i) Consistent with the core aim of this paper that our proposed sentence-aware contrastive learning solves *Contrastive Conflicts*, DCSR achieves significantly better results than DPR especially on the dataset that is severely affected by *Contrastive Conflicts*. For example, on the SQuAD dataset, our method achieves 10.9% performance gain on the Top-20 metric, and 7.1% performance gain on the Top-100 metric. (ii) For datasets that are less affected by *Contrastive Conflicts*, like NQ and Trivia, we still achieve slight performance gain on all metrics.

Model		Top-20		Top-100	
		NQ	Trivia	NQ	Trivia
DPR	+ adv-train	81.3	-	87.3	-
	+ ANCE (Xiong et al., 2020)	**81.9**	**80.3**	**87.5**	85.3
DCSR	+ adv-train	81.4	80.0	**87.5**	**85.7**

Table 3: Performance Comparison when incorporated with negative sampling strategy.

For the *Multi* setting, DPR on Trivia and SQuAD suffers from a significant performance drop compared to *Single* setting, while our model is only slightly affected. It indicates that our proposed sentence-aware contrastive learning not only solves the *Contrastive Conflicts*, but also captures the universality of datasets from different domains.

4.4 Incorporated with Negative Sampling

Different from other frontier researches which mainly devote themselves either to investigating better negative sampling strategies, like ANCE (Xiong et al., 2020), NPRINC (Lu et al., 2020), etc., or to extra pretraining (Sachan et al., 2021), or to distilling knowledge from cross-encoders (Izacard and Grave, 2021; Yang et al., 2021), our proposed method directly optimizes the modeling granularity in DPR. Therefore, our method could be naturally incorporated with these researches and achieve better results further. Due to computational resource limitation, we do not intend to replicate all these methods, but use *adversarial training* as an example. Following ANCE (Xiong et al., 2020),

[2] It is an issue that is shared by researchers on github. More discussion about this result will be discussed in Appendix B.

Model		Top-20 NQ	 Trivia	 SQuAD	Top-100 NQ	 Trivia	 SQuAD
DPR	(Karpukhin et al., 2020)	43.7	62.1	46.5	54.0	72.4	63.6
DCSR	+ 1 BM25 random	44.5	63.1	51.1	54.5	72.9	66.6
	+ 2 BM25 random	44.0	**63.5**	50.3	54.7	72.9	65.1
	+ 1 in-passage & +1 BM25 random	**45.2**	63.4	**54.5**	**55.3**	**73.2**	**68.5**

Table 4: Ablations of Negative Sampling Strategy on Wikipedia subset (1/20 of the whole corpus) in the *Single* Setting.

we conduct experiments on NQ and Trivia to show the compatibility of our method, listed in Table 3. With such a simple negative sampling strategy, our DCSR achieves comparable results with its DPR counterpart.

4.5 Ablation Study

To illustrate the efficacy of the previously proposed negative sampling strategy, we conduct an ablation study on a subset of OpenQA Wikipedia corpus[3]. We sample 1/20 of the whole corpus, which results in a collection of 1.05 million passages in total. As reference, we reproduce DPR and also list their results in Table 4. We compare the following negative sampling strategies of our proposed method.

+ 1 BM25 random In this setting, we randomly sample (i) one gold sentence from the positive passage as the positive sample, and (ii) one negative sentence from the negative passage as the negative sample per question.

+ 2 BM25 random In this setting, we randomly sample (i) one gold sentence from the positive passage as the positive sample, and (ii) two negative sentences from two different negative passages as two negative samples per question.

+ 1 in-passage & + 1 BM25 random In this setting, we randomly sample (i) one gold sentence from the positive passage as the positive sample, (ii) one negative sentence from the positive passage as the first negative sample, and (iii) one negative sentence from the negative passage as the second negative sample per question.

Ablations of Negative Sampling Strategy The results are shown in Table 4. (i) Under the circumstance where only 1.05 million passages are indexed, variants of our DCSR generally perform significantly better than DPR baseline, especially on NQ dataset (over 1% improvement on both Top-20 and Top-100) and SQuAD dataset (8.0% improvement on Top-20 and 4.9% improvement on Top-100), which verifies the effectiveness of solving *Contrastive Conflicts*. (ii) Further, we found that increasing the number of negative samples helps little, but even introduces slight performance degradation on several metrics. (iii) The in-passage negative sampling strategy consistently helps in boosting the performance of nearly all datasets on all metrics, especially on the SQuAD dataset, which is consistent with our motivation for in-passage negatives, which is to encourage a diverse generation of contextual sentence representations within the same passage in solving the *one-to-many problem*.

Model	Top-20 NQ	 Trivia	Top-100 NQ	 Trivia
$\text{DPR}_{raw-data}$	43.7	62.1	54.0	72.4
$\text{DPR}_{\textit{DPR-hard}}$	47.6	-	56.5	-
$\text{DCSR}_{\textit{DPR-hard}}$	47.6	-	57.0	-
$\text{DCSR}_{\textit{DCSR-hard}}$	**48.8**	**66.2**	**57.1**	**75.0**

Table 5: Ablations of Training Data. For Trivia, *DPR-hard* is not provided in the original paper.

Ablations of Training Data The results are shown in Table 5. (i) We first directly use the augmented adversarial training dataset provided by DPR (marked as *DPR-hard*) and train our DCSR, having achieved even better results on the NQ dataset. This augmented dataset is sub-optimal for our model, as these hard negative samples are passage-specific, while our model prefers sentence-specific ones. (ii) We then use our previous best DCSR checkpoint to retrieve a set of sentence-specific hard negatives (marked as *DCSR-hard*) and train a new DCSR, which achieves further performance gain on both metrics on NQ dataset.

---

[3] Because evaluating on the whole Wikipedia corpus takes too much resource and time (over 1 day per experiment per dataset).

	SQuAD-to-Trivia				NQ-to-Trivia			
Model	Top 20	diff	Top 100	diff	Top 20	diff	Top 100	diff
DPR	48.7/62.1	↓13.4	64.5/72.4	↓7.9	48.8/62.1	↓13.3	62.7/72.4	↓9.7
DCSR	54.0/63.4	↓**9.4**	67.8/73.2	↓**5.4**	52.7/63.4	↓**10.7**	65.9/73.2	↓**7.3**

Table 6: Transferability comparing our methods with DPR. We train the retriever model on the SQuAD dataset or the NQ dataset, and evaluate it on Trivia QA (statistics on the left). For reference, we also list the performance where the retriever model is both trained and evaluated on the Trivia QA (statistics on the right).

5 Discussion

In this section, we discuss the transferability difference and the influence of Wikipedia corpus size on both DPR and our DCSR. More discussions from different aspects are presented in the Appendices, including (i) Validation accuracy on dev sets in Appendix A, which is also a strong evidence of alleviating *Contrastive Conflicts*. (ii) Error analysis for SQuAD in Appendix B, which further shows the generalization ability of our method. (iii) Case study in Appendix C, which discusses the future improvement of DCSR.

5.1 Transferability

To further verify that our learned DCSR is more suitable in Open-Domain Passage Retrieval, especially under the *Contrastive Conflicts* circumstance, we conduct experiments to test the transferability between DPR and our DCSR. Similarly, instead of running such experiments on the entire Wikipedia corpus, we sample 1/20 of the corpus, which results in a collection of 1.05 million passages in total. We test the transferability result from SQuAD to Trivia and from NQ to Trivia, as compared to Trivia, both SQuAD and NQ suffer more from *Contrastive Conflicts*. The results are shown in Table 6.

From Table 6, when compared to DPR, our model enjoys significantly better transferability. In both scenarios, DPR shows over 2% performance gap in all metrics of the transferability tests, indicating that our method performs much better in generalization across the datasets. This phenomenon once again confirms our theorem, that by modeling passage retrieval in the granularity of contextual sentences, our DCSR well models the universality across the datasets, and shows much better transferability than DPR.

5.2 Corpus Size

In our extensive experiments, we further found out that our method can achieve overwhelming better performance than DPR on smaller corpus. In this experiment, we take *the first 0.1 million*, *the first 1.05 million* and *all passages* from the original Wikipedia corpus, and conduct dense retrieval on these three corpora varied in size. The statistic results are shown in Table 7.

Model	Top-20		Top-100		Wiki
	NQ	Trivia	NQ	Trivia	
DPR	25.5	39.4	36.7	51.9	
DCSR	**27.8**	**41.0**	**39.0**	**53.6**	0.10M
Δ	+2.3	+1.6	+2.3	+1.7	
DPR	43.7	62.1	54.0	72.4	
DCSR	**45.2**	**63.4**	**55.3**	**73.2**	1.05M
Δ	+1.5	+1.3	+1.3	+0.8	
DPR	78.4	79.4	85.4	85.0	
DCSR	**78.9**	**79.7**	**86.5**	**85.2**	21.0M
Δ	+0.5	+0.3	+1.1	+0.2	

Table 7: Retrieval performance when the size of Wikipedia Corpus is varied.

From Table 7, first of all, our model achieves better performance than DPR in all settings, where such improvement is more significant in smaller corpus. On the setting where only 0.1 million passages are indexed in the corpus, our model achieves over 2.0% exact improvement on all metrics on both NQ and Trivia. We speculate this is because of the following two strengths of our method.

- The alleviation of *Contrastive Conflicts*, which we have analyzed previously.
- Modeling passage retrieval using contextual sentences enables a diverse generation of indexes. Some sentences may not be the core aim of their corresponding passages, but can still be the clue for some questions.

Secondly, we can discover that the performance gap between DPR and DCSR is decreasing when the size of Wikipedia corpus increases. This is because with the expansion of indexing corpus, many questions that cannot be solved in the small corpus setting may find much more closely related passages in the large corpus setting, which gradually neutralizes the positive effect brought by the second strength of our proposed method discussed above. Still, our model achieves better performance under the full Wikipedia setting on all datasets and all metrics.

6 Conclusion

In this paper, we make a thorough analysis on the *Contrastive Conflicts* issue in the current open-domain passage retrieval. To well address the issue, we propose an enhanced sentence-aware conflict learning method by carefully generating sentence-aware positive and negative samples. We show that the dense contextual sentence representation learned from our proposed method achieves significant performance gain compared to the original baseline, especially on datasets with severe conflicts. Extensive experiments show that our proposed method also enjoys better transferability, and well captures the universality in different datasets.

A Validation Accuracy

One may argue that the improvement of DCSR might be due to the expansion of indexing corpus (which we have discussed in previous sections), but not the alleviation of *Contrastive Conflicts*. In this section, we present the validation accuracy comparison during the training process between DPR and our DCSR, which is a strong evidence that DCSR well handles the problem of *Contrastive Conflicts*.

Under 8 V100 GPUs with a batch size of 16 on each GPU, the validation process could be viewed as a tiny retrieval process for both DPR and DCSR. To maintain a similar validation environment for fair comparison, we use the *+1 BM25 random* version of DCSR, which results in 8*16=128 questions and 2*8*16=256 contextual sentences in one batch. Therefore, the validation process could be interpreted as *retrieving the most relevant contextual sentence for each question in a corpus of 256 sentences*. Under such a validation task, the size of the indexing corpus is restricted to the same for both DPR and DCSR.

The result is shown in Figure 4. For both Trivia and NQ, DCSR performs consistently better than DPR with a small accuracy margin. On SQuAD, especially, our DCSR can achieve higher validation accuracy than DPR with only one single epoch, and achieves nearly 20% final validation accuracy improvement. This phenomenon further verifies that improvement of DCSR is also achieved by improving the training strategy which alleviates *Contrastive Conflicts*, but not only the expansion of the indexing corpus.

B Error Analysis for SQuAD

Although achieving overwhelmingly better performance on SQuAD than DPR, our DCSR on SQuAD still lags far behind its counterparts on NQ or Trivia. Interestingly, we found that the results on SQuAD dev sets are pretty good and comparable to the results on NQ or Trivia. The results of both DPR and DCSR on dev set and test set performance are shown in Table 8.

Model	SQuAD-dev			
	Top-1	Top-5	Top-20	Top-100
DPR	15.8	34.5	52.8	71.0
DCSR	**26.9**	**47.4**	**63.7**	**78.1**
Model	SQuAD-test			
	Top-1	Top-5	Top-20	Top-100
DPR	42.5	66.8	76.2	85.0
DCSR	**49.5**	**69.6**	**79.6**	**86.4**

Table 8: Performance comparison on both SQuAD-test and SQuAD-dev.

By analyzing the training instances, we observe that there exists a severe distribution bias problem in SQuAD: SQuAD-dev and SQuAD-train share a great number of positive passages. In fact, almost all positive passages in the SQuAD-dev could also be found in SQuAD-train. Of all 7921 questions that have at least one positive passage containing the answer in SQuAD-dev, 7624 (96.25%) of these passages' titles could be found in the positive passages of SQuAD-train. More surprisingly, 6973 (88.03%) of these passages are shared between SQuAD-train and SQuAD-dev. However, this feature is exactly what SQuAD-test does not have, resulting in relatively poor performance. But again, this phenomenon reveals another strength of our DCSR, that it enjoys better generalization ability than DPR, thus is more robust in practical use.

C Case Study

To analyze the retrieval performance difference between DPR and DCSR, we especially focus on the different Top 1 predictions on SQuAD. We count the number of winning times for each baseline, where DCSR significantly outperforms DPR (893 vs. 161), shown in Figure 5.

C.1 DCSR winning cases

On the question *Who was the NFL Commissioner in early 2012?*, the strengths of our DCSR are listed as follows.

- **Capability of utilizing contextual information.** The key phrase *2012* and *NFL* is faraway from *Commisioner Roger Goodell*, while our DCSR is still capable of capturing such distant contextual information.
- **Locating the exact sentence of the answer.** This is an obvious feature of DCSR, as we are modeling on the granularity of contextual sentences.

On the contrary, due to *Contrastive Conflicts*, the question encoder of DPR is severely affected that it cannot generate fine-grained question representation. Therefore, on this question, DPR can only find out one key phrase *commissioner*, falling into a totally wrong prediction.

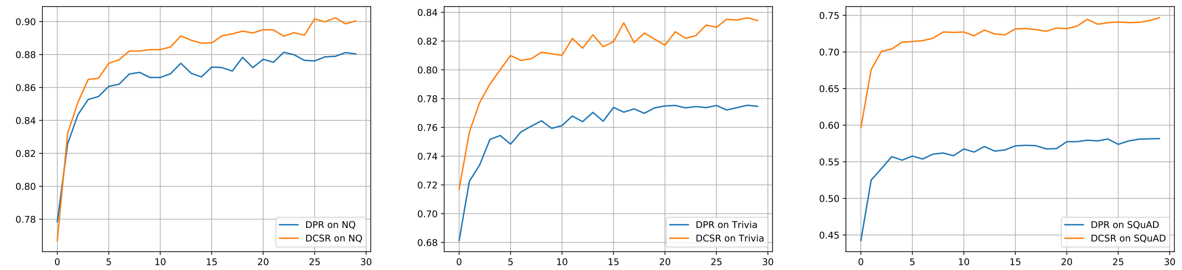

Figure 4: Dev accuracy in training the encoder of DCSR, including NQ (left), Trivia (middle) and SQuAD (right).

Figure 5: Error Case Study of Our DCSR on SQuAD. Green color represents the correct clues and correct answers, while red color represents wrong ones.

C.2 DCSR losing cases

On the question *Super Bowl 50 decided the NFL champion for what season?*, our DCSR has already found a contextual sentence that is very close to the given question, with several key phrases detected. However, this contextual sentence is actually a low-quality index, as it suddenly reaches the end of the passage. This is caused by the brute force segmentation strategy of OpenQA, which focuses on the passage level and restricts the length of each passage to 100. In this paper, we perform sentence split directly on these broken passages, which as a result breaks down many sentences into low-quality indexes, affecting the final retrieval performance. We do not intend to refine the splition strategy to have a fair comparison with DPR, and leave it for future investigation.

FaiRR: Faithful and Robust Deductive Reasoning over Natural Language

Soumya Sanyal[1] **Harman Singh**[2] **Xiang Ren**[1]

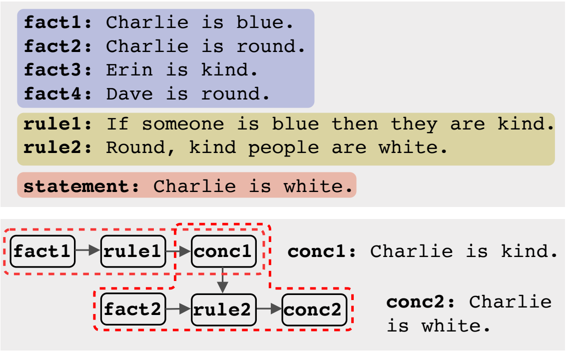
Abstract

Transformers have been shown to be able to perform deductive reasoning on a logical rulebase containing rules and statements written in natural language. Recent works show that such models can also produce the reasoning steps (i.e., the *proof graph*) that emulate the model's logical reasoning process. Currently, these black-box models generate both the proof graph and intermediate inferences within the same model and thus may be unfaithful. In this work, we frame the deductive logical reasoning task by defining three modular components: rule selection, fact selection, and knowledge composition. The rule and fact selection steps select the candidate rule and facts to be used and then the knowledge composition combines them to generate new inferences. This ensures model faithfulness by assured causal relation from the proof step to the inference reasoning. To test our framework, we propose FAIRR (Faithful and Robust Reasoner) where the above three components are independently modeled by transformers. We observe that FAIRR is robust to novel language perturbations, and is faster at inference than previous works on existing reasoning datasets. Additionally, in contrast to black-box generative models, the errors made by FAIRR are more interpretable due to the modular approach. [1]

1 Introduction

The field of AI has long pursued the goal of building systems that can automatically reason over some given *explicit* knowledge to generate conclusions and provide the reasoning steps involved in the process (McCarthy, 1959; Newell and Simon, 1956). Recently, Clark et al. (2020) proposed a modern version of this problem, where the formal representation of knowledge is replaced by natural language statements in English. Further, they proposed a transformer-based model (Vaswani et al., 2017) RuleTaker, that can predict if a candidate statement is entailed by the natural language statements, by emulating deductive reasoning. As shown in Figure 1, in this deductive reasoning task, facts and rules from the rulebase are combined iteratively to generate intermediate inferences which eventually entails the statement. Note that the reasoning process implicitly involves two steps: determining which rules and facts to combine at each iteration, followed by using them to generate an intermediate conclusion.



fact1: Charlie is blue.
fact2: Charlie is round.
fact3: Erin is kind.
fact4: Dave is round.

rule1: If someone is blue then they are kind.
rule2: Round, kind people are white.

statement: Charlie is white.

Figure 1: **Example of a theory, a statement, and a valid proof graph** - An instance contains multiple facts and rules in blue and yellow respectively, followed by a statement in red. The proof graph describes the reasoning steps required to generate the statement.

While RuleTaker focuses on just predicting the statement entailment, some recent works (Saha et al., 2020; Tafjord et al., 2021) have further developed systems that can also generate the reasoning steps (i.e., *proof graph generation*). However, these systems do not *explicitly* ensure the causality from the rule/fact selection to generating the intermediate inferences. Since these systems are inherently black-box models, it is unclear if such constraints are implicitly learned by the models without being enforced externally. This, in turn, questions the faithfulness of the model's internal reasoning process (Lipton, 2018). Because the model has access

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 1075 - 1093
May 22-27, 2022

to the full theory at input, it might use additional parts of the theory, than just the predicted proof, to generate the inference.

In this paper, we address these shortcomings by developing a modularized framework to solve the deductive reasoning task. While existing methods generate both proofs and conclusions in a single step, in our framework we break this process into three steps: rule selection, fact selection, and knowledge composition. The rule selection step decides the relevant rule to use for an iterative inference step and fact selection uses this rule to select the relevant facts. Then, the knowledge composition step reasons using only the selected rule and facts to generate the next intermediate inference. In Figure 2, we show the model schematics for our system and contrast it with previous methods. Notably, we strictly restrict the information accessible at each step of our framework to make the reasoning process more faithful. For example, the fact selection step depends only on the selected rule, instead of all the rules in the rulebase. Additionally, the generated inference depends *explicitly* on the selected rule and facts, as opposed to all the rules and facts in prior works. This makes the proof graph a *by-product* of the selection steps as we don't need to generate any separate proofs. Since we constrain the inputs to each step, this also makes each subproblem easier to learn, leading to an overall more robust reasoning model.

To model these three steps, we develop FAIRR, in which each component is a transformer-based model learning to perform the modular tasks. Specifically, we use RoBERTa-based models (Liu et al., 2019) for the two selection tasks and a T5-based model (Raffel et al., 2020) for the composition task. Similar to ProofWriter, we use synthetic rulebases to train FAIRR. To test the deductive reasoning capabilities in a more comprehensive way, we experiment with both existing deductive reasoning datasets and multiple newly-generated robustness dataset variants. Overall, we find that FAIRR is more robust to novel language perturbations than baselines. Additionally, our model is up to three times faster at inference due to the constrained input and outputs of different modules. Lastly, we find that the errors made by our model are more interpretable and easier to debug compared to baseline generative models. This further demonstrates the faithfulness of our modularized reasoning framework.

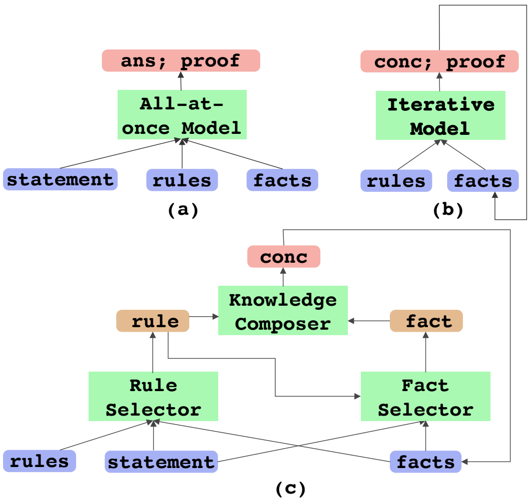

Figure 2: **Reasoning process in different models.** **(a)**: ProofWriter ("All") directly output the entailment prediction and proof graph for given input. **(b)**: ProofWriter ("Iter") iteratively generates the one-step intermediate conclusions and their proofs. **(c)**: FAIRR selects a rule, then a fact, and finally combines them to generate an intermediate inference. Note that the proof is implicitly determined by the selection steps. Please refer to Section 3.1 for details.

2 Problem Definition

Notations A theory T consists of a set of facts $F = \{f_1, f_2, \dots, f_n\}$ and rules $R = \{r_1, r_2, \dots, r_m\}$ expressed in natural language. An example of a theory is depicted in Figure 1. Here, the sentences in the blue and yellow boxes are facts and rules, respectively. Further, a *proof graph* is a directed graph connecting facts and rules that describe how a specific inference can be obtained from the theory. In Figure 1, the proof graph shows the steps involved in generating the inference "*Charlie is white.*". To generate the proof graph we may need to infer some intermediate conclusions c_i. These inferences are considered as part of the extended facts in the theory. For example, in Fig. 1, "*Charlie is kind*" is an intermediate inference required to generate the correct proof graph.

Deductive Reasoning The task of deductive reasoning is described as follows: given a theory T, and a statement s, predict if the theory supports the statement (*entailment prediction*) and if so, generate the proof graph that supports the statement (*proof generation*). For the example theory and statement in Figure 1, we see that the statement is indeed entailed by the theory and the valid proof graph is shown for the same. The main goal of this task is to evaluate if a model can generate valid reasoning chains in the form of proof graphs to justify its entailment prediction.

Reasoning Robustness We consider an auxiliary task that evaluates the robustness of the reasoning abilities used by the model. Let $\mathcal{P}$ be a perturbation function that modifies a given theory T (statement s) to a theory $T^{'}$ (statement $s^{'}$), such that $(T^{'}, s^{'})$ just has some surface changes in the natural language form but still requires the similar reasoning process as required for (T, s). A function that alters the subjects in the theory to unseen subjects is an example of such perturbation function. We perturb each theory statement pair (T, s) to create an *equivalence set* defined as the set $E_{(T,s)} = \{(T_1^{'}, s_1^{'}) \dots (T_N^{'}, s_N^{'})\}$, where each $(T_k^{'}, s_k^{'})$ is derived by perturbing the original theory, and N is the total such perturbations per theory. Note that it is possible to generate different $(T_k^{'}, s_k^{'})$ pairs by controlling the stochasticity of $\mathcal{P}$. The main goal of this task is to evaluate the consistency of the model's predictions with minimal variations in the input theory.

Evaluation Protocol We consider three main aspects for evaluating the model performance in our study: (1) ***Entailment accuracy*** measures how accurately the model is able to predict the true statement entailment. (2) ***Proof accuracy*** measures how accurately the model can predict a valid proof for the statement. Following Saha et al. (2020); Tafjord et al. (2021), we use the strict metric for proof evaluation, i.e., for a match to count, both the predicted proof should exactly match a gold proof and the entailment should be correctly predicted. (3) ***Consistency*** measures if the models are consistent in the entailment and proof prediction for different perturbation functions. For a theory statement pair (T, s) and its corresponding equivalence set $E_{(T,s)}$, consistency is defined as $C = \frac{1}{N}\sum_{k=1}^{N} \mathbb{1}[f(T, s) = f(T_k, s_k)]$, where $f(\cdot)$ is the model's prediction. We compute the average consistency for both entailment and proof predictions on an equivalence set and further average across the dataset to report the consistency.

3 The FaiRR Method

3.1 Approach Overview

As illustrated by the example in Figure 1, to reliably generate a proof graph through deductive reasoning, a model needs to generate multiple one-hop intermediate conclusions. This is the major limitation of models that use the theory to directly predict the proof (Figure 2 (a)), thus questioning the trustworthiness of the reasoning process. Next, it is also intuitive to see that in order to faithfully generate these intermediate inferences, a model should first determine the proof (i.e., know the rules and facts to use) and then use them to infer the conclusion. That is, there is a causal relation from determining the proof to then generating the conclusion. We note that ProofWriter ("Iter") lacks in this aspect. As shown in Figure 2 (b), it first generates the conclusion and then the corresponding proof.

Motivated by these points, we propose our causal reasoning framework which breaks the reasoning process into three desirable steps. As shown in Figure 2 (c), in our framework, first a rule r is selected using the rules and facts in the theory. Following that, some relevant facts are selected from the fact list based on the selected rule r. This step does not use the other rules $R \setminus \{r\}$ in the theory. Finally, the selected rule and facts are jointly used to generate a new conclusion c_i. In this framework, the one-step proof is explicitly determined first via the selection steps followed by the inference generation, making the proof a *by-product* of the whole process. In contrast, prior works learned to generate the proof along with intermediate conclusion.

3.2 FaiRR Modules

At a high level, FaiRR is an iterative model in which the one-hop intermediate conclusions are generated step-by-step. To model our framework described in Sec. 3.1, we have four components in FaiRR as follows.

Rule Selector (RS) The rule selector is a RoBERTa-based (Liu et al., 2019) classification model that takes the concatenated statement, facts, and rules as input, and selects a rule that is used to generate an intermediate conclusion in the current iterative step. It takes the input of the form $[CLS]\ s\ [SEP]\ F\ \ [[SEP]\ \ r_i\ ]_m\ [SEP]$, and generates a one-hot output vector by classifying the token embedding from the [CLS] token and [SEP] tokens in front of the rules, via a linear classifier layer. Each classification is a binary classification, but overall only one of the tokens has the positive class. Here s denotes the statement, F is the facts and concatenated with any intermediate conclusions generated in a prior iteration, and $\{r_i\}$ denotes the i^{th} rule in the theory that contains a total of m rules. $[\ ]_m$ denotes continued concatenation. An example input and output of the rule selector is shown in Figure 3. If a [SEP] token is selected, we select the rule sentence following the corresponding [SEP] token, otherwise if the [CLS] token is selected, we decide to stop the iteration. That is, the [CLS] selection acts as a stop signal for our iterative model. We note that it is possible to have more than one likely candidate rule since there can be multiple one-hop inferences possible for a given theory. Following Tafjord et al. (2021), we randomly select one of the possible candidate rules at each iteration.

Fact Selector (FS) The fact selector is RoBERTa-based (Liu et al., 2019) token classification model that takes the statement, the rule selected by the rule selector, and facts in the theory, and then predicts a set of candidate facts that can be used with the rule to generate an intermediate conclusion. It takes the input of the form $[CLS]\, s\, [SEP]\, r\ \ [[SEP]\ \ f_i]_n\ \ [SEP]$, where s is the statement, r is the selected rule, and $\{f_i\}$ is the i^{th} fact in the theory containing n total facts. Note that facts also include any previously generated intermediate conclusions. $[\ ]_n$ denotes continued concatenation. The output is generated by classifying each [SEP] token embedding in front of a fact using a linear layer, to determine if the corresponding fact is selected or not. An example input and output for the fact selector is depicted in Figure 3. We note that it is possible to have some rules that can reason over multiple facts jointly to generate a conclusion. An example of such a rule is "*rule2*" in Figure 1. Hence, this component has the ability to select multiple facts.

Knowledge Composer (KC) The knowledge composer is a generative text-to-text transformer T5 (Raffel et al., 2020) (T5-large) that can compose a set of facts and a rule to output a novel conclusion. The input to the model is the selected facts and rule concatenated together, and the output is the intermediate conclusion. An example input and output for knowledge composer is shown in Fig. 3.

Solver The final component is the solver that operates after all iterations have finished (i.e., once the rule selector selects the [CLS] token indicating to stop the iterative inference generation process). Similar to ProofWriter, our solver currently searches for the statement in the generated intermediate inferences (string matching). If found, it predicts that the statement is entailed by the theory. It also search for the negation of the statement [2], and if found, it predicts not entailed. If none of these are present, it predicts "Unknown" since it cannot prove or disprove the statement. The proof graph is constructed by using the one-hop proofs generated by the selected rule and facts at each step. For example, in Figure 1, the red dotted boxes (one-hop proofs) are stitched together to assemble the complete proof. For cases where the entailment is "Unknown", the proof returned is "None", since no proof for the statement exists in the theory. We note that our solver is not a learnable module.

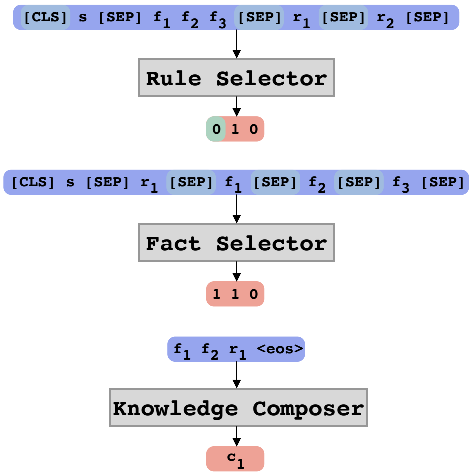

Figure 3: **Overview of components of FAIRR** - The rule selector and fact selectors are classification models whereas the knowledge composer is a generation model. The input tokens used for classification by the selectors are highlighted. Rule selector decides to stop based on the output prediction of [CLS] token (highlighted in green). Here, rule r_1, and facts f_1 and f_2 are used to generate the conclusion c_1. Please refer to Section 3.2 for more details.

3.3 Training and Inference

Each component of our model (except the solver, which is deterministic) is trained separately. We use the same dataset as ProofWriter to train these models, but process it such that each model receives only the relevant inputs according to our causal framework. More concretely, suppose for a given theory $T = R + F$, a possible intermediate inference is c obtained by using a rule r and a fact f. Then, a training instance of ProofWriter, which is a T5 (Raffel et al., 2020) model, uses the input $\{R, F\}$ and output $\{c, r, f\}$. We process the same

---

[2] Following ProofWriter, we perform regex to add/remove "not" which suffices for this dataset.

instance to generate three training instances, one for each of rule selector, fact selector, and knowledge composer, respectively, as follows:

$$\begin{aligned} RS\ Input &= \{R, F\};\ \ RS\ Output = \{r\},\\ FS\ Input &= \{r, F\};\ \ FS\ Output = \{f\},\\ KC\ Input &= \{r, f\};\ \ KC\ Output = \{c\}. \end{aligned}$$

Our selector models have the statement s as input to the model. Also, the outputs of rule selector and fact selectors are converted to class labels instead of text since our selectors are classification models. We use cross entropy loss to train the rule selector, and binary cross entropy loss to train the fact selector. The knowledge composer is trained on language modeling loss.

At inference time, the rule selector selects a rule to be used for generating one-step conclusions. Then, the fact selector selects some facts based on the selected rule, which is then collectively passed on to the knowledge composer to generate a conclusion. This three-step pipeline is run iteratively until the rule selector predicts a stop signal by selecting the [CLS] token which exits the iteration. Once the iteration finishes, the solver uses the generated intermediate inferences to decide if the statement is entailed or not, and generates a proof accordingly.

Remark on Computational Complexity A practical limitation of ProofWriter is that it performs an exhaustive forward search by enumerating all possible inferences from a given theory. This leads to redundant inferences being generated for proving a particular statement. Additionally, using a text-to-text transformer model adds to the problem since it is usually quite expensive to run at inference time. In FAIRR, we alleviate this by introducing two changes. First, our causal framework allows only selected rule and facts as input to the knowledge composer, thus restricting the input length significantly. Second, augmenting the question to our selector inputs helps reduce the candidate space because these models can learn to prioritize the selection based on the relevance to both the question and the theory. This ensures that FAIRR does not perform an exhaustive forward search and prioritizes generating relevant inferences over the others. Both these changes lead to an overall improvement in inference speed. We perform more quantitative analysis on this later in Section 5.3.

4 Experimental Setup

Datasets Following (Tafjord et al., 2021; Clark et al., 2020), we use the D* datasets for our experiments. These are a set of multiple datasets - namely D0, D1, D2, D3, D0-D3, and D5. The theory in these datasets are synthetically generated with increasing reasoning depths. For example, D3 dataset contains statements that require *at most* 3-hop reasoning steps. The D0-D3 contains all theories in D3 plus ~ 20% of the D0-D2 training set theories. We also use the ParaRules dataset (Clark et al., 2020) that contains around 2k theories expressed in paraphrased natural language.

Additionally, we generate three datasets that evaluate the robustness of the reasoning models as follows:

- ***Subject* robustness**: Here, subjects in a theory are perturbed by using some out-of-distribution proper and common names. For example, in Figure 1, "*Charlie*" can be replaced with "*Paul*" which is not used in the D* datasets. We generate five new theories corresponding to each theory of the D3 dataset, by repeatedly perturbing all the proper and common names in the theory.
- ***Attribute* robustness**: Here we sample out-of-distribution attributes. For example, "*blue*" in Figure 1 can be replaced with "*soft*". As above, we generate five new theories for each theory of the D3 dataset.
- ***Subject+Attribute* robustness**: This is a combination of subject and attribute robustness to study model performance when most of the training vocabulary is replaced by out-of-distribution words. Each theory has both novel subject and attribute.

We include more details on the perturbation sets used in our experiments in Appendix B.

Baselines We compare FAIRR with two variants of ProofWriter (Tafjord et al., 2021): All-at-once (PW ("All")) and Iterative (PW ("Iter")), wherever applicable [3]. The PW ("All") model is trained to predict the entailment and generate proof graph directly from the theory and statement in a single step. The PW ("Iter") generates one-step inferences and corresponding proofs iteratively, until all possible inferences are generated, and then stitches the proof

---

[3] The code to reproduce numbers of ProofWriter is not publicly available. We either copy results directly from the paper or run our own inference on model checkpoints made available by the authors.

	Entailment Accuracy		**Proof Accuracy**	
d	PW ("Iter")	FAIRR	PW ("Iter")	FAIRR
N/A	99.7	99.6	99.7	99.6
0	100.0	100.0	100.0	100.0
1	99.9	99.7	99.9	99.5
2	99.7	98.9	99.4	97.2
3	99.7	96.6	99.1	95.3
All	99.8	99.2	99.7	98.8

graph similar to our method. If not mentioned otherwise, ProofWriter uses a T5-large (Raffel et al., 2020) model. We omit comparisons with PRover since it was trained on a different dataset that adds specific constraints on the proof graph. Please refer to Appendix J for more details.

5 Experiment Results

We compare FAIRR with ProofWriter variants on three settings: generalization on D* datasets, robustness to perturbed theories, and efficiency in inference computation. We further conduct qualitative analysis to understand the inference errors.

5.1 Performance on Same Depth Reasoning

In this setting, we train and test both models on D0-D3 dataset. Note, D0-D3 contains statements with reasoning depths up to 3. This compares the ability of the models to generalize to *seen* reasoning depths at train time. The results with increasing depths of reasoning are shown in Table 1. Here, depth "N/A" refers to statements that cannot be proven and hence don't have an exact proof depth associated with it. We observe that overall both FAIRR and ProofWriter ("Iter") performs comparably (last row with depth 'All'). Further, we find that our model's performance is lower on $d = 3$, indicating that our models tend to perform weaker with increasing depths. This happens majorly because the rule selector in FAIRR tends to incorrectly select the [CLS] token to indicate a stop signal instead of generating more possible intermediate inferences. We discuss more about this in Sections 5.3 and 5.4. Please refer to Appendix C for more results on unseen reasoning depths.

Robustness	**PW ("Iter")**			**FAIRR**

5.2 Robustness to Perturbed Theories

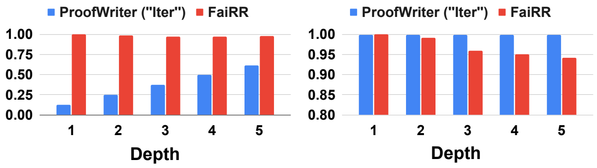
In this section, we test the robustness of ProofWriter ("Iter") and FAIRR on different perturbed theories. Since FAIRR focuses on making deductive reasoning more robust and faithful, performance on these robustness experiments are the main results of our work. As described in Section 4, we test the robustness on three different perturbations: subject, attribute, and subject+attribute. We compare the performance of both models after training on D0-D3 dataset. The consolidated results are shown in Table 2 and depth-wise results for subject robustness are shown in Table 3. We report the entailment accuracy, proof accuracy, and consistency as defined in Section 2. Please refer to appendix D for the depth-wise breakdown of all the datasets. We observe that on subject and subject+attribute robustness, our models are consistently better than ProofWriter whereas on attribute robustness both models perform similarly. Further, we find that on average, FAIRR is both more accurate and consistent than the baseline. From this, we conclude that our model relies less on spurious correlations based on the subject while both models likely suffer from similar issues on attribute perturbations. Since ProofWriter uses the theory to *generate* the intermediate conclusion and proofs, it has the capacity to exploit some spurious patterns that can inflate performance. In contrast, our causal framework restricts this capacity by constraining the inputs to each component as described in Section 3.1. Hence, these robustness evaluations demonstrate one of the prime benefits of our causal and modular approach.

5.3 Study on Inference Efficiency

Here we perform several analyses to evaluate the computational benefits of our method as described in Section 3.3. Inference efficiency is an important aspect of this problem for real-world scenarios where compute can be limited.

Relevance of generated inferences Here, we study the relevance of the intermediate inferences generated by FAIRR and ProofWriter ("Iter"). Let T be the set of intermediate inferences required for generating the proof graph for the statement. Further, let G be the set of intermediate inferences actually generated by a model. Then, the precision and recall are defined as $P = \frac{|T \cap G|}{|G|}$, and $R = \frac{|T \cap G|}{|T|}$. In Figure 4, we plot the precision and recall for both FAIRR and ProofWriter ("Iter") with increasing reasoning depths. We find that our model has close to 1.0 precision at all depths, whereas ProofWriter has low precision. This demonstrates that our model is able to successfully prune the candidate inference space to generate relevant candidate inferences almost perfectly. In contrast, we see that with increasing depths, our model's recall reduces from close to 1.0 to $\approx$ 0.95 whereas ProofWriter has a perfect recall at all depths. While the drop is not very drastic, it indicates that our model fails to generate some essential inferences at higher depths. This is mainly because our rule selector decides to stop early and not generate further relevant inferences for some provable statements. Overall, we conclude that FAIRR always generates inferences that are relevant to solving the instance, although at higher depths it can miss some relevant conclusions.

Performance under inference budget constraints We analyze the performance of FAIRR and ProofWriter under a fixed inference budget constraint by restricting the total number of conclusions that can be generated. We perform this analysis for different reasoning depths and depict the results in Figure 5. We observe that FAIRR consistently outperforms ProofWriter on lower budgets. This shows that FAIRR performs a prioritized generation of conclusions that are relevant to the statement, which can be useful in scenarios with limited inference budgets. See Appendix G for more comparisons.



(a) Precision (b) Recall

Figure 4: Comparison of ProofWriter ("Iter") and FAIRR on precision and recall of generated inferences with increasing reasoning depths.

(a) Depth 1 (b) Depth 3

Figure 5: Depth-wise comparison of ProofWriter ("Iter") and FAIRR on limited inference budgets. Please refer to Section 5.3 for details.

Inference runtime analysis We next compare the time taken by both the models to solve the complete D5 dev set. Although FAIRR has three separate modules that run sequentially, it is 3.5 times faster than ProofWriter ("Iter") at inference time on average. We attribute this to the reduced inference candidate search space due to question augmentation, and smaller input size to the T5 component (refer to Section 3.3 for details). Please refer to Appendix H for more details.

5.4 Error Analysis

We further analyze the different errors made by FAIRR and ProofWriter ("Iter") on 50 randomly sampled errors for each model, from the D0-D3 and the subject robustness dev splits. We manually inspect the proof inferences and compare it with the gold proof to classify the failures. The errors are broadly categorized as follows:

Early stop errors: This is the most frequent error type for both models, accounting for 80% and 50% errors in FAIRR and ProofWriter, respectively. This occurs when a model incorrectly gen-

Input	Output
s_1: If someone is blue then they are quiet. s_2: Chris is blue.	Chris is quiet. (s_1, s_2)
s_1: If someone is blue then they are quiet. s_2: Chris is blue. s_3: Steve is blue.	Dave is quiet. (s_1, s_2)
s_1: If someone is blue then they are quiet. s_2: Quiet people are cold. s_3: Chris is blue. s_4: Steve is blue. s_5: Chris is white.	Dave is quiet. (s_1, s_4)

Table 4: Examples of inferences made by ProofWriter. Blue text denotes incrementally added sentences in the theory and red text denotes an error. The $(\cdot)$ is the generated proof. Refer to Section 5.5 for more details.

erates the stop signal and fails to generate all the required inference to prove a statement. We find that our model makes the majority of the mistakes due to early stopping. This can be possibly fixed by improving the rule selector architecture to better model the stop criteria.

Wrong inference: This is the second error type, where the inferred conclusion is incorrect based on the predicted proof. This accounts for 20% and 30% errors in FAIRR and ProofWriter, respectively. We observe that our knowledge composer is makes lesser errors on average compared to the ProofWriter generative model.

Other generation errors: ProofWriter makes around 20% errors where the model generated output does not make sense. For example, it can hallucinate facts that are not present in the theory. Such errors are not interpretable and questions the model's inner-working. FAIRR shows no such error, since the proofs are always interpretable in our model due to the causal framework.

Overall, we find that the errors made by FAIRR are more interpretable than ProofWriter, since we can pin-point which module is at fault. Whereas, in ProofWriter, it is sometimes hard to understand the source of errors. This feature also makes our framework easier to debug to potentially fix some components with techniques like data augmentation. Please refer to Appendix I for more discussion and examples of errors.

5.5 ProofWriter Input Ablation

A key goal of FAIRR is to *explicitly* ensure causality from the rule/facts selection step (proof generation) to the reasoning step (intermediate inference generation). This is essential for a reasoning method using forward chaining to solve a deductive reasoning task [4]. To understand if ProofWriter, which uses forward chaining, implicitly does this "select-then-reason" within the model, we perform the following case study: We sample theories from our subject perturbation dataset where ProofWriter made errors, and manually evaluate the model on inputs with all irrelevant rules/facts deleted. Next we sequentially start adding back the deleted rules/facts to see if the output still remains valid. As shown in Table 4, we see that ProofWriter generates a correct inference for the first row which uses just the essential part of the theory required to generate the conclusion, and starts making errors as more sentences are included. Some more examples are shown in Table 16 in Appendix. This shows that internally ProofWriter is unable to faithfully perform the "select-then-reason" steps for larger theories. In contrast, FAIRR explicitly separates these steps, leading to a faithful reasoning model.

6 Related Works

Reasoning in Text Reasoning in text is a well studied problem in NLP. Natural Language Inference (NLI) (Dagan et al., 2006) is one of the most prominent tasks that require reasoning over text to answer if a statement is entailed, contradicted, or neutral, given a hypothesis. More recently, datasets like HotpotQA (Yang et al., 2018), bAbI (Weston et al., 2016), QuaRTz (Tafjord et al., 2019), ROPES (Lin et al., 2019), CLUTRR (Sinha et al., 2019), etc., have studied different aspects of reasoning over textual inputs. These tasks usually require implicit reasoning, where the model needs to internally infer the rules required to solve the task. In contrast, RuleTaker (Clark et al., 2020) deals with explicit reasoning (also known as deductive reasoning).

Proof Generation Recently, some works have been addressing the problem of proof generation from an NL-based theory. Prover (Saha et al., 2020) trains a RoBERTa-based model that predicts nodes and edges of the proof graph. ProofWriter (Tafjord et al., 2021) is a T5-based (Raffel et al., 2020) model, that iteratively generates one-hop conclusions and proofs from a theory. Another work MultiProver (Saha et al., 2021), generates multiple possible proofs for a statement. While we study the same problem of proof generation similar to these

---

[4] Forward chaining is described as repeated application of *modus ponens* (Hinkelmann, 2004), which requires at least two premises to then logically conclude an inference.

works, we develop a more faithful and robust model designing a modular system for proof generation.

Formal Reasoning There are some prior works that try to solve the problem of entailment prediction by first parsing the formal language from text. Neural Theorem Prover (Rocktäschel and Riedel, 2017; Weber et al., 2019) uses neural networks to parse the formal logic from natural language and then reason over them. While this approach is more symbolic, it can lead to many challenges while parsing (Kamath and Das, 2019). The proof generation setting considered here bypasses this step and directly reasons over the given natural language text making it more useful in downstream applications.

Model Interpretability With the advent of pretrained language models (BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), etc.), there has been an increasing trend on solving various reasoning tasks with high accuracy. Faithfulness of such models (Jacovi and Goldberg, 2020) aims to understand whether the models are actually learning to solve the task or rather depending on some shortcut patterns. Saliency-based explanations (Sundararajan et al., 2017; Lundberg and Lee, 2017; Murdoch et al., 2018; Sanyal and Ren, 2021) mainly focus on identifying the important phrases in the input text that helped the model in solving a task. In contrast, the task of proof generation focuses on generating a deductive chain of reasoning from the given theory to the concluded statement. Thus, proof chains are easier to understand for end users, making it more useful to debug any systematic model errors.

Causal Reasoning The study of causality and causal reasoning models (Pearl, 2000, 2004; Schölkopf, 2019) has been prevalent in machine learning. It has been applied in various domains such as algorithmic fairness (Loftus et al., 2018), gender bias mitigation (Vig et al., 2020), robustness from spurious correlations (Bühlmann, 2020; Veitch et al., 2021), counterfactual explanations (Feder et al., 2021b), etc. Causality in NLP is particularly important to learn models that go beyond exploiting correlations and to improve their overall faithfulness (Feder et al., 2021a).

7 Conclusion

In this paper, we proposed FAIRR, a faithful and robust deductive reasoning model based on three modular components: rule selection, fact selection, and knowledge composition. FAIRR ensures causality from proof generation to entailment prediction by design. We established the effectiveness of our approach through experiments on testing robustness to language variations and demonstrating the interpretability of the errors made by our model. We also show that FAIRR is faster and more precise at deductive reasoning than prior baselines.

Table 5: Statistics of datasets introduced by Tafjord et al., 2021 with the number of theories, questions and conclusions per theory for all three splits of each dataset. The splits are kept the same as the original dataset. Please refer to Appendix A for more details.

A Depth Dataset Details

For training and evaluation of FAIRR and ProofWriter, we use the D* datasets and the ParaRules dataset (Clark et al., 2020). The statistics of these datasets are shown in Table 5 which includes the number of theories, the total number of questions across all theories, and the number of conclusions per theory. The statistics are broken down split wise. We use the same splits of train/dev/test as provided in the original datasets (Clark et al., 2020; Tafjord et al., 2021). All the dataset sources are properly cited and used according to the release license.

B Robustness Dataset Details

The robustness dataset is created by replacing all subjects (attributes, subject+attributes) in the D3 dataset with unseen subjects (attributes, subject+attributes) to create the subject (attribute, subject+attributes) robustness set. For this, we first curate new sets of subjects and attributes to be used as a global pool to sample from while replacing existing subjects and attributes from the theory. These sets are detailed below:

Dataset	Split	Number of Theories	Number of Questions	Number of Conclusions per Theory (min/mean/max)
Subject	train	28896	416328	3/4.81/16
	dev	4314	61812	3/4.73/14
	test	8430	122076	3/4.72/15
Attribute	train	28866	415848	3/4.81/16
	dev	4314	61812	3/4.73/14
	test	8415	121836	3/4.73/15
Subject+Attribute	train	28866	415848	3/4.81/16
	dev	4314	61812	3/4.73/14
	test	8415	121836	3/4.73/15

Table 6: Statistics of datasets introduced in this paper with the number of theories, questions and conclusions per theory for all three splits of each dataset. We use these datasets to quantify the robustness of FAIRR and compare it with baselines. Please refer to Appendix B for more details.

Subject proper name pool: {'George', 'Paul', 'Ronald', 'Emma', 'Magnus', 'Timothy', 'Chris', 'Molly', 'Diana', 'Joseph', 'Becky', 'Kurt', 'Ivan', 'Steve', 'Laura', 'Oliver', 'Adam', 'Larry'}

Subject common name pool: {'mother', 'father', 'baby', 'child', 'toddler', 'teenager', 'grandmother', 'student', 'teacher', 'alligator', 'cricket', 'bird', 'wolf', 'giraffe', 'dinosaur', 'thief', 'soldier', 'officer', 'artist', 'shopkeeper', 'caretaker', 'janitor', 'minister', 'salesman', 'saleswoman', 'runner', 'racer', 'painter', 'dresser', 'shoplifter'}

Attribute pool: {'maroon', 'brown', 'black', 'orange', 'cordial', 'friendly', 'adorable', 'old', 'soft', 'violent', 'intelligent', 'square', 'warm', 'large', 'cylindrical', 'spherical', 'tiny', 'microscopic', 'brilliant', 'noisy', 'playful', 'tender', 'gracious', 'patient', 'funny', 'hilarious', 'thorny', 'sensitive', 'diplomatic', 'thoughtful'}

Then, for each theory in the D3 dataset, we replace *all* the subjects in the theory with randomly sampled subjects (without replacement) from the candidate set to create a perturbed theory. We perform this replacement operation to generate five different perturbed theories. These perturbed theories are called equivalence set. Note that the only change in each theory in an equivalence set is the subjects being replaced by some randomly sampled subjects. For example, "cat" in the original theory might be replaced by "child" in one perturbation, and with "teacher" in yet another perturbation. We follow the same procedure to create attribute and

subject+attribute robustness sets.

The statistics for these robustness datasets are shown in Table 6 which includes the dataset name depicting the perturbation type (subject, attribute or subject+attribute), number of theories, the total number of questions across all theories, and the number of conclusions per theory. Please note that one theory has multiple questions in general, and it is possible to have conclusions that are not a part of these questions, but can be deduced from the given theory. Each split of the original dataset is perturbed separately as described above, to create the new datasets.

C Generalization to Reasoning Depths

In this section, we experiment with a setting where models are trained on depths less than or equal to 3 (i.e., $d \leq 3$) and tested on D5 dataset that contains statements that require reasoning up to depth 5 (i.e., $d \leq 5$). Here, we test the generalization of the models to reasoning depths that are *unseen* at training time. These results are shown in Table 7. From this table, we observe that overall our model performs significantly better than ProofWriter (“All”) on proof accuracy ($+7.5\%$), but has a lower performance compared to ProofWriter (“Iter”) (-3%). This shows that compared to ProofWriter (“Iter”), our models are weaker at generalizing to unseen reasoning depths. This happens majorly because our rule selector tends to stop the inference iterations earlier, which means some essential inferences are not generated by the model. Thus, this leads to lower performance with increasing reasoning depths.

But, we make another interesting observation here. The drops in entailment and proof accuracy with increasing depths are similar for FAIRR. For instance, considering the performance drops between $d = 4$ to $d = 5$, FAIRR has $\sim 9.5\%$ drop in both entailment and proof accuracy. In contrast, ProofWriter (“All”) and ProofWriter (“Iter”) drops approximately 22% and 11%, respectively in proof accuracy for a mere 1% drop in entailment accuracy. This raises some concern on the causality of the proof generation process used for entailment prediction in these models, since it seems like the answer prediction and proof generation are not dependent via the same reasoning paths. In contrast, our causal framework grounds the entailment prediction to the proofs and this leads to more consistent performance variations in FAIRR.

D Robustness to Perturbed Theories

Here, we show the detailed depth-wise performance of FAIRR and ProofWriter (“Iter”) trained on D0-D3 dataset and evaluated on different robustness datasets as described in Section 4. The results for subject, attribute, and subject+attribute

	Entailment Accuracy		**Proof Accuracy**

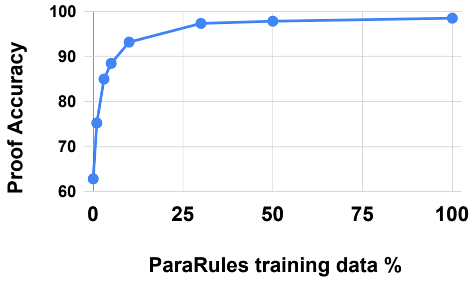

Figure 6: Proof Accuracy of FAIRR when tested on ParaRules while using limited amount of ParaRules along with D0-D3 for training. See Appendix E for more details.

robustness evaluations are shown in Tables 8, 9, and 10, respectively. We observe that ProofWriter ("Iter") performs significantly worse compared to FAIRR on subject robustness. The results on subject+attribute robustness are mostly comparable, while in attribute robustness our model performs worse. The drop in performance show that both the models are sensitive to attributes in the theory to varying degree. But the strong sensitivity of ProofWriter ("Iter") to the subject perturbations is questionable, since the causality of the model's reasoning process seems to be compromised because the model learns some spurious correlations using the subjects.

In another setting, we train different components of our model on the robustness data and check if that leads to some performance gains. These results are reported in Table 11. We find that it is indeed possible to improve the performance of individual components of our model by robust data augmentation. This also indicates that our individual components are flexible to intervention by data augmentation. Such abilities are lacking in ProofWriter.

RS + FS + KC	99.1	98.5	98.7	97.2

Table 11: Comparison of variants of FAIRR where different components (RS, FS, KC) and their combinations are trained and tested on subject robustness datasets. EA and PA refers to entailment accuracy and proof accuracy respectively. Please refer to Appendix D for more details.

	Entailment Accuracy		**Proof Accuracy**	
d	PW ("All") [T5-11B]	FAIRR	PW ("All") [T5-11B]	FAIRR
0	99.9	100.0	99.9	100.0
1	99.3	99.6	99.3	99.6
2	98.3	97.6	97.7	97.4
3	98.2	95.4	96.5	95.1
4	91.5	91.6	83.1	91.6
All	99.1	98.7	98.5	98.6

Table 12: Comparison of FAIRR with ProofWriter ("All") [T5-11B] when trained on D3+ParaRules and tested on ParaRules. Results for ProofWriter ("All") [T5-11B] are copied from the paper. Please refer to Appendix F for more details.

E Generalization to paraphrased theories

Here we test the ability of our model to generalize to unseen language in ParaRules by using limited training supervision. To test this, we first train our model on D0-D3 dataset and test it on the ParaRules dataset. This is a zero-shot evaluation on an unseen language form. In Figure 6 we observe that the performance is significantly worse on this setting as expected. We also evaluated a checkpoint of ProofWriter ("Iter") trained on D0-D3 which achieves a similar performance of 62.13% entailment accuracy [5]. Next, we gradually start adding portions of ParaRules, along with the D0-D3 data, to the training dataset. We find that FAIRR can quickly achieve reasonable performance using even 10% additional data. This shows that our modularized approach is also efficient in adapting to unseen theories with limited data supervision. For more comparisons with models trained on ParaRules, please refer to Appendix F.

---

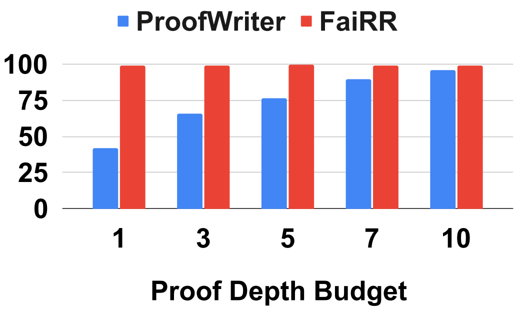
[5] data-augmented training results for ProofWriter are not reported in the figure since the training code is not available

F Results on ParaRules training

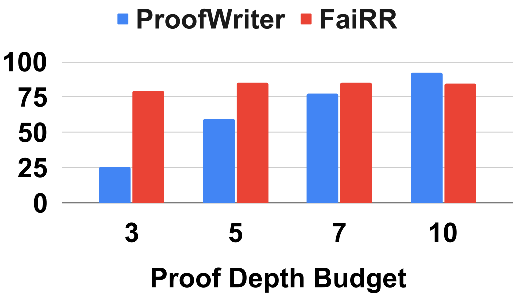
Following (Tafjord et al., 2021), we compare the performance of ProofWriter ("All") and FAIRR on the ParaRules dataset, when trained on a combined partition of D3 and ParaRules train set. The ParaRules dataset contains complex linguistic expressions in the theories that are more realistic than D* dataset theories, making it a more challenging dataset. These results are shown in Table 12, with a reasoning depth breakdown as before. We note that numbers for ProofWriter ("Iter") are not reported in the paper, and no trained checkpoint is available either, so we omit it from our comparisons. Also, the reported results for ProofWriter ("All") are from evaluating a T5-11B model while ours is a T5-large model. Here, we see that our model performs better at higher depths compared to the baseline which demonstrates that FAIRR is better at handling paraphrases.

G Inference Budget Analysis

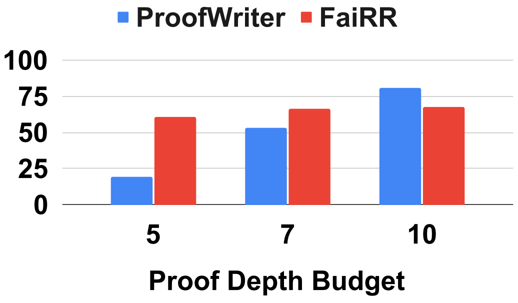
In the inference budget analysis, we compare the performance of FAIRR and ProofWriter under an inference budget constraint, i.e., we restrict the total number of intermediate conclusions that can be produced by both models. We perform this analysis on three different depth datasets ($d = \{1, 3, 5\}$) and upper bound the number of inferences by $B = \{1, 3, 5, 7, 10\}$. We ensure that the budget is at least equal to the depth of the statements under consideration since proving a statement requires a model to generate inferences equal to at least the depth. From Figure 7 we observe that for all depths FAIRR consistently outperforms ProofWriter on lower budgets. Only when the budget increases to 10, ProofWriter compares with or sometimes outperforms our model. This analysis demonstrates that FAIRR performs a prioritized generation of conclusions that are relevant to the statement, which can be useful in scenarios with limited inference budgets.



(a) Depth 1



(b) Depth 3



(c) Depth 5

Figure 7: Depth-wise comparison of ProofWriter ("Iter") and FAIRR (both trained on D0-3 dataset) on limited inference budgets. Please refer to Appendix G for details.

H Runtime Analysis

For inference runtime analysis, we time the evaluation of both FAIRR and ProofWriter ("Iter") on D5 dev set. Note that D5 dataset contains statements that require *at most* five reasoning steps to generate an answer. The runtime for both methods are shown in Table 13. These results were obtained by running the inference algorithm on NVIDIA GeForce RTX 2080 Ti GPUs for both models. We observe that ProofWriter ("Iter") has an almost constant runtime since it always generates all possible inferences for a theory. In contrast, our runtime increases almost linearly with increasing depth. On average, FAIRR is 3.5 times faster at inference than ProofWriter ("Iter").

I Error Analysis

This is a follow-up of Section 5.4, where we delve deeper into the error analysis by discussing different error examples and their potential reasons. First, the stop errors are easy to understand. These are cases where the model just decides to stop in-

d	ProofWriter ("Iter")	FAIRR
0	1.01	0.12
1	1.01	0.20
2	1.00	0.28
3	1.01	0.36
4	1.01	0.46
Avg	1.01	0.28

Table 13: Evaluation runtime (in hours) of FAIRR and ProofWriter ("Iter"). Please refer to Appendix H for more details.

stead of generating any further conclusions. For our model, this can happen if the rule selector is under confident while selecting rules and it learns that a safer fallback is to stop generating rules. This aspect can probably be improved by a better modeling of the rule selector. We plan to explore this in future works.

Next we look at some of the wrong inferences generated by both models in Tables 14 and 15. We observe that errors made by FAIRR are rather naive with small mistakes in the final conclusion (shown in red in Table 15). In contrast, ProofWriter tends to generate an invalid conclusion with no relation to the generated proof (rows 1 and 2 in Table 14). It also makes many non-interpretable generation errors where the model's output format is completely violated or the model seems to hallucinate some facts (rows 3-6 in Table 14). Thus, we observe the benefit of our causal framework as the errors are interpretable and more believable. In contrast, errors made by ProofWriter clearly show that its inference reasoning process can often not rely on the proof at or, or even the generated proof sometimes doesn't make sense.

J Comparison with Baselines

In this work we compare FAIRR with baselines introduced by (Tafjord et al., 2021). We omit comparisons with both PRover (Saha et al., 2020) and multiPRover (Saha et al., 2021), since they were trained on a different dataset that makes a closed-world assumption (CWA), whereas we use datasets that make an open-world assumption (OWA). One essential difference between these two datasets are that OWA allows for predicting the truth values as one of {True,False,Unknown} while in CWA, any fact that cannot be deduced from the theory is assumed to be false. As a result, in CWA, there are only two possible truth values {True,False} for a given statement. This CWA assumption also leads to a specific constraint in the generated proof graphs, where special NAF nodes need to be considered. Please refer to Saha et al. (2020) for more details on this. Additionally, multiPRover (Saha et al., 2021) has a goal that is different from ours. Specifically, their focus is on generating multiple possible proofs for a given rulebase, and for this their training examples contain multiple gold proofs per instance. In FAIRR and ProofWriter (Tafjord et al., 2021), only one gold proof needs to be generated, making the comparisons a bit unfair. Following Tafjord et al. (2021), we report single run numbers for every experiment.

K Hyperparameters

We use RoBERTa-large models (Liu et al., 2019) to model the rule selector and fact selector in FAIRR. For selecting the best hyperparameters for both these components, we selected the max training epochs in: $\{10, 15, 20\}$, warmup updates in: $\{0.05, 0.1\}$, weight decay in: $\{0.1, 0.01, 0.001\}$, learning rate in: $\{3e\text{-}6, 5e\text{-}6, 1e\text{-}6\}$, and batch size in $\{16, 32\}$.

We use T5 (Raffel et al., 2020) (T5-large) to model the knowledge composer in FAIRR and train it using the default hyperparameters available in the Hugging Face transformers library (Wolf et al., 2020). All models were trained on Nvidia Quadro RTX 8000 GPUs. Training a FAIRR on a single GPU takes around 20 hours on average.

Abstract

Tables are often created with hierarchies, but existing works on table reasoning mainly focus on flat tables and neglect hierarchical tables. Hierarchical tables challenge table reasoning by complex hierarchical indexing, as well as implicit relationships of calculation and semantics. We present a new dataset, HiTab, to study question answering (QA) and natural language generation (NLG) over hierarchical tables. HiTab is a cross-domain dataset constructed from a wealth of statistical reports and Wikipedia pages, and has unique characteristics: (1) nearly all tables are hierarchical, and (2) questions are not proposed by annotators from scratch, but are revised from real and meaningful sentences authored by analysts. (3) To reveal complex numerical reasoning in analysis, we provide fine-grained annotations of quantity and entity alignment. Experimental results show that HiTab presents a strong challenge for existing baselines and a valuable benchmark for future research. Targeting hierarchical structure, we devise an effective hierarchy-aware logical form for symbolic reasoning over tables. Furthermore, we leverage entity and quantity alignment to explore partially supervised training in QA and conditional generation in NLG, which largely reduces spurious predictions in QA and meaningless descriptions in NLG. The dataset and code are available at `https://github.com/microsoft/HiTab`.

1 Introduction

In recent years, there are a flurry of works on reasoning over semi-structured tables, e.g., answering questions over tables (Yu *et al.*, 2018; Pasupat and Liang, 2015) and generating fluent and faithful text from tables (Lebret *et al.*, 2016; Parikh *et al.*, 2020). But they mainly focus on simple flat tables and neglect complex tables, e.g., hierarchical tables. A table is regarded as hierarchical if its header exhibits a multi-level structure (Lim and Ng, 1999; Chen and Cafarella, 2014; Wang *et al.*, 2020). Hierarchical tables are widely used, especially in data products, statistical reports, and research papers in government, finance, and science-related domains.

- Teaching assistantships were most commonly reported as the primary mechanism of support for master's students (11%).

Figure 1: A hierarchical table and accompanied descriptions in a National Science Foundation report.[1]

Hierarchical tables challenge QA and NLG due to: **(1) Hierarchical indexing.** Hierarchical headers, such as D2:G3 and A4:A25 in Figure 1, are informative and intuitive for readers, but make cell selection much more compositional than flat tables, requiring multi-level and bi-dimensional indexing. For example, to select the cell E5 ("66.6"), one needs to specify two top header cells, "Master's" and "Percent", and two left header cells, "All full-time" and "Self-support". **(2) Implicit calculation relationships among quantities.** In hierarchical tables, it is common to insert aggregated rows and columns without explicit indications, e.g., total (columns B,D,F and rows 4,6,7,20) and proportion (columns C,E,G), which challenge precise numeri-

cal inference. **(3) Implicit semantic relationships among entities.** There are various cross-row, cross-column, and cross-level entity relationships, but lack explicit indications, e.g., "source" and "mechanism" in A2 describe A6:A19 and A20:A25 respectively, and D2 ("Master's") and F2 ("Doctoral") can be jointly described by a virtual entity, "Degree". How to identify semantic relationships and link entities correctly is also a challenge.

In this paper, we aim to build a dataset for hierarchical table QA and NLG. But without sufficient data analysts, it's hard to ensure questions and descriptions are meaningful and diverse (Gururangan *et al.*, 2018; Poliak *et al.*, 2018). Fortunately, large amounts of statistical reports are public from a variety of organizations (StatCan; NSF; Census; CDC; BLS; IMF), containing rich hierarchical tables and textual descriptions. Take Statistics Canada (StatCan) for example, it consists of $6,039$ reports in 27 domains authored by over 1,000 professionals. Importantly, since both tables and sentences are authored by domain experts, sentences are natural and reflective of real understandings of tables.

To this end, we propose a new dataset, HiTab, for QA and NLG on hierarchical tables. **(1)** All sentence descriptions of hierarchical tables are carefully extracted and revised by human annotators. **(2)** It shows that annotations of fine-grained and lexical-level entity linking significantly help table QA (Lei *et al.*, 2020; Shi *et al.*, 2020), motivating us to align entities in text with table cells. In addition to entity, we believe aligning quantities (Ibrahim *et al.*, 2019), especially composite quantities (computed by multiple cells), is also important for table reasoning, so we annotate underlying numerical relationships between quantities in text and table cells, as Table 1 shows. **(3)** Since real sentences in statistical reports are natural, diverse, and reflective of real understandings of tables, we devise a process to construct QA pairs based on existing sentence descriptions instead of asking annotators to propose questions from scratch.

HiTab presents a strong challenge to state-of-the-art baselines. For the QA task, MAPO (Liang *et al.*, 2018) only achieves 29.2% accuracy due to the ineffectiveness of the logical form customized for flat tables. To leverage the hierarchy for table reasoning, we devise a hierarchy-aware logical form for table QA, which shows high effectiveness. We propose partially supervised training given annotations of linked mentions and formulas, which helps models to largely reduce spurious predictions and achieve 45.1% accuracy. For the NLG task, models also have difficulties in understanding deep hierarchies and generate complex analytical texts. We explore controlled generation (Parikh *et al.*, 2020), showing that conditioning on both aligned cells and calculation types helps models to generate meaningful texts.

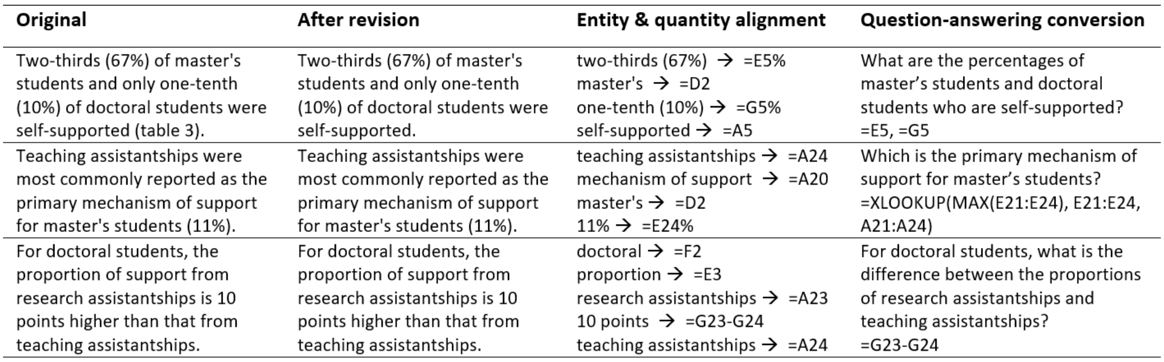
2 Dataset Construction and Analysis

We design an annotation process with six steps. To well-handle the annotation complexity, we recruit 18 students or graduates (13 females and 5 males) in computer science, finance, and English majors from top universities, and provide them with comprehensive online training, documents, and QAs. The annotation totally costs 2,400 working hours. We will discuss the ethical considerations in Section 8.

2.1 Hierarchical Table Collection

We select two representative organizations, Statistics Canada (StatCan) and National Science Foundation (NSF), that are rich of statistical reports. Different from Census; CDC; BLS; IMF that only provide PDF reports where table hierarchies are hard to extract precisely (Schreiber *et al.*, 2017), StaCan and NSF also provide reports in HTML, from which cell information such as text and formats can be extracted precisely using HTML tags.

First, we crawl English HTML statistical reports published in recent five years from StatCan ($1,083$ reports in 27 well-categorized domains) and NSF (208 reports from 11 organizations in science foundation domain). We merge StatCan and NSF and get the combination of various domains. In addition, ToTTo contains a small proportion (5.03%) of hierarchical tables, so we include them to cover more domains from Wikipedia. To keep the balance between statistical reports and Wikipedia pages, we include random $1,851$ tables (50% of our dataset) from ToTTo. Next, we transform HTML tables to spreadsheet tables using a preprocessing script. Since spreadsheet formula is easy to write, execute, and check, the spreadsheet is naturally a great annotation tool to align quantities and answer questions. To enable correct formula execution, we normalize quantities in data cells by excluding surrounding superscripts, internal commas, etc. Extremely small or large tables are filtered out (Appendix A.1 gives more details).



Original	After revision	Entity & quantity alignment	Question-answering conversion
Two-thirds (67%) of master's students and only one-tenth (10%) of doctoral students were self-supported (table 3).	Two-thirds (67%) of master's students and only one-tenth (10%) of doctoral students were self-supported.	two-thirds (67%) → =E5% master's → =D2 one-tenth (10%) → =G5% self-supported → =A5	What are the percentages of master's students and doctoral students who are self-supported? =E5, =G5
Teaching assistantships were most commonly reported as the primary mechanism of support for master's students (11%).	Teaching assistantships were most commonly reported as the primary mechanism of support for master's students (11%).	teaching assistantships → =A24 mechanism of support → =A20 master's → =D2 11% → =E24%	Which is the primary mechanism of support for master's students? =XLOOKUP(MAX(E21:E24), E21:E24, A21:A24)
For doctoral students, the proportion of support from research assistantships is 10 points higher than that from teaching assistantships.	For doctoral students, the proportion of support from research assistantships is 10 points higher than that from teaching assistantships.	doctoral → =F2 proportion → =E3 research assistantships → =A23 10 points → =G23-G24 teaching assistantships → =A24	For doctoral students, what is the difference between the proportions of research assistantships and teaching assistantships? =G23-G24

Table 1: Examples of the annotation process. All sentences describe the table in Figure 1.

2.2 Sentence Extraction and Revision

In this step, annotators manually go through statistical reports and extract sentence descriptions for each table. Sentences consisting of multiple semantic-independent sub-sentences will be carefully split into multiple ones. Annotators are instructed to eliminate redundancy and ambiguity in sentences through revisions including decontextualization and phrase deletion (Parikh *et al.*, 2020). Fortunately, most sentences in statistical reports are clean and fully supported by table data, so few revisions are needed to get high-quality text.

Operators	Formula template (ranges are placeholders)
opposite, percent	=-A5, =B2%
kth-argmax/argmin	=XLOOKUP(SMALL(D1:D3, k), D1:D3, A1:A3).
pair-argmax/argmin	=IF(B1>B2, A1, A2)[2]
sum, average	=SUM(D2:D4), =AVERAGE(D2:D4)
max, count	=MAX(D2:D4), =COUNT(D2:D4)
diff, div	=D3-D4, =D3/D4

Table 2: Example operators and formula templates.

2.3 Entity and Quantity Alignment

In this phase, annotators are instructed to align mentions in text with corresponding cells in tables. It has two parts, entity alignment and quantity alignment, as shown in Table 1. For entity alignment, we record the mappings from entity mentions in text to corresponding cells. Single-cell quantity mentions can be linked similar with entity mentions, but composite quantity mentions are calculated from two or more cells through operators like *max/sum/div/diff* (Table 2). The spreadsheet formula is powerful and easy-to-use for tabular data calculation, so we use the formula to record the calculations process of composite quantities in text, e.g., '10 points higher' (=*G23-G24*). Although quantities are often rounded in descriptions, we neglect rounding and refer to precise quantities in table cells.

2.4 Converting Sentences to QA Pairs

Existing QA datasets instruct annotators to propose questions from scratch, but it's hard to guarantee the meaningfulness and diversity of proposed questions. In HiTab, we simply revise declarative sentences into QA pairs. For each sentence, annotators need to identify a target key part to question about (according to the underlying logic), then convert it to the QA form. All questions are answered by formulas that reflect the numerical inference process. For example, the 'XLOOKUP' operator is frequently used to retrieve the header cells of superlatives, as shown in Table 1. To keep sentences as natural as they are, we do not encourage unnecessary sentence modification during the conversion. If an annotator finds multiple ways to question regarding a sentence, he/she only needs to choose one way that best reflects the overall meaning.

2.5 Regular Inspections and the Final Review

We ask the two most experienced annotators to perform regular inspections and the final review. (1) In the labeling process, they regularly sample annotations (about 10%) from all annotators to give timely feedback on labeling issues. (2) Finally, they review all annotations and fix labeling errors. Also, to assist the final review, we write a script to automatically identify spelling issues and formula issues. To double-check the labeling quality before the final review, we study the agreement of annotators by collecting and comparing annotations on randomly sampled 50 tables from two annotators. It shows 0.89 and 0.82 for quantity and entity alignment in Fleiss Kappa respectively, which are regarded as "almost perfect agreement" (Landis and Koch, 1977), and 64.5 in BLEU-4 after sentence revision, which also indicates high agreement. We further show annotation artifacts are substantially avoided

---

[2] For samples with XLOOKUP or IF formulas, we didn't explicitly provide the formulas in dataset because some reasoning logics are still too complex to be covered by them, e.g., the candidate cells are not on a continuous row/column. Instead, we manually check the answer cell(s) and provide the answer cell reference(s) for these samples.

in our dataset in Appendix A.2.

2.6 Hierarchy Extraction

We follow existing work (Lim and Ng, 1999; Chen and Cafarella, 2014; Wang *et al.*, 2020) and use the tree structure to model hierarchical headers. Since cell formats such as merging, indentation, and font bold, are commonly used to present hierarchies, we adapt heuristics in (Wang *et al.*, 2020) to extract top and left hierarchical trees, which has high accuracy. We go through 100 randomly sampled tables in HiTab, 94% of them are precisely extracted. Figure 8 in Appendix shows an illustration.

2.7 Dataset Statistics and Comparison

Table 3 shows a comprehensive comparison of related datasets. HiTab is not among the largest ones, but **(1)** it is the first dataset to study QA and NLG over hierarchical tables (accounting for 98.1% tables in HiTab) in-depth; **(2)** it is annotated with fine-grained entity and quantity alignment; **(3)** compared with TAT-QA, FinQA, and NumericNLG that are single-domain, HiTab has a wide coverage of different domains from statistical reports and Wikipedia, even wider than ToTTo or WTQ that only involves Wikipedia tables; **(4)** the number of real descriptions per table (5.0) in statistical reports (HiTab) is much richer than 1.4 in Wikipedia (ToTTo) and 3.8 in scientific papers, contributing more analytical aspects per table.

Figure 2 analyzes this dataset by domains and operations: domains are diverse, covering 28 domains from statistical reports (fully listed in Appendix A.3) and other open domains from Wikipedia; a large proportion of questions involves complex cell selection and numerical operations.

3 Hierarchical Table QA

Table QA is essential for table understanding, document retrieval, ad-hoc search, *etc*. Hierarchical tables are quite common in these scenarios like in webpages and reports, while current Table QA tasks and methods focus on simple flat tables.

Problem Statement Hierarchical Table QA is defined as follows: given a hierarchical table t and a question x in natural language, output answer y. The question-answer pair should be fully supported by the table. Our dataset $D = \{(x_i, t_i, y_i)\}, i \in [1, N]$ is a set of N question-table-answer triples.

Table QA is usually formulated as a semantic parsing problem (Pasupat and Liang, 2015; Liang *et al.*, 2017), where a parser converts the question into logical form, and an executor executes it to produce the answer. However, existing logical forms for Table QA (Pasupat and Liang, 2015; Liang *et al.*, 2017; Yin *et al.*, 2020) are customized for flat or database tables. The three challenges mentioned in Section 1 (hierarchical indexing, implicit indexing relationships, and implicit semantic relationships) make QA more difficult on hierarchical tables.

3.1 Hierarchy-aware Logical Forms

To this end, we propose a hierarchy-aware logical form that exploits table hierarchies to mitigate these challenges. Specifically, we define *region* as the operating object, and propose two functions for hierarchical region selection.

Definitions Given tree hierarchies of tables extracted in Section 2.6, we define *header* as a header cell (e.g., A7("Federal") in Figure 1), and *level* as a level in the left/top tree (e.g., A5,A6,A20 are on the same level). Existing logical forms on tables treat rows as operating objects and columns as attributes, and thus can not perform arithmetic operations on cells in the same row. However, a row in hierarchical tables is not necessarily a subject or record, thus operations can be applied on cells in the same row. Motivated by this, we define *region* as our operating object, which is a data region in table indexed by both left and top headers (e.g., B6:C19 is a rectangular region indexed by A6,B2). The logical form execution process is divided into two phases: region selection and region operation.

Region Selection We design two functions $(filter\_tree\ h)$ and $(filter\_level\ l)$ to do region selection, where h is a header, l is a level. Functions can be applied sequentially: the subsequent function applies on the return region of the previous function. $(filter\_tree\ h)$ selects a sub-tree region according to a header cell h: if h is a leaf header (e.g., A8), the selected region should be the row/column indexed by h (row 8); if h is a non-leaf header (e.g., A7), the selected region should be the rows/columns indexed by both h and its children headers (row 7-16). $(filter\_level\ l)$ selects a sub-tree from the input tree according to a level l and return the sub-region indexed by headers on level l. These two functions mitigate aforementioned three challenges: (1) hierarchical indexing is achieved by applying these two functions sequentially; (2) with $filter\_level$, data with different calculation types (e.g., rows 4-5) will not be co-selected, thus not incorrectly operated together; (3) level-wise semantics can be captured by aggregating header cell semantics (e.g., embeddings) on this level. Some logical form execution examples are shown in Appendix C.2.

Region Operation Operators are applied on the selected region to produce the answer. We define 19 operators, mostly following MAPO (Liang *et al.*, 2018), and further include some operators (e.g., *difference rate*) for hierarchical tables. Complete logical form functions are shown in Appendix C.1.

3.2 Experimental Setup

3.2.1 Baselines

We present baselines in two branches. One is logical form-based semantic parsing, and the other is end-to-end table parsing without logical forms.

Neural Symbolic Machine (Liang *et al.*, 2017) is a powerful semantic parsing framework consisting of a programmer to generate programs from NL and save intermediate results, and a computer to execute programs. We replace the LSTM encoder with BERT (Devlin *et al.*, 2018), and implement a lisp interpreter for our logical forms as executor. Table is linearized by placing headers in level order, which is shown in detail in Appendix C.4.

TaPas (Herzig *et al.*, 2020) is a state-of-the-art end-to-end table parsing model without generating logical forms. Its power to select cells and reason over tables is gained from its pretraining on millions of tables. To fit TaPas input, we convert hierarchical tables into flat ones following WTQ (Pasupat and Liang, 2015). Specifically, we unmerge the cells spanning many rows/columns on left/top headers and duplicate the contents into unmerged cells. The first top header row is specified as column names.

3.2.2 Weak Supervision

In weak supervision, the model is trained with QA pairs, without golden logical forms. For NSM, we compare three widely-studied learning paradigms:

MML (Dempster *et al.*, 1977) maximizes the marginal likelihood of observed programs. **REINFORCE** (Williams, 1992) maximizes the reward of on-policy samples. **MAPO** (Liang *et al.*, 2018) learns from programs both inside and outside buffer, and samples efficiently by systematic exploration.

Since these methods require consistent programs for learning or warm start, we randomly search $15,000$ programs per sample before training. The pruning rules are shown in Appendix C.3. Finally, 6.12 consistent programs are found per sample.

For TaPas, we use the pre-trained version and follow its weak supervised training process on WTQ.

3.2.3 Partial Supervision

Given labeled entity links, quantity links, and calculations (from the formula), we further explore to guide training in a *partially supervised* way. These three annotations indicate selected headers, region, and operators in QA[3]. For NSM, we exploit them to prune spurious programs, *i.e.*, incorrect programs that accidentally produce correct answers, in two ways. (1) When searching consistent programs, besides producing correct answers, programs are required to satisfy at least two constraints. In this way, the average consistent programs reduces from 6.12 to 2.13 per sample. (2) When training, satisfying each condition will add 0.2 to the original

---

[3] Entity and quantity alignments in text also occur in the question in most cases. In QA, we apply a simple n-gram matching algorithm to filter out the alignments not in questions.

Weak Supervision			
Method	**Dev**	**Test**	**%Spurious**
MAPO $w.$ original logical form	31.9	29.2	-
TaPas $w/o.$ logical form	39.7	38.9	-
MML $w.$ h.a. logical form	38.9	36.7	22.7
REINFORCE $w.$ h.a. logical form	42.7	38.4	39.3
MAPO $w.$ h.a. logical form	**43.5**	**40.7**	**19.0**
Partial Supervision			
TaPas $w/o.$ logical form	41.2	40.1	-
MML $w.$ h.a. logical form	**45.4**	**45.1**	**10.3**
REINFORCE $w.$ h.a. logical form	44.0	39.7	23.9
MAPO $w.$ h.a. logical form	44.8	44.3	10.7

Table 4: QA execution accuracy (*EA*) on dev/test and spurious program rate of 150 samples on dev. *h.a.* stands for *hierarchy-aware*.

binary 0/1 reward. Sampled programs with reward $r \geq 1.4$ are added to the program buffer.

For TaPas, we additionally provide answer coordinates and calculation types in training following its WikiSQL setting.

3.2.4 Evaluation Metrics

We use *Execution Accuracy* (*EA*) as our metric following (Pasupat and Liang, 2015), measuring the percentage of samples with correct answers. We also report *Spurious Program Rate* to study the percentage that incorrect logical forms produce correct answer. Since we do not have golden logical forms, we manually annotate logical forms for 150 random samples in dev set for evaluation.

3.2.5 Implementations

We split $3,597$ tables into train (70%), dev (15%) and test (15%) with no overlap. We download pre-trained models from huggingface [4]. For NSM, we utilize 'bert-base-uncased', and fine-tune 20K steps on HiTab. Beam size is 5 for both training and inference. To test MAPO original logical form, we convert flatten tables as we do for TaPas. For TaPas, we adopt the PyTorch (Paszke *et al.*, 2019) version in huggingface. We utilize 'tapas-base', and fine-tune 40 epochs on HiTab. All experiments are conducted on a server with four V100 GPUs.

3.3 Results

Table 4 summarizes our evaluation results.

Weak Supervision First, MAPO with our hierarchy-aware logical form outperforms that using its original logical form by a large margin 11.5%, indicating the necessity of designing a logical form leveraging hierarchies. Second, MAPO achieves the best *EA* (40.7%) with the lowest spurious rate (19%). But >50% questions are answered incorrectly, proving QA on HiTab is challenging. Third, though TaPas benefits from pretraining on tables, it performs worse than the best logical form-based method without table pretraining.

Partial Supervision From Table 4, we can conclude the effectiveness of partial supervision in two aspects. First, it improves *EA*. The model learns how to deal with more cases given high-quality programs. Second, it largely lowers *%Spurious*. The model learns to generate correct programs instead of some tricks. MML, whose performance highly depends on the quality of searched programs, benefits the most (36.7% to 45.1%), indicating partial supervision improves the quality of consistent programs by pruning spurious ones. However, TaPas does not gain much improvements from partial supervision, which we will discuss in the next paragraph.

Error Analysis For TaPas, 98.7% of success cases are cell selections, which means TaPas benefits little from partial supervision. This may be caused by: (1) TaPas does not support some common operators on hierarchical table like *difference*; (2) the coarse-to-fine cell selection strategy first selects columns then cells, but cells in different columns may also aggregate in hierarchical tables.

For MAPO under partial supervision, we analyze 100 error cases. Error cases fall into four categories: (1) entity missing (23%): the header to *filter* is not mentioned in question, where a common case is omitted *Total*; model failure, including (2) failing to select correct regions (38%) and (3) failing to generate correct operations (20%); (4) out of coverage (19%): question types unsolvable with the logical form, which is explained in Appendix C.1.

Spurious programs occur mostly in two patterns. In cell selection, there may exist multiple data cells with correct answers (e.g., G9,G16 in Figure 1), while only one is golden. In superlatives, the model can produce the target answer by operating on different regions (e.g., in both region B21:B25 and B23:B25, B23 is the largest).

Level-wise Analysis In Figure 3, we present level-wise accuracy of HiTab QA with MAPO and our hierarchy-aware logical form. *Level* here stands for sum of left and top header levels. As shown, the QA accuracy degrades when table level increases as table structure becomes more complex, except for level $= 2$, *i.e.,* tables with no hierarchies. The reason level $= 2$ performs relatively worse might be that only 1.9% tables without hierarchies are seen in HiTab. We also present an annotated table

---

example from our dataset to illustrate in detail the challenges mentioned in Section 1 that hierarchical tables bring in Appendix C.5.

4 Hierarchical Table-to-Text

4.1 Problem Statement

Some works formulate table-to-text as a summarization problem (Lebret *et al.*, 2016; Wiseman *et al.*, 2017). However, since a full table often contains quite rich information, there lack explicit signals on what to generate, which renders the task unconstrained and the evaluation difficult. On the other hand, some recent works propose *controlled* generation to enable more specific and logical generation: (1) LogicNLG generates a sentence conditioned on a logical form guiding symbolic operations over given cells, but writing correct logical forms as conditions is challenging for common users who are more experienced to write natural language directly, thus restricting the application to real scenario; (2) ToTTo generates a sentence given a table with a set of highlighted cells. In ToTTo's formulation, the condition of cell selection is much easier to specify than the logical form, but it neglects symbolic operations which are critical for generating some analytical sentences involving numerical reasoning in HiTab.

We place HiTab as a middle-ground of ToTTo and LogicNLG to make the task more controllable than ToTTo and closer to real application than LogicNLG. In our setting, given a table, the model generates a sentence conditioned on a group of selected cells (similar to ToTTo) and operators (much easier to be specified than logical forms). Although we use two strong conditions to guide symbolic operations over cells, there still leaves a considerable amount of content planning to be done by the model, such as retrieving contextual cells in a hierarchical table given selected cells, identifying how operators are applied on given cells, and composing sentences in a faithful and logical manner.

We now define our task as: given a hierarchical table T, highlighted cells C, and specified operators O, the goal is to generate a faithful description S. The dataset $H = (T_i, S_i), i \in [1, N]$ is a set of N table-description instances. Description S_i is a sentence about a table T_i and involves a series of operations $O_i = [O_{i1}, O_{i2}, \ldots, O_{in}]$ on certain table cells $C_i = [c_{i1}, c_{i2}, \ldots, c_{im}]$.

4.2 Controlled Generation

4.2.1 With Highlighted Cells

An entity or quantity in text can be supported by table cells if it is directly stated in cell contents, or can be logically inferred by them. Different from only taking data cells as highlighted cells (Parikh *et al.*, 2020), we also take header cells as highlighted cells, and it is usually the case for superlative ARG-type operations on a specific header level in hierarchical tables, e.g., "Teaching assistantships" is retrieved by ARGMAX in Figure 1. In our dataset, highlighted cells are extracted from annotations of the entity and quantity alignment.

4.2.2 With Operators

Highlighted cells can tell the target for text generation, but is not sufficient, especially for analytical descriptions involving cell operations in HiTab. So we propose to use operators as extra control. It contributes to text clarity and meaningfulness in two ways. (1) It clarifies the numerical reasoning intent on cells. For example, given the same set of data cells, applying SUM, AVERAGE, or COUNT conveys different meanings thus should yield different texts. (2) Operation results on highlighted cells can be used as additional input sources. Existing seq2seq models are not powerful enough to do arithmetic operations (Thawani *et al.*, 2021), e.g., adding up a group of numbers, and it greatly limits their ability to generate correct numbers in sentences. Explicitly pre-computing the calculation results is a promising alternative way to mitigate this gap in seq2seq models. Operators are extracted from annotations of formulas shown in Table 2.

4.2.3 Sub Table Selection and Serialization

Sub Table Selection Under controls of selected cells and operators, we devise a heuristic to retrieve all contextual cells as a sub table. (1) We start with highlighted cells extracted from our entity and quantity alignment, then use the extracted table hierarchy to group the selected cells into the top header, the left header, and the data region. (2) Based on the extracted table hierarchy, we use the source set of top and left header cells to include their indexed data cells, and we also use the source set of data cells to include corresponding header cells. (3) We also include their parent header cells in table hierarchy to construct a full set of headers. In the end, we take the union of of them as the result of sub table selection.

Serialization On each sub table, we do a row-turn traversal on linked cells and concatenate their cell strings using [SEP] tokens. Operator tokens and calculation results are also concatenated with the input sequence. We also experimented with other serialization methods, such as header-data pairing or template-based method, yet none reported superiority over the simple concatenation. Appendix B.1 gives an illustration.

4.3 Experiments

We conduct experiments by fine-tuning four state-of-the-art text generation methods on HiTab.

Pointer Generator (See *et al.*, 2017) A LSTM-based seq2seq model with copy mechanism. While originally designed for text summarization, it is also used in data-to-text (Gehrmann *et al.*, 2018).

BERT-to-BERT (Rothe *et al.*, 2020) A transformer encoder-decoder model (Vaswani *et al.*, 2017) initialized with BERT (Devlin *et al.*, 2018).

BART (Lewis *et al.*, 2019) A pre-trained denoising autoencoder with standard Transformer-based architecture and shows effectiveness in NLG.

T5 (Raffel *et al.*, 2019) A transformer-based pre-trained model. It converts all textual language problems into text-to-text and proves to be effective.

4.3.1 Evaluation Metrics

We use two automatic metrics, BLEU and PARENT. BLEU (Papineni *et al.*, 2002) is broadly used to evaluate text generation. PARENT (Dhingra *et al.*, 2019) is proposed specifically for data-to-text evaluation that additionally aligns n-grams from the reference and generated texts to the source table.

4.3.2 Experiment Setup

Samples are split into train (70%), dev (15%), and test (15%) sets just the same as the QA task. The maximum length of input/output sequence is set to 512/64. Implementation details of all baselines are given in Appendix B.2.

Model	Cell Highlight		Cell & Calculation	
	BLEU-4	PARENT	BLEU-4	PARENT
Pointer-Generator	5.8	8.8	9.0	10.8
BERT-to-BERT	11.4	16.7	11.7	15.4
BART	17.9	28.0	23.8	31.4
T5	**19.5**	**35.7**	**26.6**	**36.9**

Table 5: Results of hierarchical table-to-text.

4.3.3 Experiment Result and Analysis

As shown in Table 5, **first**, from an overall point of view, both metrics are not scored high. This well proves the difficulty of HiTab. It could be caused by the hierarchical structure, as well as statements with logical and numerical complexity. **Second**, by comparing two controlled scenarios (cell highlights & both cell highlights and operators), we see that adding operators to conditions greatly help models to generate descriptions with higher scores, showing the effectiveness of our augmented conditional generation setting. **Third**, results on two controlled scenarios across baselines are quite consistent. Replacing the traditional LSTM with transformers shows large increasing. Leveraging seq2seq-like pretraining yields a rise of +6.5 BLEU and +11.3 PARENT. Lastly, between pretrained transformers, T5 reports higher scores over BART, probably for T5 is more extensively tuned during pre-training.

Further, to study the generation difficulty concerning **table hierarchy**, we respectively evaluate samples at different hierarchical depths, *i.e.*, table's maximum depths in top and left header trees. In groups of 2, 3, 4+ depth, BLEU scores 31.7, 26.5, and 21.3; PARENT scores 40.9, 36.5, and 31.6. The reason could be that, as the table header hierarchy grows deeper, the data indexing becomes increasingly compositional, rendering it harder to baseline models to configure entity relationships and compose logical sentences.

5 Related Work

Table-to-Text Existing datasets are restricted in flat tables or specific subjects (Liang *et al.*, 2009; Chen and Mooney, 2008; Wiseman *et al.*, 2017; Novikova *et al.*, 2016; Banik *et al.*, 2013; Lebret *et al.*, 2016; Moosavi *et al.*, 2021). The most related table-to-text dataset to HiTab is ToTTo (Parikh *et al.*, 2020), in which complex tables are also included. There are two main differences between HiTab and ToTTo: (1) in ToTTo, hierarchical tables only account for a small proportion (5%), and there are no indication and usage of table hierarchies. (2) in addition to cell highlights, Hitab conditions on

Table 6: Results of cross-domain evaluation.

operators that reflect symbolic operations on cells.

Table QA mainly focuses on DB tables (Wang *et al.*, 2015; Yu *et al.*, 2018; Zhong *et al.*, 2017) and flat web tables (Pasupat and Liang, 2015; Sun *et al.*, 2016). Recently, there are some datasets on domain-specific table QA (Chen *et al.*, 2021; Zhu *et al.*, 2021) and jointly QA over tables and texts (Chen *et al.*, 2020b; Zhu *et al.*, 2021), but hierarchical tables still have not been studied in depth. CFGNN (Zhang, 2020) and GraSSLM (Zhang *et al.*, 2020) uses gragh neural networks to encode tables for QA, but all tables are database tables and relational web tables without hierarchies, respectively. Wang *et al.* (2021) include some hierarchical tables but only focuses on table search.

6 Discussion

HiTab also presents cross-domain and complicated-calculation challenges. (1) To explore cross-domain generalizability, we randomly split train/dev/test by domains for three times and present the average results of our best methods in Table 6. We found decreases in all metrics in QA and NLG. (2) Figure 4 shows a case that challenges existing methods: performing complicated calculations requires to jointly consider quantity relationships, header semantics, and hierarchies.

7 Conclusion

We present a new dataset, HiTab, that simultaneously supports QA and NLG on hierarchical tables, where tables are collected from statistical reports and Wikipedia in various domains. Importantly, we provide fine-grained annotations on entity and quantity alignment. In experiments, we introduce strong baselines and conduct detailed analysis on QA and NLG tasks on HiTab. Results suggest that HiTab can serve as a challenging and valuable benchmark for future research on complex tables.

8 Ethical Considerations

This work presents HiTab, a free and open English dataset for the research community to study table question-answering and table-to-text over hierarchical tables. Our dataset contains well-processed tables, annotations (QA pairs, target text, and bidirectionally mappings between entities and quantities in text and the corresponding cells in table), recognized table hierarchies, and source code. Data in HiTab are collected from two public organizations, StatCan and NSF. Both of them allow sharing and redistribution of their public reports, so there is no privacy issue. We collect tables and accompanied descriptive sentences from StatCan and NSF. We also include hierarchical tables in Wikipedia from ToTTo, which is a public dataset under MIT license, so there is no risk to use it. And in the labeling process, annotators need to check if there exist any names or uniquely identifies individual people or offensive content. They did not find any such sensitive information in our dataset. We recruit 18 students or graduates in computer science, finance, and English majors from top universities(13 females and 5 males). Each student is paid \$7.8 per hour (above the average local payment of similar jobs), totally spending 2,400 hours. We finally get 3,597 tables and 10,672 well-annotated sentences. And the data got approval from an ethics review board by an anonymous IT company. The details for our data collection and characteristics are introduced in Section 2.

A More Details on Dataset

A.1 Dataset Preprocessing

We filter tables using these constraints: (1) number of rows and columns are more than 2 and less than 64; (2) cell strings have no more than one non-ASCII character and 20 tokens; (3) hierarchies are successfully parsed via the method in 2.6. (4) hierarchies have no more than four levels on one side. Finally, 85% tables meet all constraints.

A.2 Annotation Artifacts

Annotation artifacts are common in large scale NLP datasets, which may raise unwanted statistical correlations making the task easier (Gururangan *et al.*, 2018). In HiTab, the annotation artifacts may come from homogeneous patterns of questions. To address this issue, we ask annotators to revise questions from the high-quality descriptions from statistical reports from 28 domains to guarantee the diversity and naturalness, and encourage them to choose the best way to raise question reflecting the overall meaning of the description. To further check whether and where artifacts may exist in our dataset, we conduct two experiments on QA and count the ratio of answer occurring in the question:

- Use table as only input without question, to see if there is a potential pattern between table and answer. We train BERT+MAPO for $10,000$ steps and TaPas for 10 epochs. Both methods can't converge under this setting, with 4.0% and 2.6% accuracy on the test set. The poor performance indicates model can't learn the answers by exploring and leveraging artifacts between the table and answer, and thus should learn to jointly inference the question and table.

- Shuffle the rows and columns of table randomly. Experiments show similar performance ($\pm 1\%$) between our original tables and shuffled tables. The result shows that the correlation between answer and table cell position is very little, thus model can't choose some specific positions, e.g., cell at the first row and first column, as a shortcut prediction.

- The ratio that answer occurs in the question is only 5.3%. Model that only learns to retrieve the question can't achieve high performance.

A.3 Domain Distribution

The full 29 domains of sample distribution in HiTab are shown in Figure 5.

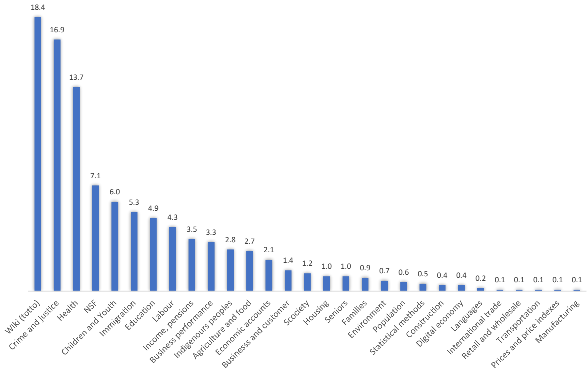

Figure 5: Proportion of samples in different 29 domains.

A.4 Annotation Interface

The annotation interface looks like Figure 6. Since spreadsheet formula is easy to write, execute, and check, the spreadsheet is naturally a great annotation tool. Annotators can use the Excel formula conveniently for cell linking and calculation in entity alignment and answering questions.

B Hierarchical Table-to-Text

B.1 Illustration on Controlled Generation in Hierarchical Table-to-Text.

Please find the illustration shown in Figure 7.

B.2 Baseline Implementation Details

We perform optimized tuning for baselines using the following settings.

Pointer Generator (See *et al.*, 2017) A LSTM-based seq2seq model with copy mechanism. The model uses two-layer bi-directional LSTMs for the encoder with 300-dim word embeddings and 300 hidden units. We perform fine-tuning using batch size 2, learning rate 0.05, and beam size 5.

BERT-to-BERT (Rothe *et al.*, 2020) A transformer encoder-decoder model (Vaswani *et al.*, 2017) where the encoder and decoder are both initialized with BERT (Devlin *et al.*, 2018) by loading the checkpoint named 'bert-base-uncased' provided by the huggingface/transformers repository. We perform fine-tuning using batch-size 2 and learning rate $3e^{-5}$.

BART (Lewis *et al.*, 2019) BART is a pre-trained denoising autoencoder for seq2seq lan-

Figure 7: An illustration on controlled generation.

guage modeling. It uses standard Transformer-based architecture and shows effectiveness in NLG. We align model configuration with the BASE version of BART, and use the model 'facebook/bart-base' in huggingface/transformers. During fine-tuning, we use a batch size of 8 and a learning rate of $2e^{-4}$.

T5 (Raffel *et al.*, 2019) T5 is also a transformer-based pre-training LM. It trains extensively on text-to-text tasks and scores high on generation tasks. We use the pre-trained model 't5-base' in hugging-face/transformers. For fine-tuning, we set batch size to 8 and learning rate to $2e^{-4}$.

We use a beam size of 5 to search decoded outputs (sequence lengths range from 8 to 60 tokens)

C Hierarchical Table QA

C.1 Logical Form Function List

We list our logical form functions in Table 7.

Union selection is required for comparative and arithmetic operations. It is achieved by allowing variable number of headers in $filter\_tree$, where "variable" is one or two in practice.

In our implementation, a function by default takes the selected region of last function as input region to prune search space. We use grammars to filter left headers before top headers, and a ($filter\_level$) is necessary after filtering one direction of tree even when only the leaf level is available. And we deactivate order relation functions (e.g., *eq* function) and the order argument *k*

Function	Arguments	Returns	Description
(**filter_tree** h)	**h**: a header	a region	Select a region indexed by sub-tree of the given header in the given region.
(**filter_level** l)	**l**: a level	a region	Select a region indexed by headers on the given level in the given region.
(**argmax** k) (**argmin** k)	**k**: a number	a list of headers	Find the header(s) with k-th largest/ smallest value in the region. [Input region should have one row or one column of data]
(**max** l) (**min** l) (**sum** l) (**average** l)	**l**: a level	a region	Maximum/minimum/sum/average of the given region, grouping by headers of the given level, *i.e.*, data values aggregate according to their header strings on the given level.
(**count** l)	**l**: a level	a number	Count the number of headers on the given level of given region.
(**difference**) (**proportion**) (**proportion_rev**) (**difference_rate**) (**difference_rate_rev**)		a number	Absolute difference, proportion and difference rate of given two elements a and b in region. rev means changing order of operands. e.g., $proportion$ applies b/a and $proportion\_rev$ applies a/b. [Input region should have two data elements]
(**greater_than** n) (**greater_eq_than** n) (**less_than** n) (**less_eq_than** n) (**eq** n) (**not_eq** n)	**n**: a number	a list of headers	Find the header(s) with data value(s) that have certain order relation with the given number. [Input region should have one row or one column of data]
(**opposite**)		a number	Take opposite value of data in a given region. [Input region should have one data element]

Table 7: Function list of hierarchy-aware logical form

Question	Logical Forms
Cell Selection Q: What is the GDP of China in 2012?	(filter_tree 2012) (filter_tree china) (filter_level LEFT_2) (filter_tree gdp) (filter_level TOP_1)
Superlative Q: Which country has the highest GDP in 2012?	(filter_tree 2012) (filter_level LEFT_2) (filter_tree gdp) (filter_level TOP_1) (argmax 1)
Q: How much more is U.S. GDP higher than China in 2013?	(filter_tree u.s. china) (filter_level LEFT_2) (filter_tree gdp) (filter_level TOP_1) (difference)

Table 8: Examples of our logical form. The table to be questioned is in Fig. 8. *LEFT_1* is a symbol for the first level on the left.

Function	Trigger Words
argmax argmin	JJR, JJS, RBR, RBS, top, first, bottom, and last.
max min	JJS, RBS
average	average, mean
sum	all, combine, total, sum
count	how, many, total, number
difference difference_rate difference_rate_rev	difference, more, than, change,compare, JJR RBR.
proportion proportion_rev	times, percent, percentage, fraction

Table 9: Trigger Words for Functions

in *argmax/argmin* because there are few questions in these types and activating them will largely increase number of spurious programs when searching.

The logical form coverage after deactivation is 78.3% in 300 iterations of random exploration. Some typical question types that can not be covered are: (1) scale conversion, e.g., 0.984 to 98.4%, (2) operating data indexed by different levels of headers, e.g., proportion of total, (3) complex composite operations, e.g., Figure 4.

C.2 Examples of Logical Form Execution

Take the table in Figure 8 as input table, we demonstrate three types of questions with complete logical forms in Table 8.

C.3 Pruning Rules in Searching

We use trigger words and POS tags for some functions in random exploration, which is inspired by (Zhang *et al.*, 2017; Liang *et al.*, 2018). Functions are allowed to be selected only when triggers appear in the question. Triggers are listed in Table 9.

C.4 Table Linearization

We linearize the question and table according to Figure 8.

The input is concatenation of question and table. Table is linearized by putting headers in level order. Each level is led by a *[LEVEL]* token to gather current level embedding. The first *[LEVEL]* token stands for level zero of left. Each header is linearized as *name* | *type*. *name* is the tokenized header string. *type* is the entity type parsed by Stanford CoreNLP, which includes "string", "number", "datetime" in our case. Headers with the same *name* will gather token embeddings by mean pooling.

C.5 Illustration on Challenges in Hierarchical Table

We present an annotated example in Figure 9 to show the challenges of hierarchical table introduced in Section 1.

To precisely answer the question in the figure, the model/method first needs to hierarchically index the grey region with "field in science" and "doctoral", which requires understanding of textual and spatial semantics of the hierarchical table since the textual headers are spatially (seen as a tree) related with the region. Second, from the phrase "most enrolled", it should further indexes "All" (column G) rather than "Percent" (column H) and infers *argmax* operation, , which calls for the ability to distinguish between different calculation relationships.

	GDP	Population
2012	30410	1792.5
U.S.	16244	313.9
China	8229	1351
Japan	5937	127.6
2013	30941	1800.5
U.S.	16800	316.1
China	9240	1357
Japan	4901	127.4

Q: *What is the GDP of China in 2012?*

A: *8229*

Figure 8: An QA example table with hierarchy and its linearized input to the encoder. Each level in the hierarchical header starts with a *LEVEL* token to learn a level representation. *LEFT_k* means the *k*th level in the left tree. Each header cell has a unique header cell representation.

Question: what is the **most enrolled** **field in science** for **doctoral** students?

Textual semantic

- **science -> A6**
- **doctoral -> G2**

Hierarchical semantic

- **field in science -> A7:A16**
- **doctoral -> G3, H3**

Spatial semantic

- **Data -> G7:H16**

Numerical/calculational semantic

- **most enrolled -> argmax(G7:G16)**

Answer: Biological and biomedical sciences

Source: National Science Foundation of U.S.

Figure 9: A detailed annotated example to illustrate challenges in hierarchical table.

Doctor Recommendation in Online Health Forums via Expertise Learning

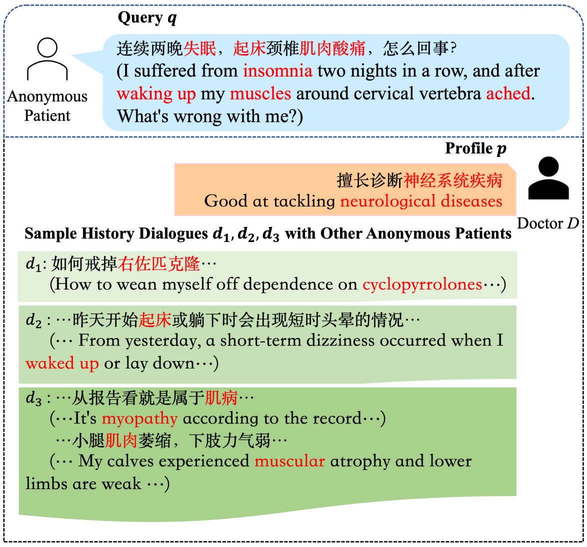
Abstract

Huge volumes of patient queries are daily generated on online health forums, rendering manual doctor allocation a labor-intensive task. To better help patients, this paper studies a novel task of doctor recommendation to enable automatic pairing of a patient to a doctor with relevant expertise. While most prior work in recommendation focuses on modeling target users from their past behavior, we can only rely on limited words in a query to infer a patient's needs for privacy reasons. For doctor modeling, we study the joint effects of their profiles and previous dialogues with other patients and explore their interactions via self-learning. The learned doctor embeddings are further employed to estimate their capabilities of handling a patient query with a multi-head attention mechanism. For experiments, a large-scale dataset is collected from Chunyu Yisheng, a Chinese online health forum, where our model exhibits state-of-the-art results, outperforming baselines only considering profiles and past dialogues to characterize a doctor.[1]

1 Introduction

The growing popularity of health communities on social media has revolutionized the traditional doctor consultancy paradigm in a face-to-face manner. Massive amounts of patients are now turning to online health forums to seek professional help; meanwhile, popular healthcare platforms are able to recruit a large group of licensed doctors to provide online service (Liu et al., 2020b). In the COVID-19 crisis, the social distancing policies further flourish the use of these forums, where numerous patients would query diverse varieties of health problems every day (Gong et al., 2020).



连续两晚失眠，起床颈椎肌肉酸痛，怎么回事?

(··· My calves experienced muscular atrophy and lower limbs are weak ···)

Figure 1: The sample patient query q on the top, followed by the profile of a sample doctor D and three dialogues D engaged before. Salient words indicating patient needs and doctor expertise are in red.[2]

Nevertheless, in much practice (Cao et al., 2017), manual doctor allocations are adopted to handle each query, largely limiting the efficiency to help patients in sheer quantities and resulting in an extremely expensive process. Under this circumstance, how can we automate and speed up the pairing of patients to doctors who are able to offer the help?

In this paper, we present a novel task of *doctor recommendation*, whose goal is to automatically figure out a patient's needs from their query on online health forums and recommend a doctor with relevant expertise to help. The solution can not be trivially found from the mainstream recommendation approaches. It is because most recommender systems acquire the past behavior of target users (e.g., their purchase history) to capture their potential requirements (Wu et al., 2020; Huang et al., 2021); whereas our target users – the patients –

May 22-27, 2022

should be anonymized to protect their privacy. Language features consequently play a role in our task because only a few query words are accessible for models to make sense of how a patient feels and who can best help them.

To illustrate our task, Figure 1 shows a patient's **query** q concerning insomnia and muscle aches, where it is hard to infer the cause of such symptoms from the short text, not to mention to recommend a suitable doctor for problem-solving. It is hence crucial to explore the semantic relations between patient queries and doctor expertise for recommendation. To characterize a doctor's expertise, the modeling of their **profile** (describing what they are good at) provides a straightforward alternative. Nevertheless, the profiles are usually written in a professional language, while a patient tends to query with layman's terms. For instance, the doctor D who later solved q's problem is profiled with "neurological diseases", whose correlations with the symptom descriptions in q are rather implicit. Therefore, we propose to adopt previous dialogues held by a doctor with other patients (henceforth **dialogues**) to narrow the gap of language styles between doctor profiles and patient queries. Take the history dialogues of D in Figure 1 as an example: the words therein like "dizziness", "muscular atrophy", and "cyclopyrrolones" (treatments for insomnia) are all helpful to bridge D's expertise in neurological diseases with q's symptoms.

To capture how a doctor's profile is related to their dialogue history, we first construct a self-learning task to predict whether a profile and a dialogue are from the same doctor. It is designed to fine-tune a pre-trained BERT (Devlin et al., 2018) and align the profile writing and colloquial languages (used in patient queries and doctor responses) into the same semantic space to help model a doctor's expertise. Profiles and dialogues are then coupled with the query embeddings to explore how likely a doctor is qualified to help the patient. Here multi-head attention in aware of the doctor profile is put over the history dialogues to capture the essential content able to indicate a doctor's suitability from multiple aspects, e.g., the capabilities of D in Figure 1 to handle both "insomnia" and "myopathy". Such design reflects the intricate nature of health issues and would potentially allow the models to focus on the salient and relevant matters instead of being overwhelmed by the massive dialogues a doctor has engaged, which may concern diverse points.

In comparison to other NLP studies concerning health forum dialogues (Xu et al., 2019; Zeng et al., 2020a), it is found that few of them attempt to spotlight doctors in these dialogues and examine how their expertise is reflected by what they say in these dialogues. Different from them, we explore doctor expertise from their profiles and history dialogues in order to fit a doctor's qualification to a patient's requests, which would advance the so far limited progress of doctor expertise modeling with NLP.

To the best of our knowledge, *we are the first to study doctor recommendation to automate the pairing of doctors and patients in online health forums, where the joint effects of doctor profiles and their previous interrogation dialogues are explored to learn what a doctor is good at and how they are able to help handle a patient's request.*

For experiments, we also gather a dataset with 119K patient-doctor dialogues involving 359 doctors from 14 departments from Chunyu Yisheng, a popular Chinese health forum.[3] The empirical results show that doctor profiles and dialogue history work together to well reflect a doctor's expertise and how they are able to help a patient. In the main comparison, our model achieves state-of-the-art results (e.g., 0.616 by P@1), outperforming all baselines and ablations without employing self-supervised learning and multi-head attention.

Moreover, we quantify the effects of doctor profiles, history dialogues, and patient queries in recommendation and our model shows consistently superior performance in varying scenarios. Furthermore, we probe into the model outputs to examine what our model learns with a discussion on multiple heads (in our attention map), a case study, and an error analysis, where the results reveal the potential of multi-head attention to capture various aspects of a doctor's expertise and point out the future direction to distinguish profile quality and leverage data augmentation and medical knowledge.

2 Data Collection and Analysis

Despite the previous contributions of large-scale data with doctor-patient dialogues (Zeng et al., 2020a), we note some essential information for doctor modeling is missing, e.g., the profiles. In this work, we present a new dataset to study the characterization of doctor expertise on health forums from both profiles and dialogue history.

---

[3] `chunyuyisheng.com`

Data Collection. We developed an HTML crawler to obtain the data from Chunyu Yisheng, one of the biggest online health forums in China. Then, seed dialogues involving 98 doctors were gathered from the “Featured QA” page. To ensure doctor coverage in varying departments, we also collected doctors from the “Find Doctors” page for each department, which results in the 359 doctors in our dataset. Finally, for each doctor, we crawled their “Favorable Dialogues” page and obtained the profile and history dialogues therein. All stop words were removed from each dialogue.

Data Analysis. The statistics of our dataset are reported in Table 1. We observe that dialogues are in general much longer than profiles. We also observe that a doctor engages in over 300 dialogues on average. It indicates that rich information are contained in dialogues to learn doctor expertise, while presenting challenges to capture the essential content therein for effective doctor embedding.

# of dialogues	119,128
# of doctors	359
# of departments	14
# of tokens in vocabulary	8,715
Avg. # of dialogues per doctor	331.83
Avg. # of doctors per department	25.64
Avg. # of tokens in a query	89.97
Avg. # of tokens in a dialogue	534.28
Avg. # of tokens in a profile	87.53

Table 1: Data statistics. Each dialogue starts with a patient query and each doctor is associated with a profile.

We further plot the distribution of dialogues a doctor engages and the dialogue length distribution in Figure 2. It is observed that doctors contribute diverse amounts of dialogues, which reflects the wide range of doctor expertise and qualifications in practice. Nonetheless, a large proportion of doctors are involved in over 100 dialogues while many dialogues are lengthy (with over 200 tokens). We can hence envision a doctor’s expertise may exhibit diverse aspects and dense information is available in history dialogues, whereas an effective mechanism should be adopted to capture salient content.

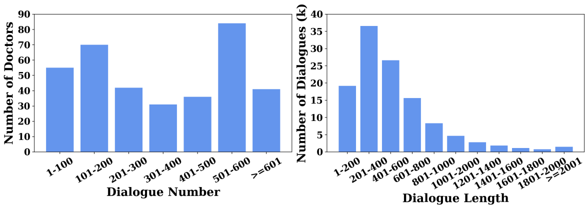

Figure 2: On the left subfigure, its y-axis shows the number of doctors and x-axis the dialogue number a doctor is involved in. For the right subfigure, the y-axis indicates the dialogue numbers in thousands (k) and x-axis the dialogue length in token number.

We finally examine doctors’ language styles by counting the number of medical terms based on THUOCL medical lexicon.[4] Results show that medical terms take 30.13% of tokens in doctor profiles, while the number is 7.83% and 5.52% for patient and doctor turns in dialogues, respectively. It is probably because doctors tend to profile themselves with professional language while adopting layman’s language to discuss with patients.

3 Doctor Recommendation Framework

We now introduce the proposed framework for our doctor recommendation task (overviewed in Figure 3). It contains three modules: a query encoder that encodes patient needs from queries, a doctor encoder that encodes doctor expertise from profiles and dialogues, and a prediction layer that couples above outputs for recommendation prediction.

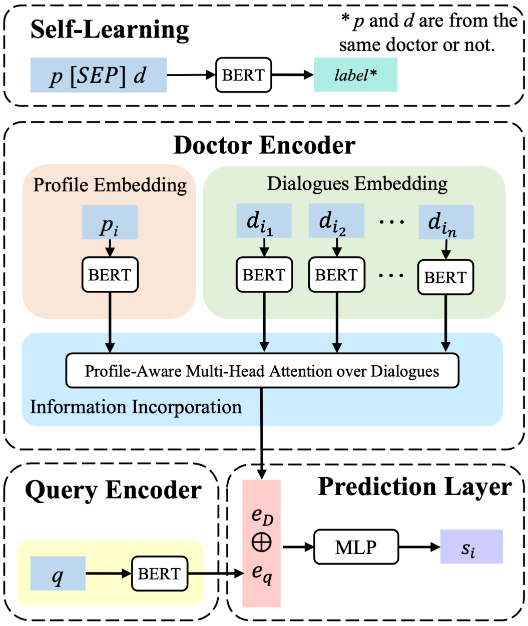

Figure 3: Overview of our framework. The doctor encoder first has its embedding layer (pre-trained BERT) fine-tuned via self-learning. It then employs profile-aware multi-head attention over dialogues to explore doctor expertise and works with the query encoder (to capture patient needs) to pair doctors with queries.

Model’s Input and Output. The input of our model is from three sources: a query q from a

---

[4] `github.com/thunlp/THUOCL/blob/master/data/THUOCL_medical.txt`

patient, the profile p_i of doctor D_i, and a collection of D_i's history dialogues $\langle d_{i_1}, d_{i_2}, ..., d_{i_n} \rangle$ (i_n denotes the number of dialogues D_i previously engaged). For each given query q, we first pair it with each doctor D_i from a candidate pool of m doctors and output a matching score s_i to reflect how likely D_i owns the expertise to handle the request of q. A recommendation is then made for q by ranking all the doctor candidates based on these matching scores s_i ($i \in \{1, ..., m\}$).

3.1 Doctor Encoder

Here we introduce how we encode embeddings for a doctor D to reflect their expertise, which starts with the embedding of their profile and dialogues.

Profile and Dialogue Embedding. Built upon the success of pre-trained models for language representation learning, we employ a pre-trained BERT (Devlin et al., 2018) to encode the profile p and obtain its rudimentary embedding $\mathbf{e}_p$. Likewise, for a dialogue d, we convert it into a token sequence via linking turns in chronological order and encode its semantic features with BERT, which yields the dialogue embedding $\mathbf{e}_d$.

Self-Learning. As analyzed in Section 2, doctor profiles are usually written in a professional language while dialogue language tends to be in layman's styles. To marry semantics of profiles and dialogues into the space, we design a self-learning task to predict whether a profile and a dialogue come from the same doctor, where random profile-doctor pairs are adopted as the negative samples. Then, the pre-trained BERT at doctor encoder's embedding layer is fine-tuned via tackling the self-learning task and shaping an initial understanding of how profiles are related to dialogues.

Multi-head Attention. We have shown in Figure 2 that a doctor may engage in massive amounts of dialogues, where only part of them may be relevant with a query. To allow models to attend to the salient information from the dense content provided by history dialogues, we put a profile-aware attention mechanism over dialogues. Here, multi-head attention is selected because of its capabilities in capturing multiple key points. It potentially reflects the complicated nature of doctor expertise, which in practice would exhibit multiple aspects.

Concretely, the profile embedding $\mathbf{e}_p$ is used to query and attend $[\mathbf{e}_{d_1}, \mathbf{e}_{d_2}, \dots, \mathbf{e}_{d_n}]^T$ (the dialogue embedding array) to both key and value argument:

$$\begin{cases} \text{Query}_{\text{att}} = \mathbf{e}_p, \\ \text{Key}_{\text{att}} = [\mathbf{e}_{d_1}, \mathbf{e}_{d_2}, \dots, \mathbf{e}_{d_n}]^T, \\ \text{Value}_{\text{att}} = [\mathbf{e}_{d_1}, \mathbf{e}_{d_2}, \dots, \mathbf{e}_{d_n}]^T. \end{cases} \quad (1)$$

For the j-th head, these three arguments are then respectively transformed through the neural perceptions with learnable weight matrices W_j^Q, W_j^K, and W_j^V (Q for query, K for key, and V for value). Their outputs $\mathbf{Q}$, $\mathbf{K}$, and $\mathbf{V}$ jointly produce an intermediate doctor representation $\mathbf{h}_j$, which characterize a doctor's expertise from one perspective:

$$\mathbf{h}_j = Att(QW_j^Q, KW_j^K, VW_j^V) \quad (2)$$

where the $Att(\cdot)$ operation is defined as:

$$Att(\mathbf{Q}, \mathbf{K}, \mathbf{V}) = softmax(\frac{\mathbf{Q}\mathbf{K}^T}{\sqrt{dim}})\mathbf{V} \quad (3)$$

Here dim is the dimension of key and value. The scaling factor $\frac{1}{\sqrt{dim}}$ helps keep the softmax output away from regions with extremely small gradients.

Finally, to combine the learning results from multiple heads, outputs are concatenated altogether and transformed with a learnable matrix W^O to obtain the final doctor embedding $\mathbf{e}_D$:

$$\mathbf{e}_D = Concat(\mathbf{h}_1, \mathbf{h}_2, ..., \mathbf{h}_l)W^O \quad (4)$$

Here l denotes the number of heads. The doctor embedding $\mathbf{e}_D$, carrying features indicating the doctor expertise of D, will then be coupled with the query encoder results for recommendation, which will later be described in the coming section.

3.2 Query Encoder and Prediction Layer

Then we describe how we measure the qualification of a doctor (embedded in $\mathbf{e}_D$) to handle a query q.

Query Embedding. For anonymous reasons, only the linguistic signals in a query are available to encode a patient's request. Therefore, we adopt a similar strategy for the embedding of profiles and dialogues to customize the query encoder with a pre-trained BERT. The learned feature is denoted as a query embedding $\mathbf{e}_q$ to represent patient needs.

Recommendation Prediction. Given a pair of doctor D and query q, the embedding results of doctor encoder $\mathbf{e}_D$ and query encoder $\mathbf{e}_q$ are coupled in the prediction layer for recommendation.

We adopt a MLP architecture to measure the matching score s of the D-q pair, which indicates the likelihood of doctor D able to provide a suitable answer to query q and is calculated as following:

$$s = \sigma(W_{MLP} \cdot Concat(\mathbf{e}_D, \mathbf{e}_q) + b_{MLP}) \quad (5)$$

Here σ denotes sigmoid activation function and W_{MLP} (weights) and b_{MLP} (bias) are trainable.

3.3 Training Processes

Our framework is based on the pre-trained BERT and then fine-tuned in the following two steps. The first is to fine-tune the embedding layer of doctor encoder (as described in Section 3.1). For the second, we fine-tune the entire framework by optimizing the weighted binary cross-entropy loss introduced in Zeng et al. (2020b):

$$L = -\sum_{(D,q)\in\tau} (\lambda \cdot \hat{s}_{D,q} \log(s_{D,q}) + (1-\hat{s}_{D,q}) \log(1-s_{D,q})) \quad (6)$$

Here τ is the training set formed with doctor-query pairs and $\hat{s}_{D,q}$ denotes the binary ground-truth labels, with 1 indicating D later responded to q while 0 the opposite. $\lambda > 1$ balances the weights of positive and negative samples in model training, where the model would weigh more on positive D-q pairs (D indeed handled q) because negative samples may be less reliable and affected by many unpredictable factors, e.g., a doctor is too busy at some time. Intuitively, this training objective encourages models to assign high matching scores $s_{D,q}$ to a doctor D who actually helped q.

4 Experimental Setup

We now describe the set up for our experiments.

Dataset Preprocessing and Split. To preprocess the data for non-neural models, we employed an open-source toolkit jieba for Chinese word segmentation.[5] For neural models, texts were tokenized with the attached toolkit of MC-BERT, a pre-trained BERT for biomedical language understanding (Zhang et al., 2020a), to be able to feed into BERT.[6] In the experiments, we maintained a vocabulary without stop words for dialogues' non-query turns while keeping them in queries and profiles, considering the high information density of the latter and colloquial styles of the former.

In terms of dataset split, 80% dialogues were randomly selected from each doctor to form the training set. For the rest 20% dialogues, we took their first turns (patient query) to measure recommendation and split the queries into two random halves, one for validation and the other for test. In the training stage, we adopted negative sampling with a sampling ratio of 10 to speed up the process while for inference, the doctor ranking is conducted on the top 100 doctors handling the most queries.

Model Settings. As discussed above, the pre-trained MC-BERT was employed to encode the queries, profiles, and dialogues, whose parameters were first fine-tuned on the self-learning task, followed by a second fine-tuning step to tackle the doctor recommendation task with the other neural modules. The maximum input length of BERT is 512, and the dimension of all text embeddings from the output of MC-BERT is 768. The hyper-parameters are tuned on validation results and the following presents the settings. The head number of multi-head attention is set to 6 and the tradeoff parameter $\lambda = 5$ (Eq. 6) to weigh more on positive samples. The MLP at the output side contains one hidden layer in size 256. For training, we employ the Adam optimizer with an initial learning rate of 0.008 and batch size 256. The entire training procedure is 50 epochs, with early stop strategy adopted and the parameter sets result in the lowest validation loss used for test.

Baselines and Comparisons. We first consider weak baselines that rank doctors (1) randomly (henceforth RANDOM), (2) by the frequency of queries they handled measured on the training dialogues (henceforth FREQUENCY), (3) by referring to the doctors who responded to K (in practice K is set to 20) nearest patient queries in the semantic space (henceforth KNN), (4) by the cosine similarity of profile and query embeddings yielded by the pre-trained MC-BERT (henceforth COS-SIM (P+Q)), and its counterpart matching dialogues and queries (henceforth COS-SIM (D+Q)). Then, a popular non-neural learning-to-rank baseline GBDT (Friedman, 2001) with TF-IDF features is adopted (henceforth GBDT).

For neural baselines, we compare with the MLP that simply matches query embeddings with profile embeddings (henceforth MLP (P+Q)), with dialogue embeddings (henceforth MLP (D+Q)), and with the average embeddings of profile

---

[5] github.com/fxsjy/jieba

[6] github.com/alibaba-research/ChineseBLUE

and dialogue (henceforth MLP (P+D+Q)).[7] We also consider Deep Structured Semantic Models (DSSM (Huang et al., 2013)), a popular latent semantic model for semantic matching. In this work, the original encoding bag-of-words module in DSSM is replaced with BERT. The query embeddings are matched with profile embeddings (henceforth DSSM (BERT WITH P)) or the average embeddings of dialogues (henceforth DSSM (BERT WITH D)).

To further examine the effects of our attention design for doctor modeling in recommendation, we attend a doctor's history dialogues in aware of their profile with two popular alternatives – dot and concat attention (Luong et al., 2015) (the former is henceforth referred to as DOT-ATT and the latter CAT-ATT). They both went through a fine-tuning with the self-learning task before the training of recommendation to gain the initial view of how profiles and dialogues are related to each other. For comparison, we also experiment on our ablation based on multi-head attention without this self-learning step (henceforth MUL-ATT (W/O SL)).

At last, we examine the other two ablations that encode profiles only with a multi-head self-attention (henceforth MUL-ATT (W/O D)) and its counterpart fed with dialogues only (henceforth MUL-ATT (W/O P)). The full model is henceforth named as MUL-ATT (FULL).

For all models, we initialize them with three random seeds and average the results in three runs for the experimental report below.

Evaluation Metrics. Following the common practice (Zeng et al., 2020b; Zhang et al., 2021), the doctor recommendation results are evaluated with the popular information retrieval metrics: precision@N (P@N), mean average precision (MAP), and ERR@N. In the experimental report, N is set to 1 for P@N and 5 for ERR@N, whereas similar trends hold for other possible numbers.

5 Experimental Results

In this section, we first present the main comparison results in Section 5.1. Then, we quantify the model sensitivity to queries, profiles, and dialogues in varying lengths in Section 5.2. Finally, Section 5.3 analyzes the effects of head number in validation performance, followed by a case study to interpret our superiority and error analysis to provide insights to future work.

5.1 Main Comparison Results

Table 2 reports the comparison results across different models. We draw the following observations.

First, it may require deep semantics to match doctor expertise with patient needs, infeasible to rely on heuristic rules (e.g., frequency or similarity) or shallow features (e.g., TF-IDF) to well tackle the task. Second, compared to profile, dialogues may better indicate how likely a doctor can help a patient, probably because of the richer content therein and the closer language style to a query (as analyzed in Section 2). Third, although the profiles and dialogues may potentially collaborate to better characterize a doctor (than the individual work), effective methods should be employed to couple their effects as their writings vary in the styles.

For models with multi-head attention, all of them yield better results than other attention counterparts. This may imply the fact doctor expertise might be multi-faceted and multi-head attention works well to capture such feature. We also notice a self multi-head attention over profile performs much worse than other ablations. It is probably because profile content is very dense and may challenge multi-head attention in distinguishing various aspects therein.

In comparison to MUL-ATT (W/O SL), MUL-ATT (W/O P) (modeling doctors with dialogues only) and the results of our full model is almost twice better. This again demonstrates the challenges present by the diverse wording patterns of profile and dialogues and the self-learning step to fine-tune pre-trained BERT would largely help in aligning them into the same semantic space.

5.2 Quantitative Analyses

In Section 5.1, we have shown our model achieves a better performance compared to various baselines. In this section, we further quantify its performance in varying lengths of queries, dialogues, and profiles, and compare the full models' results with its two ablations MUL-ATT (W/O P) and (W/O SL) – the first and second runner-up in Table 2. Afterwards, we provide the comparisons of model performance across different medical departments to examine the scenarios where patients are able to know which department they should go to.

---

[7] We also test the alternative concatenates profile and dialogue embeddings, yet it results in very poor performance. A possible reason is the diverse styles of profile and dialogue languages and it is consistent with the observations from Table 2, where concatenation operations tend to result in compromised performance. We will discuss more in Section 5.1.

Models	P@1	MAP	ERR@5
Simple Baselines			
Random	0.010	0.052	0.001
Frequency	0.005	0.032	0.001
KNN	0.082	0.151	0.008

Cat-Att	0.167	0.332	0.018
Our Ablations			
Mul-Att (w/o SL)	0.309	0.319	0.019
Mul-Att (w/o D)	0.198	0.217	0.013
Mul-Att (w/o P)	0.521	0.526	0.033
Mul-Att (full)	**0.616**	**0.620**	**0.039**

Table 2: Results for doctor recommendation (averaged over queries). For all the metrics, the higher the better. Our model obtains the best results (in boldface) and significantly outperform others ($p < 0.02$, paired t-test).

Sensitivity to Query Length. Figure 4 shows the P@1 over varying lengths of patient queries. All models perform better for longer queries, owing to more content available to infer patient needs. Besides, our full model consistently outperforms its two ablations while showing a relatively smaller performance gain for longer queries compared to Mul-Att (w/o P). A possible reason is: long queries may simplify the matching with doctors and dialogue content may be sufficient to handle recommendation, minoring the profile effects.

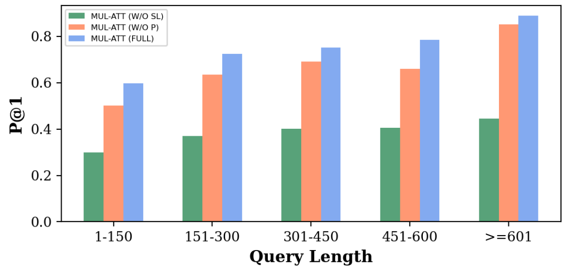

Figure 4: P@1 (y-axis) over varying query lengths (token number). For each group (x-axis), from left to right shows Mul-Att (w/o SL), (w/o P), and (full).

Sensitivity to Dialogue Length. We then study the model sensitivity to the length of dialogues for doctor modeling and show the results in Figure 5. Dialogue length exhibits similar effects to query length, possibly because they contribute homogeneous features to understand doctor-patient match. After all, other patients' queries are part of the dialogues and involved in learning doctor expertise.

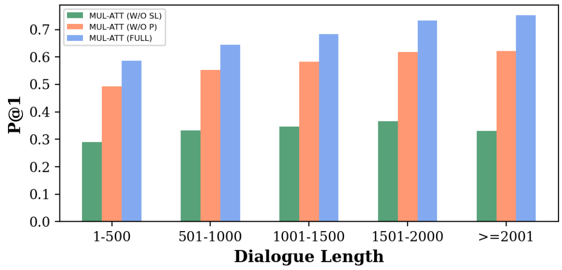

Figure 5: P@1 (y-axis) over varying dialogue lengths (token number). Bars in the x-axis are ordered the same as Figure 4 and similar observations are drawn.

Sensitivity to Profile Length. Furthermore, we quantify the profile length and display the models' P@1 in Figure 6. Here profile length exhibits different effects compared to query and dialogue length discussed above, where models suffer the performance drop for very long profiles, because of the potential noise therein hindering the collaboration with profiles and dialogues. Nevertheless, the self-learning step enables profiling language to blend in the colloquial embedding space of dialogues or queries, which hence presents more robust results.

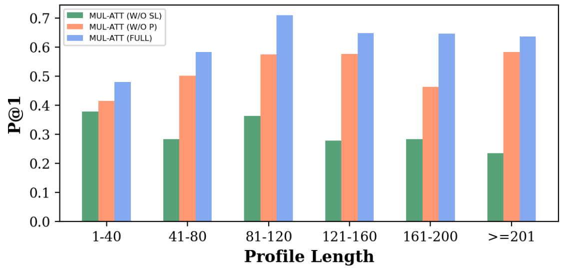

Figure 6: P@1 (y-axis) over varying profile lengths. We observe more complicated effects compared to those from queries (Figure 4) or dialogues (Figure 5).

Comparisons of Model Performance over Varying Departments. In the realistic practice, patients might have already known which department they should turn to before seeking help from doctors. To better study doctor recommendation in this scenario, here we examine the model performance within different medical departments in our data. We select 4 models with highest P@1 scores in the main experiment (Table 2) for comparison: Mul-Att (w/o SL), Mul-Att (w/o D), Mul-Att

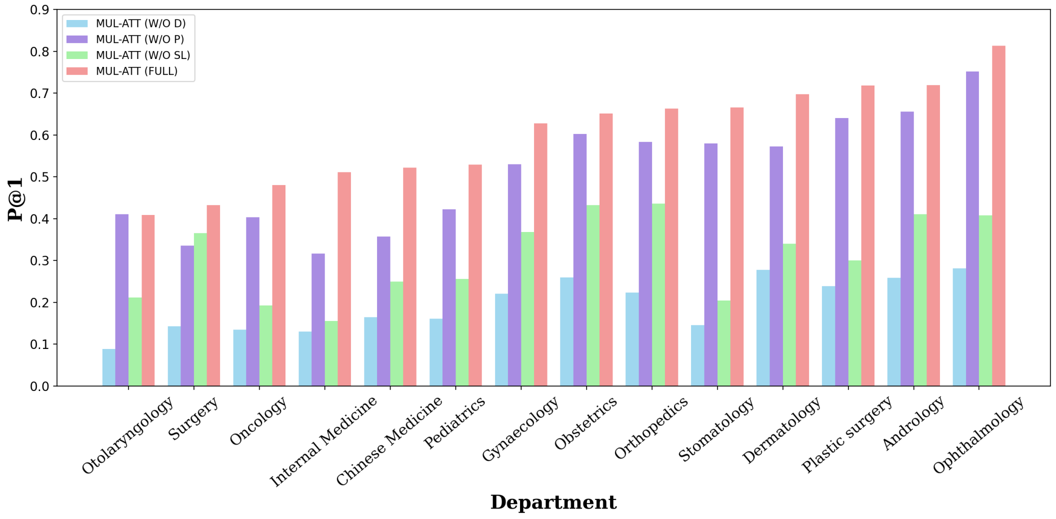

Figure 7: P@1 (y-axis) over all 14 departments (x-axis). Our model achieves the best performance in 13 departments and obtains the comparable results to the best model for the left department of Otolaryngology.

(W/O P), and MUL-ATT (FULL). Their setups are described in Section 4.

Experimental results are shown in Figure 7. We observe for all 14 departments, our model has the best performance in 13 departments and achieves comparable results with the best model for the left department (otolaryngology). We also find all models exhibit varying performance when handling queries from different departments. It is related to departments' characteristics. For example, all models obtain low scores for Internal Medicine because of its significant overlap with others and the challenges to understand the needs from queries therein. Another factor is the imbalance of training data scale from each department. For instance, the training samples for Oncology, Surgery, Otolaryngology are much fewer than the average, resulting in the worse model performance on them.

5.3 Further Discussions

Analysis of Head Number. In Table 2, multi-head attention shows the superiority to model doctors. We are hence interested in the effects of head numbers and vary them in validation set with the results shown in Table 3. It is seen that model performances first increase and then decrease, with 6 heads achieving the best performance. It indicates that head number reasonably affects model performance because it controls the granularity of aspects a model should capture to learn doctor expertise.

Case Study. To interpret what is learned by multi-head attention we take the example in Figure 1 and analyze the attention map produced by 6 heads, where 4 of them attend to dialogue d_3 and the other 2 respectively highlights d_1 and d_2. Recall that d_1, d_2, and d_3 each reflects a different aspects of doctor expertise. To further probe into the attended content, we rank the words by the sum of attention weights assigned to a dialogue they occur in and show the top 5 medical terms in Table 4. It is observed that the heads vary in their focusing point, while all related to the queried symptom of "insomnia" and "muscle ache" and further contribute to a correct recommendation of a neurological expert. This again demonstrates the intricacy of doctor expertise and the capabilities of multi-head attention to well reflect such essence. More cases are shown in Appendix A to offer more insight of how our model recommends doctors.

Head Number	P@1	MAP	ERR@5
2	0.601	0.605	0.038
4	0.609	0.613	0.038
6 (OURS)	**0.616**	**0.620**	**0.039**
8	0.564	0.568	0.035

Table 3: The validation results of our multi-head attention with different hyper-parameters in head number.

Error Analysis. We observe two major error types of our model, one resulting from doctor modeling and the other from the query.

For doctor modeling, we observe many errors come from the diverse quality of profiles. As we have shown in Figure 6, not all content from profiles is helpful. For example, some doctors tend to profile themselves generally from experience (e.g.,

Head i	**Top 5 Keywords**
1	肌肉、神经、抽搐、无力、萎缩 (muscle, nerve, convulsion, weakness, atrophy)
2	头晕，神经，头痛，内科，呕吐 (dizziness, nerve, headache, internal medicine, sickness)
3	神经，肌肉，酸痛，劳损，按摩 (nerve, muscle, ache, strain, massage)
4	睡眠，焦虑，失眠，神经，右佐匹克隆 (sleep, anxiety, insomnia, nerve, Dexzopiclone)
5	肌肉，颈部，头痛，恶心，颈椎 (muscle, neck, headache, sickness, cervical vertebrae)
6	神经，肌肉，颈部，酸痛，腰椎 (nerve, muscle, neck, ache, lumbar vertebrae)

Table 4: The top 5 medical terms attended by each head given the input sample in Figure 1. The medical terms are from the THUOCL lexicon used in Section 2.

how many years they worked) instead of the specific expertise (what they are good at). Future work should concern how to further distinguish profile quality to learn doctor expertise.

In real world, some doctors are skilled comprehensively while others are more specialized. It causes the models tend to recommend the "Jack of all trades" rather than a more relevant doctor, as the former usually engaged in more dialogues and it is safer to choose them. For example, in a query concerning "continuous eye blinking", the model recommends a doctor with 100 "eyes"-related dialogues instead of the one specialized in "Hordeolum" and "Conjunctivitis" yet involved in only 30 dialogues. To mitigate such bias, it would be interesting to employ data augmentation (Zhang et al., 2020b) to "enrich" the history for doctors handling relatively fewer queries.

In terms of queries, many patients are observed to describe their symptoms with minutiae rather than focusing on the key points. So the model, lacking professional knowledge, may consequently be trapped with these unimportant details. For instance, a patient queried a "pimple" on the "eyelid"; the model wrongly attends to "eyelid" thus recommends an ophthalmologist but not a dermatologist to solve the "pimple" problem. A future direction to tackle this issue is to exploit knowledge from medical domains (Liu et al., 2020a) to allow a better understanding of patient needs.

6 Related Work

Our work is in the research line of recommender systems widely studied because of their practical value in industry (Huang et al., 2021). For example, previous work explores users' chatting history to recommend conversations (Zeng et al., 2018, 2020b) and hashtags (Li et al., 2016; Zhang et al., 2021), browsing history to recommend news (Wu et al., 2019; Qi et al., 2021), and purchase history to recommend products (Guo et al., 2020). In contrast to most recommendation studies focusing on exploiting target users' personal interest modeling from their history behavior, our work largely relies on wordings of a short query to figure out what is needed by a target user (patient) because they are anonymous for privacy concern.

Within several branches of recommendation research, our task is by concept similar to expert recommendation for question answering (Wang et al., 2018; Nikzad–Khasmakhi et al., 2019). In this field, many previous studies encode expertise knowledge in diverse streams, such as software engineering (Bhat et al., 2018), social activities (Bok et al., 2021), etc. Nevertheless, few of them attempt to model expertise with NLP methods. On the contrary, language representations play an important role here to tackle our task: we substantially explore how semantic features help characterize doctor expertise, which has not been studied before.

Our work is also related to the previous language understanding research over doctor-patient dialogues on online health forums (Zeng et al., 2020a), where various compelling applications are explored, such as information extraction (Ramponi et al., 2020; Du et al., 2019; Zhang et al., 2020c), question answering (Pampari et al., 2018; Xu et al., 2019), and medical report generation (Enarvi et al., 2020). In comparison with them, we concern doctor expertise and characterize it from both doctor profiles and the past patient-doctor dialogues, which is a gap in previous work filled in this work.

7 Conclusion

This paper has studied doctor recommendation in online health forums. We have explored the effects of doctor profiles and history dialogues in the learning of doctor expertise through a self-learning task and a multi-head attention mechanism. Substantial experiments on a large-scale Chinese dataset demonstrate the effectiveness of our method.

Ethical Considerations

It should be mentioned that all data, including doctors' profiles, patients' queries, and doctor-patient dialogues, are collected from the openly accessible online health forum Chunyu Yisheng whose owners make such information visible to the public (while anonymizing patients). Our dataset is collected by a crawler within the constraints of the forum. Apart from the personal information de-identified by the forum officially, to prevent privacy leaks, we manually reviewed the collected data and deleted sensitive messages. Additionally, we replaced each doctor's name with a unique code randomly generated to distinguish them while protecting their privacy. We ensure there is no identifiable or offensive information in the released dataset.

The dataset, approach, and model proposed in this paper are for research purposes only and intended to facilitate studies of using NLP methods for doctor expertise learning and recommendation to allow a better user experience on online health forums. We also anticipate they could advance other NLP researches like question answering (QA) in the biomedical domain.

A More Case Study Results

To provide more insight of why our model can exhibit superior performance, we further discuss two more cases to understand how the multi-head attention mechanism makes use of the information from both the doctors' profiles and their history dialogues, in addition to example cases shown in Figure 1 and Table 4. Because a dialogue is mostly lengthy (as shown in Table 1), we only show the dialogue snippets in English translations for a better display (while the model is fed with the entire dialogues in the experiments).

We present in Table 5 a case sampled from the Department of Gynecology. As can be seen, the profile of the doctor is short, while the attended dialogues provide detailed information for the symptoms, treatments, and medicine. The top 5 keywords identified by the sum of attention weights for each head are shown in Table 5(b).While several heads seem to attend to one or two specific tokens, for example head 1, 4, and 5 attend to the token "menstruation", we observe each head has its own focus. For example, it is reasonable to infer that head 1 concerns messages related to the preparation of pregnancy, head 4 irregular period, and head 5 prognosis of abortion.

Table 6 shows another example sampled from the Department of Dermatology. In this case, the doctor's profile is more detailed while generic. Top 5 keywords for each attention head are shown in Table 6(b). Similar to the observation from Table 5, the token "pruritus" occurs in most attended keywords of 5 heads for that it is one of the most common symptoms, whereas each head focuses on different aspects related to the query.

Query q from Anonymous Patient P
There is brown secreta after my last menstruation, and it disappears after sex. What's wrong with me?

Profile p of Doctor D
30 years of experience in obstetrics and gynecology.

Attended Dialogue d_1
u_P: The urine test result for pregnancy is negative for the 24th day after my last sexual behaviour, and it is the same for the 20th, 22nd, 23rd. Can I rule out pregnancy?
u_P: I took contraceptive pill last month. I don't know my current ovulation.
u_D: Not pregnant, don't worry.
u_P: I've been getting yellowish vaginal discharge lately. Am I inflamed?
u_D: It's fungal vaginitis. I suggest you take fluconazole pills.

Attended Dialogue d_2
u_P: My boyfriend and I had sex with condom. It was the first time for me, but my boyfriend had had sex life with others. Is there a high chance I get infected with HPV?
u_D: From your description, it is not likely to happen.

Attended Dialogue d_3
u_P: My period has been lasting for 8 days. I bleed a lot and have blood clots. What' the matter with me?
u_P: In the past year my period has always been regular. But in the past two months I took Ejiao for a few days.
u_D: It's abnormal and it could be caused by Ejiao. I suggest hemostasis, or it could lead to anemia.

Attended Dialogue d_4
u_P: My vaginal opening is like white petal. I have had sexual experience, but I feel alright. Is it condyloma acuminatum?
u_D: How long has this lasted? How are you feeling?
u_P: I feel nothing.
u_D: It's normal, not condyloma acuminatum. It is likely to be hymen residue.

Query q from Anonymous Patient P
In the past week, she has been keeping saying that her back, her legs, and her whole body were all itchy. I observe she has a few dry eczema spots on her body, a little wrinkled and peeling.

Profile p of Doctor D
Good at treating common skin diseases, including diagnosis and treatment of acne, urticaria, viral warts, eczema, shingles, etc.

Attended Dialogue d_1
u_P: I've had beriberi for over a year. At night, I feel itchy and the skin of my feet peels off.
u_D: I suggest you apply topical antifungal ointment to your feet and wash socks with boiled water every day. It takes 4-6 weeks to cure tinea pedis.

Attended Dialogue d_2
u_P: It's red and itchy around my mouth and nose. What's the matter with me?
u_D: Are they blisters or pimples? You possibly got seborrheic dermatitis.
u_P: My husband has beriberi, is it possible I'm infected by him?
u_D: Not likely.

Attended Dialogue d_3
u_P: I froze this spot, is it going to scab and peel off?
u_D: It's already dark red, so theoretically it should soon peel off.
u_P: It's nearly fourteen days after freeze, can I bath now?
u_D: You could shower but should not bath. Be careful not to irritate this spot.

Attended Dialogue d_4
u_P: I have nail fungus, and I felt itchy after I applied ciclopirox amine cream the day before yesterday. Today I observe my toes swell.
u_D: There is a possible delayed allergic reaction to the drug. I suggest you rinse your toes with warm water and stop applying that cream.

Abstract

A desirable dialog system should be able to continually learn new skills without forgetting old ones, and thereby adapt to new domains or tasks in its life cycle. However, continually training a model often leads to a well-known catastrophic forgetting issue. In this paper, we present Continual Prompt Tuning, a parameter-efficient framework that not only avoids forgetting but also enables knowledge transfer between tasks. To avoid forgetting, we only learn and store a few prompt tokens' embeddings for each task while freezing the backbone pre-trained model. To achieve bi-directional knowledge transfer among tasks, we propose several techniques (continual prompt initialization, query fusion, and memory replay) to transfer knowledge from preceding tasks and a memory-guided technique to transfer knowledge from subsequent tasks. Extensive experiments demonstrate the effectiveness and efficiency of our proposed method on continual learning for dialog state tracking, compared with state-of-the-art baselines.

1 Introduction

Recently, most studies have focused on developing dialog systems for specific domains in an offline manner, assuming the data distribution stays the same. However, this is far from realistic because a deployed dialog system is often required to support new domains and provide more services constantly over time. Therefore, it is crucial for a dialog system to continually learn new tasks without forgetting old ones with high efficiency.

Previous studies on continual learning (Kirkpatrick et al., 2017; Li and Hoiem, 2018) mainly focused on solving the *catastrophic forgetting (CF)* problem (McCloskey and Cohen, 1989): when a neural model is trained on a sequence of tasks, new tasks may interfere catastrophically with old tasks. Simply storing a model version for each task to mitigate forgetting is prohibitive as the number of tasks grows, especially when the model size is large. To mitigate catastrophic forgetting with low computation and storage overhead, recent methods freeze the backbone model and propose to train a weight/feature mask (Mallya et al., 2018; Geng et al., 2021) or an adapter (Madotto et al., 2021) for each task independently. However, the techniques above are still not efficient enough, and they largely ignore knowledge transfer among tasks.

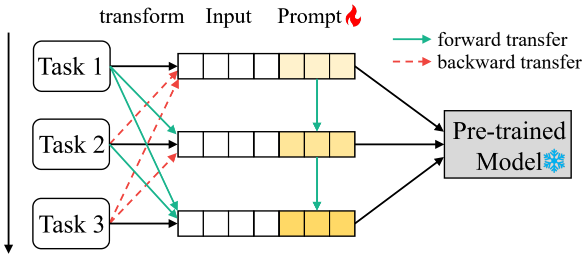

Figure 1: An illustration of *Continual Prompt Tuning*. We train a soft prompt for each task and freeze the pre-trained model. Several techniques are proposed to transfer knowledge from preceding tasks (green solid arrows) and subsequent tasks (red dashed arrows).

In this paper, we develop prompt tuning (Lester et al., 2021) for continual learning. We freeze the backbone pre-trained model and train a few prompt tokens' embeddings for each task, which is highly parameter-efficient to avoid forgetting. As illustrated by yellow components in Figure 1, we concatenate the input with a few *tunable* task-specific prompt tokens before feeding it to a *frozen* pre-trained model. Since these prompt tokens have only a small number of parameters (0.1% of the pre-trained model's parameters in our experiments), we can efficiently train and store the prompt for each task. During inference, the same pre-trained model can handle different tasks by inputting different prompts, which is friendly for deployment.

Unlike the vanilla approach of training each task's prompt from scratch and fixing it afterward, we propose *Continual Prompt Tuning*, a framework

May 22-27, 2022

that enables **knowledge transfer** between tasks. We consider transferring knowledge from both preceding tasks (forward) and subsequent tasks (backward). To realize forward transfer, we propose several techniques, including continual prompt initialization, query fusion, and memory replay (green solid arrows in Figure 1). To achieve positive backward transfer, we propose a memory-guided technique that uses subsequent tasks' data to update the previous tasks' prompts selectively (red dashed arrows in Figure 1).

We conduct experiments on Dialog State Tracking (DST), a core component of a dialog system, using the Schema-Guided Dialog dataset (Rastogi et al., 2020). The model continually learns new services that have multiple slots to fill. We concatenate all slots' descriptions with the input and insert a sentinel token after each description, formulating DST as a masked spans recovering task, which is similar to the pre-training objective of T5 (Raffel et al., 2020). We empirically show that our proposed framework effectively outperforms state-of-the-art baselines on continual learning for DST, and is extremely efficient in terms of computation and storage.[1]

To summarize, our main contributions are:

1. For the first time, we develop prompt tuning for continual learning, which avoids forgetting efficiently and is friendly for deployment.
2. We investigate several techniques for forward and backward knowledge transfer based on prompt tuning, further boosting the continual learning performance.
3. Our experiments on continual DST demonstrate the superior performance and efficiency of our proposed method.

2 Related Work

2.1 Continual Learning

Continual Learning (CL) studies the problem of continually acquiring knowledge from a data stream and reusing it for future learning while avoiding forgetting. Three kinds of CL methods have been developed. *Rehearsal* methods store and replay some training samples from previous tasks (Rebuffi et al., 2017; Lopez-Paz and Ranzato, 2017). *Regularization* methods apply additional loss to aid knowledge consolidation (Kirkpatrick et al., 2017; Li and Hoiem, 2018). *Architectural* methods introduce task-specific parameters for new tasks and fix parameters for old tasks to prevent forgetting, to which our method belongs. Previous architectural methods include dynamic expanding network structure (Rusu et al., 2016), iterative network pruning and re-training (Mallya and Lazebnik, 2018), learning a parameter mask for each task individually (Mallya et al., 2018), etc.

For continual learning in dialog system, variants of general CL methods have been applied (Lee, 2017; Shen et al., 2019; Wu et al., 2019; Mi et al., 2020; Geng et al., 2021). AdapterCL (Madotto et al., 2021) is the most related to our work, which freezes the pre-trained model and learns an adapter (Houlsby et al., 2019) for each task independently. Compared with AdapterCL, our method is more parameter-efficient, and we explore the effect of both forward and backward transfer.

2.2 Prompt-based Tuning

Recent studies have found that using a textual prompt to convert downstream tasks to the language modeling task is a more effective way to use pre-trained language models than typical fine-tuning (Brown et al., 2020; Schick and Schütze, 2021). Prompts can be manual designed (Petroni et al., 2019) or generated automatically (Shin et al., 2020; Jiang et al., 2020; Gao et al., 2021). Since searching prompts in discrete spaces is sub-optimal, some works (Qin and Eisner, 2021; Liu et al., 2021; Han et al., 2021) combine hard text prompts and soft prompts whose embeddings are learned through back-propagation. Lester et al. (2021) show that freezing the pre-trained model and only tuning soft prompts, known as prompt tuning, is parameter-efficient and becomes more competitive with fine-tuning as the model size grows.

Prompt tuning differs from embedding adapter (Zhu et al., 2021) that aims to address the multilingual embedding deficiency. An embedding adapter transforms all tokens embeddings but do not affect transformer layers' computation, while prompt tuning does not change tokens embeddings but adds new tunable prompt tokens to the input, serving as context and affecting all following transformer layers. Gu et al. (2021) and Vu et al. (2021) further explore the transferability of soft prompts across tasks. While they investigate one-step adaptation, we are interested in prompt transfer in the continual learning setting.

---

2.3 Dialog State Tracking

Dialog State Tracking (DST) aims to capture user goals in the form of (slot, value) pairs. Traditional ontology-based classification methods (Mrkšić et al., 2017; Lee et al., 2019) require access to all candidate values. To alleviate the reliance on the ontology and improve generalization to unseen values, some work extract values from a dialog context (Xu and Hu, 2018; Gao et al., 2019) while others generate values directly to handle situations where values are missing from the context (Wu et al., 2019; Hosseini-Asl et al., 2020).

Generation-based models either generate all (slot, value) pairs in one pass (Hosseini-Asl et al., 2020; Madotto et al., 2021) or generate value for each given slot separately (Wu et al., 2019). The former are more efficient but can only predict in-domain slots and lack transferability while the latter can incorporate more information about a slot as a query, such as a brief natural language description (Rastogi et al., 2020), slot type information (Lin et al., 2021), possible values (Lee et al., 2021), and the task definition and constraint (Mi et al., 2022). Our proposed method integrates multiple slot descriptions into a single query and generates all values in one pass, which improves performance without losing efficiency.

3 Method

3.1 Overview

The goal of continual learning is to sequentially learn a model $f: \mathcal{X} \times \mathcal{T} \rightarrow \mathcal{Y}$ from a stream of tasks $\mathcal{T}_1 ... \mathcal{T}_T$ that can predict the target y given the input x and task $\mathcal{T}_k \in \mathcal{T}$. We denote the data for each task $\mathcal{T}_k$ as D_k. Our method is based on pre-trained language models. Instead of fine-tuning a pre-trained model in a traditional manner (Figure 2(a)), we freeze the model but "reprogram" it to solve task $\mathcal{T}_k$ by adding m new soft prompt tokens $P_k = P_k^1 P_k^2 ... P_k^m$ to the textual input and tuning the embeddings of P_k only. Since the prompt's parameters are much less than the model's, we save P_k for each task to avoid forgetting.

We treat each service/API as a task in continual DST (service and task are used interchangeably). To incorporate informative slot descriptions and ease the decoding process, we convert the descriptions into a query with masked spans and formulate DST as a masked spans recovering task (Sec. 3.2). To enhance knowledge transfer between tasks, we propose continual prompt initialization, query fusion, and memory replay for forward transfer (Sec. 3.3) and explore a memory-guided technique for backward transfer (Sec. 3.4).

3.2 DST as Masked Spans Recovering

In DST, each service $\mathcal{T}_k$ has a set of pre-defined slots $\mathcal{S}_k = \{s_1, ..., s_{n_k}\}$ to be tracked. The input x is a dialog and the output y consists of slot-value pairs: $\{(s_1, v_1), (s_2, v_2), ..., (s_{n_k}, v_{n_k})\}$. Similar to many NLP tasks, DST can be formulated as a text-to-text generation task. Formally, we define a function $g_k : \mathcal{X} \times \mathcal{Y} \rightarrow \mathcal{V}^* \times \mathcal{V}^*$ for each service $\mathcal{T}_k$ to transform the original data (x, y) to:

$$\tilde{x}, \tilde{y} = g_k(x, y) \tag{1}$$

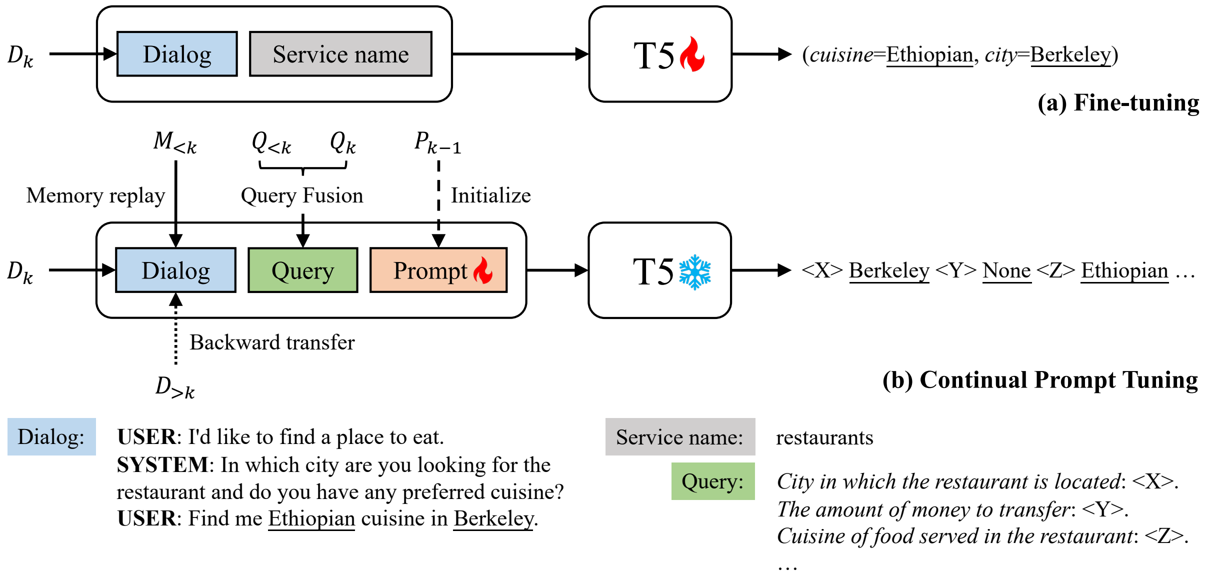
where $\mathcal{V}$ is the vocabulary and $\tilde{x}, \tilde{y}$ are texts that serve as the model input and output, respectively. For example, $\tilde{x}$ can be the concatenation of x and service name, while $\tilde{y}$ is a sequence of slot-value pairs (Madotto et al., 2021) (Figure 2(a)).

Previous research has shown that incorporating a natural language description d_i for each slot s_i is beneficial (Lin et al., 2021; Lee et al., 2021). They concatenate the dialog x with each slot description d_i and decode the value v_i independently. However, separately decoding is inefficient, especially when there are many slots. To solve this, we concatenate all slot descriptions and insert a sentinel token after each description to form a query added to the input, formulating DST as a masked spans recovering task that generates all slot values in one pass:

$$\begin{aligned} \tilde{x} &= [x; Q_k; P_k] \\ Q_k &= \text{“}d_1^k : \langle \mathrm{M}_1 \rangle . \; ... \; d_{n_k}^k : \langle \mathrm{M}_{n_k} \rangle .\text{”} \\ \tilde{y} &= \text{“}\langle \mathrm{M}_1 \rangle \; v_1^k \; ... \langle \mathrm{M}_{n_k} \rangle \; v_{n_k}^k \text{”} \end{aligned} \tag{2}$$

where $[\cdot;\cdot]$ is the concatenation operation and $\langle \mathrm{M}_* \rangle$ are distinct sentinel tokens representing masked spans. The **query** Q_k contains all n_k slot descriptions for task $\mathcal{T}_k$ with n_k masked spans and $\tilde{y}$ contains corresponding slot values leaded by the sentinel tokens. If the value of a slot can not be inferred from the input, we set it to "None". We freeze the pre-trained model's parameters θ and only optimize the prompt's parameters θ_{P_k} for each service $\mathcal{T}_k$. The loss function is:

$$\mathcal{L}_{\theta_{P_k}}(D_k) = -\sum_{j=1}^{|D_k|} \log p_\theta(\tilde{y}_j^k | [x_j^k; Q_k; P_k]) \tag{3}$$



USER: I'd like to find a place to eat.
SYSTEM: In which city are you looking for the restaurant and do you have any preferred cuisine?
USER: Find me Ethiopian cuisine in Berkeley.

…

Figure 2: An illustration of *Fine-tuning* and *Continual Prompt Tuning* for continual DST. **(a)** ***Fine-tuning*** takes the dialog and current service's name as input and tunes T5 to generate slot-value pairs. **(b)** ***Continual Prompt Tuning*** feeds the dialog, query consisting of slot descriptions and sentinel tokens, and prompt tokens to frozen T5 and tunes the prompt's embeddings to generate values for all slots in the query. Continual prompt initialization, query fusion, and memory replay are proposed to enhance forward transfer while subsequent services' data will be used for backward transfer. We show an example dialog, service name, fused query, and expected outputs. Slot *names* and *descriptions* are in italic and values are underlined. Note that the second slot description in the query belongs to another service ("banks") and is inserted by query fusion.

3.3 Forward Transfer

Reusing the knowledge acquired from preceding tasks often improves and accelerates the learning on future tasks. Therefore, we propose three types of techniques for forward transfer that can be employed in combination.

3.3.1 Continual Prompt Initialization

An intuitive way to transfer knowledge is parameter initialization. We explore two continual prompt initialization strategies. **CLInit** uses last task's prompt P_{k-1} to initialize current task's prompt P_k. **SelectInit** evaluates all $\{P_j\}_{j<k}$ on the validation set of $\mathcal{T}_k$ without training and selects the one with the lowest loss to initialize P_k. The initial prompt of CLInit has been continually trained on all previous tasks, while SelectInit only considers the most relevant task without interference from its subsequent tasks. We empirically compare these two strategies in Sec. 5.3.

3.3.2 Query Fusion

We hope the model can learn to generate values according to any slot descriptions, which is a general skill that may improve performance on future tasks. However, when training on the current task, there is only one query that consists of the slot descriptions of that task in a fixed order, which may hinder the model from learning the general skill. Therefore, we propose to augment the query by mixing slot descriptions from the current and previous tasks to help the prompt better understand the correspondence between slot descriptions and values. We fuse the query Q_k with previous tasks' queries $\{Q_j\}_{j<k}$ for each sample, including three steps: 1) sample n_1 slots from $\mathcal{S}_k$ randomly, where n_1 is sampled from $[1, |\mathcal{S}_k|]$ uniformly. 2) sample n_2 slots from previous tasks' slots $\bigcup_{i<k} \mathcal{S}_i$ randomly, where n_2 is sampled from $[1, n_1]$ uniformly. 3) combine the above n_1 and n_2 slots' descriptions in a random order as new $Q_k^{'}$, and modify $\tilde{y}$ accordingly. Note that some original slots are dropped, and values for added slots are set to "None".

3.3.3 Memory Replay

Previous studies (Rebuffi et al., 2017; Lopez-Paz and Ranzato, 2017) store a few samples for each task and replay them when training on new tasks to mitigate forgetting. Since our prompt tuning framework has already resolved forgetting, we focus on how these samples benefit the current task. We assume we can store $|M|$ samples for each task ($|M|$ should be small) and denote M_i as the memory for task $\mathcal{T}_i$. When a new task $\mathcal{T}_k$ comes, we optimize P_k on D_k and $M_{<k} = \bigcup_{i<k} M_i$ jointly, changing the loss function to $\mathcal{L}_{\theta_{P_k}}(D_k + M_{<k})$.

When combined with query fusion, query Q_i for samples in the memory M_i are also fused with queries $\{Q_j\}_{j \leq k, j \neq i}$ from other seen tasks, including the current task. Note that in this way, samples from other tasks can be viewed as "positive" samples to those added slots in $Q_i^{'}$ since these samples may have not "None" values for those added slots.

3.4 Memory-Guided Backward Transfer

Although fixing P_k immediately after training on task $\mathcal{T}_k$ can avoid forgetting, it also blocks the backward knowledge transfer from future tasks. Motivated by Chaudhry et al. (2019), we explore whether it is possible to improve the performance on previous tasks with the help of memory when a new task comes. Specifically, for each previous task $\mathcal{T}_i, i < k$, we initialize a new prompt $P_i^{(k)}$ to P_i and trained it on current task's data D_k with memory M_i as regularization. During training, we sample a batch from D_k and a batch from M_i synchronously and denote the gradient from each batch as g_{ori} and g_{ref}, respectively. We decide the gradient for update according to the angle between g_{ori} and g_{ref}:

$$g = \begin{cases} g_{ori}, & \text{if } g_{ori}^T g_{ref} > 0 \\ 0, & \text{otherwise} \end{cases} \tag{4}$$

which means we abort the update that will increase the loss on memory batch. We empirically find that this simple abortion is better than projecting g_{ori} onto the normal plane of g_{ref} (Chaudhry et al., 2019). After training, we update P_i to $P_i^{(k)}$ if $P_i^{(k)}$ obtains lower loss and better (or equal) performance on M_i than P_i.

4 Experimental Setup

Recently, Madotto et al. (2021) proposed a continual learning benchmark for task-oriented dialog systems and compared several classic CL methods. We adapt their data processing steps and baselines in our experiments.

4.1 Dataset

We conduct experiments on Schema-Guided Dialog dataset (SGD) (Rastogi et al., 2020) that has 44 services over 19 domains. It also provides a one-sentence description for each slot. We treat each service as a task and only consider dialogs involving a single service. We randomly split a service's dialogs into train/val/test sets at the ratio of 7:1:2. The number of training samples of each service ranges from 112 to 4.7K, and there are 2 to 10 slots for one service. More details about data statistics can be found in the Appendix (Table 8).

4.2 Evaluation Protocol

We evaluate DST performance using the widely adopted Joint Goal Accuracy (JGA) (Wu et al., 2019), which requires all slots' values are correctly predicted. We assign the target service during testing to avoid ambiguity since the same dialog can be parsed differently under different services. We denote $a_{j,i}$ as the JGA on the test set of task $\mathcal{T}_i$ right after training on task $\mathcal{T}_j$. We evaluate the CL performance as the average JGA on all tasks after training on the final task $\mathcal{T}_T$:

$$\textbf{Avg. JGA} = \frac{1}{T} \sum_{i=1}^{T} a_{T,i} \tag{5}$$

Following Lopez-Paz and Ranzato (2017), we define two metrics to measure the effect of forward transfer and backward transfer, respectively:

$$\begin{aligned} \textbf{FWT} &= \frac{1}{T-1} \sum_{i=2}^{T} a_{i-1,i} \\ \textbf{BWT} &= \frac{1}{T-1} \sum_{i=1}^{T-1} a_{T,i} - a_{i,i} \end{aligned} \tag{6}$$

FWT is the averaged zero-shot performance on new tasks, evaluating a model's generalization ability. BWT assesses the impact that learning on subsequent tasks has on a previous task. Negative BWT indicates that the model has forgotten some previously acquired knowledge.

4.3 Baselines and Training Details

We adopt the following models from Madotto et al. (2021) as baselines:

- ***Fine-tuning***: Fine-tune the model on new task data continually.
- ***Replay***: Save $|M|$ samples randomly sampled from the training set of each task $\mathcal{T}_i$ to memory M_i and jointly train the model on new task data D_k and memory $M_{<k}$.
- ***EWC***: Maintain the memory in the same way as *Replay* but use it to compute the Fisher information matrix for regularization (Kirkpatrick et al., 2017).
- ***AdapterCL***: Freeze the pre-trained model and train a residual Adapter (Houlsby et al., 2019) for each task independently (Madotto et al., 2021).

Above methods use the same input and output format as in Figure 2(a).

Prompt tuning based methods including our proposed *Continual Prompt Tuning* are list below:

- ***Prompt Tuning*:** Formulate DST as a masked spans recovering task (Sec. 3.2) and only tune the prompt for each task independently.
- ***Multi-task Prompt Tuning*:** *Prompt Tuning* in a multi-task manner instead of CL. Train a single prompt using all tasks' data concurrently.
- ***Continual Prompt Tuning*:** *Prompt Tuning* with CLInit (Sec. 3.3.1) and query fusion (Sec. 3.3.2).
  - ***w/ memory*** with memory replay (Sec. 3.3.3).
  - ***w/ memory & backward*** with memory replay and memory-guided backward transfer (Sec. 3.4).

We use the following setting in the experiments unless otherwise specified.

Training task sequences Since a sequence of all (44) tasks is too long for the evaluation purpose, we conduct most of the experiments on 15 tasks chosen at random to save computing resources. We run *AdapterCL*, *Prompt Tuning*, and *Multi-task Prompt Tuning* 5 times with different random seeds because they are agnostic to task order. The FWT and BWT metrics for these models are left blank. We run other methods in the same 5 task orders created by random permutation. The selected tasks and ordering are listed in the Appendix (Table 9).

Hyper-parameters We use T5-small as the backbone model and reuse its sentinel tokens (Raffel et al., 2020). For each task, *Continual Prompt Tuning* first trains 10 epochs with fused query (and using memory if available) for forward transfer. Afterward, it concentrates on the current task and continues training 10 epochs on the original data of the current task. When using backward transfer, we train 5 epochs for each previous task. Other methods train 20 epochs for each task. We use AdamW and set the learning rate to 3e-5 for *Fine-tuning*, *Replay*, and *EWC*, 3e-3 for *AdapterCL*, and 0.5 for all prompt tuning based methods. We set the batch size to 16 for prompt tuning based methods and 8 for other methods. To avoid overfitting, we perform early stopping if validation performance does not improve for 5 consecutive epochs. The weight for *EWC* regularization loss is 0.01. We set the memory size $|M|$ to 50 for each task and save the same samples for all methods that require memory. We initialize prompt tokens with the tokens randomly drawn from the vocabulary. For prompt tuning based methods, we tune 100 soft prompt tokens with the embedding size 512 for each task, resulting in 51.2K parameters. To compare parameter efficiency, we adjust *AdapterCL*'s parameters for each task to be nearly 1x or 20x as ours.

5 Experiments and Analysis

The experiments are organized as follows. We compare our method with baselines in Sec. 5.1, and present a comprehensive ablation study in Sec. 5.2. We investigate the effect of prompt initialization in Sec. 5.3, and the effect of model size and prompt length in Sec. 5.4.

5.1 Main Experiment

Computation Resource Analysis. In CL, there is a trade-off between performance and computation resources. Ideally, we hope to utilize the least amount of computation resources to achieve the best performance. We take three vital resources into our consideration. **Memory** saves previous tasks' samples, which may involve privacy issue and requires extra storage. **Additional parameters** are the extra parameters we add to our model to cope with different tasks along the CL process, which should be kept to a minimum in order to scale to long task sequences. **Tunable parameters** are the trainable parameters when we learn a task, which is important for GPU memory and computation. We show the usage of these resources in Table 1 (right). *Replay* stores $|M|$ samples for each task and does not need extra parameters. *EWC* saves the Fisher information matrix and original parameters, requiring two times additional parameters. *AdapterCL*, *Prompt Tuning*, and *Continual Prompt Tuning* require no memory and only add a small number (2% or 0.1%) of additional parameters for each task, largely reducing the computational and storage overhead. Apart from the vanilla form, *Continual Prompt Tuning* can also utilize the memory if available.

CL Performance Analysis. Overall CL results of different methods are summarized in Table 1 (left). We have the following findings:

- Consistent with Madotto et al. (2021), both *Fine-tuning* and *EWC* suffer from catastrophic forgetting while replaying memory can alleviate the problem to a large extend. *Fine-tuning* and *EWC* have a low Avg. JGA because of the large negative BWT, while *Replay* improves BWT a lot thus has a high Avg. JGA.

Method	Avg. JGA	FWT	BWT	Memory	+Params	Tune Params
Fine-tuning	$14.3_{0.8}$	$8.3_{1.0}$	$-49.9_{4.4}$	-	0	1
EWC	$13.9_{1.1}$	$8.4_{0.9}$	$-50.8_{4.3}$	$\|M\|$*T	2	1
Replay	$58.6_{3.5}$	$10.9_{0.5}$	$-3.2_{2.3}$	$\|M\|$*T	0	1
AdapterCL (20x)	$49.8_{1.7}$	-	-	-	2%*T	2%
AdapterCL (1x)	$30.6_{1.1}$	-	-	-	0.1%*T	0.1%
Prompt Tuning	$48.1_{0.9}$	-	-	-	0.1%*T	0.1%
Continual Prompt Tuning	$\mathbf{59.5}_{1.4}$	$9.9_{0.7}$	0	-		
w/ memory	$60.7_{2.4}$	$\mathbf{13.7}_{0.8}$	0	$\|M\|$*T		
w/ memory & backward	$\mathbf{61.2}_{2.5}$	$\mathbf{13.7}_{0.8}$	$\mathbf{0.5}_{0.4}$	$\|M\|$*T		
Multi-task Prompt Tuning	$64.0_{1.9}$	-	-	-	0.1%	0.1%

Table 1: Performance and resource usage on 15 tasks CL in 5 random orders. Means and standard variances are reported. "T" is the total number of tasks. "+Param" and "Tune Params" are additional parameters in total and tunable parameters for each task, respectively, measured by the ratio to the pre-trained model's parameters. We adjust *AdapterCL*'s parameters for each task to nearly 1x or 20x parameters of prompt tuning based methods.

- Our proposed *Prompt Tuning* with masked spans recovering is more parameter efficient than *AdapterCL*. In terms of Avg. JGA, *Prompt Tuning* is much better than *AdapterCL* with the same size and comparable to *AdapterCL* with 20x parameters.
- Forward transfer through CLInit and query fusion is effective for *Prompt Tuning*. *Continual Prompt Tuning* improves over *Prompt Tuning* significantly and outperforms baselines.
- When memory is available, our method achieves the best results w.r.t. all metrics, closing the gap between CL and multi-task learning. Memory improves zero-shot performance (FWT) on new tasks as *Replay* is better than *Fine-tuning* and *Continual Prompt Tuning w/ memory* is better than without memory.
- Our memory-guided backward transfer effectively utilizes subsequent tasks to help previous tasks. Although minor, *Continual Prompt Tuning w/ memory & backward* is the only method that exhibits positive BWT.

5.2 Ablation Study

	MSR	CLInit	QF	MR	Avg. JGA	FWT
1					$29.6_{1.2}$	-
2		✓			$41.8_{2.8}$	$6.7_{0.3}$
3	✓				$48.1_{0.9}$	-
4	✓	✓			$57.6_{2.5}$	$9.6_{1.2}$
5	✓	✓	✓		$59.5_{1.4}$	$9.9_{0.7}$
6	✓	✓		✓	$60.4_{1.1}$	$11.9_{0.6}$
7	✓	✓	✓	✓	$60.7_{2.4}$	$13.7_{0.8}$

Table 2: Ablation study for masked spans recovering formulation (MSR), prompt initialization (CLInit or random), query fusion (QF) and memory replay (MR).

To understand the effect of different proposed techniques, we conduct an in-depth ablation study and show the result in Table 2. Row 1 and 2 do not formulate DST as a masked spans recovering (MSR) task: the input is the concatenate of the dialog, service name, and soft prompt, while the output is a sequence of slot-value pairs as in *Fine-tuning* (Figure 2(a)). Several interesting observations can be noted: **First**, formulating DST as MSR is beneficial. Using MSR achieves better CL performance regardless of learning each task independently (row 3 v.s. row 1) or continually using CLInit (row 4 v.s. row 2). Besides, MSR formulation improves zero-shot generalization on new tasks (row 4 v.s. row 2). **Second**, forward transfer through CLInit brings large improvement for CL. CLInit outperforms random initialization greatly for both using MSR formulation (row 4 v.s. 3) and not (row 2 v.s. 1). **Third**, both query fusion and memory replay are effective. When they are used separately, memory replay (row 6) boosts the performance more than query fusion (row 5), while applying them altogether achieves the best performance (row 7).

5.3 Continual Prompt Initialization

In this experiment (Table 3), we compare CLInit with other prompt initialization strategies for *Prompt Tuning* in CL. SelectInit (see Sec. 3.3.1)

Initialization	Avg. JGA	FWT
Random	$48.1_{0.9}$	-
SelectInit	$54.5_{2.0}$	$8.2_{1.3}$
CLInit	$57.6_{2.5}$	$9.6_{1.2}$

Table 3: Comparison of different prompt initialization strategies for *Prompt Tuning*.

Training task sequence	Testing tasks $\mathcal{T}_{40:44}$	$\mathcal{T}_{30:44}$	$\mathcal{T}_{15:44}$
$\mathcal{T}_{40:44}$	45.1	-	-
$\mathcal{T}_{30:44}$	54.2	59.7	-
$\mathcal{T}_{15:44}$	59.0	64.4	64.3
$\mathcal{T}_{1:44}$	60.7	67.8	69.3

Table 4: *Prompt Tuning* with CLInit on the last 5, 15, 30, and 44 (all) tasks of the same task order. We report the Avg. JGA on the last 5, 15, and 30 tasks, respectively.

selects the prompt that has the best zero-shot performance on the current task from all previous tasks' prompts for initialization. We could see that both SelectInit and CLInit outperform random initialization significantly, demonstrating the effectiveness of transferring knowledge from previous tasks through prompt initialization. CLInit is slightly better than SelectInit in both Avg. JGA and zero-shot generalization (FWT), which reveals the benefit of accumulating knowledge from all seen tasks. In contrast, the prompt initialized by SelectInit has seen *fewer* tasks and thus contains less knowledge, which might explain the slightly worse result.

Based on the observation above, we further study that whether seeing *more* preceding tasks further helps CLInit. To this end, we choose a task order of all 44 tasks at random (see Table 8 in the Appendix) and perform *Prompt Tuning* with CLInit on the last 5, last 15, last 30, and all 44 tasks separately. Formally, we train on four CL curriculums $\mathcal{T}_{40:44}$, $\mathcal{T}_{30:44}$, $\mathcal{T}_{15:44}$, and $\mathcal{T}_{1:44}$, which have the same ending. We calculate the Avg. JGA on the $\mathcal{T}_{40:44}$, $\mathcal{T}_{30:44}$, and $\mathcal{T}_{15:44}$ if possible. As illustrated in Table 4, performance on the same tasks (in the same column) increases monotonously as the number of preceding tasks grows. This pattern validates that the benefit of CLInit becomes more evident as the number of tasks increases. This finding suggests that our method is suitable for long task sequences.

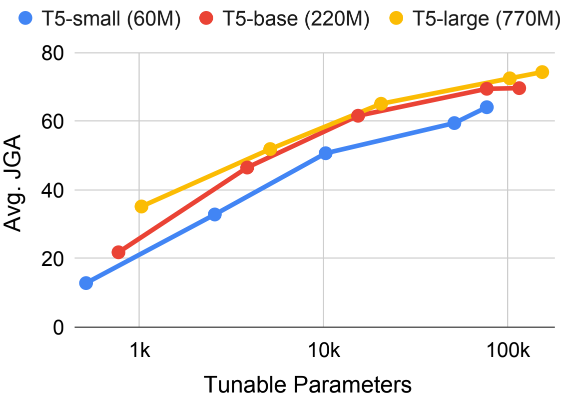

Figure 3: Avg. JGA for *Continual Prompt Tuning* with different pre-trained models and prompt lengths. The x-axis is the number of tunable parameters in log scale. The points on each curve correspond to 1, 5, 20, 100, and 150 prompt tokens from left to right.

	Prompt Length 1	5	20	100	150
T5-small (60M)	6.1	6.7	8.9	9.8	9.8
T5-base (220M)	5.7	9.9	12.9	18.3	15.0
T5-large (770M)	10.6	17.0	18.5	28.0	31.2

Table 5: FWT for *Continual Prompt Tuning* with different pre-trained models and prompt lengths.

5.4 Model Size and Prompt Length

In this experiment, we analyze the influence of pre-trained model size and prompt length. We vary the pre-trained model in {T5-small, T5-base, T5-large} and prompt length in {1, 5, 20, 100, 150} for *Continual Prompt Tuning* on the 15 tasks (the task order is in Table 9 in the Appendix). Figure 3 shows Avg. JGA and Table 5 shows FWT. We can observe that: **First**, when fixing the prompt length, increasing the model size improves the Avg. JGA as well as the generalization ability measured by FWT in most cases. **Second**, when the backbone model size is fixed, increasing the prompt length improves the overall performance in general. Furthermore, we found that increasing prompt token length from 20 to 100 improves Avg. JGA and FWT more than increasing it from 100 to 150, which is consistent with the finding in Lester et al. (2021). **Third**, our method becomes more parameter-efficient as the backbone model size grows. With the same number of tunable parameters (x-axis), using a larger pre-trained model achieves better Avg. JGA.

	Memory Size		
	10	50	100
Replay	$44.0_{1.0}$	$58.6_{3.5}$	$65.6_{0.8}$
CPT w/ mem.	$59.0_{3.3}$	$60.7_{2.4}$	$59.7_{3.2}$
CPT w/ mem. & back.	$58.6_{3.7}$	$61.2_{2.5}$	$60.4_{3.3}$
BWT	$-0.4_{0.5}$	$0.5_{0.4}$	$0.8_{0.4}$

Table 6: Avg. JGA for *Replay* and *Continual Prompt Tuning* (*CPT*) with memory replay (and memory-guided backward transfer) using different memory size. BWT for *CPT w/ mem. & back.* is also shown.

5.5 The Effect of Memory Size

In this section, we compare the role of memory in *Replay* and our method. We vary the memory size per task $|M|$ in {10, 50, 100} and show the performance of *Replay* and *Continual Prompt Tuning* with memory replay (and memory-guided backward transfer) in Table 6. We can find that increasing the memory size benefits *Replay* significantly. This is not surprising because *Replay* and other rehearsal methods rely on memory to solve the challenging forgetting problem. When the memory size is unlimited, *Replay* degenerates to multi-task learning, which is powerful but costly in storage and computation.

For *Continual Prompt Tuning*, however, the memory is not used for retaining the performance on previous tasks since parameters for previous tasks are saved.

- In forward transfer, the memory helps recall previous tasks' knowledge and serves as a complement to CLInit and query fusion. The influence on Avg. JGA depends on the effect of transfer learning on the current task via multi-task training ($\mathcal{L}_{\theta_{P_k}}(D_k + M_{<k})$). As shown in the row 2 in Table 6, increasing the memory size does not improve Avg. JGA significantly and may even distract the model from learning the current domain. This result suggests that our method does not need a large memory for forward transfer.
- In backward transfer, the memory gives reference gradients to guide the updates and serves as a filter to decide whether to accept the updates. Thus larger memory gives more accurate guidance. From the bottom row in Table 6, we can find that increasing memory size can improve the effect of backward transfer.

We also conduct experiments using a percentage memory budget, setting the memory size for each task proportional to task data size: $|M_i| \propto |D_i|$. This means low-resource tasks have fewer samples stored in the memory than in the original setting. We set the total memory size to 50 * T, where T is the number of tasks. As shown in Table 7, *Replay* performs much worse (58.6→55.8) in the unbalanced task memory setting while the effect on *Continual Prompt Tuning w/ mem.* is slight (60.7→60.3). Besides, our proposed backward transfer technique is still effective.

	Memory Size	
	fixed = 50	proportional
Replay	$58.6_{3.5}$	$55.8_{0.7}$
CPT w/ mem.	$60.7_{2.4}$	$60.3_{3.1}$
CPT w/ mem. & back.	$61.2_{2.5}$	$60.7_{3.4}$
BWT	$0.5_{0.4}$	$0.4_{0.5}$

Table 7: Avg. JGA for *Replay* and *Continual Prompt Tuning* (*CPT*) with memory replay (and memory-guided backward transfer) using the fixed/proportional memory size. The total memory sizes are the same. BWT for *CPT w/ mem. & back.* is also shown.

Overall, these results indicate that compared with *Replay*, our method uses the memory differently and benefits less from enlarging the memory.

6 Conclusion

In this paper, we develop prompt tuning for continual learning for the first time. We propose *Continual Prompt Tuning*, a highly parameter-efficient framework that avoids forgetting and enables forward/backward knowledge transfer among tasks. For forward transfer, we explore continual prompt initialization, query fusion, and memory replay techniques. For backward transfer, we devise a memory-guided technique. Extensive experiments on continual learning for DST demonstrate the effectiveness and efficiency of our proposed method compared with state-of-the-art baselines. Our method and findings will foster more future studies towards building more scalable, adaptable task-oriented dialog systems.

There's a Time and Place for Reasoning Beyond the Image

Abstract

Images are often more significant than only the pixels to human eyes, as we can infer, associate, and reason with contextual information from other sources to establish a more complete picture. For example, in Figure 1, we can find a way to identify the news articles related to the picture through segment-wise understandings of the signs, the buildings, the crowds, and more. This reasoning could provide the time and place the image was taken, which will help us in subsequent tasks, such as automatic storyline construction, correction of image source in intended effect photographs, and upper-stream processing such as image clustering for certain location or time.

In this work, we formulate this problem and introduce `TARA`: a dataset with 16k images with their associated news, time, and location, automatically extracted from New York Times[1] (NYT), and an additional 61k examples as distant supervision from WIT (Srinivasan et al., 2021). On top of the extractions, we present a crowdsourced subset in which we believe it is possible to find the images' spatio-temporal information for evaluation purpose. We show that there exists a 70% gap between a state-of-the-art joint model and human performance, which is slightly filled by our proposed model that uses segment-wise reasoning, motivating higher-level vision-language joint models that can conduct open-ended reasoning with world knowledge. The data and code are publicly available at `https://github.com/zeyofu/TARA`.

1 Introduction

Vision and language are two of most important information sources, and the fact that humans reason jointly with both sources has motivated artificial intelligence research to consider visually-grounded language understanding. Most work in this area has focused on reasoning with local evidence (Suhr et al., 2019; Hudson and Manning, 2019; Lu et al., 2020; Liu et al., 2021), e.g. asking factoid questions such as the colors or shapes of objects and numbers of people, yet very few works (Cui et al., 2021) encourage open-ended reasoning where a model needs to look beyond task inputs. However, humans can relate visual cues to corresponding contextual information that could be multi-modal, and draw on background knowledge when interpreting and grounding images. For example, as Figure 1 shows, people that are familiar with the news can infer that the location is Times Square through the iconic screen panels, and further estimate the period of time by looking at the crowds and the signs. And, this can be done without explicitly including related news pieces as input. In fact, even though some people would not have the prior knowledge to identify the relevant events, it is likely that they would have good estimate of the location and time by interpreting textual evidence in the image, the language in the signs, entity names, building styles, and other details in the input image.

Figure 1: This is an image from the New York Times. Can you tell the time and location when it was taken?

In this work, we identify and formulate this problem, spatio-temporal grounding of images, a

Figure 2: What is the time and location for this image?

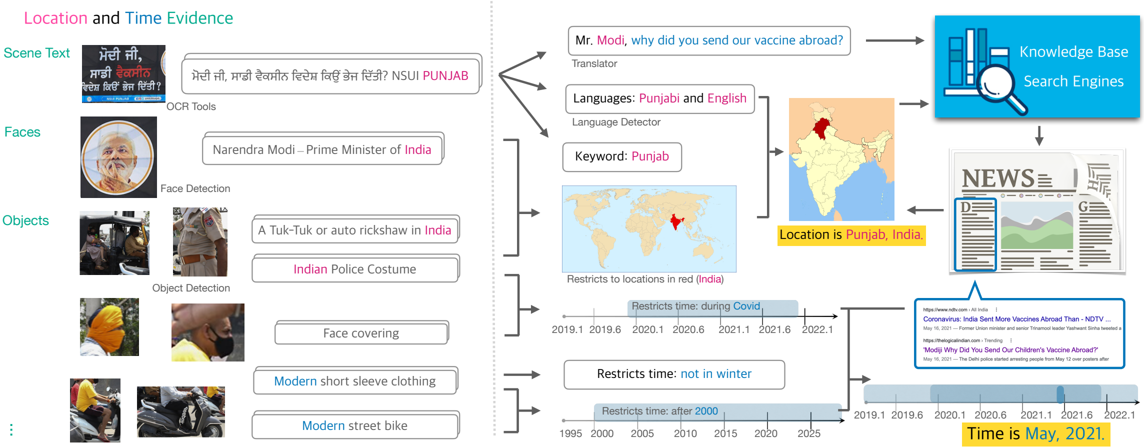

Figure 3: An example of potential joint reasoning on Figure 2 to ground its time and location. Note that people with different backgrounds may need to use different levels of reasoning, resulting in a completely accurate or just partial grounding (e.g., the decade and country), and we only show one such reasoning route. We start with grounding multiple scene text, faces, and objects segments from the image, and use the information to conduct a constrained search in a large news-base, until it locates specific textual information related to the image.

task aiming at identifying the *time* and *location* in which the given image was taken. Specifically, we develop a novel dataset TARA, (<u>T</u>ime and pl<u>A</u>ce for <u>R</u>easoning beyond the im<u>A</u>ge), a challenging dataset that tasks models with grounding images to real-world spatial and temporal information. In our collection, we make sure that for models to accurately find images' creation time and location, they would need to successfully ground the visual clues in texts such as news, stories and encyclopedias. As a result, this task motivates models to consider the association between visual information, language, and background knowledge, more closely and in a more open-ended setting. Figure 2 shows an example from TARA, and Figure 3 shows a possible way for a model to ground the image to its spatio-temporal information. The system starts with grounding multiple segments from the image, and uses the information to conduct a constrained search in a large news-base, until it locates specific textual information related to the image. This demonstrates the complexity and significance of this task.

TARA is collected via a rigorous process that involves rule-based distant supervision extraction from news-images data which results in 16k image examples. While the training data has high label correctness (around 95%), we further run a crowdsourced validation on 3k examples to form the evaluation dataset. During the validation, annotators are asked to verify that there exists a potential path for humans to derive the correct answer, which encourages proper reasoning in future works. To better support the study of domain transfer and supervision for the reasoning process, we collect an additional 61k examples from the Wikipedia domain. We apply the state-of-the-art joint model CLIP (Radford et al., 2021) and show that it only achieves accuracy of 11.11% and 0.46% for time and location, respectively, on our dataset.

Additionally, we present a new CLIP-based baseline model that reasons on object and facial segments and achieves 16.46% and 1.07% accuracy for time and location, respectively. We show that there exists a large gap (around 70% in accuracy) between state-of-the-art models and human performance, suggesting that the `TARA` data will provide a benchmark to motivate reasoning based approaches and support significant future work.

2 Related Work and Datasets

Vision and Language Learning Language understanding in the context of images has been widely studied in various datasets covering a wide range of tasks including visual question answering, image retrieval, image and video captioning, etc. Earlier datasets mostly focus on simple local object properties identification (Antol et al., 2015; Chen et al., 2016). Later on, datasets start to focus on compositional visual reasoning. For example, Suhr et al. (2017) and Johnson et al. (2017) use synthetic images or synthetic language to study spatial relations. Recently, datasets using real images and real languages such as (Hudson and Manning, 2019; Liu et al., 2021) were proposed for reasoning about natural language descriptions of photos. However, all of the datasets focus on local grounding on segments inside the image, but not globally ground beyond the image with open-ended reasoning.

While there are various tasks and datasets, the underlying associations between language and visual concepts are often common across different tasks (Lu et al., 2020). Therefore, we use CLIP (Radford et al., 2021) to study the `TARA` dataset in this paper. CLIP is a recently released state-of-the-art image representation model which has shown impressive performance on various tasks through pre-training on 400 million image and captions pairs collected from the internet.

Spatio-temporal IE from Texts There has been extensive work on identifying temporal expressions and their associations with events in texts. UzZaman et al. (2013); Ning et al. (2018) focus on temporal information extraction within the local contexts, and Zhou et al. (2020, 2021) further extends the scope to consider contextual information from external texts. The NLP community has also investigated spacial information extraction, with geocoding (Gritta et al., 2018; Kulkarni et al., 2020), which maps mentions to geological coordinates, being closest to our scope.

3 Dataset Collection

Each example in `TARA` includes a news image, along with its time, location, caption, and corresponding news background such as headline, abstract, and news type. These are included for training or analysis purposes, but the task is to guess the correct time and location as accurately as possible given only the image. In developing the dataset, our goal is to collect a large corpus of semantically rich images that human with world knowledge can correctly identify the time and location, using evidence from the image, background knowledge, and appealing to external knowledge (which we call “reasoning" here). We design the process of collecting and identifying the images so that it facilitates this type of reasoning, and then use crowd sourcing to label a random 20% of high-quality images for development and testing. Figure 4 illustrates our data collection procedure.

3.1 Image collection

We first collect all the news between January 2010 and May 2021 using the NYT API [2]. We did not collect news that are earlier than 2010 because earlier news articles contain much fewer images. Each news article comes with a list of attributions[3] such as headline, abstract, news type, and possibly a main image. We first filter the news articles that has a valid image, and then scrape image caption for each image. Since the NYT covers news in several multimedia formats, the images follow a range of formatting practices, such as representative news images, image collages, images sampled from slideshows and descriptive natural thumbnails for videos. We setup a NYT specific pipeline to scrape image captions. We define a separate scraping procedure to get image specific text information for the different media types mentioned above and remove instances where multiple and/or ambiguous captions are returned.

Image Pruning and Labeling Next, we describe how we automatically collect time and location of an image from corresponding news articles and captions. First, we filter out the images with

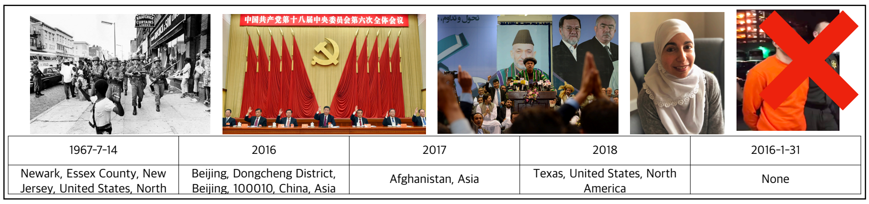
---

[2] `https://developer.nytimes.com/docs/archive-product/1/overview`

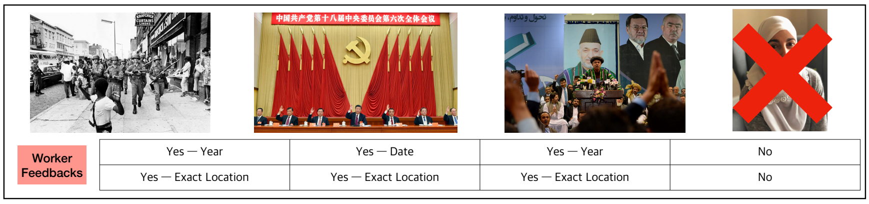
[3] For each news, the API provides attributes as listed here: `https://developer.nytimes.com/docs/archive-product/1/types/Article`

(a) **Collect Images**: We collect all the news with images from NYT between January 2010 and May 2021, and crawl captions.

(b) **Image Pruning and Labeling**: We use NER models to prune images using captions, and assign possible time and location labels. In this example, the last image is removed because there is not location detected in the caption.



(c) **Validation**: Crowdworkers are given only the images. They need to judge whether human, e.g. local people, can guess the time and location of the image, without searching online. If positive, we adjust label to the majority hierarchy; otherwise, the image will be removed.



(d) **Validation**: Crowdworkers are given the image, news headline, possible labels, and possible main event we extracted from news. They decide whether the possible labels are correct. In this example, the majority workers think the time label is wrong, so we use Null as label.

Figure 4: Data collection process. Steps (a)–(b) are described in Section 3.1; and steps (c)-(d) in Section 3.2.

unwanted news types such as reviews, series, and obituaries, and unwanted news topics such as food, fashion, and movies, because images from these articles may not be informative enough. Then, we filter out the images whose caption does not contain location and time. For those that contain temporal and spacial cues, we assign each image a possible time label and location label. Specifically, we use the Spacy NER model[4] to find if the caption has both exactly one "DATE" entity for time and one "GPE" or "LOC" typed entity for location. Note that each news comes with a publication date and possible locations in attributes. We would either directly use our NER-extracted time entity as the possible time label if it's a valid time, or adjust the publication date using the time entity. For example, if the time entity is "1936" and publication date is "2021-05-01", then we will use "1936" as the possible time label because it should be an old image occurring in a recent news; in the latter case, if the time entity is "last month" and publication date is "2015-07-18", then we will use "2015-06" as the possible time label. We also compare our NER-extracted location entity with the news attribute locations. If the only difference is granularity, e.g. one is New York, United States and the other is United States, then we will use the fine-grained one "New York, United States" as possible location label. Otherwise, we will filter our this image.

Finally, we add missing hierarchies for each possible label. For time labels, we add the decade and the century. For location labels, we use Geopy[5] to identify the location and add missing hierarchies such as country and continent.

3.2 Validation

We randomly select an equal number of images from each month, such that a total of about 20% images are assigned to devlopment and test. On

---

[4] `https://spacy.io/models/en`

[5] `https://geopy.readthedocs.io/en/stable/`

these images, we use two crowdsourcing tasks to (1) prune unanswerable images, and (2) verify correctness of the labels.

In the first task, we display a single image, and ask a worker to answer, without searching online, if any person can guess the time and location of the image. We offer different hierarchies in the choices – date, year, decade, and century for time and exact location, city, country, and continent for location – so that workers can choose one of these. If the majority of workers agree that human cannot reason time or location based on the image itself, we will mark the corresponding label as null. Otherwise, if the majority of them agree on a certain hierarchy, we adjust the possible label to that specific hierarchy. Check step(c) in Figure 4 for criteria and positive and negative examples.

The second task further verifies the correctness of current time and location labels. Specifically, we provide the same image, but including its caption, news headline, abstract, and extracted time and location labels. We ask the workers to verify if the background event is the same as in image, and if the labels are correct after reading the additional information. We use the Semantic Role Labeling (SRL) model[6] from AllenNLP to detect the main verb in the image caption by selecting the verb with most arguments, and mark it as the possible main event to provide to the workers. Detailed examples can be found in step(d) in Figure 4.

3.3 Test Set of Interest

We further select a small set of 30 interesting images as shown in Figure 5, that are related to most famous news happening after January 2021, the CLIP model date.[7] This adversarial test set is specifically chosen to cover unseen images by baseline models to better test their generalization instead of memorization.

Additionally, regarding to human baseline, annotators need to have enough knowledge to extract and interpret the key evidence segments, in order to reason about the answer. For instance, a person with an American cultural background and speaks English but not Hindi may find Figure 1 is easier to infer the precise time and location than Figure 2, compared to a person with Indian cultural background and speaks Hindi but not English, and vise versa. This test set of interest is chosen to cover most well-known news for the purpose that human baseline annotators are more likely to have enough knowledge about the key evidence so that the comparison with neural models can be more fair.

Dataset	Train	Dev	Test	All
`TARA` before validation	12,306	1,644	1,644	15,652
`TARA`	12,306	1,552	1,571	15,429
WIT				61,325

Table 1: Dataset statistics for `TARA` and additional WIT supervision.

3.4 Additional Weak Supervision

We apply the same image pruning and labeling procedures on the WIT dataset (Srinivasan et al., 2021), which contains 11.5M Wikipedia images and the surrounding paragraphs and captions. Since this dataset is much unorganized, we only select images in English Wikipedia articles, and apply two additional NER models (Lample et al., 2016; Peters et al., 2017) from AllenNLP[8] to select locations. We further use zero-shot CLIP model to prune unwanted image types. Specifically, we provide each image with text sentences in the format of "a photo of [*type*]", with *type* being *photograph*, *map*, *paint*, and *paper*, and retrieve the sentence with highest similarity score. We only keep images of type *photograph*, and use these as additional weak supervision. The benefit of adding this additional weak supervision is that it has a wider range of time and location labels than the NYT images, especially because that all the NYT images are taken from news between 2010 and 2021.

4 Dataset Analysis

4.1 Dataset Statistics

Dataset statistics can be found in Table 1. `TARA` contains about 16K images from New York Times. After crowd-sourcing validation on development and testing, about 94% of the images that either has a valid location label or time label are kept, indicating that our training set can serve as a good weak supervision. In addition, `TARA` provides a 61K weak supervision dataset built upon WIT.

[7] `https://github.com/openai/CLIP/blob/main/model-card.md`

[8] `https://demo.allennlp.org/named-entity-recognition/fine-grained-ner`

Figure 5: Some example images in our test set of interest as described in Section 3.3. These very recent images require open-ended reasoning with world knowledge and are specifically chosen such that our human baseline annotators probably have enough knowledge about the key evidence. For example, in the first image, people need to know what "BLM" is so that they can start to search statues in United States. Also in the second image, people need to know it is the President Biden for further reasoning.

4.2 Time and Location Distribution

Figure 6 shows the time and location distribution in TARA. We can see that most images are taken in North America, Asia, and Europe, between 2010 and 2021. This can be the effect of using NYT as image source.

5 Baselines

We assess the quality of our dataset through human annotation, and evaluate on existing visual reasoning approaches.

5.1 Human Performance

As introduced in Section 3.3, an expert annotator works on our test set of interest to gain a better understanding of the human performance on TARA. The expert is not allowed to directly search the image online, but can search for anything else such as the keywords she/he infers from the image. The expert is presented with all the labels in the test set just as neural models.

5.2 Evaluation Systems

We use the state-of-the-art systems in machine reading comprehension for this task: **CLIP** (Radford et al., 2021). CLIP is the state-of-the-art image representation model and has shown impressive progress on visually grounded language understanding tasks. Specifically, we use the "ViT-B/32" model[9] for zero-shot classification and analysis. During prediction, the model is given a single image and needs to classify the correct label. We use a similar prompt template "A photo taken in {label}." following the original paper, to encode all the labels. We compare the similarity between the image and each label prompt, and the highest one is the predicted label.

We also add several variants of CLIP. The first is **CLIP+**, which is the zero-shot CLIP model fine-tuned on NYT training data. Note that CLIP uses contrastive loss to train on image and text pairs. We concatenate the time and location labels into a

---

[9] `https://github.com/openai/CLIP`

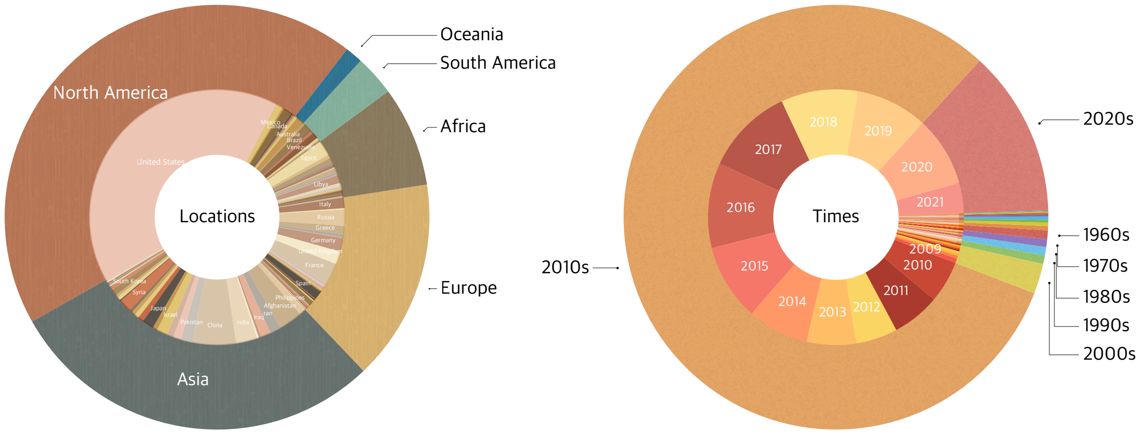

Figure 6: Label distribution in `TARA`. All of the training, development, and testing data are considered.

natural language sentence to serve as the text part for an image.

CLIP+Seg is another variant where we first extract object and face segments, and then finetune the CLIP model on the whole images along with the segments, both with time and location labels concatenated together as the final goal. As for object detection, we use the YOLOv5[10] method, specifically with model "yolov5s". The intuition is that for objects such as iPhone, the model benefits from training it to times later than 2010. We add a limit to the segments so that we only consider important objects that have size larger than 50. We further restrict the number of people segments to be no more than 3, since many of the images have crowds and adding more people do not bring in much additional information. As for face segments, we use the InsightFace (Guo et al., 2022) facial detection model[11]. The intuition is that for famous people such as President Biden, we will benefit from training the segments to location "United States". During implementation, we also add a limit to the segments so that we only consider face that have size larger than 50, which are more likely to be most important faces.

CLIP+WIT is the variant of CLIP where we finetune on the training images along with the 61K weak supervision Images extracted from WIT. We concatenate the possible time and location labels as the paired text.

6 Experiments and Results

6.1 Evaluation metrics

Two metrics are adopted in this work: Accuracy and **Example-F1** (also known as micro-Dice coefficient) following previous studies (Shen et al., 2021). Accuracy is calculated without considering hierarchies – the predicted label needs to exactly match the gold label. In contrast, **Example-F1** calculates the average F1 scores considering each hierarchy as follows:

$$\text{Example-F1} = \frac{1}{N} \sum_{i=1}^{N} \frac{2 \left| \mathbb{L}_i^{\text{true}} \cap \mathbb{L}_i^{\text{pred}} \right|}{\left| \mathbb{L}_i^{\text{true}} \right| + \left| \mathbb{L}_i^{\text{pred}} \right|} \qquad (1)$$

where $\mathbb{L}_i^{\text{true}}$ ($\mathbb{L}_i^{\text{pred}}$) is the true (model predicted) hierarchical label set of image i. For example, if the true labels for an image are "1967-7-14" and "Newark, New Jersey, United States, North America" respectively, then its true hierarchical label sets are ["Newark, New Jersey, United States, North America", "United States, North America", "North America"] and ["1967-7-14", "1967-7", "1967", "1960s", "20th century"].

6.2 Experimental results

In Table 2, we report the experimental results using the CLIP based baselines on the `TARA`. We can see that all of the model performance still have a large gap with human performance. Also, the object and facial segments boosts the model to be the highest on location prediction, proving that segment level reasoning is needed in this task. In contrast, adding the WIT weak supervision does not show consistent improvement or reduction on the performance. It can be due to that WIT images are not similar

[11] `https://github.com/deepinsight/insightface`

Model	Accuracy	Example-F1
CLIP	11.11	44.96
CLIP+	15.72	49.74
CLIP+WIT	11.11	45.20
CLIP+Seg	**16.46**	**50.52**
Human	86.21	92.41

Model	Accuracy	Example-F1
CLIP	0.46	39.90
CLIP+	1.00	**43.09**
CLIP+WIT	**1.07**	41.73
CLIP+Seg	0.92	42.82
Human	75.86	91.63

Table 2: Summary of the performance(%) for different baselines on the image location prediction (above) and time prediction (bottom). Definition of Example-F1 is in Equation 1. Note that human performance here is evaluated on the test set of interest instead of on the whole test set, please see Section 6.3 for more details.

to news images, and that WIT images are mostly taken in older times than 2010, thus not providing enough supervision for our test set. There is also an obvious gap between the location prediction and time prediction, showing that temporal reasoning in vision language learning is much under explored and needs further research. Note that the Example-F1 value is consistently higher than accuracy because if the model predicts the highest two hierarchies correctly (e.g. century and decade), then it gets an Example-F1 around 40%.

6.3 Analysis

We perform qualitative and quantitative analysis of the baseline results to better understand the strengths and weaknesses of CLIP based models, and hypothesize avenues for future work. Specifically, we look into: model performance on test set of interest; effects on performance by using news abstract.

Test Set of Interest Since we conduct human evaluation only on the test set of interest, we examine how models perform on this set and show the results in Table 3. Note that we use the same setting for the models and human experts – both are given the entire test set labels. From the results, we observe a large gap between between the model performance and human performance, indicating that existing sota model still lacks a certain level of reasoning capability required to solve a such hard task as defined in the `TARA` dataset. Comparing the results in Table 3 to those in Table 2, we can see that there is little performance difference for each model, indicating that our human performance on the test set of interest can serve as a good reference to human performance on the whole test set, under the assumption that the annotators have enough knowledge about the key evidence segments.

Model	Accuracy	Example-F1
CLIP	13.33	56.44
CLIP+	13.33	58.67
CLIP+WIT	10.00	55.11
CLIP+Seg	**23.33**	**63.11**
Human	86.21	92.41

Model	Accuracy	Example-F1
CLIP	0.00	24.65
CLIP+	0.00	26.49
CLIP+WIT	0.00	**29.83**
CLIP+Seg	**3.33**	24.43
Human	75.86	91.63

Table 3: Performance(%) of different baselines evaluated on the test set of interest for image location prediction (above) and time prediction (bottom).

Model	Accuracy	Example-F1
CLIP	**28.18**	61.63
CLIP+	26.49	**62.68**
CLIP+WIT	11.11	50.00
CLIP+Seg	26.96	62.41

Table 4: Performance(%) for different baselines predicted towards news abstracts.

News Abstracts We also experiment with news abstracts being the classification goal instead of time and location labels given an image, under the assumption that models are given corresponding news abstract for each label. The intuition is that the news abstract might provide more descriptions that can map to several local segments, and thus providing additional information. Comparing the results shown in Table 4 to Table 2, we can see that providing news abstracts improves the performance a lot, despite that there is still a large gap with human performance.

7 Conclusion

In this work, we introduce `TARA`, a new dataset and task for spatio-temporal grounding of images that requires open-ended joint reasoning with world knowledge. `TARA` provides a dataset of 16K high-quality images from NYT and Wikipedia-based supervision for additional 61K images. Compared to previous visual-language understanding datasets, `TARA` requires more complicated reasoning ability and existing state-of-the-art models such as CLIP are far from human levels, suggesting that our task remains a significant challenge with large room for improvement. We hope that `TARA` will inspire future work on reasoning beyond image's local segments in vision-language understanding.

8 Ethical Considerations

We collected data for `TARA` by downloading raw data from the official NYT API at `https://developer.nytimes.com`. According to the Terms of Use at `https://developer.nytimes.com/terms` and NYTimes.com Terms of Service located at `https://help.nytimes.com/hc/en-us/articles/115014893428-Terms-of-service`, NYT granted us a license to access the NYT APIs and scrape their data. We ensure that our dataset has been collected in a manner which is consistent with the terms of use of NYTimes.

We only release our dataset `TARA` for academic purpose. In order to retrieve the same raw data we scraped from the NYT API, multiple requests for months between January 1, 2010 and May 31, 2020 need to be made following the instructions at `https://developer.nytimes.com/docs/archive-product/1/overview`.

As introduced in Section 3.2, we annotated the data using crowd-workers through Amazon Mechanical Turk. They are voluntary participants who were aware of any risks of harm associated with their participation. We require the workers to be located in either Australia, Canada, Great Britain or the United States such that they are English speakers. We also require the workers to have HIT Approval Rate (%) for all Requesters' HITs greater than or equal to 98%. All crowd-workers were compensated by a fair wage determined by estimating the average completing time of each annotation task. Each worker earn $2.4 per 10 queries and each query should take less than a minute to annotate. Example screenshots of the NYT data and our annotation interface can be found in Appendix A.

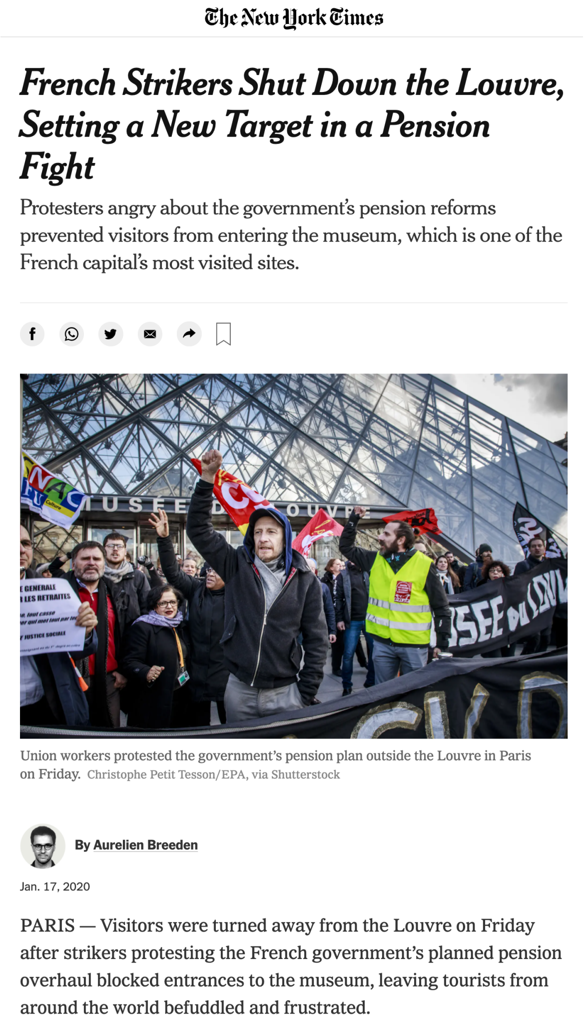
A Example Screenshots from the NYT Website and MTurk Annotation Interface

In this section, we first show an example news screenshot taken from the NYT website located at `https://www.nytimes.com/`, where we use the provided API to download the data, as in Figure 7. We then show example screenshot of our data annotation process as described in Section 3.2. For the data annotation tasks, we present the Turkers with step-by-step instructions of the tasks that we require them to do, along with carefully selected examples. More details can be found in Figure 8.



The New York Times

French Strikers Shut Down the Louvre, Setting a New Target in a Pension Fight

Protesters angry about the government's pension reforms prevented visitors from entering the museum, which is one of the French capital's most visited sites.

Union workers protested the government's pension plan outside the Louvre in Paris on Friday. Christophe Petit Tesson/EPA, via Shutterstock

By Aurelien Breeden

Jan. 17, 2020

PARIS — Visitors were turned away from the Louvre on Friday after strikers protesting the French government's planned pension overhaul blocked entrances to the museum, leaving tourists from around the world befuddled and frustrated.

Figure 7: This is an example news from the New York Times(NYT) website.

Instructions 1:

Below is an image extracted from a New York Times article.

Do not search online, by only looking at the image, Answer the Questions:

Can you tell which specific event the image is about? Events can be like a speech, celebration, etc. Non-events can be like city view, natural views, etc.

○ Yes, I know the exact event.
○ No, but it should be an event.
○ No, I don't think the image is about an event. It's just random views.

Do you think human (you or anyone you know or the local people) can guess the image creation TIME through the information in this image, without searching online?

○ Yes, I/someone can guess the date.
○ Yes, I/someone can roughly guess the year.
○ Yes, I/someone can roughly guess the decade.
○ Yes, I/someone can only guess a rough century.
○ No, because there is hardly any information about the time.

Do you think human (you or anyone you know or the local people) can guess the image creation LOCATION through the information in this image, without searching online?

○ Yes, I/someone can guess the exact location (e.g. Building, Road name, etc.).
○ Yes, I/someone can roughly guess the city.
○ Yes, I/someone can roughly guess the country.
○ Yes, I/someone can only guess a rough continent.
○ No, because there is hardly any information about the location.

Instructions 2:

Look at this image extracted from a NYT article again. Read its caption, article publication date, article headline and article abstract. Answer the questions.

Image Caption: Union workers protested the government’s pension plan outside the Louvre in Paris on Friday..

Article publication date: 2020-01-17

Article headline: French Strikers Shut Down the Louvre, Setting a New Target in a Pension Fight

Article abstract: Protesters angry about the governments pension reforms prevented visitors from entering the museum, which is one of the French capitals most visited sites.

We extracted *Caption-Time* and *Caption-Location* from the image caption and publication date. They should be the time and location of the main event in the caption.

Caption-Time: 2020-01-17

Caption-Location: Louvre Museum, Rue Croix des Petits Champs, Quartier Les Halles, 1st Arrondissement, Quartier du Palais Royal, 1st Arrondissement, Paris, Ile-de-France, Metropolitan France, 75001, France, Europe

Answer the question: Does the image show this main event?

For example, if the image is a cuisine and the caption is about a restaurant, then no; if the image is a building, and the caption is about the building being sold, then no; if the image is about car crash and caption is also about the car crash, then yes.

Does the image reflect the caption's main event? (By our extraction, the main event (not 100% correct) might possibly be **protested**.)

○ Yes.
○ No.
○ Partially -- The image can only reflect partial event discussed in the caption.

Do you think that the image creation time is same as *Caption-Time*: 2020-01-17 (extracted from the image caption and publication date)?

○ Yes, I think the image creation time is EXACTLY the same as *Caption-Time*, because the main event for *Caption-Time* is the same event described in the image.
○ No, the image creation time is not the same as *Caption-Time*, because the main event for *Caption-Time* is **not** the same event described in the image.
○ I guess no, even though the main event for *Caption-Time* is the same event described in the image, I don't think the image creation time must be *Caption-Time*.

Do you think that the image creation location is same as *Caption-Location*: Louvre Museum, Rue Croix des Petits Champs, Quartier Les Halles, 1st Arrondissement, Quartier du Palais Royal, 1st Arrondissement, Paris, Ile-de-France, Metropolitan France, 75001, France, Europe (extracted from the image caption)?

○ Yes, I think the image creation location is EXACTLY the same as *Caption-Location*, because the main event for *Caption-Location* is the same event described in the image.
○ No, the image creation location is not the same as *Caption-Location*, because the main event for *Caption-Location* is **not** the same event described in the image.
○ I guess no, even though the main event for *Caption-Location* is the same event described in the image, I don't think the image creation location must be *Caption-Location*.

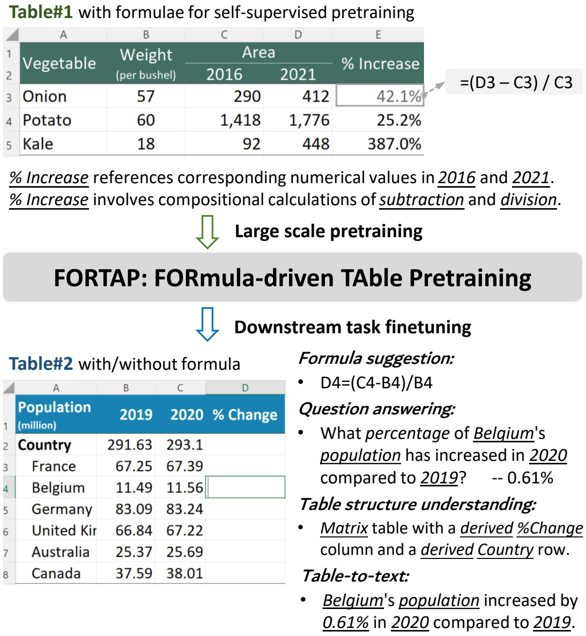
Abstract

Tables store rich numerical data, but numerical reasoning over tables is still a challenge. In this paper, we find that the spreadsheet formula, a commonly used language to perform computations on numerical values in spreadsheets, is valuable supervision for numerical reasoning in tables. Considering large amounts of spreadsheets available on the web, we propose FORTAP , the first exploration to leverage spreadsheet formulas for table pretraining. Two novel self-supervised pretraining objectives are derived from formulas, numerical reference prediction (NRP) and numerical calculation prediction (NCP). While our proposed objectives are generic for encoders, to better capture spreadsheet table layouts and structures, we build FORTAP upon TUTA, the first transformer-based method for spreadsheet&web table pretraining with tree attention. FORTAP outperforms state-of-the-art methods by large margins on three representative datasets of formula prediction, question answering, and cell type classification, showing the great potential of leveraging formulas for table pretraining. The code will be released at `https://github.com/microsoft/TUTA_table_understanding`.



Table#1 with formulae for self-supervised pretraining

	A	B	C	D	E
1	Vegetable	Weight	Area		% Increase
2		(per bushel)	2016	2021	
3	Onion	57	290	412	42.1%
4	Potato	60	1,418	1,776	25.2%
5	Kale	18	92	448	387.0%

=(D3 – C3) / C3

% Increase references corresponding numerical values in *2016* and *2021*.
% Increase involves compositional calculations of *subtraction* and *division*.

Table#2 with/without formula

	A	B	C	D
1	Population (million)	2019	2020	% Change
2	Country	291.63	293.1	
3	France	67.25	67.39	
4	Belgium	11.49	11.56	
5	Germany	83.09	83.24	
6	United Kir	66.84	67.22	
7	Australia	25.37	25.69	
8	Canada	37.59	38.01	

Formula suggestion:
- D4=(C4-B4)/B4

Question answering:
- What *percentage* of *Belgium*'s *population* has increased in *2020* compared to *2019*? -- 0.61%

Table structure understanding:
- *Matrix* table with a *derived* *%Change* column and a *derived* *Country* row.

Table-to-text:
- *Belgium*'s *population* increased by *0.61%* in *2020* compared to *2019*.

Figure 1: It's desirable to learn numerical reasoning via formula pretraining and generalize it to various tasks.

1 Introduction

Tables store rich numerical data, so a wide range of tasks require numerical reasoning over (semi-)structured tabular context, such as question answering over tables (Chen *et al.*, 2021b; Zhu *et al.*, 2021; Cheng *et al.*, 2021), table-to-text (Suadaa *et al.*, 2021; Moosavi *et al.*, 2021; Cheng *et al.*, 2021), spreadsheet formula prediction (Chen *et al.*, 2021a), and table structure understanding (Koci *et al.*, 2019). Take Table#2 in Figure 1 as an example, both suggesting the formula `(C4-B4)/B4` for cell D4 and answering "0.61%" to the question require numerical reasoning capabilities of **(1)** understanding the contextual meaning of individual numerical cells, e.g., "11.49" at `B4` and "11.56" at `C4` are "population"s of "Belgium" in "2019" and "2020"; **(2)** inferring calculational relationships of numerical cells, e.g., percentage change from "11.49" to "11.56". As Figure 1 shows, same capabilities also benefit table structure recognition and table-to-text. So it's a fundamental need to empower table modeling with stronger numerical reasoning capabilities.

However, it is challenging to endow a tabular model with robust numerical reasoning capabilities. First, understanding a local numerical cell needs dimension inference (Chambers and Erwig, 2008), unit inference (Shbita *et al.*, 2019), and index inference (Dong *et al.*, 2019a), e.g., "population" (dimension), "million" (unit), "2020" (index), and "Belgium" (index) jointly describe "11.56" in Figure 1. It is non-trivial concerning the great flexibility of table semantic structures (Wang *et al.*,

May 22-27, 2022

2021b). Second, calculational relationships among two or more numerical cells are various and often compositional, e.g., “F1 Score = 2 × (Recall × Precision) / (Recall + Precision)” in machine learning papers and “Profit Margin = Net Income / Sales” in financial reports. To make matters more challenging, **human labeling** for numerical reasoning in relevant tasks (Chen *et al.*, 2020; Suadaa *et al.*, 2021; Koci *et al.*, 2019) is labor-intensive and error-prone, largely restricting the generalization ability of large models that are rather data-hungry.

Recently, table pretraining on large amount of unlabeled tables shows promising results on table understanding and reasoning. Self-supervised objectives are derived from tables and text such as Masked Language Models (MLM) (Herzig *et al.*, 2020), masked column prediction (Yin *et al.*, 2020), masked entity recovery (Deng *et al.*, 2020b), cell cloze and corrupt detection (Wang *et al.*, 2021b; Tang *et al.*, 2020; Iida *et al.*, 2021), table-text matching and alignment (Wang *et al.*, 2021a,b; Deng *et al.*, 2020a). However, numerical and calculational relationships of cells lack sufficient attention. Then (Yoran *et al.*, 2021) and (Liu *et al.*, 2021; Yu *et al.*, 2020) synthesize questions and SQL queries, respectively, as training corpus for reasoning purpose, but SQL is only applicable to database-like relational tables, and importantly, it’s challenging to ensure synthesized questions and SQLs be realistic, meaningful, and diverse.

Gladly, tens of millions of real spreadsheet formulas are publicly available on the web and can be valuable for numerical reasoning in tables. The spreadsheet formula is an expressive yet simple language consisting of operators (e.g., `+`, `/`, `%`), functions (e.g., `SUM`, `MAX`, `COUNT`), referenced cells (e.g., `B4`), and constant values (e.g., 100) (Aivaloglou *et al.*, 2015). Since writing the formula **does not** require formal programming education, it’s widely used by non-programmers such as business professionals or other kinds of domain specialists whose jobs involve computational tasks. So spreadsheet formulas cover real numerical calculations in a great variety of domains.

To this end, we propose FORmula-driven TAble Pretraining (FORTAP) for numerical reasoning. One should master two basic concepts to use the formula language: cells as variables and operators/functions as relationships between variables. So we explicitly decompose information in formulas into *numerical reference* and *numerical calculation* and devise two complementary tasks. Given a table as well as a formula cell in it, we mask the formula and then (1) the model classifies whether “header A references header B” (we consider that “header A references header B” if the formula cell belonging to header A references a numerical cell belonging to header B, as illustrated in Figure 2); (2) the model predicts the operator/function of two or more referenced numerical cells. Furthermore, to better encode and represent formulas, we also apply MLM to the token sequence of formulas.

Considering the flexibility of table structures in spreadsheets, we base FORTAP on TUTA (Wang *et al.*, 2021b), the first transformer-based method for spreadsheet tables with carefully-designed textual, numerical, positional, and formatting embedding layers. Importantly, its tree-based position encoding and attention are highly effective in representing generally structured tables. TUTA is pretrained with MLM, cell cloze, and table-text matching.

Experiment results on three tasks demonstrate that the significance of leveraging formulas for table pretraining. For formula prediction, FORTAP achieves 55.8% top-1 accuracy, significantly surpassing TUTA (48.5%), TaPEx (43.2%), and SpreadsheetCoder (40.4%) on Enron. For table question answering, TUTA achieves comparable accuracy with the best system on HiTab. After pretraining with formulas, FORTAP delivers a huge improvement of $+6.3\%$ as over previous SOTA, comparable to TaPEx. For cell type classification, on dataset DeEx, FORTAP largely improves TUTA by $+6.6\%$ on `derived` type and $+3.2\%$ on overall Macro-F1.

2 Preliminaries

2.1 TUTA as Encoder

TUTA (Wang *et al.*, 2021b) is the first pretraining architecture for spreadsheet tables. It is effective in capturing table semantic structures, achieving SOTA results on cell type and table type classification. As mentioned in Section 1, understanding table semantic structures is critical to numerical reasoning, so we choose TUTA to be the encoder of FORTAP . Since our pretraining tasks are generic for encoders of tables, future works can also explore other encoders such as (Herzig *et al.*, 2020).

Header Recognition. Headers usually provide short yet informative descriptions of table contents in Natural Language (NL), so TUTA leverages the detected header regions and hierarchies, as presented in Section 2.2. (Chen *et al.*, 2021a) also shows that using headers (even without considering hierarchies) greatly helps formula prediction. FORTAP follows to place detected headers in inputs.

Architecture. TUTA bases on BERT (Devlin *et al.*, 2019) with several enhancements: (1) a *positional encoding layer* based on a unified *bi-dimensional coordinate tree* to describe both the spatial and hierarchical information of cells; (2) a *number encoding layer* to encode magnitude, precision, the first digit, and the last digit; (3) a *tree-based attention* mechanism that enables local cells to aggregate their structurally neighbouring contexts within a *tree-based distance* threshold.

Model Input/Output. The input consists of a table T and optional NL texts C. By traversing the cell matrix of a table from left to right and from top to bottom, the input is linearized to "`[CLS]`, C_0, ..., C_{K-1}, `[SEP]`, $T_{(0,0)}$, `[SEP]`, $T_{(0,1)}$, ..., `[SEP]`, $T_{(M-1,N-1)}$", where K is the token length of NL texts, and M and N are the numbers of rows and columns of the table, respectively. Note that $T_{(i,j)}$ refers to the token sequence of the cell string in the $(i+1)^{th}$ row and $(j+1)^{th}$ column, and each token has token, number, position, and format input embeddings. The output of the encoder contains token-level, cell-level, and table-level embeddings. FORTAP follows these input/output settings except when inputting formula token sequence.

2.2 Pretraining Corpus

Spreadsheet Source and Preprocessing. We use the same spreadsheet table corpus as TUTA: (1) 13.5 million public spreadsheet files are crawled from 1.75 million websites; (2) table ranges and headers are detected using TableSense (Dong *et al.*, 2019b,a); (3) header hierarchies are extracted with effective heuristics; (4) extreme size tables are filtered out; (5) duplicated tables are discarded. In the end, 4.5 million spreadsheet tables are left.

Formula Preprocessing. Spreadsheet Formula is a widely-used end-user language for table organization and calculation. A formula consists of four types of formula tokens: operator (e.g., `+`, `/`, `%`), functions (e.g., `SUM`), referenced cells (e.g., `B4`) and constant values (e.g., 100), which we denote as `OP`, `FUNC`, `CELL` and `CONST` in the rest part of the paper. We use XLParser (Aivaloglou *et al.*, 2015), a highly-compatible formula parser with compact grammar, to analyze formula. In this way, we derive the AST of each formula (an example AST in Figure 2) and the type of each formula token. Since we focus on single table setting, we discard the cross-table, cross-sheet, and cross-file formulas. Formulas with *Array* or *User-Defined-Function* are also discarded. The absolute reference sign "$" is deleted from formula strings, without changing their meanings. We only keep the first five occurrences of formulas in the same row/column because some spreadsheets contain hundreds of duplicated or dragged formulas in one row/column, which are inefficient for training. Formulas are linearized as formula token sequences in prefix representation of AST following SpreadsheetCoder (Chen *et al.*, 2021a). Finally, 10.8 million formulas are derived.

3 Pretraining Tasks

As mentioned in Section 1, empowering table modeling with stronger numerical reasoning capabilities is a fundamental need. Spreadsheet formulas naturally contain information of numerical references (`CELL`) and calculations (`OP`/`FUNC`), motivating us to devise effective tasks to leverage them for numerical-reasoning-aware pretraining.

Based on information parsed from the formula expression, we carefully devise two complementary objectives, Numerical Reference Prediction (NRP) and Numerical Calculation Prediction (NCP), to exploit the reasoning process behind referencing local cells (as operands) and applying calculations (on operands), respectively. Meanwhile, to get better representations of the spreadsheet formula, which could be further used in downstream applications like formula error detection (Cheung *et al.*, 2016), we extend MLM (Devlin *et al.*, 2019) from NL contexts to formulas. Figure 2 gives an illustration of these tasks.

Numerical Reference Predication (NRP) We consider "header A references header B" in a table if: in a formula, the formula cell (cell with formula) belonging to header A references a cell belonging to header B. Take the table in Figure 2 as an example, the header *"%Increase"* references headers *"2016"* and *"2021"* since `E3` in column *"%Increase"* references `C3` and `D3` in columns *"2016"* and *"2021"*. We let the model learn header reference relationship since a cell belonging to a referenced header is more likely to be involved in the calculation. It is important but usually unknown as a priori, especially when tables are from diverse or unfamiliar domains. Note that we use header cells instead of data cells in this task since headers provide high-

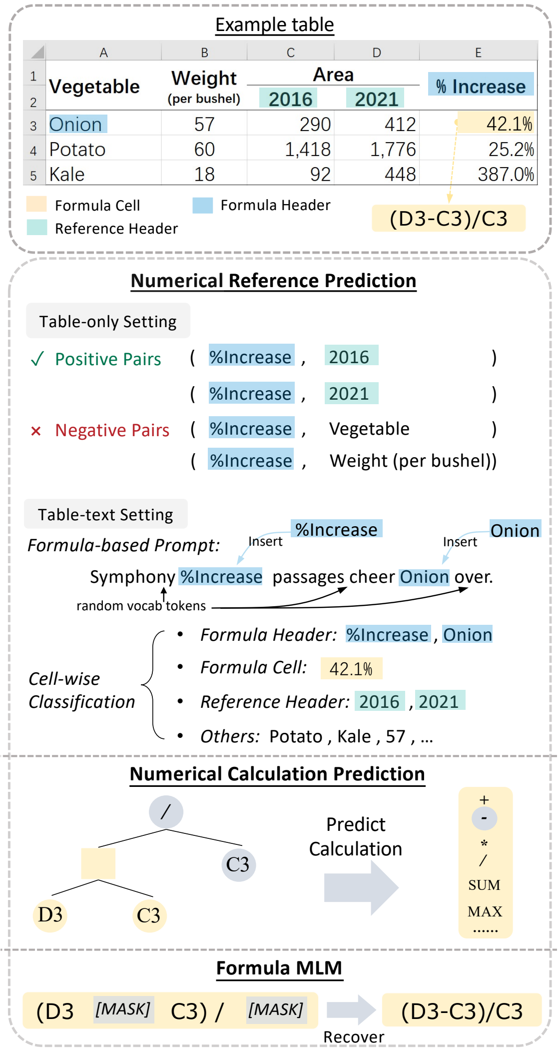

Figure 2: An illustration of formula pretraining tasks.

level descriptions of the data (Chen *et al.*, 2021a) and thus header reference relationships have more generic semantics across tables.

Given extracted header regions and hierarchies in corpus preprocessing, we first formulate NRP as a binary classification task over header pairs: given a formula cell t_f and its referenced cells $\{t_p^{(i)}\}$, we first find their non-shared headers h_f (for t_f) and $\{h_p^{(i)}\}$ (for $\{t_p^{(i)}\}$), then we group them as positive pairs $\{(h_f, h_p^{(i)})\}$. Usually a formula cell shares a header with referenced cells in the same row/column (e.g., in Figure 2, *"Onion"* is the shared header for `E3`, `C3`, `D3`). As it does not reflect header reference relationships, we exclude the shared header in this task. The negative pairs $\{(h_f, h_n^{(i)})\}$ are sampled among those unreferenced headers on the same direction (either on top or left headers) of h_f . Number of negative samples is at most 3:1 to positive ones to balance samples. The binary classification probability of the i^{th} pair $p^{(i)} = f(\mathbf{h}_f, \mathbf{h}_{p/n}^{(i)})$, where $\mathbf{h}$ is the header cell embedding derived by the encoder and $f(\cdot)$ is a two-layer binary classification module.

To inject table-text joint reasoning skills into ForTaP , which TUTA does not excel at, we further extend NRP task to table-text setting. Given a table with a formula cell, we first construct a formula-based prompt as context by picking 1 to 10 tokens randomly from the vocabulary as a noisy sentence and then inserting the row and column header of formula cell into it at random positions. Next, we jointly input the formula-based prompt and the table, and the task is to classify (1) formula header cell, (2) formula cell, (3) reference header cell, (4) other cells from the table. To precisely classify these cells, model needs to first align formula header cells in table with prompt (alignment skill), then infer the intersection cell of formula header cells as formula cell (spatial reasoning). Finally, it has to identify referenced cells (numerical reasoning) by the formula headers.

The NRP loss $\mathcal{L}_{nr}$ is calculated as the sum of binary cross entropy loss and multi-class cross entropy loss under table-only and table-text setting.

Numerical Calculation Prediction (NCP) Given data cells as operands, a model then needs to find out which operators/functions should be applied. For example, in Figure 2, subtraction and division are applied on `C3` and `D3` in the formula. We hope the model can speculate the target operator/function based on the semantics, numeracy, and positions of given operands (data cells). Thus, we design the task to predict the operator/function for a group of data cells with their contextual cell embeddings produced by the encoder.

We formulate it as a multi-class classification task: given a formula and its AST parsed in prerpocessing, we select the operators/functions $\{o^{(i)}\}$ satisfying that all direct children nodes $\{d^{(j)}\}^{(i)}$ on the formula AST of $o^{(i)}$ are in `CELL` type with integer or float data. The probability of predicting the operator/function of these data cells is $p^{(i)} = f(\texttt{POOL}(\{\mathbf{d}^{(j)}\}^{(i)}))$, where $\mathbf{d}$ is the output cell embedding by the encoder, $f(\cdot)$ is a two-layer classification module, and `POOL` is a mean-pooling layer. Note that we only include the operator/function o whose all direct children nodes are in `CELL` type in this task, because otherwise some descendant data cells will first be calculated via other operators/functions and thus have indirect connections with o (e.g., in Figure 2, "/" is not a target operator since its left child is an operator "$-$"). We include 17 common calculation operators/functions (see Appendix A) covered in spreadsheet formulas in this task. The NCP objective $\mathcal{L}_{nc}$ is the multi-class cross entropy loss.

Formula MLM To encode formulas, we expand 41 tokens in the vocabulary for all four formula token types, covering 99.1% formulas in corpus. Added tokens are listed in Appendix A. Note that a special case is the `CELL` type, like `D4`, because it references another cell. Since referenced cells can be anywhere in a large table, it is infeasible to explicitly insert all cell positions into the vocabulary. Thus, for `CELL` type token in formula, we use a `[RANGE]` tag as input token and copy all cell-level embeddings (position, format, numeric, ...) from the referenced cell to this `CELL` type token.

We then apply MLM to formula tokens. Masking and recovering operators/functions is straightforward. When masking or recovering a referenced cell in a formula, we need to avoid label leakage from embeddings of the referenced cell. Thus, to mask a referenced cell, besides using the `[MASK]` token embedding, the number embedding is set to default to mask the number, and the position and format embeddings are set to the same as the formula cell. To recover a masked referenced cell t_r, the cell $t^{(i)}$ in input sequence with the highest probability $p^{(i)} = \texttt{Softmax}(f(\mathbf{t}_r, \mathbf{t}^{(i)}))$ is selected as the predicted cell, where $\mathbf{t}$ is output cell embedding of the encoder and $f(\cdot)$ is a two-layer classification module. The objective $\mathcal{L}_{fmlm}$ is calculated as the sum of cross entropy loss over operator/function recovery and referenced cell recovery.

Finally, the total pretraining objective is

$$\mathcal{L} = \mathcal{L}_{nr} + \mathcal{L}_{nc} + \mathcal{L}_{fmlm} \tag{1}$$

4 Experiments

In this section, we describe the pretraining details and validate the effectiveness of ForTaP on three downstream tasks: formula prediction, question answering, and cell type classification. The statistics of datasets we use are listed in Table 1.

4.1 Pretrain Implementation

We initialize ForTaP with parameters of the pretrained TUTA. The input is linearized following TUTA by concatenating the text (the prompt built in NRP pretraining task) and the flattened table traversed in row order. Due to memory limit, we only place (1) header cells, (2) data cells on the same row/column of the formula cell, into the input sequence and skip the other cells. Our input pattern is reasonable as a tradeoff between performance and memory since we find that more than 89% formulas only reference cells on the same row/column. To match different downstream tasks, for the cell with formula, we input its formula token sequence (e.g. `(C4-B4)/B4`) with 40% probability, formula tag `[FORMULA]` with 30% (the number embedding is set to default) and cell literal value with 30% (e.g. number 42.1). In experiments, we find it is more effective in Formula MLM to mask either all operators/functions or all referenced cells, so we implement it this way. We first pretrain $400K$ steps on sequence length 256 with batch size 32, and $250K$ steps on sequence length 512 with batch size 8. The whole pretraining phase takes about 4 days on 4 Tesla V100 GPUs.

Dataset	**Enron**	**HiTab**	**DeEx**
# samples (train/dev/test)	$125k$ (formulas)	$10.6k$ (questions)	$711k$ (cells)
% hierarchical tables	51.0%	98.1%	43.7%
Avg. rows per table	25.7	17.1	220.2
Avg. columns per table	12.4	8.2	12.7
Avg. formula sketch length	4.13	-	
Avg. op/func per formula	1.62	-	

Table 1: Statistics of downstream datasets.

4.2 Formula Prediction

Formula prediction (Chen *et al.*, 2021a) facilitates spreadsheet end-users by recommending formulas since writing formulas could be time-consuming and error-prone. Given a table and a target cell in table, the task is to predict a formula for the target cell. Formula prediction requires complex in-table numerical reasoning capabilities to predict both referenced cells and involved calculations.

Datasets. Enron (Hermans and Murphy-Hill) is a massive database of public Excel Spreadsheet, containing over 17K spreadsheets with rich table structures and formula types. We exclude Enron from our pretraining corpus to prevent data leakage. Tables and formulas are preprocessed in the same way as the pretraining corpus. We divide Enron by sheet and the final dataset contains $100.3K$/$12.3K$/$12.9K$ table-formula pairs for train/dev/test. The formula cell in table is regarded as the target cell and the formula is seen as the ground truth in formula prediction task. We follow the evaluation metrics in SpreadsheetCoder (Chen *et al.*, 2021a): (1) Formula Accuracy, (2) Sketch Accuracy, (3) Range Accuracy measuring the percentage of correctly predicted formulas, formula sketches (formula using placeholder `[RANGE]` as referenced cells), and formula ranges (only the referenced cells of formula).

Previous to our work, SpreadsheetCoder evaluates formula prediction on collected Google Sheets and Enron. However, we do not directly use its datasets for three reasons: (1) The Google Sheet corpus is not released, and for Enron, SpreadsheetCoder only adopts formulas referencing cells within a limited rectangular neighborhood region (21×20) of the formula cell, while we argue in real tables the referenced cells can be easily beyond this region. (2) A large proportion of table headers are not properly detected (mentioned in its paper), while we adopt ranges and headers detected by TableSense (Dong *et al.*, 2019b) and extract table header hierarchies. (3) Despite the inconsistencies above, we try to backtrack the original file to align with SpreadsheetCoder and apply our preprocessing. However, the document IDs of tables in SpreadsheetCoder are mostly empty. Thus, we build our dataset based on Enron and evaluate SpreadsheetCoder on it for a fair comparison.

Baselines. We adopt SpreadsheetCoder (Chen *et al.*, 2021a), TaPEx (Liu *et al.*, 2021), and TUTA as our baselines. SpreadsheetCoder is a BERT-based model for formula prediction, incorporating headers and contextual information of neighbouring cells of the target cell. TaPEx is a BART-based (Lewis *et al.*) table pretraining model, which implicitly learns a SQL executor.

Fine-tune. FORTAP consumes all header cells in the table and data cells lying on the same row/column of the target cell just like the manner in pretraining, with a max sequence length, 512. The `[FORMULA]` tag is placed at the target cell position in input, whose number embedding is set to default. A two-stage LSTM formula decoder (Dong and Lapata, 2018; Chen *et al.*, 2021a) accepts the formula cell embedding as input, and generates the formula by first generating formula sketches and then selecting referenced cells. All models in experiments are fine-tuned $800K$ steps on Enron. The beam size is 5 for generating formula. Since SpreadsheetCoder only published part of its code, we re-implement it in PyTorch (Paszke *et al.*, 2019) based on its paper. Appendix B presents details about SpreadsheetCoder. TaPEx is built on BART model and thus naturally supports generation task.

(%)	**Formula**	**Sketch**	**Range**
	20% Train Set		
TUTA	29.8	50.5	59.0
FORTAP	**40.0**	**57.6**	**69.5**
	100% Train Set		
SpreadsheetCoder	40.4	59.6	67.7
TaPEx	43.2	-	-
TUTA	48.5	65.3	75.3
FORTAP	**55.8**	**70.8**	**78.8**

Table 2: Formula prediction accuracy on Enron.

We follow the TaPEx table linearization strategy, assign the formula position in the source, and modify the target vocabulary as SpreadsheetCoder (Chen *et al.*, 2021a) to support generating referenced cells. We use the TaPEx-base model. It is fine-tuned for $30K$ steps (converge at about $25K$) and evaluated on the checkpoint with the best dev performance.

Results. Table 2 summarizes the results of formula prediction on the test set. As shown, FORTAP delivers a big improvement over SpreadsheetCoder by $+15.4\%$ and TaPEx by $+12.6\%$ on formula accuracy. We deduce that TaPEx falls behind TUTA and FORTAP because (1) the learnt executor may not be suitable for formula prediction, (2) it doesn't leverage hierarchical table structures. FORTAP also outperforms TUTA by $+7.3\%$, showing formula pretraining effectively assists formula prediction. We also experiment under a low-resource setting (20% training data), and the improvements of FORTAP are more significant, surpassing TUTA by $+10.2\%$. Since Enron is not included in our pretraining corpus, this result well indicates formula pretraining can largely benefit formula prediction after seeing large numbers of real formulas. Moreover, we conjecture that formula pretraining potentially improves numerical reasoning capabilities of the model, because the two-stage prediction of formula sketches and ranges relies on numerical calculation and reference capabilities, respectively.

4.3 Table Question Answering

Table QA (Pasupat and Liang, 2015; Cheng *et al.*, 2021) contains a table and an NL question over the table as the model input. Its output can be cell value(s) or number(s) calculated over numerical cell value(s). Table QA calls for both in-table numerical reasoning and table-text joint reasoning.

Datasets. There are several datasets (Pasupat and Liang, 2015; Cheng *et al.*, 2021; Zhu *et al.*, 2021; Chen *et al.*, 2021b) focusing on Table QA or Table-text hybrid QA. We choose to evaluate on HiTab (Cheng *et al.*, 2021), a hierarchical web table dataset for question answering and data-to-text. First, tables in HiTab contain rich table structures (98.1% tables are hierarchical) from 29 domains, posing a challenge to numerical reasoning. Second, a large proportion of questions ($\sim$ 40%) from Statistical Reports demands complex numerical inference over table and text. Moreover, questions in HiTab are revised from sentences written by professional analysts to ensure naturalness and meaningfulness. The QA evaluation metric is Execution Accuracy measuring the percentage of correctly predicted answers.

Baselines. We employ TaPas (Herzig *et al.*, 2020), HiTab model (Cheng *et al.*, 2021), TaPEx (Liu *et al.*, 2021), and TUTA as our baselines. TaPas is an end-to-end table parsing model without generating logical forms, which enjoys pretraining on the large-scale table-text corpus from Wikipedia. HiTab devises a hierarchy-aware logical form for hierarchical tables, and predicts the answer using a weakly supervised semantic parser MAPO (Liang *et al.*, 2018), which is a reinforcement learning framework to systematically explore and generate programs. The question and table are encoded by BERT and the logical forms are generated by an LSTM decoder. TaPEx is introduced in Section 4.2.

Fine-tune. We replace the BERT encoder of HiTab model with TUTA and FORTAP , and follow the fine-tuning settings of HiTab. We find that NRP pretrain task under table-text setting mentioned in Section 3 is quite essential for QA performance and thus pretrain 80,000 steps more with it on FORTAP in QA before fine-tuning. For TaPEx, we adopt the same table QA strategy in its paper by inputting the table and text as source, and generating the answer as target. The TaPEx-base model is trained for 20,000 steps on HiTab.

Results. Table 3 summarizes QA results on HiTab. FORTAP achieves SOTA (47.0%) using MAPO as the semantic parser, surpassing the best system in HiTab paper with +6.3%. Meanwhile, replacing BERT with TUTA does not see a significant performance gain. We conjecture one of the reasons is that TUTA may be not skilled at table-text joint reasoning, and FORTAP enhances this skill by the table-text setting of the NRP task. Finally, FORTAP performs comparatively with TaPEx, a recent pretraining tabular model as a powerful neural SQL executor targeting table reasoning. Note that this result is inspiring since FORTAP is pretrained on spreadsheet tables and can generalize to web table domain (HiTab) with SOTA performance, indicating that the numerical reasoning skills learnt by FORTAP are robust to distinct scenarios.

(%)	Development	Test
TaPas	39.7	38.9
BERT (*MAPO*)	43.5	40.7
TUTA (*MAPO*)	43.5	41.3
TaPEx	**48.8**	45.6
FORTAP (*MAPO*)	47.1	**47.0**

Table 3: QA execution accuracy on HiTab. *MAPO* means using MAPO+hierarchical-aware logical forms.

(%)	M	N	Data	LA	TA	Derived	Avg.
CNN^{BERT}	76.3	1.5	95.2	59.0	75.4	57.6	60.8
RNN^{C+S}	62.7	40.8	98.6	56.9	73.5	48.8	63.6
TaBERT	66.6	5.4	94.3	29.2	59.2	45.1	50.0
TaPas	80.6	20.3	96.5	56.9	**90.1**	56.6	66.8
TUTA	**86.0**	41.6	99.1	76.7	82.0	73.1	76.4
FORTAP	85.2	**49.1**	**99.3**	**78.0**	86.4	**79.7**	**79.6**

4.4 Cell Type Classification

Cell type classification (CTC) (Koci *et al.*, 2019; Gol *et al.*, 2019; Gonsior *et al.*, 2020) aims to interpret tabular data layouts automatically via classifying table cells by their roles in data layouts (e.g., top attribute, data, derived). It requires understanding of table semantics, structures, and numerical relationships considering diverse table layouts.

Datasets. DeEx (Koci *et al.*, 2019) is a widely-studied CTC dataset with tables of various structures and semantics. DeEx includes tables from various domains by mixing three public corpora: Enron (Hermans and Murphy-Hill), Euses (Fisher and Rothermel, 2005), and Fuse(Barik *et al.*, 2015). Cells in DeEx are categorized into six fine-grained types: `metadata`, `notes`, `data`, `left attribute`, `top attribute`, and `derived`. The evaluation metric is the Macro-F1 score over all cell types.

Baselines. We compare FORTAP with two learning-based methods CNN^{BERT}(Dong *et al.*, 2019a) and Bi-LSTM (Gol *et al.*, 2019), and three table-pretraining methods TaBERT (Yin *et al.*, 2020), TaPas (Herzig *et al.*, 2020), and TUTA.

Fine-tune. To handle large tables in DeEx, we split tables into chunks with a max input sequence length (512) and distribute headers to each chunk. For cells with formulas, `[FORMULA]` tags are used as input tokens. We fine-tune 100 epochs on five folds and report the average scores. All these settings are the same as TUTA.

Table 4 lists the CTC results on DeEx. FORTAP achieves a SOTA Macro-F1 of 79.6%. Specifically, FORTAP largely improves the performance on type `derived` and `notes`, surpassing TUTA by 6.6% and 7.5%. The improvement on `derived` indicates formula pretraining helps identifying cells derived by calculations over some other cells. Note that `derived` in DeEx not only includes cells with explicit formulas, but also those cells with hidden (missing) formulas (Koci *et al.*, 2019), which poses a great challenge to existing methods since it requires discovery of numerical relationships between cells. Thus, this is a strong signal that formula pretraining endows the model with better numerical reasoning capabilities. We think that the improvement on `notes` mainly benefits from the NRP pretraining task with formula-based prompts as the context, enhancing FORTAP 's capability on table-text joint modeling.

4.5 Analysis

In this section, we analyze our method in terms of (1) the effects of different pretraining tasks, (2) whether and to what extent our model learns numerical reasoning skills.

Effects of pretraining tasks. We conduct ablation studies on different pretraining tasks on the formula prediction task. Here we pretrain TUTA with each pretraining task and fine-tune on Enron dataset, as summarized in Table 5. We can see that combining all pretraining tasks brings the most gain on formula accuracy. NRP and NCP improve more on range accuracy and sketch accuracy, respectively. This aligns with our design motivation that NRP targets on how to reference and NCP learns how to calculate. To our surprise, Formula MLM alone also largely benefits formula prediction. We deduce the reason is that both MLM and formula prediction requires encoding and recovering/generating capabilities of the formula token sequence.

Numerical reasoning skills. We have shown our model learns numerical reasoning skills by two facts: (1) NRP and NCP improve more on the range and sketch accuracy on the formula prediction task, respectively; (2) our model boosts the performance of `derived` cell type on cell type classification. Here we further decompose QA accuracy of different operations on HiTab. The comparison between previous SOTA system BERT(MAPO) and our FORTAP (MAPO) is shown in Table 6. As shown, our model improves most on complex cell selection (cell indexed by ≥ 3 headers) and arithmetic (e.g., *difference*, *sum*) problems. Note that complex cell selection not only requires table-text alignment, but also the references between headers considering that mentions of headers in question could be implicit or missing. Meanwhile, our model also handles superlative (e.g., *argmax*) and comparative (e.g., *less than*) problems better than BERT, despite these types are relatively infrequent in our formula pretraining corpus. To summarize, our model mainly improves numerical skills regarding cell reference and arithmetic, as well as other aspects like comparing and ranking.

(%)	**Formula**	**Sketch**	**Range**
TUTA	48.5	65.3	75.3
TUTA + NRP	54.3	69.0	78.7
TUTA + NCP	54.7	**71.2**	76.8
TUTA + FormulaMLM	54.6	70.2	77.7
All (FORTAP)	**55.8**	70.8	**78.8**

Table 5: Ablation study on formula prediction.

Operation	**BERT**	**FORTAP**
Complex Cell Selection	48.4%	56.4% (+8.0%)
Arithmetic	6.0%	13.3% (+7.3%)
Superlative	22.7%	26.8% (+4.1%)
Comparative	27.5%	30.5% (+3.0%)

5 Related Works

Table Pretraining. Table pretraining has been widely studied in recent years. Some works mine large-scale table-text pairs as pretraining corpus (Deng *et al.*, 2020b; Yin *et al.*, 2020; Herzig *et al.*, 2020; Wang *et al.*, 2021b), some leverage annotated table-text datasets (Deng *et al.*, 2021; Yu *et al.*, 2020), and some synthesize a table-text corpus by templates (Yu *et al.*, 2020; Eisenschlos *et al.*, 2020). Regarding pretraining tasks, they either train the model to recover masked tokens/column/cell/entity (Yin *et al.*, 2020; Herzig *et al.*, 2020; Wang *et al.*, 2021b; Deng *et al.*, 2020b), or explicitly learn table-text alignments (Deng *et al.*, 2021; Yu *et al.*, 2020). Recently, TaPEx (Liu *et al.*, 2021) adopts BART (Lewis *et al.*) as a neural executor for synthesized SQLs to improve table reasoning. Whereas, our method explores to use real spreadsheet formulas to guide table pretraining.

Numerical reasoning over Natural Language. Numerical reasoning is important in NL domain (Dua *et al.*, 2019). Numbers even account for 6.15% of all unique tokens in English Wikipedia (Thawani *et al.*, 2021). Various works target improving numerical reasoning skills on NL (Andor *et al.*, 2019; Geva *et al.*, 2020; Jin *et al.*, 2021). Except using pure NL, MathBERT (Peng *et al.*, 2021) pretrains NL documents with mathematical formulas. In this paper, we target numerical reasoning over (semi-) structured tables.

6 Conclusion

In this paper, we present FORTAP , a numerical-reasoning-aware table pretraining model that learns numerical reasoning capabilities from spreadsheet formulas. Specifically, we design two pretraining tasks to capture numerical reasoning capabilities by explicitly predicting cell reference and calculation relations. Experiments show that FORTAP achieves new SOTA on formula prediction, question answering, and cell type classification. Further analyses indicate that formula pretraining indeed improves numerical reasoning skills of the model. One limitation of FORTAP is that we haven't fully exploit spreadsheet formulas beyond numerical reasoning. For example, logic functions like `VLOOKUP` and text functions like `LEN` can be leveraged to guide complex logic and text reasoning, which will be a promising direction in the future.

7 Ethical Considerations

In this work, we present a table pretraining method leveraging spreadsheet formulas.

Dataset. Our pretraing corpus is built upon public English spreadsheet files crawled from webs via the search engine (Wang *et al.*, 2021b), covers various domains, and has been checked by a compliance team in a company to ensure that does not contain sensitive names or uniquely identifies individual people or offensive content. All datasets used for evaluation are licensed public datasets, e.g., for formula prediction, Enron (Hermans and Murphy-Hill) is a public spreadsheet dataset consisting of over 17K spreadsheet files, and we re-purpose it for formula prediction following (Chen *et al.*, 2021a).

Application. Our model shows its effectiveness in three representative table-related tasks. Formula prediction helps spreadsheet end-users to write formulas which could be tedious and error-prone. Table QA enables users to query on the table without the need of domain background knowledge. Cell type classification assists interpreting fine-grained table semantic structures, which help users to better understand table structures and contents. There may be risks that crooks use tabular models to automatically parse tables/forms to obtain private personal or company data in bulk, which should be prevented.

A Involved Operators/Functions of Formula

We include 17 common operators/functions in Numerical Calculation Prediction pretraining task, which consists of all the operators and four most commonly used aggregation functions in spreadsheet formula. The operators/functions are: $+$, $-$, $*$, $/$, $\wedge$, $\%$, $\&$, $=$, $<>$, $>$, $<$, $\geq$, $\leq$, `SUM`, `AVERAGE`, `MAX`, `MIN`.

To encode formula token sequence, we expand 41 tokens in vocabulary for all four formula token types `OP`, `FUNC`, `CELL`, `CONST`, covering 99.1% formulas in corpus. Here we list these tokens: (1) 1 token for `CELL` token type: `[RANGE]`. (2) 3 tokens for `CONST` token type: `[C-STR]`, `[C-NUM]`, `[C-BOOL]`. All constant tokens are categorized according to "string", "number", and "bool". And they are replaced with these three tokens when encoding the formula. (3) 34 tokens for `OP`/`FUNC` token type: [+](32.1%), `[SUM]`(20.6%), [−](17.8%), [/](6.7%), `[IF]`(2.6%), `[ROUND]`(1.2%), `[AVERAGE]`(1.2%), `[VLOOKUP]`(1.0%), [>](0.98%), [=](0.79%), [<](0.57%), `[ABS]`(<0.5%), `[OFFSET]`, `[SUBTOTAL]`, `[MAX]`, [<>], [∧], `[LN]`, `[COUNTA]`, `[SQRT]`, `[MIN]`, `[ISERROR]`, `[EOMONTH]`, `[COUNT]`, `[AND]`, [%], `[INDEX]`, `[YEAR]`, `[MONTH]`, `[MATCH]`, [≥], `[MATCH]`, [≤], [&], `[UNKOP]`. The number in parentheses is the ratio of `OP`/`FUNC` to the total number of `OP`/`FUNC` in corpus. Here `UNKOP` stands for unknown operator/function, similar to `[UNK]` in NL vocabulary. To distinguish formula `OP`/`FUNC` with some eponymous tokens in vocabulary (e.g., "sum", "+"), we enclose formula `OP`/`FUNC` with square brackets. (4) special tokens `[START]`, `[END]`, [:].

B Implementation Details

More on Hyperparameters. For pretraining, we first pretrain $400K$ steps with max sequence length 256, batch size 32, then pretrain $250K$ steps with max sequence length 512, batch size 8. The whole pretraining phase is estimated to 3 epochs, i.e., samples in the corpus are seen 3 times in pretraining. The optimizer is Adam with learning rate $2e$-5.

For formula prediction, we set max sequence length 512 and fine-tune $800K$ steps with batch size 2 on single GPU. The tokens beyond 512 are truncated. If the formula cell is truncated (rare case), we input the `[CLS]` embedding to the formula decoder. The two-stage decoder is first trained $100K$ for generating sketches, and then trained to generate sketches and ranges together. The optimizer is Adam with learning rate $2e$-5.

For table question answering, we follow HiTab hyperparameters except that we find it is unnecessary to freeze encoder parameters at the first $5,000$ steps, so we train the encoder-decoder model together.

For cell type classification, since some tables are extremely large in DeEx, we truncate the tables into sequences of max length 512 by preserving the header cells (both top and left) and traversing the data cells to fill the max sequence length. We fine-tune 100 epochs on five folds with batch size 12. The optimizer is Adam with learning rate $8e$-6.

SpreasheetCoder We implement SpreadsheetCoder mainly following its paper including the BERT-based table context (row/column) encoder, two-stage decoder. One difference is that we did not implement the convolution layers for row and columns which is rather complicated . Instead, since SpreadsheetCoder uses convolution layer aiming to incorporate contextual information from different positions (row/column), we explicitly add row embeddings and column embeddings (Herzig *et al.*, 2020) for input table tokens, which derives the similar accuracy gain of convolution layers (4% according to its paper), from 35.6% to 40.4% on Enron dataset. Furthermore, SpreadsheetCoder can only decode referenced cells in a rectangle window ($[-10, 10]$) of the target cell since it only keeps the formulas of this kind in dataset. We enable SpreadsheetCoder to predict referenced cells in a larger window which it can not solve by extending the vocabulary of range tokens from $[-10, 10]$ to $[-256, 256]$. Different from SpreadsheetCoder, FORTAP predicts ranges by selecting from input table cells instead of from a fixed cell vocabulary. In this way, theoretically (without memory limit) our model can potentially predict referenced cells in an arbitrarily large table. Detailed error analysis of FORTAP on formula prediction is in Appendix C.

C Error Analysis of Formula Prediction

Figure 3 presents the proportion and accuracy regarding different formula sketch lengths in prefix order (parentheses excluded). As shown, sketch length 3 and 4 account for two-thirds of formulas, since length 3 is typical for binary operations like `C4-B4`, and length 4 is a common pattern for ag-

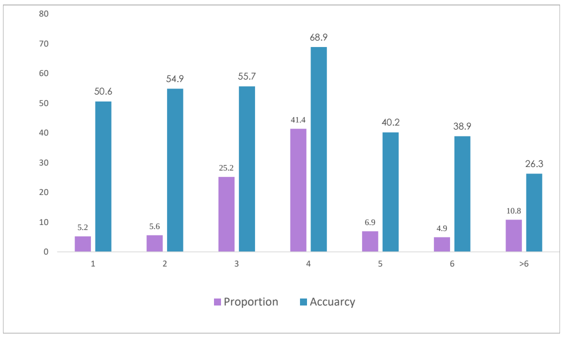

Figure 3: Proportion and accuracy of samples with different formula sketch lengths in formula prediction task.

gregation functions like `SUM(B4:C5)`. Thus, the accuracy of length 3/4 is higher than shorter sketch length 1/2 since more samples in its length are seen in training. And for longer formulas (>6), a significant performance drop occurs because complex nested references and calculations may be involved when the sketch gets longer.

To further analyze the errors in formula prediction, we randomly pick 100 false generation results in dev set and divide these errors into three groups: (i) sketch failure (54%): a wrong sketch is generated, which occurs more frequently when the formula gets longer and nested. A typical case is the formula with function `IF`, involving multiple arguments and nested calculations; (ii) reference unreachable (27%): referenced cells are not in the sequence since we only consider the cells on the same row/column of the target cell as input; (iii) reference failure (19%): wrong referenced cells are selected, which often occurs at the start or end of a cell range. Future works may improve formula prediction in these directions: handling long nested formulas, inputting more cells of table matrix as reference candidates conquering memory issues, and designing a module to match generated sketch with input table cells more accurately.

D Real examples of spreadsheet tables with formulas

Here we show several real examples for spreadsheet tables in Figure [4-6].

E Real examples of formula prediction on Enron

We also developed an Excel plug-in to run formula prediction powered by ForTaP. We simulate that ForTap suggests formulas for a user when she is editing a spreadsheet. Here we show several formula prediction demonstrations on Enron test set in Figure [7-11]. For the fist case, we tried different column names, and the results are promising and robust.

Multimodal fusion via cortical network inspired losses

Shiv Shankar
University of Massachusetts
`sshankar@cics.umass.edu`

Abstract

Information integration from different modalities is an active area of research. Human beings and, in general, biological neural systems are quite adept at using a multitude of signals from different sensory perceptive fields to interact with the environment and each other. Recent work in deep fusion models via neural networks has led to substantial improvements over unimodal approaches in areas like speech recognition, emotion recognition and analysis, captioning and image description. However, such research has mostly focused on architectural changes allowing for fusion of different modalities while keeping the model complexity manageable. Inspired by neuroscientific ideas about multisensory integration and processing, we investigate the effect of introducing neural dependencies in the loss functions. Experiments on multimodal sentiment analysis tasks with different models show that our approach provides a consistent performance boost.

1 Introduction

Human beings perceive the world as a unified whole, not in individual sensory modalities. While traditionally different sensory models have been studied in isolation, it has been well recognized that perception operates via integration of information from multiple sensory modalities.

Research in multimodal fusion aims to achieve a similar goal in artificial models: extract and integrate all information from different input modalities. For example, if someone is sarcastic, the facial expression and voice intonation provide information not directly decipherable from the uttered words. If a model only looks at the text of the interaction, then it is unlikely to classify this interaction currently. Current research in deep multimodal fusion primarily deals with architectural improvements to create complex feature-rich, yet efficient representations (Zadeh et al., 2017; Liu et al., 2018; Hazarika et al., 2020). The hope is that more complex models will be able to integrate the complementary information from different unimodal representations into a unified common representation. Learning such unified representations, however, is a challenging task. Different modalities can present the same information in radically different ways with emphasis on different aspects of the content. These heterogeneities across different modalities mean that learning multimodal representations must deal with feature shifts, distributional effects, nuisance variation and a variety of related challenges (Baltrušaitis et al., 2018).

Inspiring from work in multisensory neural processing, we define a loss regularizer that we call *synergy* to train these models. Synergy has a specific meaning in information-theoretic literature (Cover, 1999). The synergy between random variables X and Y refers to the unique mutual information that X provides about Y. While our loss function is not the same as information theoretic synergy, the intuition behind our proposed loss is the same as actual synergy; to try to maximize dependencies between the representations. As our method uses neural networks or kernel-based methods to capture distributional divergences, we expect that this method will allow our model to capture complex dependencies which cannot be captured via techniques like subspace alignment.

We test our proposed training loss on different multimodal fusion architectures including LFN(Zadeh et al., 2017), MFN (Zadeh et al., 2018a), MAGBERT(Rahman et al., 2020) and MIM (Han et al., 2021). Our experiments show that training with synergy maximization improves the result by a significant margin.

2 Preliminaries

In this section, we give an overview of the basic ideas relevant to this work; primarily mutual information, and existing work on deep multimodal fusion and neural synergy.

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 1167 - 1178
May 22-27, 2022

2.1 Multimodal Fusion

The problem in the most abstract terms is a supervised learning problem. We are provided with a dataset of N observations $\mathcal{D} = (x_i, y_i)_{i=1}^N$. All x_i come from a space $\mathcal{X}$ and y_i from $\mathcal{Y}$. We are provided a loss function $L : \mathcal{Y} \times \mathcal{Y} \rightarrow \mathbb{R}$ which is the task loss. Our goal is to learn a model $\mathcal{F}_\theta : \mathcal{X} \rightarrow \mathcal{Y}$ such that the total loss $\mathcal{L} = \sum_i L(\mathcal{F}(x_i), y_i)$ is minimized. In multimodal fusion the space of inputs $\mathcal{X}$ naturally decomposes into K different modalities $\mathcal{X} = \prod_{j=1}^K \mathcal{X}_j$. We use X_j to represent random variables which form the individual modality specific components of the input random variable X.

A common way to learn such a multimodal function is to decompose it into two components: a) an embedding component E which fuses information into a high dimensional vector in $\mathbb{R}^d$ and b) a predictive component P which maps vector from $\mathbb{R}^d$ to $\mathcal{Y}$. Furthermore since the different modalities are often no directly compatible with each other (for eg text and image), E itself is decomposed into a) modality specific readers $F_i \mathcal{X}_i \rightarrow \mathbb{R}^{d_i}$ which are specifically designed for each individual modality $\mathcal{X}_i$ and b) a fusion component $F : \prod_i \mathbb{R}^{d_i} \rightarrow \mathbb{R}^d$ which fuses information from eah individual modality embedding. F is provided with uni-modal representations of the inputs $X_i = (X_1, X_2, \dots X_K)$ obtained through embedding networks f_i. F has to retain both unimodal dependencies (i.e relations between features that span only one modality) and multi-modal dependency (i.e relationships between features across multiple modalities).

This decomposition has two advantages a) the individual modality reader can be pre-trained on the task at hand or even from a larger dataset (for example BERT (Devlin et al., 2018) for language, Resnet (He et al., 2016) for images) which allows us to leverage wider modality specific information and b) often but not always each individual modality is in principle enough to correctly predict the output

2.2 Distributional Divergences

Divergence is a functional which characterizes the distance or "discrepancy" between two probability distributions on the same space. Divergence however is a different notion than distance because divergences are not necessarily symmetric. A common measure of discrepancy between two distributions is the Kullback-Liebler divergence (KL divergence) (Cover, 1999). The KL divergence of the density p relative to the density q is given by

$$d(p; q) = \mathbb{E}_{x \sim p} \left[\log \frac{p(x)}{q(x)} \right]$$

This divergence is often also used implicitly for estimating dependence between two random variables. Mutual information (MI) is a measures of dependence between two random variable X and Y capable of incorporating multiple types of relationships between them. If we have variables X and Y, then the mutual information between them is given by

$$I(X; Y) = KL\left[p_{XY}(x, y) \| p_X(x) p_Y(y)\right]$$

where p_{XY} is the joint probability density of the pair (X, Y), and p_X, p_Y are the marginal probability densities of X, Y respectively.

Estimation of Divergence Estimating entropic differences between two distributions purely from their samples is a difficult task (Kinney and Atwal, 2014). As such there have been multiple types of divergences proposed over the years (Gretton et al., 2005; Studenỳ and Vejnarová, 1998). Moreover in recent years, several estimators have been proposed for entropic divergences based on variational methods (Belghazi et al., 2018; Hjelm et al., 2018; Amjad and Geiger, 2019). These estimators use flexible neural networks as a contrast function and optimize a variational bound. We describe two such methods which are used in our experiments

- **Neural Mutual Information** (Belghazi et al., 2018) is a variational method to estimate the KL divergence between two distributions. It is estimated via gradient ascent on the Donsker-Varadhan bound (Donsker and Varadhan, 1985). The Donsker Varadhan bound shows that:

  $$\begin{aligned} KL(P, Q) \geq \sup_g \mathbb{E}_{X \sim P}[g(X)] \\ - \mathbb{E}_{X \sim Q}[\exp^{g(X)}] \end{aligned}$$

  The Young-Fenchel duality shows that the gap is zero; i.e. at the optima the right side of the above expression matches the KL divergence. Instead of a global maximization over all functions one can instead use a family of functions parameterized via neural networks. The bound obtained thus is necessarily lower than the actual KL, but now one can use gradient descent to optimize the network.

- **Maximum Mean Discrepancy** or MMD (Gretton et al., 2012) is a kernel based estimator of divergence between distributions. Mathematically the MMD between two distributions P and Q is given by the norm of the difference of the mean embeddings of P and Q in the RKHS space of the chosen kernel. Further extensions to MMD have been developed based on neural networks which provide non-universal but more powerful kernel based tests (Liu et al., 2020).

  $$\mathcal{MMD}(P,Q) = ||\mu_P^{\phi} - \mu_Q^{\phi}||$$

  The above formula can be estimated purely via samples by using the Kernel matrix $K(x_i, x_j) = \phi(x_i)^T\phi(x_j)$ where ϕ represents the corresponding RKHS embedding function The final monte carlo estimator is given by:

  $$\begin{aligned}\mathcal{MMD}(P,Q) = &\sum_{p_i,p_j \sim P} K(p_i,p_j) \\ &+ \sum_{q_i,q_j \sim Q} K(q_i,q_j) \\ &- \sum_{p_i,q_j \sim P,Q} 2K(p_i,q_j)\end{aligned}$$

2.3 Kurtosis

Kurtosis is a statistical measure which is used to categorize the behavior of the distribution tails. It is more sensitive to rare events and hence is used for distributions with "fatter tails". For univariate variables, kurtosis is the standardized fourth moment i.e

$$\frac{\mathbb{E}[(X-\mu)^4]}{(\mathbb{E}[(X-\mu)^2])^2}$$

It is often used to measure deviations from normality. Mardia (1970) defined a measure of multivariate kurtosis as follows:

$$\mathbb{E}[((X-\mu])^T\Sigma^{-1}(X-\mu))^2]$$

where X is a $p \times 1$ dimensional random vector and μ, Σ are the mean and covariance matrix of X respectively. Multivariate cokurtosis between random variables is also sometimes used as a measure of dependence between them. It is one of the metrics used by Rosas et al. (2019); Barrett and Seth (2011) to analyze neural complexity and brain functional connectivity.

2.4 Other works on multimodal fusion

Earlier work on neural fusion models primarily relied on an early fusion of features. These approaches simply concatenated inputs of different modalities and used simple models to combine requisite information. Despite their simplicity, such models often perform well and are robust (Narayanan et al., 2019). More modern methods, however, deploy fancier methods to induce information aggregation. One set of models used gradient descent to try to force different feature networks to learn about each other and embed information jointly. This process can be enhanced by adding specific forms of regularization such as reconstruction loss (Mai et al., 2020), or auxiliary task loss (Chen et al., 2017; Yu et al., 2021). Another family of models uses linear algebra based methods to combine unimodal representations. Methods like those of Liu et al. (2018); Chen and Mitra (2018); Chachlakis et al. (2019) try to fuse information via tensor decomposition of high dimensional product tensors of individual unimodal representations. Other methods use subspace alignment (Lee et al., 2019; Yu et al., 2012) or correlation loss (Sun et al., 2020; Hazarika et al., 2020) to merge different representations. However, in some form or other, these models rely primarily on architectural changes. We, on the other hand, do not want to focus on such changes. Instead, our goal was to use insights from neuroscience to provide a methodology that can be deployed atop any standard multimodal fusion model.

3 Dependency Coding in Multisensory Processing

A common and vital feature of nervous systems is the integration of information arriving simultaneously from multiple sensory pathways. The underlying neural structures have been found to be related in both vertebrates and invertebrates. The classic understanding of this process is that different sensory modalities are processed individually and then combined in various multimodal convergence zones, including cortical and subcortical regions (Ghazanfar and Schroeder, 2006), as well as

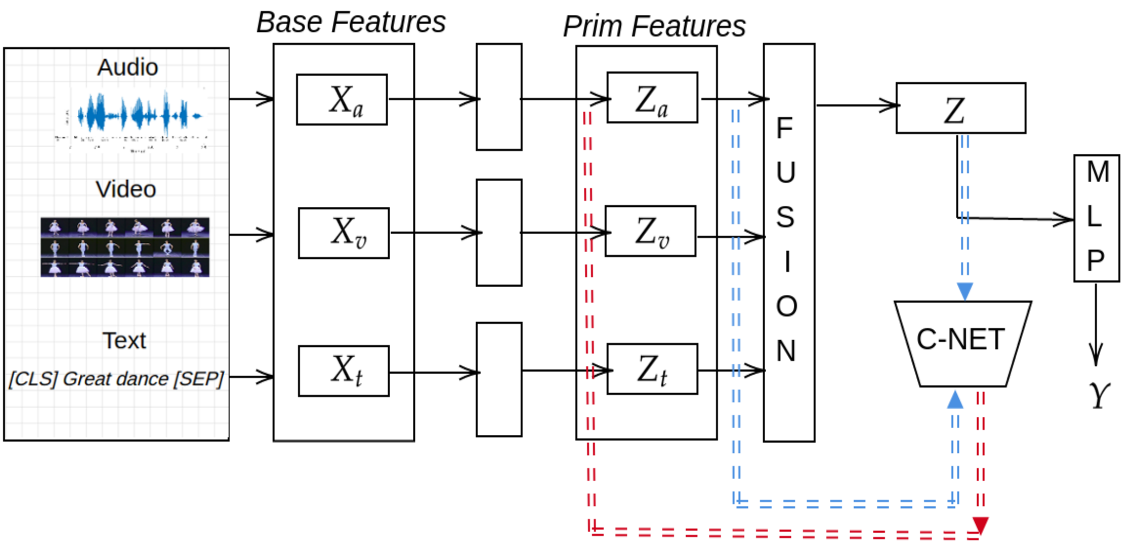

Figure 1: A general multimodal fusion Architecture. We depict in colour the additional components proposed in this work viz the proposed cortical network (C-Net) and its connection to individual layers

multimodal association areas (Rauschecker et al., 1995). Studies in the superior colliculus (Meredith et al., 1987) showed that multiple sensory modalities are processed in this brain stem region, with some neurons being exclusively unimodal and others being multimodal. Hypotheses of encoding of multimodal information include changes in neuronal firing rates (Pennartz, 2009) or a combinatorial code in population of neurons (Osborne et al., 2008; Rohe and Noppeney, 2016).

Evidence shows that while multimodal representations are distinct from unimodal ones, there is sufficient overlap between the set of neurons that process different sensory modalities. For example, Follmann et al. (2018) show that even in a simple crustacean organism, more than half the neurons in the commissural ganglion are multimodal. Moreover, they show that in 30% of these multimodal neurons, responses to one modality were predictive of responses to other modalities. *Both these facts suggest that the neural representations across different modalities have high information about each other.*

Studies of multisensory collicular neurons suggest that their crossmodal receptive fields (RF) often overlap (Spence et al., 2004). This pattern is also found in multisensory neurons present in other brain regions. As such, a spatiotemporal hypothesis of multisensory integration has been suggested: superadditive multimodal processing is observed when information from different modalities comes from spatiotemporally overlapping receptive fields (Recanzone, 2003; Wallace et al., 2004; Stanford et al., 2005). Since multimodal cortical neurons are generally downstream of modality-specific regions, the information about RF overlap is present in their input unimodal neural representations. Moreover, the sensory-specific nuclei of the thalamus have been shown to feed multisensory information to primary sensory specific-cortices (Kayser et al., 2008). *This suggests the existence of explicit feedback connection from the multimodal representations to unimodal representations.*

Cortical and subcortical networks often contain clusters of strongly connected neurons. Functionally the existence of such cliques imply highly integrated pyramidal cells that handle a disproportionately large amount of traffic (Harriger et al., 2012). In cortical circuits, around 20% of the neurons account for 80% of the information propagation (Nigam et al., 2016; Van Den Heuvel and Sporns, 2011). Timme et al. (2016); Faber et al. (2019) demonstrate that multimodal computation tends to concentrate in such local cortical clusters. They also found significantly lower kurtosis in such clusters and that dependence between oscillations was proportional to the amount of information flow. Sherrill et al. (2020) show that highly kurtotic neural activity positively related when multiple external stimuli are provided. Thus, kurtosis in neural firings is a representation of the dependence between inputs. *This suggests that when input kurtosis is high there is more significant cognitive processing and information flow required to extract relevant* *information.*

4 Model

For our purposes we will limit ourselves to talk about tasks similar to the MOSI dataset. In this setting the input has three modalities viz audio (a), visual (v), and textual language (l). The fusion problem involves learning a representation $\mathcal{M}_f$ that combined the uni-modal representations of the inputs $X_{a,v,l} = (X_a, X_v, X_l)$.

4.1 Dependency Coding and C-Network

We modify the base neural architecture to incorporate the global structure explained in the last section. We propose a way to incorporate such changes without major architectural change into current baseline designs. The key component is the additional network (colored in red) in Figure 1 which we shall call as C-network. The C-network takes as input the individual unimodal representations and the fused representation and attempts to force a specific form of dependency as explained below.

C-Network The purpose of the C-Network is to try to enforce on the model the three primary characteristics of real neural circuits explained in the earlier section. We list them here and describe how we attempt to incorporate those characteristics in a more standard model.

- Individual uni-modal representations should be predictive of other uni-modal representations. We try to achieve this by simply predicting on modality representation by the combination of others. Q_i refers to a modality associated neural network which attempts to reconstruct the unimodal representation Z_i from the other representations Z_{-i}. The error between the two is penalized in the form of a reconstruction loss between modalities i.e. we add a penalty of the form:

$$\mathcal{L}_{L2} = ||Q_i(Z_{-i}) - Z_i||^2$$

- Multimodal representation should be feedback into input neurons to align and capture information between them. Providing feedback during inference time from the multimodal representation would be ideal. However this would make the overall prediction recurrent, something fundamentally different from most current architectures. Moreover given current high dimensional encoders; doing such processing would be extremely resource intensive. As such we aim to achieve this feedback by treating the multimodal representation and unimodal representation spaces as different domains and adding a loss of the form:

$$\mathcal{L}_d = d(p(g_i(Z_i)), p(g_i(Z)))$$

The purpose of the aforementioned loss is to align the distributions of the features in the same embedding space of the mapping from the multimodal and unimodal domains. d represents a measure that captures the discrepancy between the distributions, g_i refers to neural networks for projecting and aligning the combined representation Z with unimodal representations Z_i, and p denotes the empirical/sample distribution of the corresponding features. In our experiments, for d we use the MMD discrepancy (Gretton et al., 2012) and KL divergence as the metric; though other divergences can also be used. Note that this loss by itself can be minimized by forcing the g functions to ignore their inputs. We prevent this by first doing a random projection of the features[1] into a smaller dimensional vector space and then apply an invertible neural network. Such alignment losses have been used in works on domain adaptation (Motiian et al., 2017) under the name semantic loss or confusion loss. We refer the readers to Motiian et al. (2017); Li et al. (2019) for more details on semantic losses.

Note that instead of aligning the features via some kind of embedding based distributional distance, one could try to maximize mutual information between the embeddings as well. We experiment with one such model in our experiment and as the results show, found it to be slightly worse than using MMD based alignment loss.

- Individual unimodal and multimodal representations should have low kurtosis. To ensure this condition we estimate the multivariate kurtosis by plugging in standard estimators for the mean and covariates. The final kurtosis estimator used is given by:

---

[1] similar to Johnson Lindenstrauss projections (Landweber et al., 2016)

$$\kappa = \frac{1}{n}\sum_{i}^{n}[((z_i - \bar{z})^T S^{-1}(z_i - \bar{z}))^2]$$

where z_i here are samples from the Z features in the model (where Z can be unimodal features like Z_a or fused final feature Z). $\bar{z}$ refers to the empirical mean feature $\bar{z} = \frac{\sum_i^n z_i}{n}$ and S is the empirical covariance matrix $S = \frac{\sum_i^n (z_i - \bar{z})(z_i - \bar{z})^T}{n}$.

An important thing to note here is that high dimensional kurtosis values can be highly sensitive to outliers. As such we regularize the estimate by doing three things: a) We cap the max norm of the difference vectors during estimation. b) We scale up the diagonal of the covariance matrix to reduce its condition number c) Finally the covariance matrix itself is computed via a decaying moving average over a window of multiple batches to produce smoother estimates before the inversion operation.

During training we add the regularization penalties described earlier along with the usual maximum likelihood based objective. The different loss components are weighted with seperate hyperparameters. Note that the C-Network is purely a training time addition, and is not invoked during inference. Hence the additional network invoke zero additional time during testing. An algorithmic description of the full method is presented in the Appendix D

5 Experiments

5.1 Datasets

We empirically evaluate our methods on two commonly used datastes for multimodal training viz CMU-MOSI and CMU-MOSEI.

CMU-MOSI (Wöllmer et al., 2013) is sentiment prediction taks on a set of short youtube video clips. CMU-MOSEI (Zadeh et al., 2018b) is a similar dataset consisting of around 23k review videos taken from YouTube. The output in both cases is a sentiment score in $[-3, 3]$. For each dataset, three modalities are available; audio, visual frames, and language. Preliminary features on each modality is obtained as follows:

- Audio: Features are extracted from the sund recordings using the method of Degottex et al. (2014).
- Language: The video transcripts are converted to word embeddings using BERT (Devlin et al., 2018) or Glove (Pennington et al., 2014)
- Visual: Visual features are extracted using FACET (iMotion) which provides facial action units vectors.

5.2 Models

We run our experiments with the following architectures:

- FLSTM (Narayanan et al., 2019) is the baseline early fusion LSTM architecture used by Zadeh et al. (2017)
- Tensor Fusion Network or TFN (Zadeh et al., 2017) combined information via pooling of a high dimensional tensor representation of multimodal features. More specifically it does a multimodal Hadamard product of the aggregated features with RNN based language features.
- Memory Fusion Network or MFN (Zadeh et al., 2018a) incorporate gated memory-units to store multiview representations. It then performs an attention augmented readout over the memory units to combine information into a single representation.
- MAGBERT (Rahman et al., 2020) is a transformer based architecture that uses the Wang gate (Wang et al., 2019). The multimodal information is send to the multimodal gate to compute modified embeddings which are passed to a BERT (Devlin et al., 2018) based model. This model achieves state-of the-art results on multimodal sentiment benchmark MOSI (Wöllmer et al., 2013) and MOSEI (Zadeh et al., 2018c).
- MIM (Han et al., 2021) is a recent near SOTA architecture. It combined BERT based text embeddings with modality specific visual and acoustic LSTMs (Hazarika et al., 2020).
- Recently Colombo et al. (2021) conducted experiments introducing a information regularizer on existing architectures. The main differences between the our method and their

method are a) our method focuses on synergy terms whereas their proposal is optimizing joint mutual information between different unimodal representations; and b) they experiment with variational measures of information. We replicate our experiments with their best performing model and present the results with the label I_{Was}.

Split	CMU-MOSI	CMU-MOSEI
Train	1284	16326
Validation	229	1871
Test	686	4659
All	2199	22856

Table 1: Dataset summary

5.3 Evaluation

We report both the Mean Absolute Error (MAE) and the correlation of model predictions with true labels. In the literature, the regression task is also turned into a binary classification task for polarity prediction. We follow Rahman et al. (2020) Accuracy Acc_7 denotes accuracy on 7 classes and Acc_2 the binary accuracy) of our best performing models. We also report the Mean Absolute Error (MAE) and the correlation of model intensity predictions with true values.

5.4 Results

We present and discuss here the results obtained in our experiments. Results on MOSI are presented in Table 2 while Table 3 present results for MOSEI dataset. We trained each of the models with the standard cross entropy loss (labeled as NLL); and with cross entropy loss regularized with the synergy penalty discussed earlier. On both datasets, regularization via synergy leads to performance improvement. For example, a MFN on CMU-MOSI trained with MMD based synergy (NLL+S_{MMD}) outperforms by more than 4 points on Acc_7 than standard likelihood training. On CMU-MOSEI too the gains are significant when trained with synergy regularization. In general training via MMD synergy tends to be better than via KL synergy. This might be the inherent behavior of the MMD dependency which is always well defined; or it might reflect the hardness of information estimation. For example it is well known that good bounds on standard mutual information are difficult to obtain (Kinney and Atwal, 2014); while MMD estimator are asymptotically consistent (Gretton et al., 2012)

5.5 Modality Dropout

Zadeh et al. (2018a); Rahman et al. (2020) have demonstrated that while multimodal fusion does improve performance, the primary modality continues to be textual data. Hence in this experiment, we want to assess the effect of corruptions of text modality in our model. Following Colombo et al. (2021) we experiment with dropping the text modality either by itself (T) or with one of the other modalities (T+V or T+A). The results are presented in Table 4

Since the C-Networks forces a reconstruction and distributional divergence loss between the unimodal and multimodal representations, one would expect that models trained using our approach would be more resistant to modality errors. This is borne out in the experiments, where we see that

	Acc_7	Acc_2	MAE	CORR
	FLSTM			
NLL	44.1	75.1	0.72	0.52
NLL+S$_{KL}$	44.4	75.6	0.70	0.52

Table 3: Results on sentiment analysis on CMU-MOSEI. Acc_7 denotes accuracy on 7 classes and Acc_2 the binary accuracy. MAE denotes the Mean Absolute Error and Corr is the Pearson correlation

training with synergy based loss has better performance than training with simple max-likelihood.

Note that the C-network itself is not active at test time; instead this effect is due to the alignment forced by the network during training. An interesting future direction would be to explicitly use the C-network outputs to ameliorate modality corruption.

Drop Modality	None	T	T+V	T+A
NLL	83.7	36.4	35.1	34.4

5.6 Ablation Study

Our overall proposal has multiple components viz a) the reconstruction loss (also called $\mathcal{L}_{L2}$ loss); b) the distribution alignment loss (which we call $\mathcal{L}_d$ Loss); and c) the kurtosis loss $\mathcal{L}_\kappa$. As such we ran experiments to assess the importance of each component. Specifically we trained the model without each of the three loss components prescribed in our method, and assessed the test performance. The results are presented in Appendix A.

First we note the performance improvement by incorporating kurtosis in the regularization which shows the efficacy of this term. Second one can also note that removing any individual component leads to reduction in performance, suggesting all components act together in a synergistic way to improve the results.

6 Concluding Remarks

In this paper, we used the idea of regularizing via a term which we label neural synergy maximization. This regularizer is inspired by neural cicruit design in the vertebral cortex. We experimented with different measures of synergy based on discrepancy measures such as KL and MMD. We also show that training with synergy can produce benefit on even SOTA architectures.

Limitations The most prominent limitation of this approach, is that it is inherently limited by the architecture with which it is being used. While our additional loss did improve performance, one can observe that the final performance is dependent on the initial performance. For example, while we tested on four architectures, the final performance of each model was in the same range as the initial performance. An entirely different architecture can possibly improve over our results. On the other hand our approach is model agnostic and applicable on any model trained only via max-likelihood.

A Ablation Study Results

,

In this section we run ablation experiments to assess the individual impact of each component of the overall synergy loss. For this purpose we use the MIM model on the MOSEI dataset, and the divergence type was chosen to be MMD. We activated each of the three loss components viz. ($\mathcal{L}_{L2}$, $\mathcal{L}_{d/MMD}$, $\mathcal{L}_{\kappa}$), trained the MIM model, and report the test accuracies on all the metrics.

	Acc_7	Acc_2	MAE	CORR
	MIM			
MLE	53.3	79.6	0.54	0.75
+ $\mathcal{L}_{L2}$	53.6	80.0	0.55	0.77
+ $\mathcal{L}_{d/MMD}$	53.1	80.3	0.57	0.73
+ $\mathcal{L}_{\kappa}$	53.9	79.9	0.54	0.76
+ S_{MMD}	54.3	82.4	0.52	0.77

Table 5: Ablation results on sentiment analysis on CMU-MOSEI. Acc_7 denotes accuracy on 7 classes and Acc_2 the binary accuracy. MAE denotes the Mean Absolute Error and Corr is the Pearson correlation

We note the performance improvement caused by adding the Kurtosis loss. We also note that directly adding the distributional divergence while mildly helpful can also degrade the performance. Each component overall has some value to add over others. We leave the exact nature of interactions between these terms for future work.

B Additional Experiments

We present results on the UR_FUNNY dataset which is another common affective sentiment prediction dataset. The model is evaluated on accuracy so higher numbers are better.

	NLL	NLL+S_{KL}	NLL+S_{MMD}
MISA	68.6	68.9	**69.6**
MFN	65.2	66.5	**67.2**
TFN	64.7	67.3	**67.8**

Table 6: Results on sentiment analysis on UR-FUNNY. The performance is evaluated in terms of accuracy

C Training details

We perform a grid-search for the best set of hyper-parameters: batch size in {32, 64}, learning rate in {1e-2, 5e-3,1e-3, 5e-4, 1e-4}. We did gradient clipping with clip value of 5. Model selection was done following (Zadeh et al., 2017), by selecting the model with the best MAE on validation data. Optimization was done using the AdamW (Loshchilov and Hutter, 2018) optimizer. For both the Q and the g function we used a four layer MLP with LeakyRelu activation. The dataset statistics are given in Table 1. All our experiments were conducted on Nvidia Titan X GPUs.

D Algorithm

As a reminder the input the fusion problem involves learning a representation $\mathcal{M}_f$ that combined the uni-modal representations Z_i of the input $X = (X_1, X_2, .., X_k)$ where X_i are individual input modalities. We shall denote observations as X^j and the fused representations as Z^j. Q_i, g_i are multi-layer perceptrons.

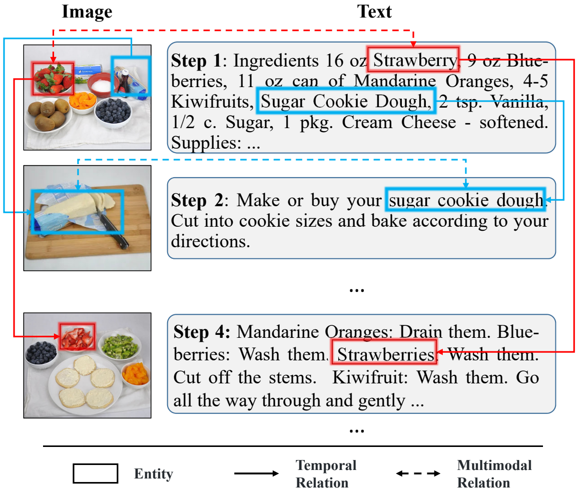
Abstract

Procedural Multimodal Documents (PMDs) organize textual instructions and corresponding images step by step. Comprehending PMDs and inducing their representations for the downstream reasoning tasks is designated as Procedural MultiModal Machine Comprehension (M^{3}C). In this study, we approach Procedural M^{3}C at a fine-grained level (compared with existing explorations at a document or sentence level), that is, entity. With delicate consideration, we model entity both in its temporal and cross-modal relation and propose a novel Temporal-Modal Entity Graph (TMEG). Specifically, a heterogeneous graph structure is formulated to capture textual and visual entities and trace their temporal-modal evolution. In addition, a graph aggregation module is introduced to conduct graph encoding and reasoning. Comprehensive experiments across three Procedural M^{3}C tasks are conducted on a traditional dataset RecipeQA and our new dataset CraftQA, which can better evaluate the generalization of TMEG.

1 Introduction

Multi**M**odal **M**achine **C**omprehension (M^{3}C) is a generalization of machine reading comprehension by introducing multimodality. Due to its differences from Visual Question Answering (VQA) (Antol et al., 2015) in the form of understanding multimodal contexts and conducting multimodal questions and answers, there has been a lot of attention in recent years devoted to this field. In this paper, we investigate a task that has been typical of M^{3}C recently, named Procedural M^{3}C, a task of reading comprehension of **P**rocedural **M**ultimodal **D**ocuments (PMDs).

As shown in Figure 1, a recipe that contains successive multimodal instructions is a typical PMD. Reading a recipe seems trivial for humans but is still complex for a machine reading comprehension system before it can comprehend both textual and visual contents and capture their relations.



Step 1: Ingredients 16 oz Strawberry, 9 oz Blueberries, 11 oz can of Mandarine Oranges, 4-5 Kiwifruits, Sugar Cookie Dough, 2 tsp. Vanilla, 1/2 c. Sugar, 1 pkg. Cream Cheese - softened. Supplies: ...

Step 2: Make or buy your sugar cookie dough. Cut into cookie sizes and bake according to your directions.

...

Step 4: Mandarine Oranges: Drain them. Blueberries: Wash them. Strawberries: Wash them. Cut off the stems. Kiwifruit: Wash them. Go all the way through and gently ...

...

Figure 1: A PMD instance: a recipe about making mini fruit pizza. The entities and relations (i.e. temporal and multimodal) among them are highlighted.

Current Procedural M^{3}C studies (Yagcioglu et al., 2018; Liu et al., 2020) comprehend PMDs by encoding text and images at each procedure step. These efforts, however, only scratch the surface and lack deep insight into the elementary unit of PMDs, that is, **entity**. From now on, we use entity to refer uniformly to entity in text and object in image. For instance, the recipe in Figure 1 involves multiple entities, i.e., Strawberry and Sugar Cookie Dough, etc. In this work, we target at approaching the Procedural M^{3}C task at a fine-grained entity level.

We observe that a PMD essentially assembles an evolution process of entities and the relations between them. Specifically, the relation between entities can be summarized in the following two categories:

- **Temporal Relation.** The state of an entity may change as steps progress. Still looking at Figure 1, strawberries are complete at step 1 and

---

*Corresponding authors.

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 1179 - 1189

by step 4 they are washed and cut into pieces. We use temporal relation to depict the association between an entity's changing visual signals in images or changing contexts in text.

- **Multimodal Relation.** An entity is naturally and powerfully associated with other entities within a single modality. Meanwhile, the cross-modal association of an entity is worth exploiting to contribute to distinct modality understanding. For example, the visual signal and context about sugar cookie dough can be interpreted by each other at step 2. We generalize the intra- and inter- modal associations of entities with the multimodal relation.

Based on the above observations, we believe that simultaneously modeling entities and the temporal and multimodal relations is a key challenge in understanding PMDs. Recent efforts (Amac et al., 2019; Huang et al., 2021) are devoted to encoding temporal relations of entities, while it neglects the multimodal relation. Heterogeneous graphs have become the preferred technology for representing, sharing, and fusing information to modern AI tasks, e.g., relation extraction (Christopoulou et al., 2019) and recommendation (Fan et al., 2019). Inspired by this, we construct a heterogeneous graph, with entities as nodes and relations as edges. Therefore, the research goal of the procedural M^{3}C task will shift from understanding unstructured PMDs to learning structured graph representations.

In this work, we propose a novel **T**emporal **M**odal **E**ntity **G**raph model, namely **TMEG**. Our model approaches Procedural M^{3}C at a fine-grained entity level by constructing and learning a graph with entities and temporal and multimodal relations. Specifically, TMEG consists of the following components: 1) **Node Construction**, which extracts the token-level features in text and object-level features in images as the initial entity embeddings; 2) **Graph Construction**, which constructs the temporal, intra-modal, and cross-modal relations separately to form a unified graph; and 3) **Graph Aggregation**, which utilizes the graph-based multi-head attention mechanism to perform fusion operations on graphs to model the evolution of entities and relations. Finally, the graph representation is fed into a graph-based reasoning module to evaluate the model's understanding ability.

In addition, in order to further advance the research of Procedural M^{3}C, we release CraftQA, a multimodal semantically enriched dataset that contains about 27k craft product-making tutorials and 46k question-answer pairs for evaluation. We evaluate three representative subtasks, i.e., visual cloze, visual coherence, and visual ordering, on CraftQA and a public dataset RecipeQA (Yagcioglu et al., 2018). The quantitative and qualitative results show the superiority of TMEG compared to the state-of-the-art methods on all three tasks. The main contributions of this paper can be summarized as follows:

- We innovatively study the Procedural M^{3}C task at a fine-grained entity level. We comprehensively explore the relations between entities in both temporal and multimodal perspectives.
- We propose a Temporal-Modal Entity Graph model TMEG, which constructs a graph with entities as nodes and relations as edges, and then learns the graph representation to understand PMDs.
- We release a dataset CraftQA. The experimental results on CraftQA and RecipeQA show TMEG outperforms several state-of-the-art methods.

2 Related Work

Procedural Text Comprehension. Procedural text comprehension requires an accurate prediction for the state change and location information of each entity over successive steps. Several datasets have been proposed to evaluate procedural text comprehension, e.g., Recipe (Bosselut et al., 2018), ProPara (Mishra et al., 2019), and OPENPI (Tandon et al., 2020). To model entity evolution, KG-MRC (Das et al., 2019) constructs knowledge graphs via reading comprehension and uses them for entity location prediction. DYNAPRO (Amini et al., 2020) introduces a pre-trained language model to dynamically obtain the contextual embedding of procedural text and learn the attributes and transformations of entities. ProGraph (Zhong et al., 2020) enables state prediction from context by constructing a heterogeneous graph with various knowledge inputs. KoalA (Zhang et al., 2021b) utilizes the external commonsense knowledge injection and data enhancement to reason the states and locations of entities. TSLM (Faghihi and Kordjamshidi, 2021) formulate comprehension task as a question answering problem and adapt pre-trained transformer-based language models on other QA benchmarks. REAL (Huang et al., 2021) builds

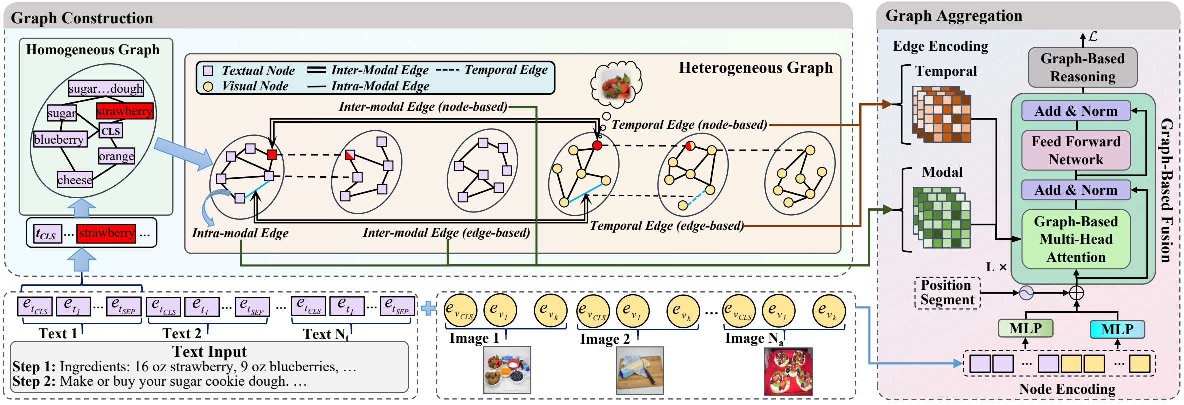


Figure 2: Overview of our proposed TMEG framework. We reuse the example in Figure 1. Initial nodes are generated from input text and images. Considering the temporal and cross-modal relation of entities, we apply various types of edges to construct a unified temporal-modal entity graph. By combining the encoding of nodes and edges, a graph aggregation module is designed to conduct graph encoding and reasoning.

a general framework to systematically model the entity, action, location by using a graph neural network.

Inspired by these previous works, we propose a temporal-modal entity graph model, which is designed with temporal encoding and modal encoding to model multiple types of entities.

Multimodal Graph. In recent multimodal research, graph structure has been utilized to model the semantic interaction between modalities. (Yin et al., 2020) propose a graph-based multimodal fusion encoder for neural machine translation, which converted sentence and image in a unified multimodal graph. (Khademi, 2020) convert image regions and the region grounded captions into graph structure and introduced graph memory networks for visual question answering. (Zhang et al., 2021a) propose a multimodal graph fusion approach for named entity recognition, which conducted graph encoding via multimodal semantic interaction. (Yang et al., 2021) focus on multimodal sentiment analysis and emotion recognition, which unified video, audio, and text modalities into an attention graph and learned the interaction through graph fusion, dynamic pruning, and the read-out technique.

In contrast to the above methods, we formulate our multimodal graph on temporal entities and successfully deploy it in Procedural M^{3}C.

3 Proposed Method

In this section, we introduce: (1) problem definition of Procedural M^{3}C in Section 3.1; (2) The homogeneous graph of each textual instruction (image) and our TMEG in Section 3.2 and Section 3.3, respectively; and (3) graph aggregation module to conduct graph encoding and reasoning in Section 3.4. Figure 2 gives a high-level overview of TMEG.

3.1 Problem Definition

Here, we define the task of Procedural M^{3}C, given:

- Context $\boldsymbol{S} = \{s_t\}_{t=1}^{N_t}$ in textual modality, which represents a series of coherent textual instructions to perform a specific skill or task (e.g., multiple steps to complete a recipe or a craft product).
- Question $\boldsymbol{Q}$ and Answer $\boldsymbol{A}$, which is either a single image or a series of images in a reasoning task (e.g., visual cloze, visual coherence, or visual ordering).

Following (Liu et al., 2020), we combine the images contained in $\boldsymbol{Q}$ and $\boldsymbol{A}$ to form N_c candidate image sequences $\{a_1, ...a_j, ...a_{N_c}\}$. Let N_a be the length of the j-th candidate image sequence $a_j = \{I_{j,1}, ...I_{j,N_a}\}$. Take the visual cloze task as an example, we fill the placeholder of the question with candidate answers to form N_c image sequences with length $N_a = 4$. The model requires to select the most relevant candidate by calculating the similarity between text sequence $\boldsymbol{S} = \{s_t\}_{t=1}^{N_t}$ and each image sequence a_j.

3.2 Homogeneous Graph Construction

As shown in Figure 2, we first extract the tokens (objects) in text (image) as the initial nodes of homogeneous graph, respectively.

Textual Node. Let N_t be the number of textual instructions $\boldsymbol{S} = \{s_t\}_{t=1}^{N_t}$. First, each instruction s_t is tokenized into a token sequence $\{e_{t_{[\text{CLS}]}}, e_{t_1}, ...e_{t_{[\text{SEP}]}}\}$, where [CLS] and [SEP] are the special tokens introduced to mark the start and the end of each instruction. Then, we utilize an off-the-shelf POS tagger (Akbik et al., 2018) to identify all nouns and noun phrases in the token sequence. Finally, we concatenate all the token sequences of textual instructions $\boldsymbol{S}$ and feed the token embedding into the graph aggregation module.

Visual Node. For each image sequence a_j, we employ a pre-trained Faster-RCNN to extract a set $\{e_{v_{[\text{CLS}]}}, e_{v_1}, ...e_{v_k}\}$ with k object features as visual tokens. Following (Messina et al., 2020; Dosovitskiy et al., 2021), we reserve [CLS] as the beginning token for each image whose final embedding is regarded as the representation of the whole image. The operation of visual node is in a similar manner as textual and any two nodes in the same instruction (image) are connected to construct a homogeneous graph.

3.3 Heterogeneous Graph Construction

Based on the homogeneous graph of each textual instruction (image), we introduce various types of edges to construct our heterogeneous graph TMEG.

3.3.1 Temporal Edge

It is essential to model the temporal evolution of entities for comprehending procedural content. Let us revisit the example in Figure 1. When a human reads step 4, the connection between entities (e.g., strawberries and oranges) and their descriptions in step 1 is naturally established.

We design the temporal edge to model the evolution of entities in text and image. It can be seen that the temporal edge describes the evolution at different steps. For the textual nodes, the same entity appearing in different steps are connected by a textual temporal edge (node-based). While for the visual nodes, we directly calculate the Euclidean Distance between object features due to the absence of accurate object detection. Following (Song et al., 2021), if the distance between node (object) i and node (object) j is less than a threshold λ_t, we treat them as the same object and connect node i to node j via a visual temporal edge (node-based). Meanwhile, we consider that there may also be temporal evolution for edges, such as changes in the relationship between entities. Therefore, we also introduce temporal edge (edge-based) to characterize the change of edges.

3.3.2 Modal Edge

As shown in Figure 1, the textual instruction of each image can be viewed as a noisy form of image annotation (Hessel et al., 2019). The association between image and sentence can be inferred through entity representations under different modalities. Correspondingly, we design the intra-modal edge and the inter-modal edge to represent the modal interactions. In Section 3.2, any two nodes in the same modality and the same instruction (image) are connected by an intra-modal edge. It is worth noting that for each instruction (image), the special [CLS] node is connected to all other nodes in order to aggregate graph-level features.

On the other hand, the textual node representing any entity and the corresponding visual node are connected by an inter-modal edge. We employ a visual grounding toolkit (Yang et al., 2019) to detect visual objects for each noun phrase. Specifically, we predict the bounding box corresponding to the text entity and compute the Intersection over Union (IoU) between all visual objects. If the IoU between the prediction box and the visual box exceeds a threshold λ_m, the textual node and the corresponding visual node are connected by an inter-modal edge (node-based). Similar to section 3.3.1, considering the influence of entity-relationship under different modalities, we also introduce inter-modal edge (edge-based) to characterize the interaction between edges.

3.4 Graph Aggregation

3.4.1 Node Encoding

As described in Section 3.2, we have obtained the embeddings of the textual tokens and visual objects. Similar to (Li et al., 2020), all embeddings are mapped to a set of initial node embeddings, and each node embedding is the sum of 1) a textual token embedding or visual object embedding; 2) a position embedding that identifies the position of the token or object in the image[1]; and 3) a segment embedding generated from the step number in PMD which indicates different textual instructions or images.

3.4.2 Edge Encoding

To encode the structural information into TMEG, we consider the temporal encoding and the modal encoding separately. For any two nodes v_i and v_j in

---

[1] We exploit the bounding box feature extracted by Faster-RCNN as the position embedding of the object.

TMEG, we construct two mappings: $\phi_t(v_i, v_j) \rightarrow \mathbb{R}$ and $\phi_m(v_i, v_j) \rightarrow \mathbb{R}$ which encode the temporal edge and the modal edge between them. The temporal encoding and the modal encoding of the total graph are fed into the graph-based aggregation module.

3.4.3 Graph-Based Fusion

As shown in the right part of Figure 2, we first introduce two multi-layer perceptrons (MLP) with Tanh activation function to project different node embeddings from two modalities into the same space. Then, we extend the VisualBERT (Li et al., 2020) to the graph-based fusion layer, which concatenates the node embeddings from MLPs as input and outputs their graph-based joint representations. Specifically, in each fusion layer, updating the hidden states of textual node and visual node mainly involve the following steps.

Firstly, we exploit a graph-based multi-head attention mechanism to generate contextual representations of nodes. Formally, the output of the h-th attention head in the $l-1$ layer can be obtained as follows:

$$A\left(\boldsymbol{q},\boldsymbol{k},\boldsymbol{v}\right)_j^{h,l-1}=\sum_{i=1}^{N}\boldsymbol{v}_i^h\left(\mathit{Softmax}(\boldsymbol{e}_{i,j}^h)\right),\tag{1}$$

$$\boldsymbol{e}_{i,j}^h=\frac{\boldsymbol{q}_j^h\left(\boldsymbol{k}_i^h\right)^T}{\sqrt{\boldsymbol{d}}}+\boldsymbol{b}_{\phi_m(i,j)}^h+\boldsymbol{b}_{\phi_t(i,j)}^h,\tag{2}$$

where q, k, v are the query matrix, key matrix, and value matrix generated from the hidden state $H^{(l-1)}$ of nodes in the $l-1$ layer. $\phi_t(i,j)$ and $\phi_m(i,j)$ denote the temporal encoding and the modal encoding of TMEG, which serve as bias terms in the attention module. It is worth noting that each head in the multi-head attention mechanism exhibits a broad range of behaviors (Vig, 2019); thus, we add different temporal encoding and modal encoding separately for each attention head. Meanwhile, in order to model the relationship of edges, the temporal encoding and the modal encoding are learned separately for each layer.

We concatenate the output of each head and pass them to a position-wise Feed Forward Networks (FFN) which is preceded and succeeded by residual connections and normalization layer (LN),

$$\begin{aligned}\hat{\boldsymbol{H}}^{(l)}&=\mathrm{LN}\left(W[\boldsymbol{A}^1,\ldots\boldsymbol{A}^h]+\boldsymbol{H}^{(l-1)}\right),\\ \boldsymbol{H}^{(l)}&=\mathrm{LN}\left(\mathrm{FFN}(\hat{\boldsymbol{H}}^{(l)})+\hat{\boldsymbol{H}}^{(l)}\right),\end{aligned}\tag{3}$$

where W is a learnable parameter and [ ] denotes the concatenation manipulation. Finally, based on TMEG, we stack multi-layer graph-based fusion layers to conduct graph encoding. Algorithm 1 shows the aggregation of TMEG in detail.

Algorithm 1: Graph Aggregation of TMEG

```
Input  : The initial hidden states of TMEG $H^0$; the
         graph-based fusion layer number $N$; the
         temporal encoding $\Phi_t$; the modal encoding
         $\Phi_m$; the attention head $A$
Output : The final hidden states $H^N$
for $l \leftarrow 1$ to $N$ do
    // Graph-Based Fusion Layer
    foreach attention head $A^{h,l}$ in layer $l$ do
        Generate $q, k, v$ from hidden states $H^{l-1}$;
        Obtain edge encoding $b^h_{\phi_t(i,j)}$ and $b^h_{\phi_m(i,j)}$;
        Calculate attention weight $e^h_{i,j}$ (Eq. 2) with
          $\{q, k, b^h_{\phi_t(i,j)}, b^h_{\phi_m(i,j)}\}$;
        Acquire output of head $A^{h,l}$ (Eq. 1) with
          $\{v, e^h_{*,j}\}$;
    end
    Aggregate each attention head $A^h$
    update
    $\hat{H}^{(l)} \leftarrow \mathrm{LN}(W[A^1, \ldots A^h] + H^{(l-1)})$;

end
return $H^N$
```

3.4.4 Graph-Based Reasoning

As mentioned in Section 3.2, we regard the hidden state of [CLS] as the representations of each instruction (image), where their final hidden states H^T and H^V are passed into the graph reasoning module for task completion.

Firstly, we leverage the one-to-one correspondence between instruction and image, e.g., each instruction has an image to visualize it (Alikhani et al., 2021). TMEG involves a Contrastive Coherence Loss for keeping the alignment between instruction and image. Let H^{V^+} and H^{V^-} represent the positive and negative examples, the loss $\mathcal{L}^{\text{Coh}}$ of the i-th step can be defined as follows:

$$\boldsymbol{L}_i^{\text{Coh}}=-\log\frac{\exp\{sim(\boldsymbol{H}_i^T,\boldsymbol{H}_i^{V^+})/\boldsymbol{\tau}\}}{\sum_{j=1}^{K}\exp\{sim(\boldsymbol{H}_i^T,\boldsymbol{H}_j^{V^-})/\boldsymbol{\tau}\}},\tag{4}$$

where K is the total number of negative samples (He et al., 2020) generated from the min-batch, $sim(\cdot,\cdot)$ and τ are the standard cosine similarity function and temperature.

In a downstream reasoning task, the model needs to predict the correct candidate $a_j = \{I_{j,1}, \ldots I_{j,N_a}\}$ based on the instructions $\boldsymbol{S} = \{s_t\}_{t=1}^{N_t}$. Referring to the sentence image prediction task in (Li et al., 2020), we concatenate all representations of each candidate image sequence to generate a instruction candidate pair as: $(\boldsymbol{S}, a_j) = [\text{CLS}, H_1^T, ...H_{N_t}^T, \text{SEP}, H_{j,1}^V, ...H_{j,N_a}^V]$, where [CLS] and [SEP] are special tokens as used in (Li et al., 2020). We pass this input through a shallow transformer followed by a fully connected layer to obtain the prediction score $P(\boldsymbol{S}, a_j)$ for the j-th candidate, and the prediction loss can be defined as

$$\boldsymbol{L}^{\text{Pre}} = -\log \frac{\exp\left(P\left(\boldsymbol{S}, \boldsymbol{a}_j\right)\right)}{\sum_{i=1, i\neq j}^{N_a-1} \exp\left(P\left(\boldsymbol{S}, \boldsymbol{a}_i\right)\right)}, \quad (5)$$

where a_j is the correct candidate and N_a is the number of candidates. We get the final loss function and optimize it through the Adam optimizer:

$$\boldsymbol{L} = \boldsymbol{L}^{\text{Pre}} + \lambda_b \boldsymbol{L}^{\text{Coh}}, \quad (6)$$

where λ_b is the balance parameter. Unless otherwise specified, all the results in this paper use $\lambda_b = 0.1$ which we find to perform best.

4 Experiments

4.1 Datasets and Metrics

RecipeQA. RecipeQA (Yagcioglu et al., 2018) is a multimodal comprehension dataset with 20K recipes approximately and more than 36K question-answer pairs. Unlike other multimodal reading comprehension datasets (Tapaswi et al., 2016; Iyyer et al., 2017; Kembhavi et al., 2017) analyze against movie clips or comics, RecipeQA requires reasoning real-world cases.

CraftQA. We collect CraftQA from Instructables[2], which is an online community where people can share their tutorials for accomplishing a task in a step-by-step manner. Specifically, we collect the most visited tutorials and remove those that contain only text or video. For question and answer generation, we also remove the tutorials that contain less than 3 images. To construct the distractor of each task, we compute the Euclidean distance between the image features that are extracted from a pretrained ResNet-50 (He et al., 2016). Taking the visual cloze task as an example, the distractor is sampled from the nearest neighbors of the ground-truth image based on Euclidean distance. Finally, CraftQA contains about 27k craft product-making tutorials and 46k question-answer pairs. We employ CraftQA to evaluate the reading comprehension performance of TMEG in different domains as well as its domain transfer capability. More statistics about these two datasets are shown in Table 1.

Dataset	Statistics	Train	Valid	Test
RecipeQA	# of recipes	15,847	1,963	1,969
	avg. # of steps	5.99	6.01	6.00
	avg. # of words	443.01	440.51	435.33
	avg. # of images	12.67	12.74	12.65
CraftQA	# of tutorials	21,790	2,601	2,604
	avg. # of steps	7.53	7.47	7.56
	avg. # of words	535.88	531.01	541.97
	avg. # of images	20.14	20.19	20.37

Table 1: Statistics of RecipeQA and CraftQA dataset. Each dataset is split into training, validation, and test sets based on the number of recipes or craft-making tutorials. We also provide the average count of steps, images, and words contained in each split dataset.

Metric. In three Procedural M^{3}C tasks that are tested in the following experiments (visual cloze, visual coherence, and visual ordering), we use classification accuracy as the evaluation metric, which is defined as the percentage of yielding the ground-truth answer during testing (Yagcioglu et al., 2018; Amac et al., 2019; Liu et al., 2020).

4.2 Implementation Details

For visual node construction, we employ the pre-trained Faster R-CNN (Ren et al., 2015) model provided by Detectron2 (Wu et al., 2019) and limit the number of objects to 36 for each image. Following (Yang et al., 2019; Song et al., 2021), we set the thresholds λ_t and λ_m as 7 and 0.5, respectively, for the temporal and the modal edge constructions.

The framework of the graph-based fusion module is built on VisualBERT (Li et al., 2020) with its initialized parameters and tokenizer implemented by HuggingFace's transformers library (Wolf et al., 2020). The shallow transformer in the graph-based reasoning module is designed as 2 hidden layers with a size of 512 and 8 attention heads. During the training stage, the batch size is fixed to 16 and the number of negative samples K is set to 8. The temperature parameter τ in Eq.(4) is set to 0.07. The balance parameter λ_b in Eq.(6) is set to 0.1. Adam with the learning rate 5×10^{-5} is used to update parameters. We introduce an early stopping mechanism and set the patience value to 5, which means the training will stop if the model performance is not improved in five consecutive times. Our source code will be released online.

	RecipeQA				*CraftQA*			
Model	Cloze	Coherence	Ordering	Average	Cloze	Coherence	Ordering	Average
Human (Amac et al., 2019)	77.60	81.60	64.00	74.40	55.33	61.80	54.60	57.24
HS (Yagcioglu et al., 2018)	27.35	65.80	40.88	44.68	27.81	42.61	35.23	35.22
PRN (Amac et al., 2019)	56.31	53.64	62.77	57.57	35.14	33.67	42.31	37.04
MLMM-Trans (Liu et al., 2020)	65.57	67.33	63.75	65.55	39.43	46.52	43.62	43.20
VisualBERT (Li et al., 2020)	66.49	68.15	63.09	65.91	40.56	47.84	46.18	44.86
TMEG (Our Model)	**73.27**	**70.38**	**65.56**	**69.73**	**48.01**	**51.36**	**49.25**	**49.54**
w/o Temporal Encoding	70.18	68.81	63.91	67.63	45.91	47.71	47.24	46.95
w/o Modal Encoding	71.50	69.63	64.15	68.42	46.67	49.06	48.35	48.02
w/o Both Encoding	68.97	67.72	63.34	66.67	44.87	46.29	46.77	45.98
w/o Contrastive Loss $\mathcal{L}^{Coh}$	71.66	68.54	64.54	68.24	47.49	50.03	48.79	48.77

Table 2: Experimental comparison of procedural multimodal machine comprehension on RecipeQA and CraftQA: "*w/o* Temporal Encoding" and "*w/o* Modal Encoding" denote to remove the temporal or modal edges respectively and "*w/o* Both Encoding" denotes to remove both of them. "*w/o* Contrastive Loss $\mathcal{L}^{Coh}$" denotes excluding the contrastive coherence loss $\mathcal{L}^{Coh}$ from the final loss. Similar to RecipeQA, 100 questions in CraftQA are extracted from its validation set to evaluate the "Human" performance.

4.3 Baselines

We compare our model with the following models: (1) **Hasty Student (HS)** (Yagcioglu et al., 2018) discards textual context and directly exploits the similarities and dissimilarities between answer images to rank candidates. (2) **PRN** (Amac et al., 2019) introduces external relational memory units to keep track of textual entities and employs a bi-directional attention mechanism to obtain a question-aware embedding for prediction. (3) **MLMM-Trans** (Liu et al., 2020) modifies the framework of the transformer (Vaswani et al., 2017) and conducts an intensive attention mechanism at multiple levels to predict correct image sequences. (4) **VisualBERT** (Li et al., 2020) consists of a stack of transformer layers that extend the traditional BERT (Devlin et al., 2019) model to a multimodal encoder. The performance of some baselines on RecipeQA has been previously reported in (Amac et al., 2019; Liu et al., 2020).

4.4 Experimental Results

4.4.1 Comparison Analysis

As shown in Table 2, TMEG shows favorable performance in different reasoning tasks, with an average accuracy of 69.73 and 49.54 on RecipeQA and CraftQA, following behind the "Human" performance. Besides, the performance on the *visual ordering* task exceeds human accuracy for the first time, which proves that the temporal and modal analysis in TMEG is effective in comprehending PMDs. MLMM-Trans performs comparably with VisualBERT while inferior to TMEG, which may be attributed to their superficial consideration of entities.

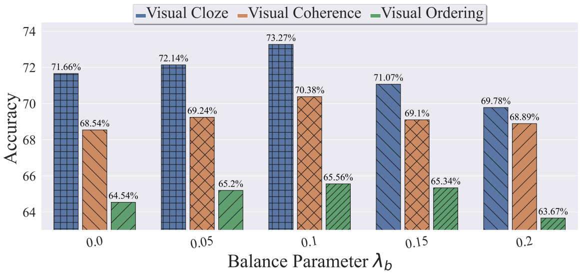

Figure 3: Experimental results of our model with different balance parameter λ_b in Eq.(6) on RecipeQA.

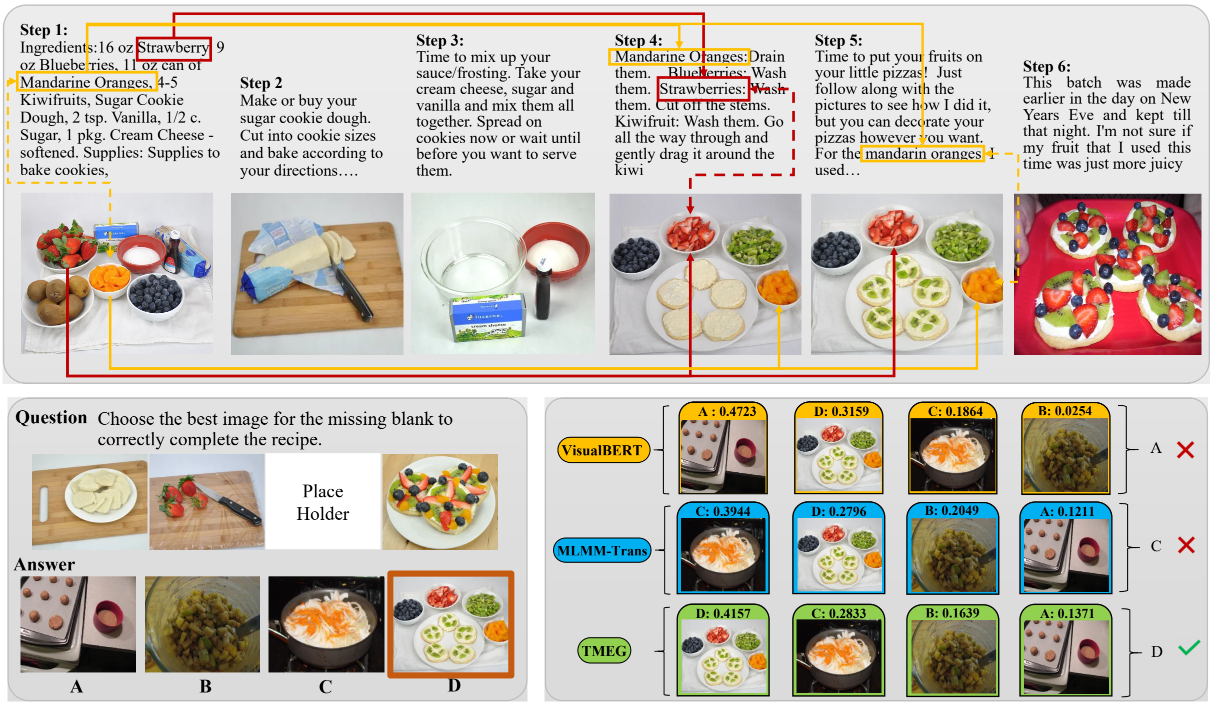
MLMM-Trans ignores the entity information contained in text (e.g., the correspondence between entities in text and images) and VisualBERT directly fuses textual and visual features without considering entity evolution. In TMEG, we explicitly identify and model entity evolution in PMD, whereas MLMM-Trans and VisualBERT assume entity information to be learned implicitly alongside other data.

Meanwhile, CraftQA has more images (20.14 vs 12.67) and tokens (535.88 vs 443.01) on average than RecipeQA. More diverse complex cases in CraftQA require better comprehension and reasoning capacities for both models and humans. We believe this can explain the lower results on CraftQA. This emphasizes the necessity of comprehending entity coherence in a multimodal context.

4.4.2 Ablation Study

We evaluate the effects of temporal encoding, modal encoding, and contrastive coherence loss



Step 1: Ingredients:16 oz Strawberry 9 oz Blueberries, 11 oz can of Mandarine Oranges, 4-5 Kiwifruits, Sugar Cookie Dough, 2 tsp. Vanilla, 1/2 c. Sugar, 1 pkg. Cream Cheese - softened. Supplies: Supplies to bake cookies,

Step 2 Make or buy your sugar cookie dough. Cut into cookie sizes and bake according to your directions….

Step 3: Time to mix up your sauce/frosting. Take your cream cheese, sugar and vanilla and mix them all together. Spread on cookies now or wait until before you want to serve them.

Step 4: Mandarine Oranges: Drain them. Blueberries: Wash them. Strawberries: Wash them. Cut off the stems. Kiwifruit: Wash them. Go all the way through and gently drag it around the kiwi

Step 5: Time to put your fruits on your little pizzas! Just follow along with the pictures to see how I did it, but you can decorate your pizzas however you want. For the mandarin oranges I used…

Step 6: This batch was made earlier in the day on New Years Eve and kept till that night. I'm not sure if my fruit that I used this time was just more juicy

Question Choose the best image for the missing blank to correctly complete the recipe.

Figure 4: An illustrated example of the visual cloze task on RecipeQA to clarify the workflow of TMEG when dealing with the downstream tasks.

$\mathcal{L}^{\text{Coh}}$ to examine the three modules.

Edge Encoding. Table 2 also shows the ablation results of our model when each module is respectively removed. In terms of edge encoding, removing temporal encoding makes more negative effects on TMEG than moving the modal encoding, reflecting the significance of modeling temporal entity evolution for procedural M^3C.

Contrastive Coherence Loss. As shown in the last row of Table 2, we find that $\mathcal{L}^{\text{Coh}}$ can indeed improve TMEG. The reason is that $\mathcal{L}^{\text{Coh}}$ helps enhance the learning of textual entity representation and visual entity representation in Procedural M^3C.

4.5 Analysis of TMEG

4.5.1 Balance Parameter

In Figure 3, we illustrate the influence of the balance parameter λ_b in Eq.(6), which balances the contrastive coherence loss $\mathcal{L}^{\text{Coh}}$ and the candidate prediction loss $\mathcal{L}^{\text{Pre}}$. We tune λ_b from 0 to 0.2 with 0.05 as the step size. We observe that the model beats the highest accuracy when $\lambda_b = 0.1$. Generally, (1) introducing the contrastive coherence loss can improve TMEG for better fitting downstream tasks, and (2) appropriately balancing the prediction loss $\mathcal{L}^{\text{Pre}}$ and contrastive coherence loss $\mathcal{L}^{\text{Coh}}$ helps TMEG comprehend PMDs.

Model	R2C	C2R	Average
MLMM-Trans (Liu et al., 2020)	33.98	40.14	37.06
VisualBERT (Li et al., 2020)	35.24	42.15	38.69
TMEG (Our Model)	**39.06**	**45.42**	**42.24**
TMEG (*w/o* Edge Encoding)	36.02	43.17	39.60

Table 3: Results of the domain transfer experiments, where "R2C" denotes training models on RecipeQA while testing on CraftQA, and "C2R" represents the opposite.

4.5.2 Cross-Domain Investigation

To study the domain transfer capability of our framework, we evaluate TMEG in different domains, as shown in Table 3. Specifically, The model trained on RecipeQA is evaluated on CraftQA, and the reverse is true for CraftQA. Results show that compared with other baselines, our model achieves more generalized and better comprehension performance on domain transfer by incorporating TMEG.

4.5.3 Case Study

Figure 4 further presents a visual cloze example on RecipeQA which requires a correct image in the missing piece after reading the context. We compare the highest-scored candidate images respectively picked out by MLMM-Trans (Liu et al., 2020), VisualBERT (Li et al., 2020), and TMEG.

By considering the temporal-modal entity evolution, TMEG can capture the salient entities (e.g., Strawberry and Sugar Cookie Dough) and trace their evolution at each step, thereby inferring the ground-truth answer.

5 Conclusion

In this paper, we propose a novel temporal-modal entity graph (TMEG) to approach Procedural M^3C. Based on TMEG, we introduce graph-based fusion module and reasoning module, which are used to aggregate node features and solve downstream reasoning tasks.

What's more, we introduce another Procedural M^3C dataset called CraftQA to assist in evaluating the generalization performance of TMEG in different domains and domain transfer. Extensive experiments on the RecipeQA and CraftQA validate the superiority of TMEG. A promising future direction is to introduce temporal-modal entity graphs into the video understanding task (Lin et al., 2020; Xu et al., 2020), which also calls for an enhancement of the temporal and the cross-modal reasoning capability.

Ethical Considerations

Intellectual Property. CraftQA contains question answer pairs generated from copyright free tutorials found online[3]. All of the tutorials are licensed with the Creative Commons license[4] which helps share knowledge and creativity for common use.

The collection of CraftQA is in accordance with the Terms of Service of Instructables as follows: by posting, providing, uploading, submitting, sharing, publishing, distributing, making available or allowing others to access and/or use Your Content to or through the Service You are solely responsible and liable for the consequences of doing so and you acknowledge and agree that Your Content can and may be viewed worldwide[5].

We also construct experimental evaluations on the RecipeQA dataset. Referring to the official dataset descriptions of RecipeQA[6], Legal and Ethical Considerations had been taken into account during the construction of RecipeQA. We have cited the corresponding papers in this study.

Privacy. According to the Privacy Statement of Instructables[7], users can choose whether or not to expose their information when publishing tutorials. Respecting personal privacy, we have removed all of the personal information of users from CraftQA and promise CraftQA isn't involved with any privacy issues.

Explanation Graph Generation via Pre-trained Language Models: An Empirical Study with Contrastive Learning

Swarnadeep Saha **Prateek Yadav** **Mohit Bansal**
UNC Chapel Hill
`{swarna, prateek, mbansal}@cs.unc.edu`

Abstract

Pre-trained sequence-to-sequence language models have led to widespread success in many natural language generation tasks. However, there has been relatively less work on analyzing their ability to generate structured outputs such as graphs. Unlike natural language, graphs have distinct structural and semantic properties in the context of a downstream NLP task, e.g., generating a graph that is connected and acyclic can be attributed to its structural constraints, while the semantics of a graph can refer to how meaningfully an edge represents the relation between two node concepts. In this work, we study pre-trained language models that generate explanation graphs in an end-to-end manner and analyze their ability to learn the structural constraints and semantics of such graphs. We first show that with limited supervision, pre-trained language models often generate graphs that either violate these constraints or are semantically incoherent. Since curating large amount of human-annotated graphs is expensive and tedious, we propose simple yet effective ways of graph perturbations via node and edge edit operations that lead to structurally and semantically positive and negative graphs. Next, we leverage these graphs in different contrastive learning models with Max-Margin and InfoNCE losses. Our methods lead to significant improvements in both structural and semantic accuracy of explanation graphs and also generalize to other similar graph generation tasks. Lastly, we show that human errors are the best negatives for contrastive learning and also that automatically generating more such human-like negative graphs can lead to further improvements.[1]

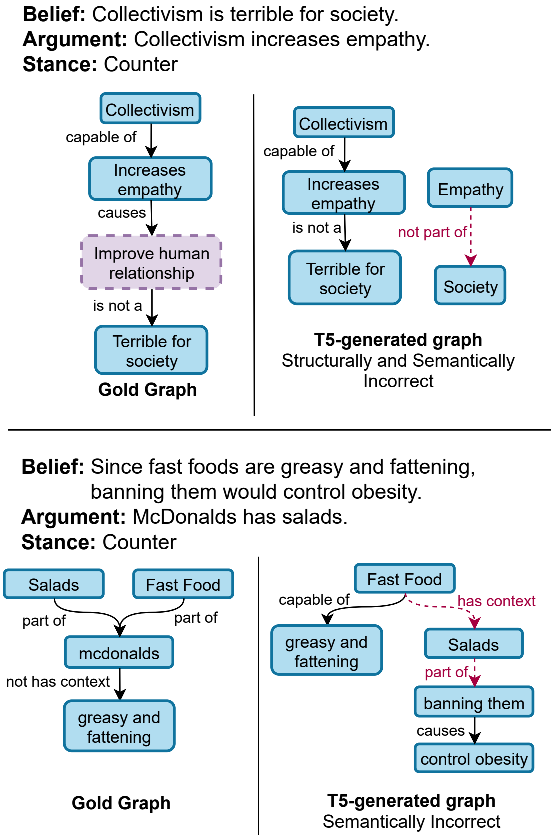

Figure 1: Two representative examples from ExplaGraphs (Saha et al., 2021b) showing the belief, argument, stance, gold explanation graph, and T5-generated explanation graph. The dashed nodes represent commonsense nodes and the dashed edges are incorrect edges. The first generated graph is structurally incorrect and the second graph is semantically incorrect.

1 Introduction

Pre-trained sequence-to-sequence language models (PLMs) like BART (Lewis et al., 2020) and T5 (Raffel et al., 2020) have led to significant advances in many natural language generation tasks like text summarization and machine translation. The models are pre-trained on massive amounts of text data with self-supervision, thus enabling them to construct coherent natural language sentences for downstream tasks. This then raises the question whether pre-trained language models, trained on free-form natural language data, can also adapt themselves to generate structured outputs like graphs. Graphs are common in NLP tasks

that involve representing structured knowledge in the form of knowledge bases (Guarino and Giaretta, 1995), constructing event chains from documents (Chambers and Jurafsky, 2009), or more recent work on encoding reasoning chains, explanations, or deductive proofs (Saha et al., 2020; Tafjord et al., 2021; Dalvi et al., 2021).

Graphs differ from free-form natural language. In the context of NLP, natural language graphs (consisting of textual nodes and edges) can have distinct structural and semantic properties. For example, consider a recently proposed commonsense explanation graph generation task shown in Fig. 1 (Saha et al., 2021b). Each example shows a belief, an argument and an explanation graph explaining how the argument supports or refutes the belief. These explanation graphs encode structured knowledge (augmented with commonsense) and consist of concepts as nodes and relations from ConceptNet (Liu and Singh, 2004) as edges. For example, the second graph encodes the knowledge that "both salads and fast food are part of mcdonalds and hence mcdonalds is not greasy and fattening", thus explicitly refuting the belief. From prior work, the structural constraints enforce the graphs to be connected directed acyclic and the nodes to contain at least two concepts from the belief and two from the argument. The semantic aspect deals with commonsense and evaluates whether each edge expresses coherent relational knowledge and if the whole graph explains the stance.

Following Saha et al. (2021b), we represent graphs as strings composed of concatenated edges and fine-tune T5 to generate graphs in an autoregressive manner. We observe that while moderate amount of supervision enables the model to learn valid graph encodings, the graphs frequently violate task-specific structural constraints (like connectivity). For instance, the first example in Fig. 1 shows a graph generated by T5 that is disconnected and hence structurally incorrect. Moreover, for the fraction of graphs that are structurally correct, the model also makes commonsense mistakes, a type of semantic error, by inferring wrong or incoherent relations between concepts. Both T5-generated graphs shown in Fig. 1 contain incoherent or non-commonsensical edges (marked by dashed arrows) like "fast food; has context; salads". Based on these observations, we study PLMs that generate explanation graphs in an end-to-end manner and analyze their ability to learn the structural constraints as well as the semantics of such graphs.

While a general recipe towards improving the structural and semantic aspects of graph generation can be via large-scale training with more human-annotated graphs, it is prohibitive under most practical scenarios because of the cognitive load associated with a complex data creation task like graph annotation (Dalvi et al., 2021; Saha et al., 2021b). Hence, we propose simple yet effective methods of graph perturbations that perform various kinds of node and edge addition, deletion, and replacement operations to construct structurally and semantically positive (correct) and negative (incorrect) graphs. Overall, we leverage three types of negative graphs (synthetic structural, synthetic semantic, and human-created semantic) and develop multiple contrastive learning models (Hjelm et al., 2018; Chen et al., 2020a; Khosla et al., 2020; Gunel et al., 2020) for effectively distinguishing between correct and incorrect graphs. Our first method is a *Generate-and-Refine* model that first generates an initial graph and further refines it using another T5 model. Next, we propose two improved models – one that uses the negative graphs in a max-margin formulation and another that uses both positive and negative graphs with a InfoNCE (van den Oord et al., 2018) contrastive loss. On two real-world tasks of explanation graph generation and temporal graph generation, with varied node and edge semantics, we observe that our proposed methods and graph perturbation techniques generalize well and lead to improvements in both structural and semantic accuracy of graphs. Further analysis of different types of negative graphs reveal that the human-error graphs are the hardest, most diverse, and hence the best type of negatives to learn from in contrastive learning. Hence, we also develop methods to automatically generate more such human-like semantic negative graphs, which leads to further improvements. We summarize our contributions as follows.

- We present a detailed analysis of graph structure and semantics for end-to-end explanation graph generation via pre-trained language models.
- We propose simple yet effective graph perturbation techniques for constructing positive and negative graphs and use them in different graph contrastive learning models.
- Our methods lead to significant improvements in both structural and semantic accuracy of explanation graphs and also generalize to other similar graph generation tasks.

2 Related Work

Graph Generation from Language Models. Representative works on graph generation from language models include knowledge graph completion models like Comet (Bosselut et al., 2019; Hwang et al., 2021) that fine-tune GPT (Radford et al., 2019; Brown et al., 2020) and BART (Lewis et al., 2020), generation of event influence graphs (Tandon et al., 2019; Madaan et al., 2020), partially ordered scripts (Sakaguchi et al., 2021), temporal graphs (Madaan and Yang, 2021), entailment trees (Dalvi et al., 2021), proof graphs (Saha et al., 2020; Tafjord et al., 2021; Saha et al., 2021a) and commonsense explanation graphs (Saha et al., 2021b). Linguistic tasks like syntactic parsing (Zhou et al., 2020; Mohammadshahi and Henderson, 2021; Kondratyuk and Straka, 2019) and semantic parsing (Chen et al., 2020b; Shin et al., 2021) have also made use of language models. There is also a large body of work on building generative models for learning unconditional graph distributions (You et al., 2018; Simonovsky and Komodakis, 2018; Grover et al., 2019; Liao et al., 2019; Shi* et al., 2020) without any semantics attached to the graphs. Our novelty lies in presenting the first systematic analysis of structure and semantics of graph generation for two downstream NLP tasks using pre-trained language models and improving them via constrastive learning.

Data Augmentation and Contrastive Learning. Data Augmentation for NLP (Hedderich et al., 2020; Feng et al., 2021; Chen et al., 2021) has been a powerful tool in low-data settings, ranging from its early usages with synonym replacement (Kolomiyets et al., 2011; Wang and Yang, 2015) to more recent methods of perturbing hidden representations (Miyato et al., 2016; Shen et al., 2020). Contrastive learning, beyond its historical use in learning robust image representations (Chopra et al., 2005; Hadsell et al., 2006; Gutmann and Hyvärinen, 2010; Hoffer and Ailon, 2015; Hjelm et al., 2018; Chen et al., 2020a; He et al., 2020) has been explored in supervised scenarios (Khosla et al., 2020; Gunel et al., 2020) and for NLP, in training self-supervised language models (Fang et al., 2020), learning sentence representations (Gao et al., 2021), document clustering (Zhang et al., 2021), summarization (Liu and Liu, 2021; Cao and Wang, 2021) and generic text generation (Lee et al., 2020). It has also been used in unconditional graph representation learning (You et al., 2020; Hassani and Khasahmadi, 2020; Zhu et al., 2021). We follow this rich line of work to explore their applicability in supervised graph generation tasks from pre-trained language models in low-resource settings.

Generative Commonsense Reasoning. While traditional commonsense reasoning tasks are discriminative in nature (Zellers et al., 2018; Talmor et al., 2019; Sap et al., 2019; Bisk et al., 2020; Sakaguchi et al., 2020; Talmor et al., 2021), recent focus on generative evaluation have led to the development of tasks and benchmarks that explore unstructured commonsense sentence generation (Lin et al., 2020), event influence graph generation (Madaan et al., 2020), commonsense explanation graph generation (Saha et al., 2021b), etc. We experiment with two graph generation tasks, primarily focusing on ExplaGraphs (Saha et al., 2021b) because of the clear distinction in the underlying structural constraints and the semantic aspect dealing with commonsense.

3 Motivation and Background

Our primary task of interest is a recently proposed commonsense explanation graph generation task called ExplaGraphs (Saha et al., 2021b). In Sec. 6.4, we also experiment with another related task of temporal graph generation (Madaan et al., 2020). In both these tasks, the structural aspect deals with satisfying certain task-specific constraints on the graph (like connectivity) and the semantic aspect deals with the construction of meaningful edges (that adhere to commonsense). Below we discuss ExplaGraphs briefly and analyze pre-trained language models for their ability to generate explanation graphs.

ExplaGraphs (Saha et al., 2021b). In this task, given a belief and an argument, an agent has to perform two sub-tasks – predict the stance (support/counter) and also generate an explanation graph explaining the stance. Explanation graphs are structured explanations that capture explicit reasoning chains between the belief and the argument, thereby making models more interpretable. Formally, an explanation graph is a connected DAG with nodes as concepts and edges as commonsense relations between two concepts (See Fig. 1). The concepts are either part of the belief or the argument (represented with solid boxes) or any external commonsense phrase (represented with dashed boxes). Each edge in the graph forms a coherent sentence and the graph, when read as a whole, forms reasoning structures explaining why the argument supports or refutes the belief. Saha et al. (2021b) evaluate explanation graphs by defining two accuracy metrics – (1) *Structural Correctness Accuracy (StCA)*: Fraction of graphs that satisfy all structural constraints, and (2) *Semantic Correctness Accuracy (SeCA)*: Fraction of graphs that are both structurally and semantically correct. A graph is considered structurally correct if it satisfies the following constraints: (1) it is connected, (2) it is a DAG, (3) the edge relations belong to a pre-defined list, (4) there are at least two concepts from the belief and two from the argument. If all these constraints are satisfied, the graph is next evaluated for semantic correctness by a model-based metric (Saha et al., 2021b). It works on the principle that an explanation graph is semantically correct if the stance inferred from the belief and the graph matches the gold stance. Refer to Appendix A for a detailed description of all evaluation metrics.

Baseline T5 Model. Following prior work (Saha et al., 2021b), we generate explanation graphs as post-hoc explanations by conditioning on the belief, argument and the predicted stance.[2] The stance prediction model is a fine-tuned RoBERTa model (Liu et al., 2019) which we keep unaltered from prior work and focus on the graph generation sub-task. We generate graphs as linearized strings in an end-to-end manner by leveraging an encoder-decoder pre-trained language model, T5 (Raffel et al., 2020). The input to the model is the concatenated belief, argument and the stance along with a prefix *"Generate an Explanation Graph for"*. The graphs are encoded as concatenated bracketed edges, in which the edges are ordered according to the Depth First Search (DFS) order of the nodes. While we choose T5 because of its superior performance (Saha et al., 2021b), we do not make any model-specific assumptions and graphs can be generated via any encoder-decoder style pre-trained language model (e.g., see Appendix E for results with BART).

Analysis of T5 Baseline. We analyze the quality of the explanation graphs generated by T5 in Table 1. We vary the amount of training data from 500 to 2368 samples (all) and report StCA and SeCA along with other metrics like Graph-BertScore (G-BS) introduced in prior work (Saha et al., 2021b).

Count	StCA↑	SeCA↑	G-BS↑	GED↓	EA↑
500	42.5	20.7	36.3	0.68	20.4
1000	49.2	23.7	42.2	0.63	26.2
1500	50.7	33.2	43.4	0.61	28.2
2368	51.0	34.7	43.9	0.61	29.5

Table 1: Performance of T5-large with varying amount of training data on ExplaGraphs test set.

While the structural accuracy improves with increase in training data, the gain saturates quickly and even after training on the entire data, we find a significant fraction of graphs to violate the structural constraints. We note that a high 91% of T5's generations are valid graph encodings i.e., the generated strings can be parsed into graphical structures (without any post-processing), suggesting that T5 is able to learn the graph encoding from a fairly small amount of supervision. However, it fails to satisfy the various structural constraints – (1) 20% of the graphs are disconnected, (2) 6% of the graphs contain cycles, and (3) 14% of the graphs have less than two concepts from the belief or from the argument. Note that these constraints are not encoded in the model, thus making them fairly hard to learn from limited supervision. On the fraction of structurally correct graphs, the model makes further semantic errors and a lower SeCA of 35% demonstrates that. In Fig. 1, we show examples of structurally incorrect and semantically incorrect graphs generated by T5. Overall, these results indicate that there is a significant scope for improvement both on graph structure and semantics, thus motivating us to develop methods with design choices aimed at improving both aspects.

4 Graph Perturbations

Most prior works that collect human-annotated graphs for a downstream NLP task have found such collection processes to be quite expensive and tedious (Tandon et al., 2019; Dalvi et al., 2021; Saha et al., 2021b). For instance, Saha et al. (2021b) obtained high-quality data only after multiple rounds of refinement and Dalvi et al. (2021) employ trained expert annotators for entailment tree construction. The corresponding datasets are also relatively small in size (2-3k), thus limiting the prospect of large-scale training. Hence, our approach towards improving explanation graph generation is through data augmentation techniques that perturb human-curated graphs to construct positive and negative graphs. As noted earlier, we wish to construct graphs that enable better learning of

---

[2] These are rationalizing models (Rajani et al., 2019; Hase et al., 2020) that first predict the stance, followed by the graph. While graphs can also be generated first, followed by the stance, we experiment with one model family for this work.

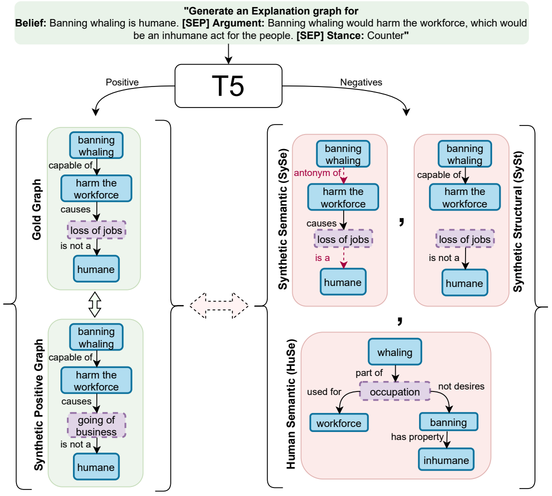

Figure 2: Our T5-based contrastive learning framework for graph generation using positively and three kinds of negatively perturbed graphs.

structural graph constraints and their semantics.

4.1 Positive Graph Perturbations

One simple method to augment existing training data is to create synthetic positive graphs. These graphs should be created such that all the task-specific constraints continue to hold upon perturbations. E.g., removing a node that makes the graph disconnected is a prohibitive action. Hence, we choose nodes (concepts) that are not part of the belief or the argument (also termed as commonsense nodes) and replace them with phrases that are synonymous to the original phrases. To do so, we select words from the concept with POS tags of Adjective, Noun, Adverb, or Verb and replace them with that synonym from Wordnet (Miller, 1995) for which the cosine similarity of their word2vec representations (Mikolov et al., 2013) is the highest.[3] Fig. 2 shows an example of a positive graph perturbation where the node "loss of jobs" is replaced with "going of business". Note that our node replacement operations will always lead to structurally similar graphs. Automatically constructing structurally diverse positive graphs is a challenging problem and we leave that for future work.

4.2 Negative Graph Perturbations

In order to enable the model to learn from explicit hard negatives, we construct three diverse types of graphs – synthetically constructed structural negatives for learning graph constraints and synthetic and human-created semantic negatives to capture a fairly large space of semantically incorrect graphs. Below we discuss the construction of these graphs.

Synthetic & Structurally Negative Graphs (SySt). As shown previously, one common source of errors in the generated explanation graphs is the violation of structural constraints. To enable learning these constraints, we generate four types of negative graphs by performing the following perturbations on each ground-truth graph: (1) removing an edge at random such that the resultant graph becomes disconnected, (2) adding an edge between two randomly chosen nodes such that the resultant graph becomes cyclic, (3) adding and removing one edge at random such that the resultant graph becomes both disconnected and cyclic, (4) removing a node randomly such that the resultant graph contains less than two concepts from the belief or argument. Fig. 2 shows an example of a disconnected graph created as part of the structurally negative graphs.

Synthetic & Semantic Negative Graphs (SySe). We also construct semantically incorrect negative explanation graphs. While the previous category of negative graphs (SySt) captures structural constraints, SySe captures the relational knowledge in graphs. Semantic incorrectness typically arises from inappropriate relations that do not adhere to human commonsense ("loss of jobs; is a; humane"). We create such negative graphs by selecting a random number of edges and then replacing the relations with some other relations. Fig. 2 shows a semantic negative graph in which the relations marked with dashed lines are perturbed.

Human-created & Semantic Negative Graphs (HuSe). The space of semantically incorrect graphs is fairly large and in order to augment our synthetic negative graphs with harder structurally-diverse negatives, we make use of human-created incorrect graphs from prior work (Saha et al., 2021b).[4] Humans make subtle errors, thus making them ideal negative candidates for contrastive learning. ExplaGraphs was constructed via an iterative framework in which the graphs are iteratively refined (up to two times) until they are verified as correct. We treat these refined graphs as negatives. Specifically, in two rounds, if an initial graph $\mathcal{G}_1$

---

[3] We also tried similar replacement operations with antonyms. However, they often lead to semantically inconsistent graphs. E.g., *A causes B* does not always imply *A not causes not B* or *not A not causes not B*.

[4] Publicly released by Saha et al. (2021b) at `https://github.com/swarnaHub/ExplaGraphs/blob/main/data/refinement_graphs_train.tsv`.

is refined into graphs $\mathcal{G}_2$ and $\mathcal{G}_3$ successively, then $\mathcal{G}_1$ and $\mathcal{G}_2$ are considered as negative graphs. Unlike SySe which only perturb the relations, these negatives are structurally diverse (see Fig. 2) and capture semantics not just at the level of each edge but for the graph as a whole (e.g., a graph might be refined because it does not explain the stance). Note that human-created graphs can only be semantically incorrect, since their structural correctness is already ensured during construction.

5 Augmentation with Perturbed Graphs

Next we propose different methods of leveraging these positive and negative graphs for explanation graph generation. Our models either use only positive graphs as simple data augmentation, only negative graphs in a max-margin model, or both in a *Generate & Refine* model and a Contrastive model.

5.1 Augmentation with Positive Graphs

In this first simple approach, we augment the training data with the synthetically created positive graphs and retrain the baseline T5 model.

5.2 Max-Margin Graph Generation Model

Our next model leverages the negatively perturbed graphs in a max-margin formulation. During training, given a (belief, argument, stance) context x, a ground truth graph $\mathcal{G}^{(g)}$ and a negative graph $\mathcal{G}^{(n)}$, linearized into a sequence of words $\{y_i^{(g)}\}_{i=1}^{k}$ and $\{y_i^{(n)}\}_{i=1}^{l}$ respectively, we define the loss function $\mathcal{L}$ as a linear combination of the standard cross-entropy loss $\mathcal{L}_{CE}$ and a max-margin loss $\mathcal{L}_{MM}$, defined between a word $y_i^{(g)}$ of the positive graph and a word $y_i^{(n)}$ of the negative graph.

$$\mathcal{L}_{CE} = \sum_i -logP_\theta(y_i^{(g)}|y_{<i}^{(g)}, x)$$

$$\mathcal{L}_{MM} = \sum_i \max(0, logP_\theta(y_i^{(g)}|y_{<i}^{(g)}, x) - \log P_\theta(y_i^{(n)}|y_{<i}^{(n)}, x) + \beta)$$

$$\mathcal{L} = \mathcal{L}_{CE} + \alpha\mathcal{L}_{MM}$$

where α and β (margin) are hyperparameters. As noted earlier, the baseline model often makes commonsense mistakes in distinguishing between positive and negative relations ("causes" vs "not causes") and our relation perturbing negative graphs and the max-margin loss component facilitate learning a better boundary between them.

5.3 Generate & Refine Graph Generation

ExplaGraphs was constructed using a "Refinement" phase wherein the initially constructed graphs that are marked incorrect by human verifiers are further refined by another set of annotators. Here we emulate the graph refinement phase with the help of a model. Specifically, our approach is a 2-stage pipeline – first, an initial graph is generated by the baseline T5 model and second, an *Explanation Graph Refinement* model conditions on the initial graph, along with the belief, argument and the stance to refine the graph. The refiner is also a T5 model fine-tuned with the prefix "Refine the Explanation Graph for" on all positive and negative graphs described in Sec. 4. Note that our approach differs from the actual data collection process in two aspects. Unlike the human-annotated graphs, which are refined only for semantic correctness, the model-generated graphs can be both structurally and semantically incorrect. Second, our approach does not involve a graph verification stage and thus, the refiner model acts on all (correct and incorrect) graphs generated in stage 1 and is thus trained with both correct and incorrect graphs.

5.4 Contrastive Graph Generation Model

Our Contrastive Graph Generation Model (Fig. 2) also leverages both positive and negative graphs but instead of doing so in a 2-stage *Generate & Refine* model, uses a contrastive learning framework (Khosla et al., 2020; Gunel et al., 2020). Given a ground-truth graph $\mathcal{G}^{(g)}$, a positive graph $\mathcal{G}^{(p)}$ and a set of negative graphs $\{\mathcal{G}_i^{(n)}\}_{i=1}^{M}$, contrastive learning aims to learn the graph representations such that the gold graph's representation is close to that of the synthetic positive graph while being distant from those of the negative graphs. Similar to Cao and Wang (2021), we use the last layer of the decoder in T5 as the representation of each token in the graph and obtain the graph representation by averaging over the constituent token representations. Let the graph representations be denoted by $h^{(g)}$, $h^{(p)}$ and $\{h_i^{(n)}\}_{i=1}^{M}$. Given $\mathcal{H}^{(g)} = \{h^{(p)}\} \bigcup \{h_i^{(n)}\}_{i=1}^{M}$, our overall loss combines the cross-entropy loss $\mathcal{L}_{CE}$ and the InfoNCE contrastive loss (van den Oord et al., 2018) $\mathcal{L}_{CL}$ as shown below.

$$\mathcal{L}_{CL} = -\log \frac{\exp(\text{sim}(h^{(g)}, h^{(p)})/\tau)}{\sum_{h_i \in \mathcal{H}^{(g)}} \exp(\text{sim}(h^{(g)}, h_i)/\tau)}$$

$$\mathcal{L} = \mathcal{L}_{CE} + \alpha\mathcal{L}_{CL}$$

6 Experiments

6.1 Impact of Different Models on Graph Structural and Semantic Accuracy

In Table 2, we compare the various modeling techniques described in Sec. 5 and their effect on the structural and semantic correctness of the generated graphs. While our primary metrics of interest are Graph Structural Accuracy (StCA) and Semantic Accuracy (SeCA), following prior work (Saha et al., 2021b), we also report Stance Accuracy (SA), Graph-BertScore (G-BS), Graph Edit Distance (GED) and Edge Accuracy (EA).

Effect of Model Size and Training Data. The T5-Large model uses the same setup as the T5-Base model experimented with in Saha et al. (2021b). We observe that using a larger T5 model improves StCA by 12% and SeCA by 16%. This finding is in line with other commonsense reasoning tasks (Lourie et al., 2021; Elazar et al., 2021) which also show that fine-tuning a larger language model typically leads to better performance. Together with the results reported in Table 1, we conclude that much of the improvement in explanation graph generation comes from increasing the training data and using a larger model. Given its superior performance, we build our proposed models on T5-large.

Results with Generate & Refine Model. The *Generate & Refine* model (Sec. 5.3) improves all metrics; however the gains are small. Note that this model refines all graphs (correct or not) and can lead to already correct graphs becoming incorrect after refinement. In practice, we observe that most graphs do not change much after refinement which we believe stems from the model's inability to distinguish between correct and incorrect graphs.

Effect of Positive Graph Perturbations. On retraining T5 augmented with the positively perturbed graphs (Sec. 5.1), we observe that it obtains significant improvement over T5 and *Generate & Refine* both in structural and semantic accuracy. Note that, by construction, the positive graphs only differ in the commonsense concepts (not part of the belief or argument) while keeping the structure intact. Hence, the model has more supervision about the semantics of the graphs as opposed to the structural constraints. This is reflected in the larger improvement in SeCA. The positive graphs, being structurally correct, also reinforces the model's belief about structural correlation with correct graphs, thus leading to some improvement in StCA as well.

Effect of Negative Graph Perturbations. The *Max-Margin* model (Sec. 5.2) leverages all structurally and semantically incorrect graphs and obtains up to 6% and 9% improvement in StCA and SeCA respectively over the baseline T5 model. The model implicitly learns the structural constraints through relevant supervision and the margin-based loss enables it to learn a better boundary between correct and incorrect graphs. Similarly, the semantically perturbed graphs improves the model's relation prediction capability between concepts. The *Max-Margin* model outperforms the *Pos Data Aug* model because of the former having access to both structural and semantic supervision while the latter is only augmented with structurally similar graphs.

Effect of Positive and Negative Graph Perturbations with Contrastive Learning. The *Contrastive Graph Generation* model (Sec. 5.4) leverages both positive and negative graphs and improves StCA to 60% with comparable SeCA to the *Max-Margin* model. The overall improvements in StCA and SeCA are 9% and 8% respectively compared to T5. We hypothesize that the constrastive model does not lead to further improvement in SeCA because of the structurally similar positive

graphs. This can potentially be improved by incorporating more structurally diverse graphs. Finally, our best SeCA is far from perfect and significant future work can be done in improving the graph semantics. Further ablations of negative graphs and human evaluation are done on the *Max-Margin* model, due to its slightly higher SeCA.

6.2 Human Evaluation of Graph Semantics

Automatically evaluating graphs for semantic correctness is challenging. We conduct human evaluation to further validate our findings. We compare the graphs generated by T5 and our *Max-Margin* model on Amazon Mechanical Turk where three annotators choose which graph is better or if they are mostly similar (instructions in Appendix F). For fair comparison, we evaluate only those samples where both models predict the correct stance and the graphs are also structurally correct. In fact, this lets us evaluate the semantic aspect in isolation when both graphs are structurally correct. With majority voting on 150 samples, we observe that our *Max-Margin* model's graphs are preferred 13% more times compared to those of the T5 model (43% vs 30% and statistically significant with $p < 0.05$) while in 22% cases, the graphs are marked similar (remaining have no majority).

6.3 Ablation with Negative Graphs

In Table 3, we show the effect of different types of negative graphs. We compare the results on the ExplaGraphs validation set by leveraging Synthetic Structural (SySt), Synthetic Semantic (SySe) and Human-created Semantic (HuSe) graphs with the *Max-Margin* graph generation model. All types of negatives graphs lead to consistent increase in SeCA. Leveraging human-created negative graphs leads to a bigger gain in SeCA because of the hardness and diversity in these graphs and hence are the best candidates for contrastive learning.

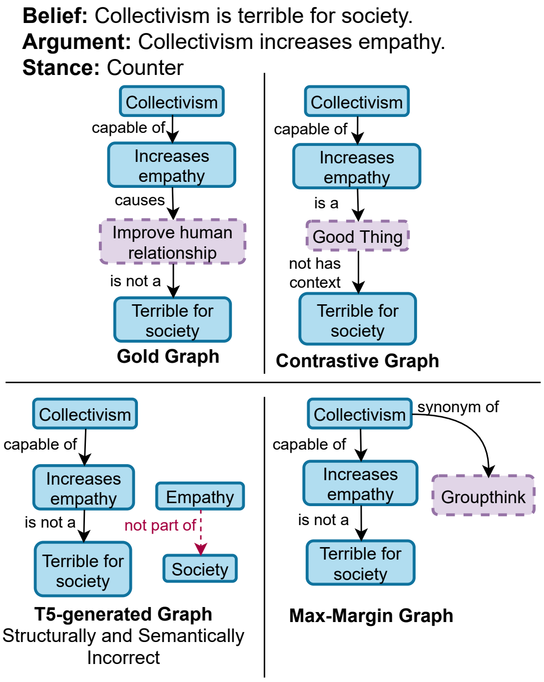

Figure 3: Qualitative analysis of explanation graphs.

6.4 Generalization to Other Graph Generation Tasks

We test the generalizability of constructing structurally and semantically perturbed graphs for contrastive learning by also experimenting on a temporal graph generation task (Madaan and Yang, 2021) that requires constructing a temporal graph from a document. The nodes in the graph are events from the document and the edges are temporal relations between events ("before", "after", etc). Following our overall goal of improving graph generation with limited data, we randomly sample 1.3% of the overall corpus (∼9.5k samples) as the training data such that all graphs are connected DAGs. Similar to ExplaGraphs, we create structurally negative graphs with disconnected and cyclic graphs and semantic negative graphs by perturbating the temporal relations. E.g., if an edge relation is "before", we replace it with "after". We construct positive graphs by replacing edges like "A before B" with "B after A" (more details in Appendix C). In Table 4, we report structural correctness accuracy (StCA) (percentage of connected DAGs) and Graph-BertScore (G-BS) for measuring approximate semantic correctness wrt gold graphs. We observe that our contrastive model not only generates more valid graph encodings but also improves StCA by 8% and G-BS by 3%.

	StCA↑	SeCA↑	G-BS↑	GED↓	EA↑
SySt + SySe + HuSe	49.5	38.4	39.4	0.64	26.1
SySt + SySe + HuSe + *HuSe-Gen (IP)*	53.5	38.7	42.1	0.62	28.1
SySt + SySe + HuSe + *HuSe-Gen (AE)*	52.0	40.2	41.3	0.62	28.2

Table 5: Effect of training the Max-Margin model with additional Human-like Semantic Negative Graphs on ExplaGraphs dev set. IP and AE refer to the two thresholding techniques for filtering generated negatives.

6.5 Analysis of Generated Graphs

Fig. 3 shows an example of the graphs generated by different models (more examples in Appendix F). Unlike T5, our models' graphs are both structurally and semantically correct with diverse commonsense nodes ("Groupthink", "Good Thing"). While our models generate more correct graphs, they lack in structural diversity – the Contrastive model generates 77% of linear graphs (i.e., the nodes are in a linear chain) which is comparable to 75% in the T5 model. This can be attributed to our structurally similar positive graphs as the model does not obtain enough supervision to generate diverse graphs. Structural diversity is not a measure of graph correctness; however, like diverse text generation (Vijayakumar et al., 2018), generating diverse graphs is an interesting direction for future work.

6.6 Generating Human-like Semantic Negatives (HuSe-Gen)

In ExplaGraphs, human-created negatives account for 38% of the samples for which the initially constructed graph was incorrect and was refined. Moreover, we see in the previous section that human-error graphs are the best negative candidates for contrastive learning (which is intuitive since tricky and subtle errors made by expert human annotators would make for some of the hardest negatives/distractors for a contrastive learning model to learn from). Hence, in this final section, we further explore whether it is also possible to automatically imitate and generate more of such *harder human-like* incorrect graphs for the remaining samples as well. Our method consists of the following steps.

Human-like Negative Edge Generation. We first fine-tune a T5 model that conditions on the belief, argument and the stance to generate a set of incorrect edges (which is the set of edges that are present in the incorrect graph and not in the refined graph).

Human-like Negative Graph Construction. This generated set of incorrect edges is then added to the correct graph to construct the incorrect graph, such that it is structurally correct and hence representative of human-like erroneous graphs.

Filtering High-quality Negative Graphs. Contrastive models will only benefit from these negatives if the negative edge generation model is accurate and generates edges that are actually incorrect. Hence, we control the quality of the generated incorrect graphs by the following two techniques – (a) *Thresholding via fraction of Acceptable Edges (AE):* We say that a generated incorrect edge is acceptable if it is not part of the correct graph and can be added to the correct graph without violating any structural constraints. We compute the fraction of acceptable edges for every generated negative graph and choose only those graphs with AE above a certain threshold δ. Intuitively, this ensures that a high fraction of the generated edges are actually incorrect and hence when added to the correct graph, will lead to a sufficiently different (human-like) incorrect graph. (b) *Thresholding via Incorrect Probability of a graph (IP):* We use our SeCA metric model (that classifies a graph into support, counter, or incorrect class) to compute the probability of the generated graph being incorrect and choose those graphs that are above a certain threshold γ of incorrect probability.

We set $\delta = 0.4$ and $\gamma = 0.5$ (tuned on the dev set) and train the Max-margin model using these additionally generated human-like negative graphs. As shown in Table 5 both thresholding approaches lead to further improvements over using just the human-created negative graphs. These initial promising results for emulating hard/tricky human errors as strong negatives for contrastive learning will hopefully lead to further future work in this interesting direction.

7 Conclusion

We presented an empirical study of graph structure and semantics for end-to-end explanation graph generation from pre-trained language models and showed that the generated graphs often violate structural constraints or are semantically incorrect. We significantly improve both the structural and semantic accuracy of graph generation by proposing contrastive learning models that leverage simple yet efficient methods of graph perturbations and also generalize to similar graph generation tasks.

Ethical Considerations

From an ethics standpoint, we provide a brief overview and show samples from the datasets that our models are trained on throughout the paper and also in the Appendix. Explanation graph generation improves the interpretability of neural commonsense reasoning systems and could prove to be effective in understanding and debugging such models. Hence we do not foresee any major risks or negative societal impact of our work. However, like any other ML model, the graphs generated by our models may not always be completely accurate and hence should be used with caution for real-world applications.

A Evaluation Metrics for ExplaGraphs

Below we provide brief descriptions of the evaluation metrics used for the ExplaGraphs task. For further details, we refer readers to prior work (Saha et al., 2021b).

Structural Correctness Accuracy of Graphs (StCA). It computes the fraction of graphs where all the structural constraints are satisfied.

Semantic Correctness Accuracy of Graphs (SeCA). SeCA is a model-based metric that computes the fraction of graphs that are both structurally and semantically correct. For computing SeCA, prior work trains a 3-way RoBERTa (Liu

SySt	SySe	HuSe	Total
7522	2368	1336	11226

Table 6: Count of negative graphs in each category.

et al., 2019) classifier that given a belief and a generated explanation graph, infers whether the graph supports the belief, counters the belief or is incorrect (because of incoherent edges). If it predicts support or counter and this stance matches the gold stance, then the graph is considered semantically correct. In essense, SeCA works on the principle that an explanation graph is semantically correct if a stance can be unambiguously inferred from it (by a model in this case or a human) and that stance is the same as the gold stance. Note that SeCA is a reference-free metric (does not use the ground-truth graph) and hence is invariant to structural variations in explanation graphs.

Graph-BertScore (G-BS). Graph-BertScore is an extension of BertScore (Zhang* et al., 2020) for computing the degree of match between the predicted graphs and the ground-truth graphs. It treats a graph as a set of edges and computes the best match between the gold edges and the predicted edges, where the matching score between a pair of edges is given by the BertScore F1.

Graph Edit Distance (GED). GED is the standard Graph Edit Distance for graphs, measuring the number of edit operations (addition, deletion, and replacement of nodes and edges) to transform one graph to the other and further normalized by an appropriate normalizing constant.

Edge Accuracy (EA). The final metric, Edge Accuracy (EA) measures the fraction of edges in the graph that are important. An edge is considered important if removing it from the graph leads to a drop in the gold stance prediction confidence.

B Statistics of Graph Perturbations

We create a total of 11k negative graphs. Table 6 shows the respective counts of the negative graphs belonging to synthetic structural (SySt), synthetic semantic (SySe) and human-created semantic (HuSe) categories.

C Temporal Graph Generation

The task of temporal graph generation requires constructing a temporal graph from a document (see Fig. 4). The nodes in the graph are events from the document (e.g., "Markovic jailed" or "Covering up attempted murder") and the edges are temporal relations between the events (e.g., "Markovic jailed; before; Covering up attempted murder"). The authors consider five temporal relations ("before", "after", "simultaneous", "is included" and "includes") and build an automatically constructed large-scale dataset for the task. Following our overall goal of improving graph generation in limited data settings, we randomly sample 1.3% of the overall corpus ($\sim$ 9.5k samples) as the training corpus such that all graphs are connected DAGs.[5] Following Madaan and Yang (2021), we represent graphs in DOT format (Koutsofios and North, 1996) as shown in Fig. 4. We find that the specifics of the graph representations do not matter much, as long as all the edges are concatenated in one particular ordering (either DFS, BFS or Topological order).

Dataset	Train	Dev	Test
ExplaGraphs	2368	398	400
Temporal (Sampled)	9531	953	949

Table 7: Train, validation and test split sizes of the two datasets. For Temporal Graph Generation, we randomly sample 1.3% of the overall corpus (Madaan and Yang, 2021).

We construct semantic negative graphs by randomly sampling a fraction of the edges and performing the following operations. If an edge relation is one of "before", "after" or "simulatenous", we replace it with any other relation from this set and if the relation is one of "is included" or "includes" we replace it with the other relation. Note that these perturbations will always lead to incorrect graphs because "A before B" implies that "A after B" or "A simultaneous B" do not hold. Finally, we construct positive graphs by randomly sampling a fraction of edges and replacing them using the following rules: (1) "A before B" with "B after A" and viseversa, (2) "A simultaneous B" with "B simultaneous A", (3) "A includes B" with "B is included A". Note that all these operations preserve the temporal meaning of the graph and are done in a way such that the perturbed graph continues to be a connected DAG.

---

[5] Since the dataset was constructed automatically, we found about 10% of the graphs to be disconnected or cyclic.

	SA↑	StCA↑	SeCA↑	G-BS↑	GED↓	EA↑

D Experimental Setup

Table 7 shows the number of train, validation and test samples of the two datasets we experiment with. We build our models on top of the Hugging Face transformers library (Wolf et al., 2020).[6] All models for the ExplaGraphs dataset[7] (Saha et al., 2021b) are trained with a batch size of 8 and an initial learning rate of $3 * 10^{-5}$ for a maximum of 15 epochs. The maximum input and output sequence lengths are both set to 150. For the max-margin graph generation model, we set both the hyperparameters α (mixing ratio) and β (margin) to 1.0 while for the contrastive graph generation model, we set α to 0.1. For the temporal graph generation task[8] (Madaan and Yang, 2021), we train all models with a batch size of 4 and an initial learning rate of $3 * 10^{-5}$ for a maximum of 10 epochs. The maximum input and output sequence lengths are set to 512 and 256 respectively. On this task, the hyperparameters α and β for the max-margin model are again set to 1.0 while for the contrastive graph generation model, we set α to 0.2.

Across all models and tasks, graphs are generated using beam search decoding with a beam size of 4. The batch size and learning rate are manually tuned in the range $\{4, 8, 16\}$ and $\{10^{-5}, 2 * 10^{-5}, 3 * 10^{-5}\}$ respectively and the best models are chosen based on the respective validation set performance. Similarly, the mixing ratio hyperparameter α is manually tuned in the range $\{0.1, 0.2, 0.5, 1.0\}$. The random seed is set to 42 in all our experiments. The total number of parameters in our models is similar to T5-Base (220M) or T5-Large (770M) depending on the base architecture. All our experiments are executed on a single A100 Nvidia GPU. Each epoch of the contrastive model has an average runtime of 30 mins for ExplaGraphs and 2.5 hours for Temporal Graph Generation.

Task Description

Open Task Description

Overview

In the question below, you are given a belief about a topic and an argument either supporting or countering the belief. Correspondingly, you are also given two explanation graphs, explaining with commonsense knowledge how the argument supports or counters the belief. Your goal is to decide which of the two graphs (if any) does a better job in providing a coherent and meaningful explanation.

How to read the graphs?

The way to read the graphs is to follow the arrows from top to bottom and read them in simple English. For example, consider the below graph

A graph is composed of commonsense facts. For example, in the above graph, "Vegans desire vegetarian diet" is a commonsense fact. In order to read a graph, start from the top. The above graph conveys the knowledge that "Vegans desire vegetarian diet and vegans are opposite of meat eaters who do not desire vegetarian diet. Further, vegetarian diet causes healthy heart and healthy heart causes reduction in mortality which in turn causes someone to live longer."

Overall, this graph represents an argument explaining why vegans live longer compared to meat eaters.

We will provide you with two such graphs generated by two AI models and your task is to decide which one better explains how the argument supports or refutes the belief.

Guidelines

Open Guidelines

1. **The order in which the two graphs will appear in every HIT will be random. For example, the first AI model's graph will be shown on the left for some HITs while for others, it will be opposite. So, it's important to look at the graphs very carefully.**
2. **Since these graphs are generated by AI models who do not possess commonsense like humans, you will often find facts that are incoherent or non-commonsensical like "good; is a; bad". Your task is to spot such bad facts and compare the two graphs.**
3. **Since a graph is not an English sentence or paragraph, the grammar is not important here. However, every fact in the graph should be meaningful and should make sense in explaining why an argument is supportive or not.**
4. **In cases when both graphs contain incoherent facts, choose the one which has less such errors. If you think they are equally good or bad, mark both as equal.**

Task

Question: You are given the following belief, argument, and the stance mentioning whether the argument supports or counters the belief. Given two commonsense explanation graphs explaining the stance, mark which one is better.

Belief:

People can relax on a journey when the autonomous car does the driving, allowing them to arrive refreshed.

Argument:

Driving is exhausting.

Stance

Support

Two Commonsense Graphs (to be compared)

Choose one of the following.

○ **The first graph is strictly better than the second.**
○ **The second graph is strictly better than the first.**
○ **Both graphs are equal.**

Figure 5: Interface for human evaluation of commonsense explanation graphs.

T5 model on the facts based on ConceptNet relations from ATOMIC-2020 (Hwang et al., 2021), a large-scale commonsense knowledge base. The fine-tuning objective is to predict the target concept given the source concept and the relation. Next, we fine-tune this model further on the end-task of graph generation which leads to small improvements in both StCA and SeCA. This suggests that better methods of inducing commonsense knowledge in these models can potentially lead to bigger gains with more semantically coherent graphs.

F Human Evaluation

In Fig. 5, we show the interface for human verification of commonsense explanation graphs on Amazon Mechanical Turk. We select crowdworkers who are located in the US with a HIT approval rate higher than 96% and at least 1000 HITs approved. Since graph evaluation is a challenging task, we first explain how to read the graphs and also provide clear guidelines for comparing the quality of the two graphs.[9]

G Examples of Generated Explanation Graphs

In Fig. 6, 7, 8 and 9, we show various examples of explanation graphs generated by our models. In Fig. 6 and 7, our proposed models improve upon

---

[9] The payment for each HIT is 0.25$ at the rate of 12-15$ per hour.

Belief: Since fast foods are greasy and fattening, banning them would control obesity.
Argument: McDonalds has salads.
Stance: Counter

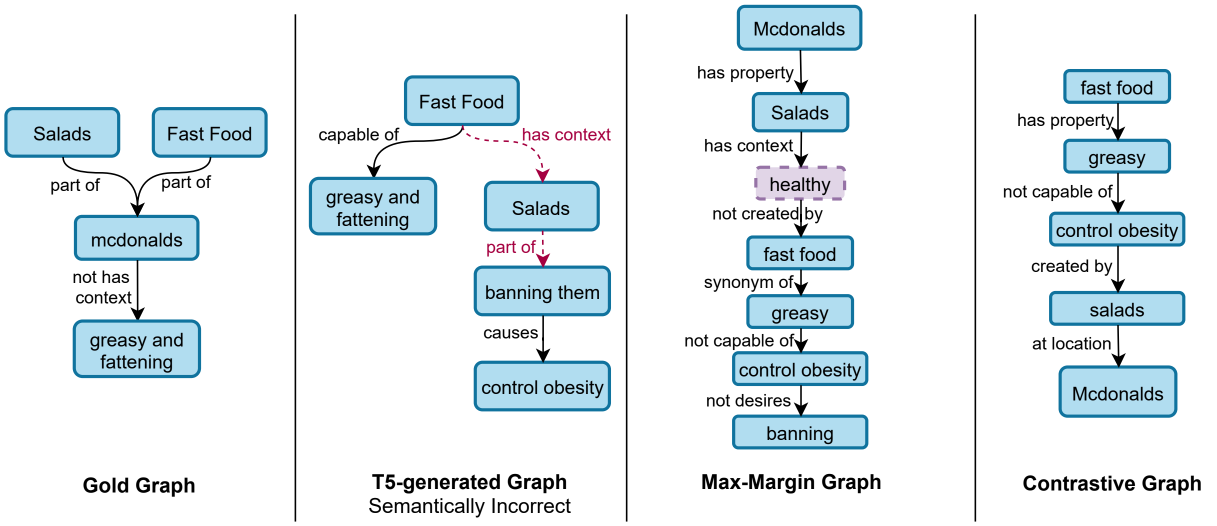

Figure 6: Example of explanation graphs generated by different models. The baseline T5-generated graph is semantically incorrect (incoherent relations marked in dashed red) while our proposed models generate both structurally and semantically correct graphs.

the incorrect semantic relations from the T5 baseline graphs. Fig. 8 shows an example where all generated graphs, while different, are correct. Finally, Fig 9 shows an example where although our proposed models improve the semantic aspect compared to the baseline graph, the generated graphs are disconnected and hence structurally incorrect. Overall, our quantitative results and human evaluation suggest that there is significant room for improvement on the task of commonsense explanation graph generation.

Belief: Homeschooling is not great for children.
Argument: There are plenty of ways for children in homeschooling to socialize.
Stance: counter

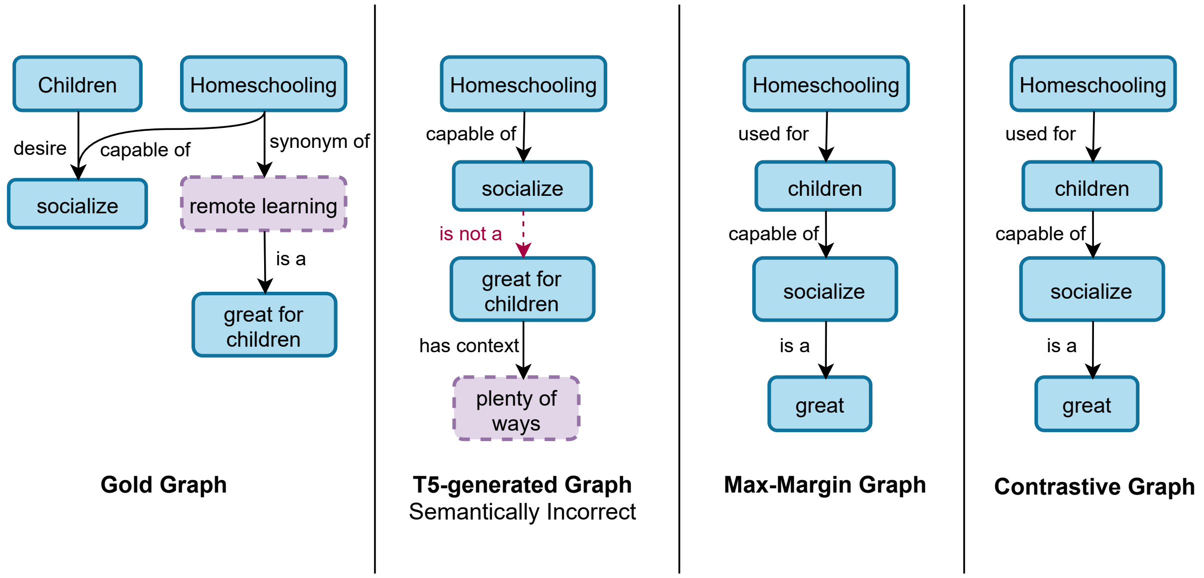

Figure 7: Example of explanation graphs generated by different models. The baseline T5-generated graph is semantically incorrect (incoherent relations marked in dashed red) while our proposed models generate both structurally and semantically correct graphs.

Belief: People can relax on a journey when the autonomous car does the driving, allowing them to arrive refreshed.
Argument: Driving is exhausting.
Stance: support

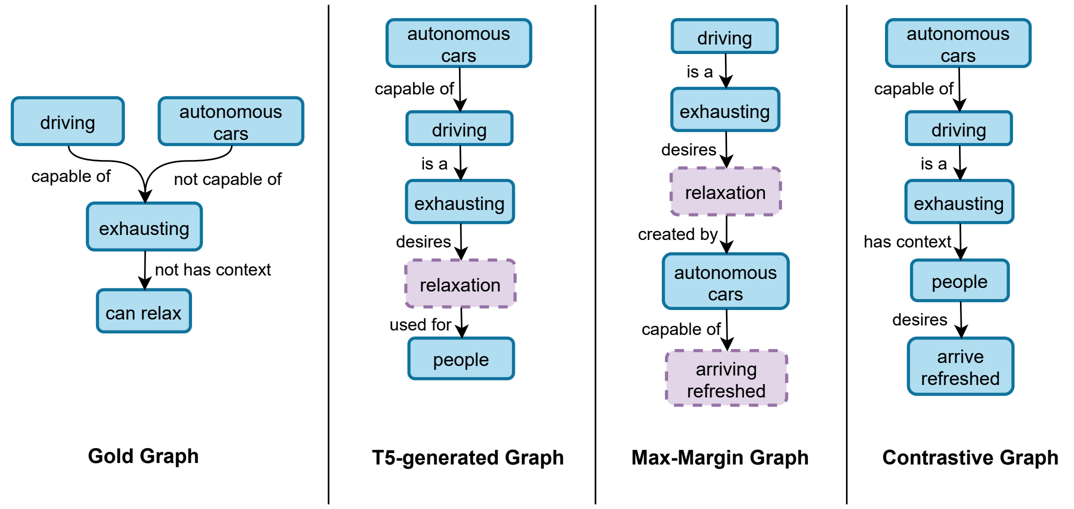

Figure 8: Example of explanation graphs generated by different models. All models generate structurally and semantically correct graphs while the individual nodes and edges differ.

Belief: Autonomous cars are more dangerous than man-driven cars.
Argument: Autonomous cars are not safe for humans.

Unsupervised Extractive Opinion Summarization Using Sparse Coding

Somnath Basu Roy Chowdhury **Chao Zhao** **Snigdha Chaturvedi**
{somnath, zhaochao, snigdha}@cs.unc.edu
UNC Chapel Hill

Abstract

Opinion summarization is the task of automatically generating summaries that encapsulate information from multiple user reviews. We present *Semantic Autoencoder* (SemAE) to perform extractive opinion summarization in an unsupervised manner. SemAE uses dictionary learning to implicitly capture semantic information from the review and learns a latent representation of each sentence over semantic units. A semantic unit is supposed to capture an abstract semantic concept. Our extractive summarization algorithm leverages the representations to identify representative opinions among hundreds of reviews. SemAE is also able to perform controllable summarization to generate aspect-specific summaries. We report strong performance on SPACE and AMAZON datasets, and perform experiments to investigate the functioning of our model. Our code is publicly available at https://github.com/brcsomnath/SemAE.

1 Introduction

Opinion summarization is the task of automatically generating digests for an *entity* (e.g. a product, a hotel, a service, etc.), from user opinions in online forums. Automatic opinion summaries enable faster comparison, search, and better consumer feedback understanding (Hu and Liu, 2004; Pang, 2008; Medhat et al., 2014). Although there has been significant progress towards summarization (Rush et al., 2015; Nallapati et al., 2016; Cheng and Lapata, 2016; See et al., 2017; Narayan et al., 2018; Liu et al., 2018), existing approaches rely on human-annotated reference summaries, which are scarce for opinion summarization. For opinion summarization, human annotators need to read hundreds of reviews per entity across different sources for writing a summary, which may not be feasible.

This lack of labeled training data has prompted a series of works to leverage unsupervised or weakly-supervised techniques for opinion summarization (Mei et al., 2007; Titov and McDonald, 2008; Angelidis and Lapata, 2018a; Angelidis et al., 2021). Recent works in this direction have focused on performing opinion summarization in an abstractive setting (Coavoux et al., 2019; Isonuma et al., 2019; Bražinskas et al., 2020; Amplayo et al., 2021b; Iso et al., 2021; Wang and Wan, 2021). Abstractive models are able to produce fluent summaries using novel phrases. However, they suffer from problems common in text generation like hallucination (Rohrbach et al., 2018), text degeneration (Holtzman et al., 2020), and topic drift (Sun et al., 2020). Also, these approaches have been evaluated on small scales (10 reviews per entity or fewer), which does not reveal their utility in the real world where there are hundreds of reviews per entity.

To overcome these issues, another thread of works focuses on extractive opinion summarization, which creates summaries by selecting review sentences to reflect the popular opinions corresponding to an entity. A recently proposed extractive summarization approach is Quantized Transformer (QT) (Angelidis et al., 2021), which leverages vector quantization (van den Oord et al., 2017) for assigning texts to a latent representation that is supposed to capture a semantic sense. However, a text phrase can encapsulate multiple semantic senses, making this representation learning approach restrictive.

Building on the framework introduced by QT, we introduce an unsupervised extractive model, *Semantic Autoencoder* (SemAE), which learns a representation of text over latent semantic units using *dictionary learning* (Dumitrescu and Irofti, 2018). Similar to QT, SemAE leverages Transformer (Vaswani et al., 2017) for sentence reconstruction to simultaneously learn latent semantic units and sentence representations. However, while QT assigns texts to a latent representation (codebook), SemAE models text as a combination of semantics and forms a distribution over latent units (dictionary). This allows sentence rep-

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 1209 - 1225
May 22-27, 2022

resentations to capture fine-grained and diverse semantics. Unlike QT that relies on identification of aspect-specific head representations, we achieve controllable summarization by utilizing information-theoretic measures (such as relevance, redundancy, etc) on sentence representations. Our sentence selection algorithm is more flexible and allows a broader spectrum of controllable summarization. We experimentally show strong performance on two opinion summarization datasets. Our main contributions are:

- We present Semantic Autoencoder (SemAE), which learns representation of sentences over latent semantic units.
- We introduce novel inference algorithms for general and controllable summarization utilizing information-theoretic measures.
- We show that SemAE outperforms previous methods using automatic and human evaluations.
- We perform analysis to understand how the learnt representations align with human semantics.

2 Related Work

Unsupervised opinion summarization can be conducted either abstractively or extractively. Abstractive approaches aim to summarize the opinion text using novel phrases. Traditional statistical approaches create abstractive summaries using graphical paths (Ganesan et al., 2010) or hand-written templates (Di Fabbrizio et al., 2014). Recent neural approaches leverage the encoder-decoder architecture to aggregate information from multiple reviews and generate summaries accordingly (Chu and Liu, 2019; Bražinskas et al., 2020; Iso et al., 2021; Wang and Wan, 2021).

In contrast to abstractive approaches, extractive approaches rank and select a subset of salient sentences from reviews to form a concise summary (Kim et al., 2011). Saliency computation has been explored using traditional frequency-based approaches (Nenkova and Vanderwende, 2005), similarity with the centroid in the representation space (Radev et al., 2004), and lexical similarity with all sentences in a graph-based representation (Erkan and Radev, 2004). Weakly supervised approaches (Angelidis and Lapata, 2018a; Zhao and Chaturvedi, 2020) extract opinions based on their aspect specificity, and nature of sentiment polarity.

Our work is most similar to the extractive opinion summarization QT (Angelidis et al., 2021) as discussed in Section 1. It is also similar to neural topic model-based approaches (Iyyer et al., 2016; He et al., 2017; Angelidis and Lapata, 2018a) that use a variant of dictionary learning (Elad and Aharon, 2006; Olshausen and Field, 1997) to represent text as a combination of specific semantics (e.g. aspect, relationships etc). In contrast to these models, where text from same topics are trained to have similar representations using max-margin loss, SemAE uses an autoencoder setup to capture diverse latent semantics.

3 Task Description

We follow the task setup in (Angelidis et al., 2021), where given a set of entities (e.g. hotels), a review set $\mathcal{R}_e = \{r_1, r_2, \ldots\}$ is provided for each entity e, where each review r_i is a sequence of sentences $\{s_1, s_2, \ldots\}$. The review set $\mathcal{R}_e$ covers a range of aspects $\mathcal{A} = \{a_1, a_2, \ldots\}$ relating to the domain (e.g. *service*, *location* for hotels). We denote S_e to be the set of sentences from all reviews for an entity e. SemAE is evaluated to perform two types of extractive opinion summarization introduced by Angelidis et al. (2021): (a) *general summarization*, which involves selecting a subset of sentences $O_e \subset S_e$ such that it best represents the reviews in $\mathcal{R}_e$, and (b) *aspect summarization*, where the generated summary $O_e^{(a)} \subset S_e$ focuses on a specific aspect $a \in \mathcal{A}$.

4 The Semantic Autoencoder

The intuition behind Semantic Autoencoder is that instead of representing text as a single latent semantic unit, we represent text as a distribution over latent semantic units using *dictionary learning*. Learning semantic representations over a common dictionary makes them structurally aligned, enabling comparison of sentences using information-theoretic measures.

Semantic Autoencoder consists of three stages (i) *sentence encoding* - an input sentence s is converted into a multi-head representation (H heads) using Transformer encoder $\{\mathrm{s}_h\}_{h=1}^{H}$; (ii) *reconstruction* - a latent representation of head vectors s_h is formed over elements of the dictionary $D \in \mathbb{R}^{K \times d}$, to produce reconstructed representations $\mathbf{z} = \{z_h\}_{h=1}^{H}$; and (iii) *sentence decoding* - a Transformer-based decoder takes as input the reconstructed representations $\mathbf{z}$ to produce the output sentence $\hat{s}$. SemAE is trained on the sentence reconstruction task. The overall workflow of SemAE

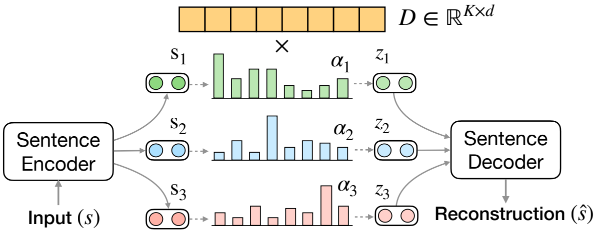

Figure 1: An example workflow of SemAE. The encoder produces $H = 3$ representations (s_h) for a review sentence s, which are used to generate latent representations over dictionary elements. The decoder reconstructs the input sentences using vectors (z_h) formed using latent representations (α_h).

is shown in Figure 1.

4.1 Sentence Encoder

We follow the setup of QT (Angelidis et al., 2021) for sentence encoding. Each sentence s starts with a special token `[SNT]`, which is fed to a Transformer-based encoder. We only consider the final-layer representation of the `[SNT]` token $s_{\text{snt}} \in \mathbb{R}^d$. The sentence representation s_{snt} is split into H contiguous vectors $\{s'_h\}_{h=1}^H$, where $s'_h \in \mathbb{R}^{d/H}$. A multi-head representation is formed by passing s'_h through a layer-normalization layer:

$$\mathrm{s}_h = \mathrm{LN}(s'_h \mathrm{W}^T + b) \tag{1}$$

where $\mathrm{W} \in \mathbb{R}^{d \times d/H}, b \in \mathbb{R}^d$ are trainable parameters and $\mathrm{s}_h \in \mathbb{R}^d$ is the h^{th} head representation.

For each s_h, we obtain a latent representation α_h over the dictionary D, by reconstructing the encoded sentence representation s_h as shown below

$$z_h = \alpha_h D, \quad \alpha_h = \mathrm{softmax}(s_h D^T) \tag{2}$$

where the reconstructed vector $z_h \in \mathbb{R}^d$, and the latent representation $\alpha_h \in \mathbb{R}^K$. We hypothesize that the dictionary D captures the representation of latent semantic units, and α_h captures the degree to which the text encapsulates a certain semantic. The vectors formed $\mathbf{z} = \{z_h\}_{h=1}^H$ are forwarded to the decoder for sentence reconstruction. The dictionary D and s_h are updated simultaneously using backpropagation. For summarization (Section 5), different from QT, we consider α_h (not z_h) as the sentence representation.

4.2 Sentence Decoder

We employ a Transformer-based decoder that takes as input the reconstructed representations $\mathbf{z} = \{z_h\}_{h=1}^H$. $\mathrm{MultiHead}(\mathbf{z}, \mathbf{z}, \mathbf{t})$ attention module in the decoder takes $\mathbf{z}$ as key and value, and the target tokens $\mathbf{t}$ as the query. The reconstructed sentence is generated from the decoder as $\hat{s} = \mathrm{Decoder}(\mathbf{z}, \mathbf{t})$. As our goal is sentence reconstruction, we set the target tokens to be same as the input sentence s. Prior work (Angelidis et al., 2021) has also used a similar Transformer-based decoder for sentence reconstruction but they attend directly over quantized head vector formed using codebook elements.

A sentence can capture only a small number of semantic senses. We ensure this by enforcing sparsity constraints on the representations α_h, so that z_h is a combination of only a few semantic units. The encoder, reconstructor and decoder are trained together to minimize the loss function:

$$\mathcal{L} = \mathcal{L}_{\text{CE}}(s, \hat{s}) + \lambda_1 \sum_h |\alpha_h| + \lambda_2 \sum_h H(\alpha_h) \tag{3}$$

where $\mathcal{L}_{\text{CE}}$ is the reconstruction cross-entropy loss of the decoder, and to ensure sparsity of α_h we penalize the L1-norm ($|\alpha_h|$) and its entropy $H(\alpha_h)$.

5 Summarization using Latent Representations

We leverage the latent representations α_h generated by SemAE to perform opinion summarization.[1]

5.1 General Summarization

For obtaining the general summary of an entity, we first compute a mean representation of all the review sentences in S_e, which represents the aggregate distribution over semantic units. Thereafter, the general summary is obtained as the collection of sentences that resemble the mean distribution.

Mathematically, every sentence s is associated with a representation over dictionary elements $\alpha^s = [\alpha_1, \ldots, \alpha_H]$, where $\alpha^s \in \mathbb{R}^{H \times K}$. We form the mean representation of review sentences for an entity S_e over dictionary elements as:

$$\bar{\alpha} = \frac{1}{|S_e|} \sum_{s \in S_e} \alpha^s \tag{4}$$

where α^s is the representation for sentence $s \in S_e$.

For general summarization, we compute the *relevance* score $\mathcal{R}(\cdot)$ for each sentence s based on its similarity with the mean representation $\bar{\alpha}$:

$$\mathcal{R}(\alpha^s) = \Delta(\bar{\alpha}, \alpha^s) = -\sum_h \mathrm{KL}(\bar{\alpha}_h, \alpha^s_h) \tag{5}$$

---

[1] We experimented with different variations of the sentence selection scheme using α_h in Appendix A.4.

where α_h^s is latent representation of sentence s for the h^{th} head. $\Delta(x, y)$ denotes the similarity between two representations x and y. It is implemented as negation of the sum of KL-divergence between head representations. We also experimented with other divergence metrics and observed similar summarization performance (Appendix A.3).

We rank sentences according to descending order of $\mathcal{R}(\cdot)$ and select the top N (a constant hyperparameter, $N < |S_e|$) sentences as the summary O_e (shown in Figure 2). The extracted summary is a concatenation of the text from N selected input sentences (Input (s) in Figure 1). However, modeling relevance only using $\Delta(\cdot, \cdot)$ results in selection of similar sentences. We overcome this by designing variations of our system that have additional information-theoretic constraints.

(a) **Redundancy**: We introduce diversity in the generated summary by penalizing sentences that have a high similarity value with already selected sentences. This is achieved by adding the *redundancy* term in relevance score:

$$\mathcal{R}(\alpha^s, \hat{O}_e) = \Delta(\bar{\alpha}, \alpha^s) - \gamma \max_{s' \in \hat{O}_e} \Delta(\alpha^{s'}, \alpha^s) \quad (6)$$

where $\hat{O}_e$ is the set of sentences selected so far for the summary. The selection routine proceeds in a greedy fashion by choosing $s_0 = \arg\max_{s \in S_e} \Delta(\bar{\alpha}, \alpha^s)$ when $\hat{O}_e = \phi$.

(b) **Aspect-awareness**: Another drawback with sentence selection using $\Delta(\cdot, \cdot)$ is that the summary frequently switches context among different aspects (example shown in Table 7). To mitigate this issue, we identify the aspect of a review sentence using occurrences of aspect-denoting keywords provided in the dataset (Section 5.2). We then cluster the sentences into aspect-specific buckets $\{S_e^{(a_1)}, S_e^{(a_2)}, \ldots\}$ and rank sentences within each bucket. We ignore sentences that are not part of any bucket. We select sentences using two different strategies:

- We iterate over sentence buckets $\{S_e^{(a_i)}\}$ and select the first m sentences ranked according to $\mathcal{R}(\alpha^s)$, from each bucket.
- We prevent selection of similar sentences from a bucket by introducing the redundancy term. We iterate over individual buckets and select first m sentences ranked according to their relevance $\mathcal{R}(\alpha^s, \hat{O}_e^{(a)})$ (Equation 6).

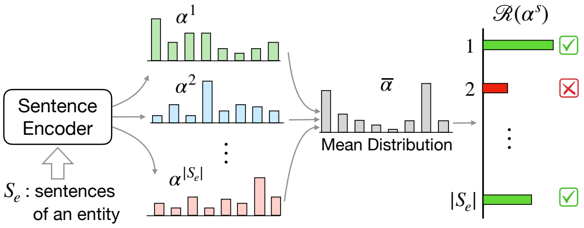

Figure 2: General summary generation routine. The relevance score of each sentence w.r.t mean representation is computed, and top N sentences (O_e) with highest $\mathcal{R}(\cdot)$ are selected as the summary.

5.2 Aspect Summarization

SemAE can perform aspect summarization without needing additional training. For this, we require a small set of keywords to identify sentences that talk about an aspect. For example, *food* aspect is captured using keywords: "breakfast", "buffet" etc.

For a given aspect a, let the keyword set be $Q_a = \{w_1, w_2, \ldots\}$. We use Q_a to identify a set of sentences $S_e^{(a)}$ for each entity e, belonging to aspect a from a held-out dev set S_{dev}. Similar to general summarization, we proceed by computing the mean representation of sentences $S_e^{(a)}$ belonging to the aspect a:

$$\bar{\alpha}^{(a)} = \frac{1}{|S_e^{(a)}|} \sum_{s \in S_e^{(a)}} \alpha_s \quad (7)$$

We then select sentences most similar to the mean representation as the summary.

(a) **Informativeness**: Sentences selected for aspect summarization should talk about the aspect but not the general information. We model *informativeness* (Peyrard, 2019) by ensuring that a selected sentence representation α_s resembles the aspect mean $\bar{\alpha}^{(a)}$, but is divergent from the overall representation mean $\bar{\alpha}$, for a given entity e. For an aspect a, we iterate over sentences in $S_e^{(a)}$ and compute the relevance score for a sentence s as follows:

$$\mathcal{R}_a(\alpha^s) = \Delta(\bar{\alpha}^{(a)}, \alpha^s) - \beta\Delta(\bar{\alpha}, \alpha^s) \quad (8)$$

We rank sentences $s \in S_e$ according to their *aspect-specific relevance* score $\mathcal{R}_a(\cdot)$, and select first N sentences as the summary for aspect $O_e^{(a)}$.[2]

6 Experimental Setup

In this section, we discuss the experimental setup, results and analysis.

---

[2] We experimented with incorporating the informativeness term in general summarization also but did not find it useful (see Appendix A.3 for more details).

	Reviews	Train / Test Ent.	Rev./Ent.
SPACE	1.14M	11.4K / 50	100
AMAZON	4.75M	183K / 60	8

Table 1: Dataset statistics for SPACE and AMAZON datasets. (Train/Test Ent.: Number of entities in the *training* and *test* set; Rev./Ent.: Number of reviews per entity in the *test* set.)

6.1 Datasets

We evaluated our model on two public customer review datasets SPACE hotel reviews (Angelidis et al., 2021) and AMAZON product reviews (He and McAuley, 2016; Bražinskas et al., 2020). The dataset statistics are reported in Table 1. Test sets of both datasets contain three human-written general summaries per entity. The SPACE corpus was created in a two-step process of sentence selection and then summarization of selected sentences by annotators (further details in Appendix A.2). SPACE dataset also provides human-written summaries for six different aspects of hotels: *building*, *cleanliness*, *food*, *location*, *rooms*, and *service*.

6.2 Implementation details

We build on the implementation framework introduced by Angelidis et al. (2021) for our experiments. We used a 3-layer Transformer with 4 attention heads as the encoder and decoder. The input and hidden dimensions are 320. The encoder and decoder for SemAE was trained for 4 warmup epochs, before the dictionary learning based reconstruction component was introduced. We split the encoded vector into $H = 8$ head representations. We have $K = 1024$ dictionary elements, each with dimension $d = 320$. The dictionary elements are initialized using k-means clustering of review sentence representations. All hyperparameters were tuned on the development set (see Appendix A.1 for more details).

6.3 Metrics

We report ROUGE F-scores that compares the overlap between generated text with gold summaries. For SPACE dataset, we measure how much general summaries cover different aspects by computing the mean ROUGE-L score with the gold aspect summaries (denoted by RL_{ASP}).

We also compute *perplexity* (PPL) score to evaluate the readability of summaries. Perplexity is computed using cross-entropy loss from a BERT-*base* model. We measure *aspect coverage* of a system, by computing the average number of *distinct aspects* N_{ASP} in the generated summaries. Lastly, to evaluate *repetition* in summaries, we compute the percentage of distinct n-grams ($n = 2$).

6.4 Baselines

Following prior work (Angelidis et al., 2021), we compare SemAE with three types of systems:
(a) *Best Review* systems: We report the performance of *Centroid* method, where reviews are encoded using BERT or SentiNeutron (Radford et al., 2017), and the review most similar to the mean representation is selected.
(b) *Abstractive* systems: We report the performance of *Opinosis* (Ganesan et al., 2010) (a graph-based approach), *MeanSum* (Chu and Liu, 2019), *CopyCat* (Bražinskas et al., 2020) and *AceSum* (Amplayo et al., 2021a) summarization models.
(c) *Extractive* systems: We report the performance of *LexRank* (Erkan and Radev, 2004), where sentences were encoded using BERT, SentiNeutron or tf-idf vector. We also report the performance achieved by selecting review sentences *randomly*.

6.5 Results

General Summarization: We present the results of general summarization on SPACE dataset in Table 2. SemAE and its variants show strong improvements over previous state-of-the-art QT, and other baselines, across all ROUGE metrics. They also outperform abstractive systems (like CopyCat and Meansum) by a large margin, which shows that SemAE can effectively select relevant sentences from a large pool of reviews. All variants of SemAE outperform other models in RL_{ASP} metric, showcasing that general summaries from SemAE cover aspects better than baselines. We compiled some baseline results from Angelidis et al. (2021).

We further evaluate the quality of the summaries, for all variations of SemAE along with our strongest baseline QT, using other automatic metrics in Table 3. The first row in Table 3 reports the performance of QT, which achieves the highest distinct n-gram score, but has poor perplexity score. This shows that QT generates summaries with diverse text but they are not coherent. SemAE achieves the best perplexity score (second row in Table 3) but produces less diverse text (lowest distinct n-gram score). The third row in Table 3 reports the performance of SemAE with redundancy term. Comparing rows 2 and 3 of Table 3, we observe that the summaries from SemAE

Table 4: Evaluation results on AMAZON dataset. Best performance achieved using an extractive systems are in **bold**. Overall best results for each metric is <u>underlined</u>. System performance that access reference summaries are reported in gray.

(w/ redundancy) have more distinct n-grams (less repetition), while falling behind in perplexity and aspect coverage. Performance results for aspect-aware variants of SemAE are reported in last two rows of Table 3. We observe that iteratively covering aspects reduces repetition (increase in distinct-n score). As expected the mean aspect-coverage ($\mathbb{E}[N_{\text{ASP}}]$) improves in aspect-aware SemAE variants. However, a slight drop in aspect-coverage is observed when the redundancy term is introduced (last row in Table 3). We also observe an increase in perplexity for aspect-aware variants, which can be caused due to multiple changes in aspect context. Overall, SemAE (w/ aspect + redundancy) is able to produce diverse text with a high aspect coverage and a decent perplexity score, appearing to be the best performing model.

Evaluation results on AMAZON dataset are reported in Table 4. SemAE and its variants[3] achieve similar performance, with SemAE achieving the best performance among all extractive summarization system. SemAE falls short of only abstractive summarization systems that have the advantage of generating novel phrases not present in the input reviews. Also, while SemAE beats most baselines for AMAZON dataset, the performance gain isn't as much as SPACE dataset. We believe this is because the number of reviews per entity in AMAZON (8) is much lower compared to SPACE (100). As SemAE is dependent on the mean representation $\bar{\alpha}$, having more reviews helps in capturing the popular opinion distribution accurately.[4] For practical purposes, opinion summarization systems are useful when there are hundreds or more reviews per entity. A larger improvement on SPACE shows the efficacy of SemAE in the real world.

Aspect Summarization: For aspect summarization, we compare against four unsupervised systems MeanSum, CopyCat, LexRank and QT on the SPACE dataset. For general summarizers: MeanSum, CopyCat and LexRank, sentence embeddings retrieved from BERT (Vaswani et al., 2017) were clustered using k-means and each cluster $S_e^{(a)}$ was assigned an aspect a based on frequency of aspect-denoting keywords in the cluster's sentences. The models then produced summaries for each aspect a given the input set $S_e^{(a)}$. All models including

---

[3] We do not have aspect-aware selection variants in AMAZON, as it does not provide aspect-denoting keywords.

[4] We observed a drop in performance when the number of reviews/entity in SPACE dataset was reduced (experimental details in Section 6.6).

[†] Reported results are obtained using the publicly released implementation of QT (Angelidis et al., 2021).

SPACE [Aspect]	Building	Cleanliness	Food	Location	Rooms	Service	$\overline{\text{R1}}$	$\overline{\text{R2}}$	$\overline{\text{RL}}$

w/o informativeness	18.38	24.08	19.03	23.32	23.89	25.05	27.85	8.61	22.29

Table 5: Evaluation results of Aspect Summarization on SPACE dataset. ROUGE-L scores are reported for six different aspects. $\overline{\text{R1}}$, $\overline{\text{R2}}$ and $\overline{\text{RL}}$ are the average ROUGE-1, ROUGE-2 and ROUGE-L F scores respectively. Best system results are in **bold**.

SPACE [General]	Inform.	Coherence	Redund.
QT	-31.3	-47.3	-39.3
SemAE (w/ asp. + redun.)	**-21.3***	**-28.0***	**-27.3***
Human	+52.7	+75.3	+66.7

SPACE [Aspect]	Asp. Inform.	Asp. Specificity
QT	-35.0	-24.7
SemAE	**-13.0***	**-11.0**
Human	+48.0	+35.7

Table 6: Human evaluation results of general and aspect summarization for SPACE dataset. Best human evaluation results obtained for a system are in **bold** and human performance is in gray. (*): statistically significant difference with QT model ($p < 0.05$, using paired bootstrap resampling Koehn (2004)).

SemAE, use the same aspect-denoting keywords.

Evaluation results on SPACE are reported in Table 5. SemAE outperforms the state-of-the-art QT in all aspects except *cleanliness*, where the performance is comparable. We observe that adding the *informativeness* term ($\Delta(\bar{\alpha}, \alpha^s)$ in Equation 8) helps improve the specificity of the aspect thereby boosting performance. SemAE also shows significant gains in terms of average ROUGE-1/2 and ROUGE-L across different aspects.

Human Evaluation: We performed human evaluations for the general and aspect summaries. We evaluated general summaries from QT, best performing variant SemAE (w/ aspect + redundancy) and gold summary. Summaries were judged by 3 human annotators on three criteria: *informativeness*, *coherence* and *non-redundancy*. The judges were presented summaries in a pairwise manner and asked to select which one was better/worse/similar. The scores (-100 to +100) were computed using *Best-Worst Scaling* (Louviere et al., 2015). The first half of Table 6 reports the evaluation results, where we observe that SemAE (w/ aspect + redundancy) outperforms our strongest baseline, QT, for all criteria (statistical significance information provided in the caption of Table 6). However, summaries generated from both systems are far from gold summaries on all criteria.

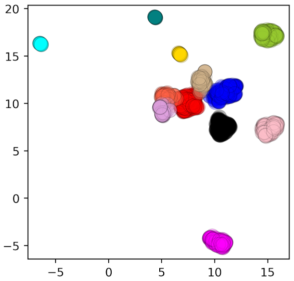

Figure 3: Visualization of UMAP projections of dictionary elements. Projections form clusters, which are shown in different colors.

We also evaluated aspect summaries generated by SemAE and QT in a similar manner. Aspect summaries were judged based on two criteria: *aspect informativeness* (usefulness of opinions for a specific aspect, consistent with reference) and *aspect specificity* (how specific the summary is for an aspect without considering other factors). The bottom half of Table 6 reports the results for aspect summaries. We observe that both QT and SemAE produce aspect-specific summaries. However, SemAE shows a statistically significant improvement over QT in aspect informativeness.

6.6 Analysis

Latent Dictionary Interpretation. In this section, we investigate the semantic meanings learnt by individual dictionary elements, D_k. We visualized the UMAP projection (McInnes et al., 2018) of dictionary element representations (shown in Figure 3). For different runs of SemAE, we found that the dictionary representations converged into clusters as shown in Figure 3 (elements are color-coded according to their cluster identities as assigned by k-means algorithm with k=12).

We hypothesize that the clusters should capture certain semantic meaning. We explore this hypothesis by identifying sentences sharing similar representations with the mean representations

SemAE	**SemAE** (w/ redun.)	**SemAE** (w/ aspect)	**SemAE** (w/ aspect + redun.)
The **staff** is great. The Hotel Erwin is a great **place** to stay. The **staff** were friendly and helpful. The location is perfect. We ate **breakfast** at the hotel and it was great. The hotel itself is in a great **location**. The **service** was wonderful. It was great. The **rooms** are great. The rooftop **bar** HIGH was the icing on the cake. The **food** and **service** at the restaurant was awesome. The **service** was excellent.	The hotel itself is in a great **location**. The **rooms** were clean and we were on the 5th. The best part of the **hotel** is the 7th floor rooftop deck. The **staff** is great. The **hotel** has so many advantages over the other options in the area that it is a no contest. If you want to stay in Venice, this is a great **place** to be. The **food** and **service** at the restaurant was awesome.	The **staff** is great. The **staff** were friendly and helpful. The Hotel Erwin is a great **place** to stay. The **location** is perfect. We ate **breakfast** at the hotel and it was great. The **food** and **service** at the restaurant was awesome. The **rooms** are great. The **room** is epic! The rooftop **bar** HIGH was the icing on the cake. The rooftop **bar** at the hotel, "High", is amazing.	The **staff** is great. We had a great stay at the Erwin, and the **staff** really made it more enjoyable. The Hotel Erwin is a great **place** to stay. It was great. We ate **breakfast** at the hotel and it was great. The **food** and **service** at the restaurant was awesome. The **rooms** are great. We had a **kitchen and balcony** and partial ocean view. The rooftop **bar** HIGH was the icing on the cake.

Table 7: Example summaries from different variants of SemAE. Redundant sentences are highlighted. The aspect denoting words are in **bold**. For SemAE & SemAE (w/ redun.), we observe frequent context switch among aspects. SemAE (w/ aspect) & SemAE (w/ aspect + redun.) summaries cover different aspects in a coherent manner.

(h, k)	Sentences w/ high activation	Explanation
$(3, 5)$	• I wish all hotels or any business for that matter, had employees a dedicated to service as he was. • Very polite and very professional approach.	Service
$(0, 10)$	• Stayed here in August for the our first trip to Vancouver. • I stayed at this motel with my partner in August 2010.	Phrase "stayed"
$(6, 0)$	• Empty water bottles were never thrown out and no one put the iron and ironing board away. • Facing St Paul St can be a very noisy experience.	Bad experience
$(2, 8)$	• A full cooked to order breakfast (including omlettes, ..., fruit, etc.) • Pizza hut, Mc donalds, KFC all round the corners...	Food
$(5, 8)$	• The rooms seem small, tight fit for a family of 4. • You may have a difficult fit.	Small rooms

Table 8: List of sentences with high activation value with cluster means of dictionary elements. For each head representation, cluster means capture different semantics. h: head index; k: cluster index.

SPACE [General]	5%	10%	50%	100%
Copycat	26.1	26.2	31.8	36.7
QT	36.9	37.1	37.7	38.7
SemAE	37.8	40.9	41.2	42.5

Table 9: ROUGE-1 scores with different training data.

$\{\mu_1, \ldots, \mu_K\}$ for each cluster. For each head h in the encoder (Section 4.1), we compute cosine similarity of sentences with cluster means. Table 8 shows some examples of sentences having highest similarity with a cluster mean μ_k for a head representation h. We observe in most cases sentences closest to a cluster share a similar semantic meaning. For hotel reviews, we observe that sentences often talk about a specific aspect like service, food and rooms, as shown for (h, k) configurations (3, 5), (2, 8) and (5, 8) in Table 8. The clusters sometimes capture certain coarse semantics like presence of a word or phrase (e.g. config. (0, 10) in Table 8). It can also capture high-level semantics like the experience of a customer (e.g. config. (6, 0)). It was interesting to observe that a single cluster can capture different semantics for distinct heads (cluster 8 in configurations (2, 8) and (5, 8)).

Qualitative Examples. Table 7 shows summaries generated by SemAE and its variants for the SPACE dataset. While the summary generated by SemAE talks about *location*, *staff* & *service* multiple times (shown as highlighted text), summary from SemAE (w/ redundancy) doesn't have that repetition.

Also, the summary generated by SemAE switches context frequently. For example, the aspect of the first three sentences changes from service→location→service. We observe that compared to SemAE, both aspect-aware SemAE variants generate summaries without abrupt context switches. The summary generated by SemAE (w/ aspect) covers aspects like service, hotel, food and rooms sequentially, but sentences referring to an aspect are quite similar. SemAE (w/ aspect + redundancy) overcomes this shortcoming, and introduces diversity among the aspect-specific sentences.

Training Data Efficiency. We analyze the performance of SemAE, QT and CopyCat for general summarization (ROUGE-1) on SPACE for varying training data fractions in Table 9. We observe that both QT and SemAE perform well with low training data. However, SemAE outperforms QT in all

Rev./Ent.	R1	R2	RL
5	40.49	12.92	26.23
10	40.76	13.14	26.26
25	41.17	13.18	26.05
50	41.55	13.16	26.01
100	**42.48**	**13.48**	**26.40**

Table 10: ROUGE-F scores of SemAE with varying number of reviews per entity.

low resource settings. SemAE (with 10% data) yields significant ROUGE-1 improvements over QT (with access to 100% data).

Impact of number of reviews. We investigate whether SemAE's performance gain on SPACE is due to the larger number of reviews available (reviews per entity – AMAZON: 8, SPACE: 100). Specifically, we perform ablation experiments by reducing the number of reviews/entity in SPACE dataset. We remove user reviews with low relevance scores (relevance score of a review is the average $\mathcal{R}(\cdot)$ of its sentences). Table 10 reports the performance of SemAE with different number of reviews/entity in the test set. We observe a gradual decline in ROUGE-1 score when the reviews/entity is reduced, which shows that having more reviews per entity helps in better extractive summarization.

Additional Controllable Summarization. We showcase that SemAE can perform different forms of controllable summarization. Specifically, we perform sentiment-based summarization using a small number (10) of seed sentences belonging to *positive*, *negative* and *neutral* sentiment class. Seed sentences were annotated using the rule-based system VADER (Hutto and Gilbert, 2014). An example of sentiment-based summarization is shown in Table 11. We observe SemAE is able to generate summaries aligning with the seed sentiments. We also perform multi-aspect summarization using SemAE, by controlling the aspect of the selected sentences. Table 12 showcases an example of multi-aspect summarization. An interesting observation is that SemAE is able to select sentences, which have mutliple aspects (shown in **blue**) and not independent sentences from different aspects. These experiments show that SemAE is able capture and leverage granular semantics for summarization.

In Appendix A.5, we perform additional analysis to investigate the head-wise analysis, efficacy of sparsity constraints, dictionary evolution, and qualitatively compare SemAE with baselines (QT and CopyCat).

SENTIMENT	SUMMARY
Positive	**Love the warm chocolate chips cookies and the service has always been outstanding.** Excellent morning breakfasts and the airport shuttle runs every 15 minutes but we have made the 10 minute walk numerous times to the airport terminal.
Negative	To add insult to injury, for people who use the parking lot to "park and fly", the charge is \$7.95/day, almost half of what the hotel guests are charged!! **Cons - Hotel is spread out so pay attention to how to get to your room as you may get lost**, Feather pillows (synthetic available on request), Pay parking (\$16 self/day \$20 valet/day), warm cookies on check in.
Neutral	Stayed at this hotel beause the park n fly. **We have stayed at this hotel several times in the family suite (2 bedrooms/1 king and 2 queen beds).** Despite the enormity of this hotel, it very much feels almost family run.

Table 11: An example of sentiment-based summarization for a hotel entity in SPACE dataset.

ASPECTS	SUMMARY
(food, staff)	**The staff was friendly and helpful and we enjoyed the warm, chocolate chip cookie we were given at check-in.** The **breakfast** in the restaurant was amazing, and the **staff** was very attentive.
(room, cleanliness)	**The bed was very nice, room was clean, we even had a balcony.** The beds were comfortable and the room was very **clean**.

Table 12: Examples of multi-aspect summarization for a hotel entity in SPACE dataset.

7 Conclusion

We proposed a novel opinion summarization approach using Semantic Autoencoder, which encodes text as a representation over latent semantic units. We perform extractive summarization by selecting sentences using information-theoretic measures over representations obtained from SemAE. Our experiments reveal that dictionary element representations from SemAE form clusters, which capture distinct semantics. Our model provides fine-grained control to users to model surface-level text attributes (like redundancy, informativeness etc.) in the representation space. SemAE outperforms existing extractive opinion summarization methods on SPACE and AMAZON datasets. Finally, SemAE representations can be leveraged to explore different forms of control on the summary generation (e.g. multi-aspect sumamrization) using our inference framework. Future works can focus on better representation learning systems to handle use-cases with noisy or sparse textual data.

This work was supported in part by NSF grants IIS2112635 and IIS2047232. We also thank the anonymous reviewers for their thoughtful and constructive comments.

Ethical Considerations

We do not foresee any ethical concerns from the technology presented in this work. We used publicly available datasets, and do not annotate any data manually. The datasets used have reviews in English language. Human evaluations for summarization were performed on Amazon Mechanical Turks (AMT) platform. Human judges were compensated at a wage rate of $15 per hour.

A Appendix

A.1 Implementation Details

The Transformer is trained without the dictionary learning reconstruction for 4 warmup epochs. We tokenized text in an unsupervised manner using SentencePiece[5] tokenizer with 32K vocabulary size. The model was trained using Adam Optimizer with a learning rate of 10^{-3}, and a weight decay of 0.9. Our model was trained for 10 epochs on a single GeForce GTX 2080 Ti GPU in 35 hours. The loss function parameters are reported in Table 13. The hyperparameters were tuned on the development set of the dataset based on ROUGE-1 F score. For aspect summarization, we set $\beta = 0.7$ after tuning (grid search between 0.1 and 1, with intervals of 0.1) on the development set. We choose the redundancy term constant $\gamma = 0.1$ in a similar manner. Post training, the summaries were generated with $N = 20$. We limit the summary length to 75 tokens. Each keyword $w_i \in Q_a$ is associated with a confidence score for aspect a. In case a sentence has multiple keywords belonging to different aspects we use the confidence score to assign the aspect.

A.2 Dataset Construction

In this section, we provide some background information about the dataset creation process for SPACE and AMAZON. SPACE corpus has a large number of reviews per entity. Therefore, Angelidis et al. (2021) collected summaries from reviews following a two-step procedure (a) sentence voting, and (b) summary collection. *Sentence voting* step involves selecting informative review sentences using a majority vote from the annotators. Annotators were prompted to select between 20-40% of the total sentences. *Summary collection* involves generating a overview summary of the selected sentences upto a 100-word budget. For aspect summaries, selected sentences were annotated using an off-the-shelf aspect classifier (Angelidis and Lapata, 2018b). Human annotators were asked to summarize selected sentences belonging to an aspect. AMAZON dataset has a relatively lower number of reviews per entity. The evaluation set of AMAZON was created by sampling 60 entities and 8 reviews per entity. These were provided to the human annotators for summarization (Bražinskas et al., 2020).

A.3 Ablations

- **Divergence metric**: SemAE uses KL divergence to measure the relevance of a sentence α^s when compared to the mean $\bar{\alpha}$, we used KL-divergence earlier. In this setup, we experiment with cosine similarity as our divergence function $\Delta(\cdot,\cdot)$. The modified divergence $\Delta(\cdot,\cdot)$ score is defined as:

  $$\Delta(\alpha^s, \bar{\alpha}) = \sum_h \frac{\bar{\alpha}_h^T \alpha_h^s}{||\bar{\alpha}_h||_2 ||\alpha_h^s||_2} \quad (9)$$

  The second row in Table 14 reports the performance in this setup, which is similar to the baseline SemAE performance. This shows that cosine similarity can serve as a good proxy to measure relevance $\mathcal{R}(\cdot)$.

- **Informativeness**: In this ablation experiment, we incorporate the informativeness term in general summarization. The modified relevance score is:

  $$\mathcal{R}(\alpha^s) = \Delta(\bar{\alpha}, \alpha^s) - \beta' \Delta(\alpha^{(b)}, \alpha^s) \quad (10)$$

  where $\alpha^{(b)} = \mathbb{E}[\alpha^s]$, the mean representation of all sentences across all entities. $\alpha^{(b)}$ captures *background knowledge* distribution (Peyrard, 2019), and a good summary should be divergent from the background information. Third row in Table 14 reports the performance in this setup, where we do not observe any gain over the baseline. We believe this maybe due to the fact that $\alpha^{(b)}$ doesn't capture the background knowledge properly, as it is the mean representation of hotel review sentences across all entities.

  For both ablation setups, we observe almost no change in perplexity, aspect coverage and distinct n-grams metrics.

	w/ Clustering	31.42	5.27	16.58

Table 15: Summarization performance of SemAE with different sentence selection schemes on SPACE and AMAZON datasets.

A.4 Variations of Sentence Selection

(a) **Herding** (Chen et al., 2010): In this setup, we modify selection mechanism of SemAE by updating the mean representation every time a sentence is selected. We consider the mean of the sentences that have not been selected so far. The intuition behind this approach is that the next selected sentence should best capture information, which is not present in the summary so far. The sentence selection process is described below:

$$\alpha_t^s = \max_{\alpha^s} \mathcal{R}(\alpha^s) = \max_{\alpha^s} \Delta(\bar{\alpha}_t, \alpha^s) \tag{11}$$

$$\bar{\alpha}_t = \mathop{\mathbb{E}}_{s\sim(S_e \backslash \hat{O}_e)} [\alpha^s] \tag{12}$$

where α_t^s is the representation selected at time step t, $\bar{\alpha}_t$ is mean representation of the set of sentences that are not part of the summary yet and $\hat{O}_e$ is the set of selected sentences so far. Table 15 reports the result of this setup. We observe a significant drop in performance compared to SemAE. We believe that removing the selected sentences skews the mean towards outlier review sentences resulting in a drop in performance.

(b) **Optimal Transport**: In this setup, we consider the Wasserstein distance between two probability distributions. Wasserstein distance (Peyré et al., 2019) arising from the concept of optimal transport takes into account the underlying geometry of the representation space. Let $\mathcal{M}_+^1(\mathbb{R}^d)$ be the space of probability distributions defined on $\mathbb{R}^d$ with $d \in \mathbb{Z}^+$. Wasserstein distance between two arbitrary probability distributions $\mu \in \mathcal{M}_+^1(\mathcal{X})$ and $\nu \in \mathcal{M}_+^1(\mathcal{Y})$ is denoted by $\mathcal{W}(\mu, \nu)$. Following (Colombo et al., 2021), we compute a Wasserstein barycenter of all sentences for each head h as:

$$\mu_h^c = \mathop{\arg\min}_{\mu\in\mathcal{M}_+^1(\mathbb{R}^d)} \sum_{i=1}^{|S_e|} \mathcal{W}(\mu, \alpha_h^s) \tag{13}$$

The overall representation for the barycenter is $\mu^c = [\mu_1^c, \ldots, \mu_H^c]$. Next, we derive the relevance score of each sentence s with the barycenter as:

$$\mathcal{R}(\alpha^s) = -\sum_{h=1}^{H} \mathcal{W}(\mu_h^c, \alpha_h^s) \tag{14}$$

As shown in Equation 14, we select sentences with low Wasserstein distance from the barycenter. We report the results for this optimal transport setup in Table 15. We find that the performance of this setup is significantly lower than SemAE on SPACE dataset, but comparable to other baselines on AMAZON dataset.

(c) **Clustering-based Sentence Selection**: In this setup, instead of selecting sentences similar to the mean representation, we identify clusters formed by the representations. For clustering we flatten the sentence representation $\alpha^s \in \mathbb{R}^{HK}$, and use k-means[6] clustering (K is a hyperparameter). We select sentences that are representative samples in each cluster. The relevance score for each sentence is computed as follows:

$$\mathcal{R}(\alpha^s) = -||\alpha^s - \alpha_{\mathcal{C}}||_2^2 + \gamma|\mathcal{C}| \tag{15}$$

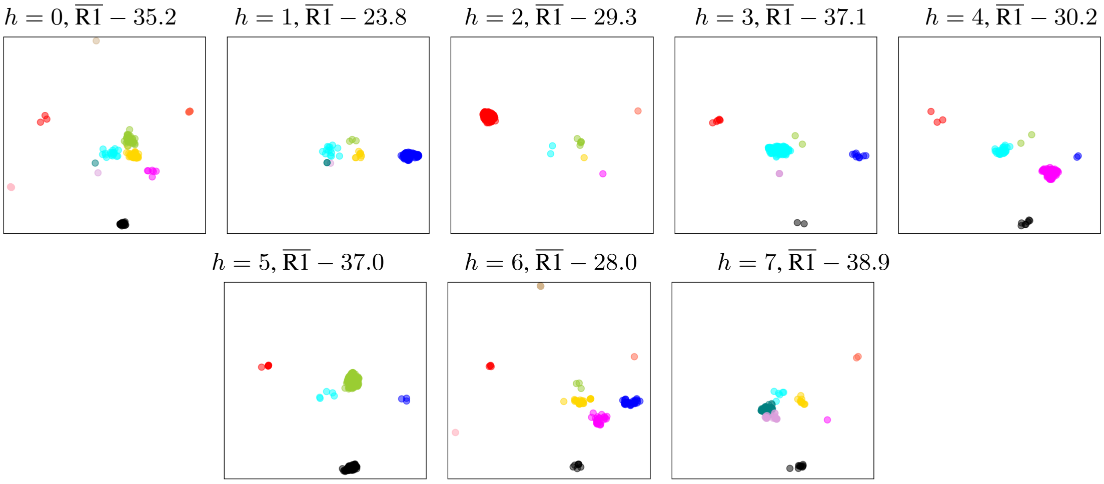
where $\alpha_{\mathcal{C}}$ is the representation of the cluster center where s belongs, and $|\mathcal{C}|$ is the size of the cluster. The first term in Equation 15 penalizes the relevance of a sentence for being too far away from the cluster center, and the second term selection of samples from a large cluster. The hyperparameters $\gamma = 0.005, K = 5$ in our experiments, were selected using the development set performance. In Table 15, we observe that this clustering-based sentence selection work poorly for SPACE dataset but the performance on AMAZON is decent. The performance on SPACE dataset is poor as it has a large number of reviews, and identification of representative clusters is difficult using this approach.

A.5 Extended Analysis

(a) **Efficacy of Sparsity Losses**: In this section, we evaluate the performance of SemAE in different

---

[6] We experimented with algorithms (like Affinity Propagation, DBSCAN) that identify clusters automatically, but found them to struggle with outliers. K-means performed better than them albeit requiring finetuning of the hyperparameter.



$h = 0, \overline{\text{R1}} - 35.2$ $h = 1, \overline{\text{R1}} - 23.8$ $h = 2, \overline{\text{R1}} - 29.3$ $h = 3, \overline{\text{R1}} - 37.1$ $h = 4, \overline{\text{R1}} - 30.2$

$h = 5, \overline{\text{R1}} - 37.0$ $h = 6, \overline{\text{R1}} - 28.0$ $h = 7, \overline{\text{R1}} - 38.9$

Figure 5: UMAP (McInnes et al., 2018) projections of dictionary element over different epochs (warmup epoch #4 to epoch 10). We observe that dictionary elements gradually evolve to form clusters over the epochs.

DATASET	METHOD	R1	R2	RL
SPACE	SemAE	42.48	13.48	26.40
	w/o L1	41.01	11.91	24.23
	w/o H	38.70	10.45	22.87
AMAZON	SemAE	32.03	5.38	16.47
	w/o L1	29.16	4.77	16.19
	w/o H	29.60	4.85	16.63

Table 16: Performance of SemAE in different configurations of sparsity constraints.

configurations of sparsity losses. Specifically, we gauge SemAE' performance when L1-loss and entropy loss are removed. Table 16 reports the results with different loss setups. We observe a drop in performance when either of the sparsity losses are removed. This shows that ensuring sentence representations are a sparse combination of semantic units helps in summarization.

(b) **Head-wise Analysis**: We analyze whether there is a correlation between the head-wise representations and clusters formed by dictionary elements. For each dictionary element, we compute the average attention (α_h) it receives from each head h, and assign the element to a head where it received the maximum mean attention (head-wise dictionary elements are shown in Figure 4). We also compute the performance of general summarization when only a single head representation is considered $\Delta(\alpha^s, \bar{\alpha}) = \text{KL}(\bar{\alpha}_h, \alpha^s_h)$. In Figure 4, we observe that heads that have instances in mul-

Human	SemAE	QT	Copycat
All staff members were friendly, accommodating, and helpful. The hotel and room were very clean. The room had modern charm and was nicely remodeled. The beds are extremely comfortable. The rooms are quite with wonderful beach views. The food at Hash, the restaurant in lobby, was fabulous. The location is great, very close to the beach. It's a longish walk to Santa Monica. The price is very affordable.	The staff is great. The Hotel Erwin is a great place to stay. The staff were friendly and helpful. The location is perfect. We ate breakfast at the hotel and it was great. The hotel itself is in a great location. The service was wonderful. It was great. The rooms are great. The rooftop bar HIGH was the icing on the cake. The food and service at the restaurant was awesome. The service was excellent.	Great hotel. We liked our room with an ocean view. The staff were friendly and helpful. There was no balcony. The location is perfect. Our room was very quiet. I would definitely stay here again. You're one block from the beach. So it must be good! Filthy hallways. Unvacuumed room. Pricy, but well worth it.	This hotel is in a great location, just off the beach. The staff was very friendly and helpful. We had a room with a view of the beach and ocean. The only problem was that our room was on the 4th floor with a view of the ocean. If you are looking for a nice place to sleep then this is the place for you.

Table 17: Human-written and system generated summaries from SemAE, QT and Copycat. We showcase the summary for the same instance reported by previous works.

Food: The food and service at the restaurant was awesome. The food at Hash, the restaurant just off of the lobby, was fabulous for breakfast. The food was excellent (oatmeal, great wheat toast, freshberries and a tasty corned beef hash).

Location: The Hotel Erwin is a great place to stay. The hotel is not only in the perfect location for the ideal LA beach experience, but it is extremely hip and comfortable at the same time.

Cleanliness: The room was spacious and had really cool furnishings, and the beds were comfortable. The room itself was very spacious and had a comfortable bed. We were upgraded to a partial ocean view suite and the room was clean and comfortable.

Service: The hotel staff were friendly and provided us with great service. The staff were friendly and helpful. The staff was extremely helpful and friendly. The hotel staff was friendly and the room was well kept.

Building: The rooftop bar at the hotel, "High", is amazing. The rooftop bar HIGH was the icing on the cake. The Hotel Erwin is a great place to stay. The best part of the hotel is the 7th floor rooftop deck.

Rooms: The room was spacious and had really cool furnishings, and the beds were comfortable. The room itself had a retro 70's feel with a comfortable living room and kitchen area, a separate bedroom with a nice king size bed, and a sink area outside the shower/toilet area.

Table 18: Aspect-wise summaries generated by SemAE.

tiple dictionary element clusters ($h = 0, 3, 5, 7$) perform better than heads where instances are concentrated over few clusters ($h = 1, 2$).

(c) **Output summaries**: Table 17 shows the summaries generated by SemAE, QT and Copycat along with human-written summary. We observe that SemAE selects well formed sentences, avoiding truncated sentences or the ones in a first-person setting. Table 18 reports the summaries generated by SemAE for different aspects of a hotel entity. We observe that SemAE is able to produce summaries that talk about the specific aspect only.

(d) **Evolution of Dictionary Representations**: We plot the UMAP projections of dictionary elements from epochs 4 (after encoder warmup is complete) to 10 in Figure 5. During the training process, we observe that the UMAP project of dictionary elements form a set of clusters. We observe the first signs of cluster formation in epoch 7, which becomes more distinct over the later epochs.

Space [General]	R1	R2	RL
QT	36.1	7.6	20.2
QT (+SS)	35.7	8.1	22.4
SemAE	**37.8**	**9.7**	**22.8**

Table 19: Summarization performance with SemAE's sentence selection (SS) scheme using representations from QT and SemAE. We also report the performance of the baseline QT. The experiments were conducted on 5% Space dataset.

(e) **Ablations with QT**: In this section, we analyze the efficacy of our sentence selection (SS) module. We evaluate the summarization performance using our sentence selection scheme by retrieving sentence representations from QT and SemAE. The experiments were performed using 5% data from the Space dataset. For QT's representations, we obtain α_h (Equation 2) as follows:

$$\alpha_h = \mathrm{softmax}(-||s_h - D||_2^2) \qquad (16)$$

In Table 19, we observe that incorporating our sentence selection (SS) improves QT's performance in terms of ROUGE-2 and ROUGE-L scores, with a small drop in ROUGE-1. However, the performance still falls behind SemAE, showcasing that the our representation learning model complements the sentence selection scheme. From these two results, we can conclude that the better performance of SemAE can be attributed to a combination of the two components. Note that using QT's sentence selection with SemAE's representations is not feasible as SemAE doesn't quantize sentences to a single latent code.

LexSubCon: Integrating Knowledge from Lexical Resources into Contextual Embeddings for Lexical Substitution

George Michalopoulos, Ian McKillop, Alexander Wong, Helen Chen
University of Waterloo,
Waterloo, Canada
{gmichalo, ian, alexander.wong, helen.chen}@uwaterloo.ca

Abstract

Lexical substitution is the task of generating meaningful substitutes for a word in a given textual context. Contextual word embedding models have achieved state-of-the-art results in the lexical substitution task by relying on contextual information extracted from the replaced word within the sentence. However, such models do not take into account structured knowledge that exists in external lexical databases.

We introduce LexSubCon, an end-to-end lexical substitution framework based on contextual embedding models that can identify highly-accurate substitute candidates. This is achieved by combining contextual information with knowledge from structured lexical resources. Our approach involves: (i) introducing a novel mix-up embedding strategy to the target word's embedding through linearly interpolating the pair of the target input embedding and the average embedding of its probable synonyms; (ii) considering the similarity of the sentence-definition embeddings of the target word and its proposed candidates; and, (iii) calculating the effect of each substitution on the semantics of the sentence through a fine-tuned sentence similarity model. Our experiments show that LexSubCon outperforms previous state-of-the-art methods by at least 2% over all the official lexical substitution metrics on LS07 and CoInCo benchmark datasets that are widely used for lexical substitution tasks.

1 Introduction

Lexical Substitution (McCarthy and Navigli, 2007) is the task of generating appropriate words which can replace a target word in a given sentence without changing the sentence's meaning. The increased research interest in Lexical Substitution is due to its utility in various Natural Language Processing (NLP) fields including data augmentation, paraphrase generation and semantic text similarity.

Contextual word embedding models (such as ELMo (Peters et al., 2018) and BERT (Devlin et al., 2019)) have achieved state-of-art results in many NLP tasks. These models are usually pre-trained on massive corpora and the resulting context-sensitive embeddings are used in different downstream tasks (Howard and Ruder, 2018). Zhou et al. (2019) have achieved state-of-the-art results on the lexical substitution task by improving the BERT's standard procedure of the masked language modeling task. However, the current state-of-the-art contextual models have yet to incorporate structured knowledge that exists in external lexical database into their prediction process. These lexical resources could boost the model's performance by providing additional information such as the definitions of the target and candidate words (in order to ensure that the candidate word is semantically similar to the target word and not only appropriate for the sentence's context) or by enriching the proposed candidate word list so it will not only be based on the vocabulary of the contextual model.

In this paper, we present and publicly release[1] a novel framework for the lexical substitution task. Specifically, (i) we are the first, to the best of our knowledge, to propose a novel mix-up embedding strategy that outperforms the previous state-of-the-art strategy of word embedding dropout for the input embedding of the target word in a contextual model (Zhou et al., 2019) for the task of predicting accurate candidate words; (ii) we propose the combined usage of features from contextual embedding models and external lexical knowledge bases in order to determine the most appropriate substitution words without modifying the meaning of the original sentence, such as introducing a new gloss (definition) similarity metric which calculates the similarity of the sentence-definition embeddings of the target word and its proposed candidates; (iii) we generate a highly accurate fine–tuned sentence similarity model by taking advantage of popular data augmentation techniques (such

---

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 1226 - 1236

as back translation), for calculating the effect of each candidate word in the semantics of the original sentence; and, (iv) finally, we show that LexSubCon achieves state-of-the-art results on two popular benchmark lexical substitution datasets (McCarthy and Navigli, 2007; Kremer et al., 2014).

2 Related Work

The lexical substitution task consists of two subtasks: (i) generating a set of meaning preserving substitute candidates for the target word and (ii) appropriately ranking the words of the set by their ability to preserve the meaning of the initial sentence (Giuliano et al., 2007; Martinez et al., 2007). However, lexical substitution models can also be tested in a "simpler" problem where the set of substitute candidates is composed of human-suggested words and the task is to accurately rank the substitute words that are provided (Erk and Padó, 2010).

The authors in (Melamud et al., 2015b) proposed the use of a word2vec model which utilizes word and context embeddings to represent the target word in a given context. Their model ranked the candidate substitutions by measuring their embedding similarity. In (Melamud et al., 2016) the context2vec model was introduced where the context representation of the word was calculated by combining the output of two bidirectional LSTM models using a feed-forward neural network.

Peters et al. (2018) introduced contextualized word embeddings in a bidirectional language model (ELMo). This allowed the model to change the embedding of a word based on its imputed meaning which is derived from the surrounding context. Subsequently, Devlin et al. (2019) proposed the Bidirectional Encoder Representations from Transformers (BERT) which uses bidirectional transformers (Vaswani et al., 2017) to create context-dependent representations. The authors in (Garí Soler et al., 2019) used ELMo in the lexical substitution task by calculating the cosine similarity between the ELMo embedding of the target word and all the candidate substitutes. In addition, Zhou et al. (2019) achieved state-of-the-art results on the lexical substitution task by applying a dropout embedding policy to the target word embedding and by taking into account the similarity between the initial contextualized representation of the context words and their representation after replacing the target word by one of the possible candidate words. An analysis of state-of-the-art contextual model on the lexical substitution task was presented in (Arefyev et al., 2020).

Finally, external knowledge from knowledge bases has been used to enhance the performance of deep learning models. Sense-BERT (Levine et al., 2020) was pre-trained to predict the semantic class of each word by incorporating lexical semantics (from the lexical database WordNet (Miller, 1995)) into the model's pre-training objective. Furthermore, Faruqui et al. (2015) and Bahdanau et al. (2017) used external knowledge (namely WordNet) in order to enhance word embeddings and to create more accurate representations of rare words.

3 LexSubCon Framework

In the lexical substitution task, a model aims to firstly generate a set of candidate substitutions for each target word and secondly to create an appropriate ranking of the elements of the candidate set. In addition, there are two main conditions for a lexical substitute model to satisfy: (i) to be semantically similar to the target word and (ii) and to be compatible with the given context (sentence) (Melamud et al., 2015b). We present the LexSubCon framework which achieves state of the art results on the lexical substitution task by combining contextual information with knowledge from structured external lexical resources.

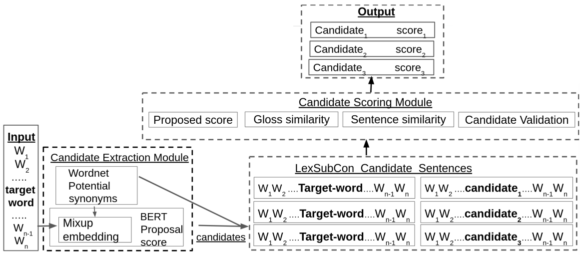

Figure 1: LexSubCon framework

The architecture of LexSubCon is depicted in Figure 1. The key characteristic of LexSubCon is its capability of unifying different substitution criteria such as contextualized representation, definition and sentence similarity in a single framework in order to accurately identify suitable candidates for the target words in a specific context (sentence).

3.1 Proposed Score: Mix-Up Embedding Strategy

The standard BERT architecture (Devlin et al., 2019) can be used in the lexical substitution task by masking the target word and letting the model to propose appropriate substitute candidates that preserve the initial meaning of the sentence. Zhou et al. (2019) argued that applying embedding dropout to partially mask the target word is a better alternative than masking the whole word. This is because the model may generate candidates that are semantically different but appropriate for the context of the initial sentence. Their experiments showed that this policy is indeed more beneficial than completely masking, or not masking, the target word.

However, in this paper we demonstrate that a mix-up embedding strategy can yield even better results. The main disadvantage of dropout embedding is that it sets random positions in the embedding vector of the target words to zero. We propose that by using external knowledge, we can obtain probable synonyms of the target word and use that knowledge in a mix-up scenario (Zhang et al., 2018) through linearly interpolating the pair of the target input embedding and the average embedding of its synonyms. This allows the model to generate a new synthetic input embedding by re-positioning the target embedding around the neighborhood of the embedding of its synonyms. In order to obtain appropriate synonyms we use WordNet (Miller, 1995) which is an extensive lexical database where words are grouped into sets of synonyms (synsets). In our experiments, the best performance was achieved when the list of synonyms was extracted from the complete set of synsets for each word as it minimizes the chance of having a synonym set that only includes the target word itself.

Finally, we use a mix-up strategy to calculate a new input embedding for the target word X'_{target} as shown in equation 1:

$$X'_{target} = \lambda X_{target} + (1 - \lambda)\overline{X}_{synonyms} \quad (1)$$

Where X_{target} is the initial input embedding of the target word, $\overline{X}_{synonyms}$ is the average embedding of all the synonyms. It should be noted that Wordnet does not contain information about some words, such as pronouns, conjunctions, or nouns that are not commonly used in the English vocabulary. To address this limitation, whenever a target word cannot be found in the WordNet database, we replace the mix-up strategy by injecting Gaussian noise to the input embedding of the target word. This produces a similar effect as the mix-up strategy since the target embedding is re-positioned around itself in the embedding space (equation 2):

$$X'_{target} = X_{target} + e \quad (2)$$

where e is a Gaussian noise vector with components $e_i \sim \mathcal{N}(\mu_i, \sigma_i^2)$.

We use the BERT architecture to calculate the proposal score for each candidate. The input embedding vectors pass through multiple attention-based transformer layers where each layer produces a contextualized embedding of each token. For each target word x_t, the model outputs a score vector $y_t \in \mathbb{R}^D$, where D is the length of the model's vocabulary. We calculate the proposal score s_p for each candidate word x_c, using the score vector y_t of the BERT's language modeling process, as the probability for the BERT model to propose the word x_c over all the candidates words x'_c when the target word's sentence is provided as input to it:

$$s_p(x_c) = \frac{exp(y_t[x_c])}{\sum_{x'_c} exp(y_t[x'_c])} \quad (3)$$

3.2 Gloss-Sentence Similarity Score

In the previous section, we analyzed our model which ranks candidate substitute words by calculating their individual proposal scores. However, Zhou et al. (2019) and Arefyev et al. (2020) showed that the proposal score does not provide sufficient information about whether the substitute words will modify the sentence's meaning. Thus, in this section, we present a new metric which ranks the candidate words by considering the gloss (a dictionary-style definition) of each word. By extracting the appropriate information from the Wordnet database, a list of potential glosses is created for each target or candidate word. In addition, we can determine the most appropriate gloss based on the word and its specific context (sentence) by taking advantage of recent fine-tuned contextual models that have achieved state-of-the-art results in the Word Sense Disambiguation (WSD) task (Huang et al., 2019). As the glosses are sentences (sequence of words) they can be represented in a semantic space through a sentence embedding generating model. A ranking of each candidate word is produced by calculating the cosine similarity between the gloss sentence embedding of the target word and the gloss sentence embedding of each candidate word.

There are many methods for generating sentence embeddings, such as calculating the weighted average of its word embeddings (Arora et al., 2017). We select the sentence embeddings of the stsb-roberta-large model in (Reimers and Gurevych,

2019) which has been shown to outperform other state-of-the-art sentence embeddings methods.

Given a sentence s, a target word x_t and a candidate word x_c, our model first identifies the most appropriate gloss g_t for the target word given its context. After replacing the target word with the candidate x_c to create a new sentence s', the most appropriate gloss g_c for the candidate word is also determined. A gloss-similarity score s_g for each candidate is then calculated as the cosine similarity between the two glosses-sentences embeddings.

$$s_g(x_c) = cos(g_t, g_c) \tag{4}$$

3.3 Sentence Similarity Score

We also chose to calculate the effect of each substitution in the semantics of the original sentence by calculating the semantic textual similarity between the original sentence s and the updated sentence s' (a sentence where we have replaced the target word with one of its substitutions).

In order to accurately calculate a similarity score between s and s', we fine-tune a semantic textual similarity model based on the stsb-roberta-large model (Reimers and Gurevych, 2019) by using the training portion of the dataset in order to create pairs of sentences between the original sentence and an updated sentence where we have substitute the target word with one of its proposed candidates. Using the methods that we described in section 3.2, we can identify the most appropriate synset (from WordNet) for each target word and create a new pair of sentences between the original sentence and an updated sentence where we have updated the target word with the synonyms of the previous mentioned synset. However, due to the limited size of the training dataset, our model is still not provided with enough training data in order to be fully fine-tuned.

This is the reason why we employ a data augmentation technique in order to produce the examples needed for this task. Specifically, we create a back-translation mechanism in order to generate artificial training data. Back-translation or round-trip translation is the process of translating text into another language (forward translation) and then translating back again into the original language (back translation) (Aiken and Park, 2010). Back-translation has been used in different tasks in order to increase the size of training data (Sennrich et al., 2016; Aroyehun and Gelbukh, 2018). In our case, we provide to the back-translation module the initial sentence s and it produces a sightly different 'updated' sentence s'_u. For the s'_u sentences that still contain the target word we can create pair of sentences between the s'_u and an alternative version of the s'_u sentence (s''_u) where the target word is substituted with one of the candidate words or synonyms that we mentioned in the above paragraph. The main disadvantage of this techniques is that it may return the same initial sentence without any changes. In this case, we add a second translation level where the initial sentence is translated into two different languages before being translated back.

3.4 Candidate Validation Score

In our experiments we have also included the substitute candidate validation metric from (Zhou et al., 2019) as it has been shown to have a positive affect on the performance of a lexical substitution model. The substitute candidate validation metric is represented as the weighted sum of the cosine similarities between the contextual representation of each token in the initial and in the updated sentence where the weight of the cosine similarity of the token i is calculated as the average self-attention score of all heads in all layers from the token of the target word to token i. As mentioned in (Zhou et al., 2019), this metric evaluates the influence of the substitution on the semantic of the sentence.

Finally, LexSubCon uses a linear combination of the above mentioned features to calculate the final score for each candidate word.

3.5 Candidate Extraction

The candidates for each target word are extracted using the external lexical resource of WordNet and the BERT-based lexical substitution approach where the model provides probabilities for each candidate based on the context (sentence). We create a list of candidates based on the synonyms, the hypernyms, and hyponyms of each target word that could be identified in WordNet. In addition, we include in the list the candidate words with the higher probability that could be identified using the mix-up strategy that we described in section 3.1. We chose to include candidates from WordNet because we do not want our model to only include candidates words from the BERT vocabulary and we also include candidates words from a BERT-based model because target words may not be included in WordNet.

4 Experiments

4.1 Dataset

We evaluate LexSubCon on the English datasets SemEval 2007 (LS07)[2] (McCarthy and Navigli, 2007) and Concepts-In-Context (CoInCo)[3] (Kremer et al., 2014) which are the most widely used datasets for the evaluation of lexical substitution models. (i) The LS07 dataset is split into 300 train and 1710 test sentences where for each of the 201 target words there are 10 sentences (extracted from http://corpus.leeds.ac.uk/internet.html). The gold standard was based on manual annotation where annotators provided up to 3 possible substitutes. (ii) The CoInCo dataset consists of over 15K target word instances (based on texts provided in the Open American National Corpus) where 35% are training and 65% are testing data. Each annotator provided at least 6 substitutes for each target word. Our experiments with all datasets are consistent with their intended use, as they were created for research purposes. We manually investigate the existence of information that names individuals or offensive content, however, we did not find any indication of either of them.

In order to have a fair comparison with the previous state-of-the-art models, for both datasets we used their processed versions as used in (Melamud et al., 2015b, 2016).

4.2 Experimental Setup

LexSubCon was evaluated in the following variations of the lexical substitution tasks:

All-ranking task: In this task no substitution candidates are provided. We use the official metrics that the organizers provided in the original lexical substitution task of SemEval-2007 [4]. These were *best* and *best-mode* which validate the quality of the model's best prediction and both *oot* (out-of-ten) and *oot-mode* to evaluate the coverage of the gold substitute candidate list by the 10-top predictions. We also use $Precision@1$ to have a complete comparison with the model in (Zhou et al., 2019).

Candidate ranking task: In this task the list of candidates are provided and the goal of the model is to rank all the candidate words. For the candidate ranking task we follow the policy of previous works and construct the candidate list by merging all the substitutions of the target lemma and POS tag over the whole dataset. For measuring the performance of the model we use the GAP score (Kishida, 2005)[5] which is a variant of the MAP (Mean Average Precision). Following (Melamud et al., 2015b), we discard all multi-words from the gold substitutes list and remove the instances that were left with no gold substitutes.

We use the uncased BERT large model (Devlin et al., 2019) for the calculation of the proposal score and candidate validation score. For the identification of the most appropriate glosses we employ the pre-trained model in (Huang et al., 2019) which has achieved the state-of-the-art results in the Word Sense Disambiguation (WSD) task. Finally, the sentence-similarity metric is computed by finedtuning the stsb-roberta-large model in (Reimers and Gurevych, 2019) and by employing the OPUS-MT models (Tiedemann and Thottingal, 2020) (namely opus-mt-en-romance, opus-mt-fr-es and opus-mt-romance-en) for the creation of the back-translated sentences.

We use the LS07 trial set for training the sentence similarity metric model (for 4 epochs) and for fine-tuning the parameters of our framework based on the *best* score. Empirically, the λ parameter of the mix-up strategy was set to 0.25 and the weights to $0.05, 0.05, 1, 0.5$ for the proposal score, gloss-sentence similarity score, sentence similarity score and candidate validation score respectively (with the search space for all the parameters being $[0, 1]$[6]). Finally, for the Gaussian noise we choose a mean value of 0 and standard deviation 0.01. We propose 30 candidates for each target word. In order to achieve more robust results, we run LexSubCon on five different (random) seeds and we provide the average scores and standard deviation. All the contextual models are implemented using the transformers library (Wolf et al., 2019) on PyTorch 1.7.1. All experiments are executed on a Tesla K80 GPU with 64 GB of system RAM on Ubuntu 18.04.5 LTS. It should be noted that LexSubCon contains 1136209468 parameters.

4.3 Lexical Substitution Model Comparison

To enable direct comparison and to isolate gains due to improvements solely on the post-processing strategy that each model uses (which has the potential to change its performance (Arefyev et al., 2020)), we opt to reproduce and use the same strat-

Table 1: Results of mean ± standard deviation of five runs from our implementation of LexSubCon and Bert_{s_p,s_u}(Zhou et al., 2019). We also provide the performance of previous state-of-the-art models. Transfer learning (Hintz and Biemann, 2016), Substitute vector (Melamud et al., 2015a), Addcos (Melamud et al., 2015b), Supervised learning (Szarvas et al., 2013b), KU (Yuret, 2007), UNT (Hassan et al., 2007). Best values are **bolded**.

egy for the tokenization of the target words from Bert_{s_p,s_u} (Zhou et al., 2019). We focus our comparison on Bert_{s_p,s_u} as it has achieved impressive state of the art results on both benchmark datasets[7].

The results of LexSubCon and the previous state-of-the art results in both LS07 and CoInCo benchmark datasets are presented in Table 1. LexSubCon outperformed the previous methods across all metrics in the LS07 and the CoInCo datasets due to the fact that all features have a positive contribution on its performance (see ablation details in section 4.5) as they encourage LexSubCon to take into consideration different substitution criteria. The standard deviation of the results of LexSubCon is not zero due to the fine-tuning process of the sentence similarity model. However, the results indicate that there are no large fluctuations. LexSubCon and our implementation of Bert_{s_p,s_u} had a running time of 74k and 30k for LS07 and 580K and 266K seconds for the CoInCo dataset respectively.

Policy	best	best-m	oot	oot-m	P@1
		LS07

Table 2: Comparison of different strategies for modifying the input embedding of the proposal model. *Mix.* is the mix-up strategy that we proposed, *Gaus.* is the Gaussian noise strategy, *Drop.* is the dropout embedding strategy in (Zhou et al., 2019), *Mask* is the strategy of masking the target word and *Keep* is the strategy of unmasking the target word in the input of the proposal model. Best values are **bolded**.

4.4 Mix-Up Strategy Evaluation

In order to evaluate the mix-up strategy for the input embedding of the proposal model, we study the effect of different input embedding policies. The results of this study are listed in Table 2. It can be observed that even the simpler strategy of injecting Gaussian noise to the input embedding outperformed the standard policy of masking the input word. These results indicate that a contextual model needs information from the embedding of the target word in order to predict accurate candidates but it may over-rely on this information when it is provided with an intact input embedding. Fur-

---

[7] Note that the method proposed by (Zhou et al., 2019) was implemented to the best of our abilities to be as faithful to the original work as possible using elements of code that the method's authors kindly provided upon request. However, the authors could not make the complete original code available to us.

thermore, the mix-up strategy outperformed all the other policies and specifically the dropout embedding strategy (Zhou et al., 2019) as the mix-up strategy re-positions the target embedding around the neighborhood of the embedding of its synonyms and it does not erase a part of the embedding that the model can learn from.

4.5 Ablation Study

Sen.	10.9	22.5	34.0	54.9	40.5
Val.	11.7	23.7	35.3	55.2	44.2

Table 3: Ablation study of LexSubCon: *Pr.* is the Proposal score using the mix-up embedding strategy. *Gl.* is the Gloss similarity score. *Sen.* is the Sentence Similarity score and *Val.* is the Validation score. *-w/o* indicates a LexSubCon framework **without** the specific feature.

In order to evaluate the effect of each feature on the performance of LexSubCon, we conducted an ablation study. The results are presented in Table 3. As Table 3 shows, LexSubCon achieved its best performance when it has access to information from all the features described in section 3. By testing the performance of the individual features, we observe that the gloss sentence similarity feature achieves the worst performance out of all the features. This is likely because many candidate words cannot be identified in Wordnet and thus we assign a zero value to their gloss sentence score. Another factor is that the models that were used for the selection of the most appropriate gloss for each word may introduce noise in the process of the gloss-similarity score model as they may select not-optimal glosses.

4.6 Candidate Ranking Task

We also evaluate LexSubCon in the candidate ranking task for both the LS07 an CoInCo dataset. In this sub-task the candidate substitution words are provided and the main task of the system is to create the most appropriate ranking of the candidates.

Method	LS07	CoInCo
LexSubCon	**60.6**	**58.0**
-w/o Pr.	58.8	56.3
-w/o Gl.	60.3	57.4
-w/o Sen.	59.8	57.1
-w/o Val.	56.8	53.8
Bert_{s_p,s_u}*	58.6	55.2
LexSubCon (trial+test)	60.3	58.0
Bert_{s_p,s_u}* (trial+test)	57.9	55.5
XLNet+embs	57.3	54.8
context2vec	56.0	47.9
Trans. learning	51.9	-
Sup. learning	55.0	-
PIC	52.4	48.3
Substitute vector	55.1	50.2
Addcos	52.9	48.3
Vect. space mod.	52.5	47.8

Table 4: Comparison of GAP scores (%) in previous published results in the candidate ranking task of our implementation of LexSubCon and Bert_{s_p,s_u} (Zhou et al., 2019). We also provide the results on the entire dataset with (trial+test). Models: XLNet+embs (Arefyev et al., 2020), Context2vec (Melamud et al., 2016), Transfer learning (Hintz and Biemann, 2016), Supervised learning(Szarvas et al., 2013b), PIC (Roller and Erk, 2016), Substitute vector (Melamud et al., 2015a), Addcos (Melamud et al., 2015b), Vector space modeling (Kremer et al., 2014).

Table 4 provides the evaluation results in the candidate ranking task of LexSubCon and of the previous state-of-the art models. We report the results both on the test set and on the entire dataset (trial+test), in order to have a complete comparison as some of the previous state of the art models were evaluated on the entire datasets and some were evaluated only in the testing portion of the datasets. It can be observed that all the features have a positive effect on the performance of LexSubCon thus allowing it to outperform the previous state-of-the-art methods. Specifically, the results demonstrate the

Word	Sentence	Gold Ranking	LexSubCon	BERT$_{\text{based}}$
terrible	..have a **terrible** effect on the economy	awful, very bad, appalling, negative, formidable	horrible, horrific, awful	negative, major, positive
return	..has been allowed to **return** to its wild state	go back, revert, resume, regress	revert, retrovert, regress	recover, go, restore

Table 5: Examples of target words and their top lexical substitutes proposed by LexSubCon and BERT$_{\text{based}}$ model.

positive effect of the features on accurately ranking a list of potential candidates as LexSubCon outperforms the previous methods even in the scenario where they are all provided with the same substitution candidate list.

4.7 Qualitative Substitution Comparison

In Table 5, we provide different examples of target words and their top lexical substitutes proposed by LexSubCon and the BERT$_{\text{based}}$ model in order to demonstrate the effect of external lexical resources on the performance of a contextual model. As it can be observed, for the target word *terrible*, the BERT$_{\text{based}}$ model proposes a candidate word (*positive*) which may fit in the sentence but has the opposite meaning of the target word. However, LexSubCon provides semantically similar candidates by using information from different signals (e.g comparison of the definition of each word). In addition, for the target word *return*, our model identifies appropriate candidates that are not in the vocabulary of the contextual model (the word *regress*) by introducing candidates from a external lexical database. These examples showcase that enriching contextual models with external lexical knowledge can assist the model to provide more accurate candidates.

5 Extrinsic Evaluation: Data Augmentation

We evaluate the performance of LexSubCon in the context of textual data augmentation. Specifically, we conduct experiments on a popular benchmark text classification tasks of the English subjectivity/objectivity dataset (SUBJ) (Pang and Lee, 2004)[8]. The SUBJ dataset contains 5000 subjective and 5000 objective processed sentences (movie reviews). We train the LSTM model (with the same hyperparameters) which was used in (Wei and Zou, 2019) to measure the effect of different data augmentation techniques. We compare our method with previous state-of-the-art lexical substitution models and with other popular textual data augmentation techniques: (i) the back-translation technique (described in section 3.3) (ii) the EDA framework (Wei and Zou, 2019) which utilizes four operations of Synonym Replacement and Random Insertion/Swap/Deletion in order to create new text. Following the data generation algorithm in (Arefyev et al., 2020), LexSubCon creates new examples by sampling one word for each sentence, generating the appropriate substitute list for this word and sampling one substitute with probabilities corresponding to their substitute scores (which were normalized by dividing them by their sum) to replace the original word with the sampled substitute.

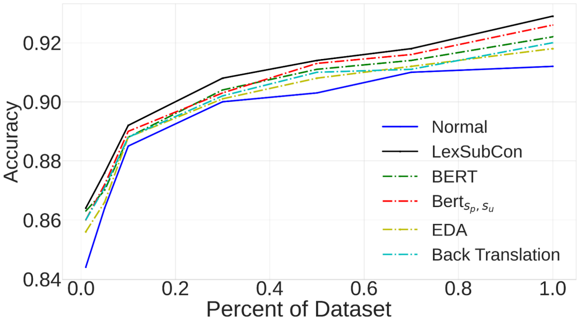

Figure 2: Accuracy with different train sizes for different text augmentation techniques on the SUBJ dataset.

Figure 2 demonstrates how data augmentation affects the classification depending on the size of the training set (Arefyev et al., 2020; Wei and Zou, 2019). As it is expected the effect of each text augmentation technique on the performance of the model becomes more significant while the size of the train set is reduced. Figure 2 also shows that the data created with lexical substitution have a more positive effect to the performance of the model than the other data augmentation techniques since back translation techniques may provide text that does not follow the syntactic rules of the target language and the EDA framework may create examples that could confuse the model by changing the structure of the sentence due the random insertion and

---

[8] license: https://tinyurl.com/t-license

swapping of words. Finally, since LexSubCon can create more accurate substitution candidates than the standard BERT model and the Bert$_{s_p,s_u}$ model, the texts that were created with LexSubCon have a more positive effect on the model's performance.

6 Conclusion

This paper presents LexSubCon, an end-to-end lexical substitution framework based on contextual embedding models. LexSubCon establishes a new mix-up embedding strategy that outperforms the previous SOTA strategy of word embedding dropout for the embedding of the target word for the task of predicting accurate candidate words. LexSubCon introduces the combined usage of features from contextual embedding models and external lexical knowledge bases in order to calculate accurately the semantic similarity between a target word and its candidates. We confirm that these features can improve the LexSubCon's performance as it outperforms other state-of-the-art results on two benchmark datasets.

As for future work, we plan to address the limitations of this study including: (i) examining the effect of using other models as the basis of our features (e.g. Albert (Lan et al., 2020)); (ii) exploring other candidate features for the ranking of the candidates (e.g. parser information (Szarvas et al., 2013a)) (iii) testing LexSubCon in datasets of other languages using multi-language lexical databases (e.g. MultiWordNet (Pianta et al., 2002) or BalkaNet (Oflazer et al., 2001)) to investigate further the model's general availability.

Ethical Consideration

Lexical substitution can be useful in various natural language processing (NLP) tasks such as textual data augmentation, paraphrase generation and text simplification. The results that we present in this paper suggest that contextual word embeddings models, such as our framework (LexSubCon), can be a valuable tool for providing accurate substitution candidates that can be further used in a variety of down-stream tasks.

We believe that there are many benefits of using our contextual embeddings models. For example, LexSubCon can be used as a data augmentation tool to provide artificial training data for tasks where the lack of sufficient training data may hurt the performance of the model. However, there are potential risks of over-relying on any lexical substitution tool. Particularly, a lexical substitution model can unintentionally change the meaning of the original text thus leading to erroneous conclusions.

Abstract

Implicit knowledge, such as common sense, is key to fluid human conversations. Current neural response generation (RG) models are trained to generate responses directly, omitting unstated implicit knowledge. In this paper, we present Think-Before-Speaking (TBS), a generative approach to first externalize implicit commonsense knowledge (*think*) and use this knowledge to generate responses (*speak*). We expect that externalizing implicit knowledge allows more efficient learning, produces more informative responses, and enables more explainable models. We analyze different choices to collect knowledge-aligned dialogues, represent implicit knowledge, and transition between knowledge and dialogues. Empirical results show TBS models outperform end-to-end and knowledge-augmented RG baselines on most automatic metrics and generate more informative, specific, and commonsense-following responses, as evaluated by human annotators. TBS also generates *knowledge* that makes sense and is relevant to the dialogue around 85% of the time[1].

1 Introduction

Human communication strives to achieve *common ground*, consisting of mutual beliefs and common knowledge (Stalnaker, 1978; Clark and Schaefer, 1989). Such common ground depends not only on utterances, but also implicit knowledge. For example, in Figure 1, this common ground includes the relevant implicit background knowledge "*rose is a type of flower*". Integrating such common ground in utterances is an implicit process often referred to as *knowledge grounding* (Clark and Brennan, 1991). Recent state-of-the-art neural response generation (RG) models based on pre-trained language models (LM) mostly produce responses in an *end-to-end* manner (Vaswani et al., 2017; Zhang et al., 2020a; Lewis et al., 2020), *i.e.*, models are trained to take history and produce a response. Since implicit knowledge is unstated in dialogue history, RG models do not explicitly learn knowledge grounding and may generate uninformative and hallucinated responses (Serban et al., 2017; Welleck et al., 2019; Roller et al., 2021). Knowledge-grounded RG (Ghazvininejad et al., 2018; Dinan et al., 2019; Gopalakrishnan et al., 2019) addresses this issue, however, most approaches require a knowledge base (KB) to *retrieve* knowledge for RG (Zhou et al., 2018; Zhao et al., 2020; Eric et al., 2021), which may suffer from the limited knowledge coverage of the used KBs. Some work also casts knowledge as a *latent* factor in generation (Tuan et al., 2020; Xu et al., 2021), which makes it hard to examine the quality of knowledge generation and how *exactly* RG uses the implicit knowledge, posing interpretability concerns.

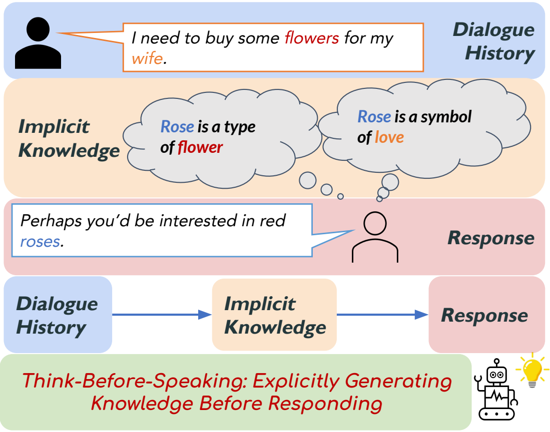

Figure 1: **A motivating example for our study.** We look to train models to externalize the implicit knowledge grounding step by explicitly generating knowledge before responding.

We propose *Think-Before-Speaking* (TBS), an RG framework that trains the RG model to *explicitly generate* the implicit knowledge and use this knowledge to generate a response, inspired by inquiry-based discovery learning (Bruner, 1961).

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 1237 - 1252
May 22-27, 2022

We argue that this decomposition brings three major benefits: 1) compared with end-to-end RG, generated knowledge *augments* and/or *constrains* RG to produce more informative responses; 2) compared with knowledge-retrieval models, *explicitly generating* intermediate groundings can potentially generalize to knowledge not included in KBs and synergize with the RG process; 3) explicitly generated implicit knowledge used in RG provides a faithful explanation of the response intent.

This new RG paradigm poses three main challenges: (1) how to *identify* implicit commonsense knowledge associated with dialogue turns for training the knowledge generation module; (2) how to *represent* structured knowledge in natural language (NL) for neural generative models; and (3) how to *integrate* knowledge and dialogues while *distinguishing* implicit and explicit parts in responses. To collect knowledge associated with each dialogue instance for training the TBS generative model, we propose weak supervision procedures to automatically align knowledge with each dialogue turn, rather than manually collecting human-annotations, which is expensive and unscalable. This is achieved by using ConceptNet (Speer et al., 2017) as our knowledge base and different matching approaches to identify the implicit knowledge. We explore several ways to *format* knowledge originally represented as structured triples into natural language so that RG models can adapt to the *knowledge+response* generation task easily. We experiment with structured triples, triples converted to natural language, and a more colloquial question answering format. To ensure a smooth transition between knowledge and dialogues, we consider using special symbols or prompts as separators.

To evaluate the TBS framework, we introduce new evaluation protocols to cover different aspects of the system, including response quality, knowledge quality, and how TBS models leverage generated knowledge. We conduct extensive human evaluations for different variants of our training procedure. Our experimental results show that our models produce more informative, specific, and responses that make more common sense compared to end-to-end RG models and other knowledge-augmented models such as knowledge-selection. Knowledge quality analysis shows that at least 85% of generated knowledge makes sense and is relevant, and the generated novel knowledge (not in ConceptNet) also has high quality. Furthermore, our TBS model even outperforms an RG model that takes in knowledge obtained using *ground-truth* responses, showing that explicitly generating implicit knowledge is a promising direction for response generation in open domain dialogue systems.

2 Problem Formulation

Our TBS RG paradigm extends the traditional RG setting by incorporating an additional component of *implicit knowledge* in the generation process to externalize the knowledge grounding step in RG.

2.1 Response Generation

We follow the common dialogue response generation setup (Weizenbaum, 1966; Ritter et al., 2011; Sordoni et al., 2015): given a dialogue *history* H (a sequence of dialogue utterances), generate an appropriate *response* R. Current neural RG models often frame this task as a *conditional language modeling* problem. Specifically, given a *history* (H) consisting of a sequence of n dialogue turns: $X_1, X_2, ..., X_n$ (each turn refers to an utterance containing a sequence of t_i tokens: $x_{i,1}, x_{i,2}, ..., x_{i,t_i}$) and a *response* (R) sentence Y comprised of a sequence of m tokens $y_1, y_2, ..., y_m$, RG models aim to learn the conditional probability distribution by training on human dialogues:

$$P_\theta(R|H) = \prod_{i=1}^{m} P_\theta(y_i|y_{<i}, X_1, ..., X_n). \quad (1)$$

2.2 Implicit Knowledge Generation

To make the implicit knowledge grounding step explicit, we introduce a new component to RG – implicit knowledge that is *conditioned on* the dialogue history H. We use I to denote the implicit knowledge for brevity, which contains multiple natural language (NL) statements $I = Z_1, Z_2, ...$ (each containing a sequence of tokens: $z_{i,1}, z_{i,2}, ...$) expressing commonsense knowledge. For example, in Figure 1, "*rose is a type of flower*" and "*rose is a symbol of love*" are two NL statements expressing the implicit commonsense knowledge. To emulate realistic conversation scenario, we also *fuse* dialogue history H in traditional RG with implicit knowledge I for each turn and denote it with H'. i.e. $H' = X_1, I_1, X_2, I_2..., X_n$, where I_i indicates the implicit knowledge statements for the i-th turn in the dialogue history.

To externalize the knowledge grounding step, inspired by how humans communicate and inquiry-based learning (Bruner, 1961; Shwartz et al., 2020a), our TBS RG paradigm requires models to first *generate* implicit knowledge I conditioned on H', *i.e.* $P_\theta(I_n|H' = X_1, I_1, X_2, I_2..., X_n)$.

3 Learning to Generate Implicit Knowledge by Self-Talk

This section introduces our proposed TBS method to train a generative model that can *both* talk with itself to explicitly generate background commonsense knowledge ($P_\theta(I|H')$) and then generate response afterwards, $P_\theta(R|H', I)$. Figure 2 illustrates the process to train the TBS models. To pair each dialogue with appropriate implicit knowledge, we first define a *matching process* and use ConceptNet (Speer et al., 2017) as the implicit knowledge source (Section 3.1). Then, to construct training instances, we face two key method design choices: how to represent knowledge (3.2) and how to connect the knowledge with the dialogue (3.3). Finally, we train TBS RG models to learn $P_\theta(I|H')$ and $P_\theta(R|H', I)$ with the same parameters θ. The following sections explain these components in details.

3.1 Knowledge-Aligned Dialogues

To train TBS models we need dialogue datasets consisting of a dialogue history, a response, and the knowledge statement connecting them. We focus on two methods that create *weakly-supervised knowledge labels* for dialogues as they are more scalable and cost less than human annotations.

Hard-Matching The hard-matching process first *lemmatizes* all the non-stop words in each utterance, then it identifies knowledge triples whose two concepts appear in an utterance and the next turn respectively. This is the same as the filtering process in Zhou et al. (2021a) and is closely related to distant supervision methods for relation extraction (Craven et al., 1999; Mintz et al., 2009). For more details, refer to Appendix A.1.

Soft-Matching Using Embedding Similarity Hard-matching only captures the surface form and neglects many important semantic relations between words. We thus develop a soft-matching procedure using embedding similarity from SentenceBERT (Reimers and Gurevych, 2019) to measure semantic relations between dialogue turns and triples in ConceptNet. Specifically, we first extract candidate triples from ConceptNet with one concept appearing in the i^{th} turn. Next, we form a *query* by concatenating the i^{th} turn and the next $(i+1)^{th}$ turn response. Finally, we encode the query and all triple candidates using SentenceBERT and use cosine similarity to find the semantically closest triples as matched knowledge. More details are presented in Appendix A.1.

3.2 Knowledge Representation

Implicit commonsense knowledge I stored in ConceptNet is in the form of *(subject* s*, relation* r*, object* o*)* triples, such as *(rose, TypeOf, flower)*, which is not compatible with RG models, which operate on NL sentences and may not include relation tokens in their trained vocabulary. Here we design two alternatives to represent the grounded knowledge and use the implicit knowledge in Figure 1 as a running example.

Map Relations to Natural Language (NL) To convert ConceptNet triples into NL, we follow a common practice and map every relation r in the triple to its NL template, and fill in s and o in the template (Levy et al., 2017). We use the same mapping as that used in COMET (Bosselut et al., 2019), covering all standard types of relations in ConceptNet. For example, *rose is a type of flower; rose is a symbol of love*.

Information-Seeking Question-Answer Pairs Another format to convert triples to NL sentences is through asking and answering information-seeking questions. Shwartz et al. (2020b) designed templates of information-seeking questions and answers to provide background knowledge for LMs. We adopt a similar strategy and design a template for each relation in ConceptNet. For example, *What is a type of flower? Rose is a type of flower. Rose is a symbol of what? Rose is a symbol of love*. The mappings we use for these two types of representations are shown in Appendix A.2.

3.3 Knowledge-Dialogue Transition

To help our RG models learn the TBS paradigm and generate outputs structured similarly, i.e., implicit knowledge first and then responses, we need to properly connect knowledge and dialogues in our data. Here we consider two alternatives for creating such a transition.

Special symbols. Following the common practice of separating sequences in neural LMs (Radford et al., 2018; Devlin et al., 2019), we use a

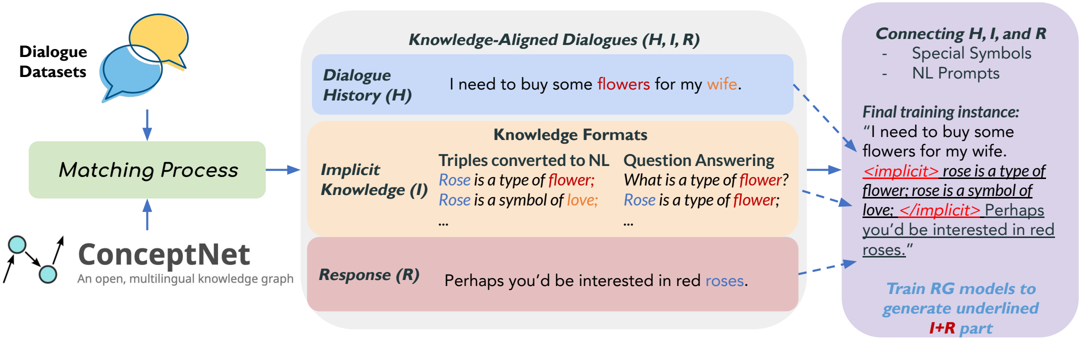

Figure 2: **Method illustration.** We first propose matching approaches to construct *knowledge-aligned dialogues*. Then we consider different alternatives to represent implicit knowledge. Finally, we connect knowledge and dialogue and ask models to generate both knowledge and responses given history.

special symbol to serve as the separator. We enclose the implicit knowledge I with special symbols "<implicit>" and "</implicit>" and add it between H' and R, for example, "*<speaker1> I need to buy some flowers for my wife. <implicit> rose is a type of flower </implicit> <speaker2> Perhaps you'd be interested in red roses.*"

Natural language prompts. More recent work has found that NL prompts help LMs to perform better on various downstream tasks, including natural language generation (NLG) (Brown et al., 2020; Liu et al., 2021; Zheng and Huang, 2021). Here we use the NL prompts to prompt RG models to *generate* implicit knowledge and responses. We use "*The following background knowledge is helpful for generating the response:*" to elicit knowledge and "*Grounded on the background knowledge, what does the speaker probably say in the next response?*" to elicit response.

3.4 Model Training

After constructing knowledge-aligned dialogues, each of our data instances is a sequence of tokens with three components: a dialogue history H' fused with potential implicit knowledge after each turn, implicit knowledge (empty or non-empty) I, and a response R. We split each instance $d(H', R, I) \in D$ to first train the model to generate just the knowledge I based on H', $P_\theta(I|H')$, and then train it to generate R based on both I and H', $P_\theta(R|H', I)$.

Formally, we follow standard way of modeling P_θ in auto-regressive neural RG models and use Maximum Likelihood Estimation (MLE) to train our model to maximize $P_\theta(I|H')$ (knowledge generation KG) by minimizing the conditional negative log-likelihood loss (NLL):

$$\mathcal{L}_{KG} = -\sum_{i=1}^{m} \log P_\theta(Z_i|Z_{<i}, X_1, ..., X_n),$$

where Z_i is the i-th statement in I. And to model $P_\theta(R|H', I)$ we minimize:

$$\mathcal{L}_{RG} = -\sum_{i=1}^{m} \log P_\theta(y_i|y_{<i}, X_1, I_1..., X_n).$$

We train one generative model on these losses in one-pass with splitted instances for KG and RG instead of multiple training phases. During inference, we only provide dialogue history as input and the model has to generate knowledge and responses.

4 Experiment Setup

4.1 Dataset

We consider dialogues from four datasets: DailyDialog (Li et al., 2017), EmpatheticDialogues (Rashkin et al., 2019), MuTual (Cui et al., 2020), and SocialIQA-prompted Commonsense-Dialogues (Zhou et al., 2021a). For training, we use the filtered version of the four datasets from Zhou et al. (2021a), which ensures each dialogue contains at least one commonsense knowledge triple from ConceptNet. In total, the training data contains 31k dialogues with 159k utterances. We reserve 10% of data as a development set for evaluating model training and selecting hyperparameters. Table 1 shows the number of instances resulted from applying our hard- and soft-matching procedures to our training data in order to construct knowledge-aligned dialogues.

For testing dialogues, to not bias our evaluation toward where common sense is crucial in making

	# Instances	Avg # turns	Avg # knowledge
Dialogues-Only	159k	4.3	0
Hard-match	57k	4.5	1.4
Soft-match	71k	4.6	2.8

Table 1: Dialogue data statistics.

the response, we use the test data from the *original data distribution* of the 4 datasets mentioned above. The testing data consists of around 3k dialogues.

4.2 Compared Methods

We use DialoGPT-medium (Zhang et al., 2020a) as our base model, which is a commonly-used end-to-end RG model. We fine-tune **DialoGPT** using all of the 159K dialogue instances. We also use DialoGPT to serve as the backbone model and consider three variables in our TBS model configuration introduced from Sections 3.1 to 3.3: **hard**-matching or **soft**-matching, special **symbol** as separator or NL **prompt**, and triple-converted-**NL** to represent knowledge or information seeking **QA** pairs. To justify our choice of using one model to do both KG and RG, we also compare with **TBS-Two Model** where we train separate models for knowledge generation (KG) and RG using the same training data. Our default model configuration is *hard-symbol-NL*.

We also compare several knowledge-grounded RG baselines that *retrieve* external knowledge or *generate* knowledge with another model. For retrieval, we follow most common approaches in knowledge-selection (Zhao et al., 2017; Wolf et al., 2020; Eric et al., 2021) and train RoBERTa (Liu et al., 2019) to classify triples using our knowledge-aligned data (matched or not matched), and use it to label candidate triples during testing (**KS-RoBERTa**). For the generative model, we use COMET (Bosselut et al., 2019) as a commonsense knowledge generator (**KG-COMET**).

Furthermore, we consider RG models that take the hard-matched or soft-matched knowledge obtained from the *ground-truth response* (**Hard-GT** and **Soft-GT**). Note that though there is noise in hard-matching or soft-matching procedure, this setting uses the next turn response and is likely to provide relevant knowledge. Implementation details for all the models are shown in Appendix B.1.

4.3 Evaluation Protocol

Automatic Evaluation We use standard natural language generation metrics such as BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), ROUGE (Lin, 2004), CIDEr (Vedantam et al., 2015) and SkipThoughts (Kiros et al., 2015). We also use GRADE (Huang et al., 2020), a reference-free metric shown to have consistent correlation with human judgements (Yeh et al., 2021) to ensure the validity of experimental results.

Human Evaluation We conduct extensive human evaluation using 300 randomly sampled instances from unseen test dialogues described above. For **response quality**, we conduct *pairwise comparison* where we present a dialogue history and two responses made by two different models and ask them to choose one or select "*not sure*" based on different criteria (Zhou et al., 2018; Zhang et al., 2020b)[2]. We evaluate on *six* dimensions: which response is more *grammatical*, *coherent*, *engaging*, *informative*, *specific*, and *makes common sense* (Zhang et al., 2020b; Roller et al., 2021). More details of the instructions for annotators on each dimension with examples are included in Appendix B.2. For **knowledge quality**, we evaluate the generated knowledge in isolation ("*does this knowledge make sense*") and in conjunction with the context for relevance. We perform majority voting per instance using three annotators from Amazon Mechnical Turk (AMT). We use Fleiss' Kappa (κ) (Fleiss, 1971) to measure agreement among the annotators.

5 Results

By evaluating our TBS model variants with other baselines, we aim to address the following questions: 1) do TBS models produce better responses than standard end-to-end RG models? 2) compared with other approaches to retrieve or generate additional knowledge, is TBS more helpful for RG? 3) do TBS RG models generate knowledge that makes sense and is relevant to the dialogue context? 4) do TBS models faithfully leverage the generated knowledge?

5.1 Performance of Response Generation

Model variant analysis To find the best-performing configuration of our TBS method, we consider alternatives as discussed in Sections 3.1 to 3.3, and conduct 4 pairwise comparisons: *soft* vs.

---

[2] We choose to conduct pairwise comparison since multiple previous work has shown that it produces a more reliable evaluation than directly asking humans to score the response, which is a highly subjective task (Amidei et al., 2019; Callison-Burch et al., 2007; Celikyilmaz et al., 2020)

Model Variants	Grammatical	Coherent	Engaging	Informative	Specific	Common Sense	**Avg**
TBS-**soft**-symbol-NL	**53.0/10.0%**	46.3/8.7%	48.7/9.3%	41.7/20.6%	51.7/6%	**52/7%**	50.5/10.3%
TBS-hard-**prompt**-NL	50.3/4%	49/7.3%	47/9%	49.4/6%	51/3%	48.3/2.7%	49.2/5.3%
TBS-hard-symbol-**QA**	**53/6.7%**	**53.6/5.6%**	51.3/4.7%	51.3/3.7%	51.3/5%	**54/3.7%**	**52.4/4.8%**

Table 2: Human evaluation on **response quality** when comparing different model variants. We show the percentage of times annotators prefer each variant to *TBS-hard-symbol-NL* and ties, *i.e.* wins/ties%. Bold-faced numbers indicate statistical significance ($p < 0.05$) improvement.

Models	**GRADE**	BLEU-1	BLEU-2	BLEU-3	BLEU-4	METEOR	ROUGE-L	CIDEr	SkipThoughts
DialoGPT-ft (Zhang et al., 2020b)	0.704	0.060	0.026	0.013	0.007	0.061	0.076	0.087	0.700

KG-COMET (Bosselut et al., 2019)	0.648	0.080	0.032	0.015	0.007	0.069	0.076	0.069	0.690
TBS-Two Model	0.722	**0.091***	0.033	0.014	0.006	0.070	0.073	0.054	0.677
TBS	**0.739****	**0.091***	**0.037**	**0.020**	**0.012**	**0.075***	**0.084***	**0.087***	**0.703**
Hard-GT	0.702	**0.091**	0.035	0.017	0.008	**0.075**	**0.084**	0.086	0.696
Soft-GT	0.642	0.070	0.024	0.011	0.005	0.063	0.069	0.053	0.680

Table 3: Automatic evaluations using multiple metrics on **response quality**. All models are based on DialoGPT-medium. Bold-faced are the best performance. One "*" indicates statistical significant ($p < 0.05$ in Wilcoxon signed-rank test) improvement upon the best-performing non-GT baseline and "**" indicates significant improvement upon the GT baselines.

hard, *prompt* vs. *symbol*, and *QA vs. relation-converted NL format*. From Table 2, we find that using soft-matching to create knowledge-aligned dialogue dataset produces more grammatical responses and responses that make more common sense, with κ=0.64-0.73, indicating substantial agreement according to one interpretation from Landis and Koch (1977). Using QA to represent knowledge makes the responses more grammatical, coherent, commonsensical, and also achieves the best performance on average on six dimensions. We also compare results that combine these alternatives, *e.g., soft-symbol-QA* (due to space constraints, results are shown in Appendix C.1), however, we do not observe significant improvements after combining these alternatives and our best configuration in terms of average improvement is still *hard-symbol-QA*. We thus use *hard-symbol-QA* as our final configuration and refer to it as *TBS* throughout this section.

Does TBS produce better responses vs. end-to-end RG? By comparing TBS and *end-to-end* DialoGPT-ft model in Table 3 and Figure 3, we find that TBS models produce better-quality responses using both automatic and human evaluations. Specifically, even though hard-matching only annotates about 33% of the training instances, TBS outperforms end-to-end RG model significantly on most automatic metrics. From human evaluation (κ=0.62-0.69), we find our TBS model performs on par with DialoGPT trained on more data in grammar, coherence, and engagingness, and achieves statistically-significant ($p< 0.05$) improvement on informativeness, specificity, and the common sense aspects of generated responses[3]. We argue that by providing weakly-supervised knowledge labels and TBS training, RG models require less data and can generate quality responses with improvement in the informativeness, specificity, and common sense aspects of the responses.

Is TBS knowledge generation better than other knowledge-augmented RG? We compare TBS models with other knowledge-augmented baselines that retrieve knowledge from ConceptNet using embedding scores (KS-SBERT) or a trained selector (KS-RoBERTa), or generate from *another* model (KG-COMET). From Table 3, we find that these models perform similarly to the end-to-end DialoGPT model and are outperformed by TBS models on most automatic metrics. Figure 3 shows that while TBS methods have significant improvements on all dimensions against knowledge-selection baselines, COMET as a knowledge generator has smaller gaps on informativeness, specificity, and common sense, but is outperformed significantly on grammar, coherence, and engagingness.

Next we compare against the setup where we feed the model the knowledge that is derived using the *ground-truth* response (Hard/Soft-GT), *i.e.*, the provided knowledge is obtained using concepts appearing in the ground-truth response. From Table 3, we surprisingly find that even though our

---

[3] We also conducted direct scoring in human evaluations and observed significant improvement (on average 7.3 out of 10 for TBS vs. 5.9 for DialoGPT-ft), but since it results in lower agreement (κ=0.49), we focus on comparative evaluation.

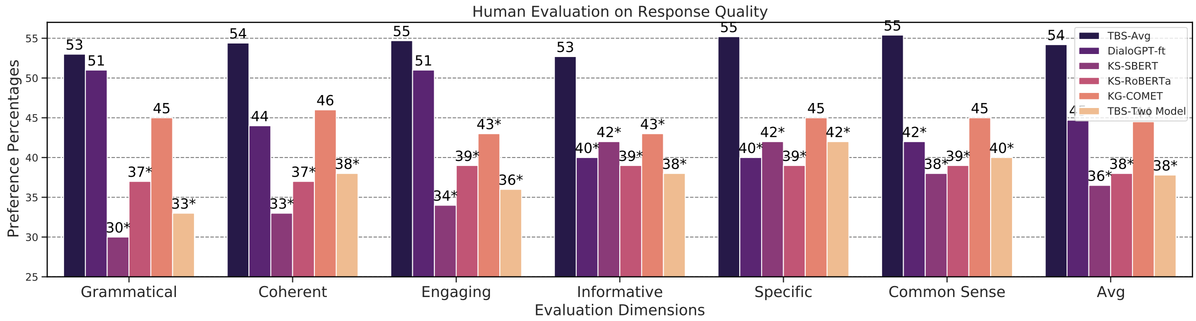

Figure 3: **Human evaluation results** for pairwise comparison between TBS and a baseline. We show preference percentages for each model. "*" indicates statistical significance difference. For TBS we show averaged preferences.

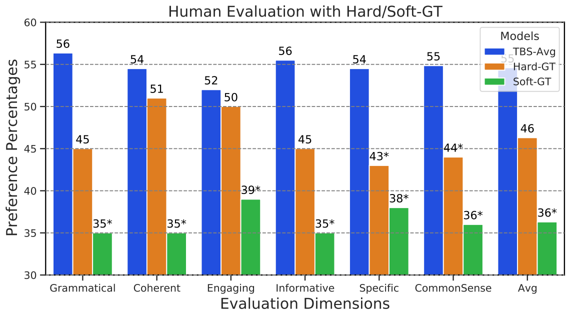

Figure 4: **Human evaluation** comparing TBS with models that have access to *ground-truth* responses.

Model	Novel	Makes Sense	Relevant
KS-SBERT	0%	91.7%*	85.0%
KS-RoBERTa	0%	77.7%*	76.3%
KG-COMET	63.3%	68.3%/63.2%	67.5%/68.9%
TBS-two-model	46.3%	89.0%/85.6%	90.7%/90.2%
TBS-one-model	44%	86.3%/85.9%	85.7%/86.5%

Table 4: Human evaluation on **knowledge quality**. For models that generate novel (not in ConceptNet) knowledge, we show *non-novel/novel* percentages. "*" means knowledge is from ConceptNet (not generated).

proposed TBS model has no access to response-leaking knowledge labels and is trained on much less data, the TBS RG model still achieves statistically significant improvement on GRADE and BLEU-4. And from human evaluation results in Figure 4, TBS model significantly improves the specificity and common sense aspect of responses while stays on par on other evaluation dimensions compared with the hard-GT model and improves even more compared with soft-GT. We find that one potential explanation is that only around 55% of Hard-GT knowledge is labeled as *used in response* whereas it is 77% in our TBS model (see Section 5.3). This is also related to how the RG model leverages the knowledge in training. Further analysis is needed to understand the effect of knowledge and the relationship between knowledge and responses.

5.2 Quality of Generated Knowledge

We then examine how well TBS RG models learn to generate knowledge on unseen dialogues. We use human evaluation and focus on three dimensions: does the model generate *novel* knowledge that does not appear in ConceptNet? does the generated knowledge statement *make sense* as a standalone fact? and is the generated knowledge *relevant* to the dialogue context? For the first question we directly query from ConceptNet and show percentages. For the latter two we follow Section 4.3 and show the percentages that MTurkers think the knowledge makes sense and is relevant from the 300 sampled test instances (the same used in response quality). We test our TBS model, the two-model variant, and other knowledge-augmented baselines introduced in Section 4.2.

Around 85% of knowledge generated from TBS makes sense and is relevant Table 4 shows that TBS models can generate implicit knowledge that makes sense and is relevant to the context for around 85% of the time as judged by human annotators (κ=0.73-0.80). Compared with knowledge-selection models that retrieve knowledge from ConceptNet, TBS generates knowledge that is similar in terms of common sense and has better relevance to the dialogue history. Compared with COMET that also generates knowledge, we find TBS models generate more knowledge that follows common sense and is relevant to the dialogue. Comparing two-model and one-model TBS, we find that two-model generates more knowledge that makes sense and is relevant, although its response quality is poorer (Table 3 and Figure 3). This might be due

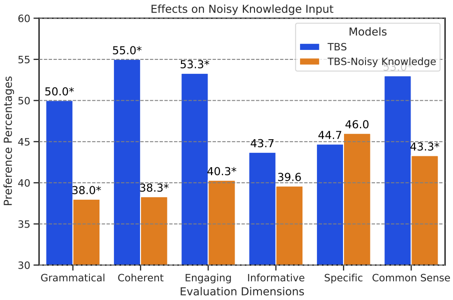

Figure 5: Effects of **noisy knowledge** on response quality.

to model synergies when learning both knowledge generation and response generation.

Model generates *novel* knowledge We find a significant portion of *novel* knowledge generated from the COMET and TBS models that is not present in the training data. Furthermore, the quality of the generated novel knowledge is similar to that of knowledge existing in ConceptNet. COMET generates more new knowledge but the quality (both common sense and relevance) is significantly lower than TBS models. We include some examples of novel knowledge generated in Appendix C. In general we find that the new knowledge is complimentary to ConceptNet, not just a paraphrased version of existing triples (since in those cases the model will directly generate the ConceptNet triple). This shows a promising sign that TBS RG models can potentially generate good-quality novel knowledge labels for unseen dialogues.

5.3 Performance Analysis

Most responses are knowledge grounded To examine how TBS methods leverage knowledge for RG, we also present annotators a history, generated knowledge, and generated response, and ask them whether the knowledge is *used in response*. We find that around 77% of generated knowledge is used in the generated response, *i.e.*, the response is *grounded* in the knowledge generated from TBS.

Noisy knowledge heavily impacts quality To better showcase the connection between knowledge and response, we examine how knowledge quality generated from TBS methods can affect response quality. During inference, we randomly sample *noisy knowledge* from another dialogue, feed it to the model to generate a response conditioned on irrelevant knowledge, and compare the response quality with response generated from TBS knowledge. Fig 5 shows that there is a statistically significant ($p \leq 0.05$) drop in response quality in four dimensions. This indicates that the quality of knowledge input heavily influences response quality and that TBS models generate better responses because of its decent knowledge quality.

Qualitative examples and limitations We show several qualitative examples from different models and human responses in Table 5. We find that TBS generates relevant knowledge and responses grounded properly in that knowledge, whereas KS/KG models retrieve noisy knowledge and Hard-GT generates response not grounded in knowledge.

Here we present a summary of error patterns of TBS models and discuss potential directions to improve. More examples can be found in Table 6. First, our matching procedures do not concern multi-hop triples that might be needed for complex reasoning chains. Second, ConceptNet mostly contains taxonomic and lexical knowledge ("*RelatedTo, IsA, etc*"), limiting the diversity of generated knowledge from TBS models. We plan to explore other knowledge resources such as ATOMIC2020 (Hwang et al., 2021) in the future. Third, currently the model always generates implicit knowledge. In future work, we are interested in training RG models that understand *when* implicit knowledge is needed based on the dialogue context.

6 Related Work

Open-Domain Dialogue Generation Recent work focused on fine-tuning large pre-trained transformer models (Radford et al., 2019; Zhang et al., 2020a; Roller et al., 2021) on massive dialogue data. Knowledge-augmented RG has been studied extensively to alleviate the issue of generic or hallucinated responses (Serban et al., 2017; Welleck et al., 2019; Roller et al., 2021). Most work retrieves relevant knowledge from knowledge candidates (wikipedia or KBs) and generates responses after incorporating additional knowledge in dialogue context (Ghazvininejad et al., 2018; Zhou et al., 2018; Wu et al., 2020). More recent work also explored other ways of constructing knowledge, such as by considering knowledge as a latent variable (Tuan et al., 2020; Li et al., 2020) and generating it implicitly. Our TBS framework differs from these two lines of work in that it *explicitly generates* knowledge in text and uses one generative model for both knowledge generation and RG.

Dialogue History		A: My last day of work was yesterday. I got so emotional driving home and I cried. B: I'm sorry to hear you were upset! Why did you have to quit? A: I'm going back to school full time. I was there for more than 10 years. I will miss everyone.	A: I am calling friends to let you know that I am moving out of state. B: What happened? Why? A: I got a new job.
Human Response		B: Wow that is a long time! Hopefully you can stay in touch with all of your former coworkers.	B: It must pay well for you to move.
DialoGPT-ft		B: That's a long time. I bet you'll miss your friends.	B: I am not sure where I want to live.
TBS	Gen. Knowledge	*What is school related to? school is related to college;*	*What is job related to? job is related to work;* *What is pay related to? pay is related to job;*
	Response	B: I'm sorry to hear that. I hope you have a good college experience!	B: Oh wow! Will they pay you a lot?
KS-RoBERTa	Retr. Knowledge	*year is related to book; angry is a synonym of upset;* *cry is related to upset;*	*move is an antonym of easy; move is related to leave;* *move is related to change;*
	Response	B: You're not alone in that. I'm sorry you had to go through that.	B: I am sure you will be able to make it work.
KG-COMET	Gen. Knowledge	*I will miss everyone causes sadness*	*I got a new job causes work*
	Response	B: I'm sure you will. I'm sure you'll do great.	B: I'm so sorry! I hope you are able to get a new job!
Hard-GT	Hard-Matched Knowledge	*year is related to long; long is related to miss;* *long is related to full*	*pay is related to job*
	Response	B: I know the feeling. I'm going back to school too.	B: I am sorry to hear that. I hope you find a better job.

Table 5: Randomly sampled qualitative examples from our TBS model (TBS-hard-symbol-QA).

Dialogue History	**Generated Knowledge**	**Generated Response**
<speaker1>My last day of work was yesterday. I got so emotional driving home and I cried. <speaker2>I'm sorry to hear you were upset! Why did you have to quit? <speaker1>Im going back to school full time. I was there for more than 10 years. I will miss everyone.	What is school related to? school is related to college;	<speaker2>I'm sorry to hear that. I hope you have a good college experience!
<speaker1>I am calling friends to let you know that I am moving out of state. <speaker2>What happened? Why? <speaker1>I got a new job.	What is job related to? job is related to work; What is pay related to? pay is related to job;	<speaker2>Oh wow! How long will you be working there?
<speaker1>There was something moving in the woods. I looked out of the hunting shack and saw movement so I grabbed my gun.	What is move related to? move is related to change;	<speaker2>Did you change your mind?
<speaker1>I love all of you guys! This was the most special performance that I have ever had because of you all!	What is happy related to? happy is related to special;	<speaker2>Awww, you're so happy. It's always nice to see a happy couple.
<speaker1>Two years ago, I discovered that my now ex-wife was cheating on me with someone she worked with. When I first discovered it, i was angry and hurt. <speaker2>I bet you were, I did that to my husband when I was young. I thought it was the solution to relief from abuse.	What is man related to? man is related to young; What is young? young is a man; What is man related to? man is related to woman;	<speaker1>Yeah, I was so angry and hurt, I thought I was going to be physically ill or something.

Table 6: Randomly sampled qualitative examples from TBS-hard-symbol-QA. We can find that in most cases the generated knowledge makes sense and responses are grounded in the knowledge and not generic. However, we do find some error cases such as the last example the response does not use the knowledge.

Generating Knowledge for Natural Language Understanding (NLU) Although explicit knowledge generation (KG) for RG has not been explored, similar methods have been proposed for NLU tasks such as question answering (Shwartz et al., 2020b). Previous work has also explicitly generated *rationales* that can be seen as helpful additional knowledge (Rajani et al., 2019). TBS differs from such work in that we consider a generative task and use the same generative model to do both KG and RG.

7 Conclusion

Inspired by how humans contribute to the common ground during communication, We propose to train RG models that explicitly generate implicit knowledge and then respond (TBS). This brings us three main benefits compared with prior end-to-end RG models: 1) more informative and coherent responses by augmenting with knowledge; 2) generated knowledge provides faithful explanations of RG model's inner-workings; 3) models do not rely on external knowledge bases in response generation time. We first identify implicit knowledge in dialogues, explore different knowledge representation and transition choices, and demonstrate promising results compared with end-to-end and knowledge-grounded RG models from extensive evaluations. We find strong and promising results for TBS RG model compared with end-to-end RG. In particular, TBS can produce good quality and novel knowledge, outperform end-to-end RG models despite training on less data, and even produce better responses than RG models that take ground-truth knowledge. We hope our findings encourage more future studies on making RG models better emulate human communication process and produce better-quality responses.

Ethics and Broader Impact

Our work aims to train RG models that explicitly generate implicit knowledge before responding. Sheng et al. (2021) have found biases in DialoGPT (our base model) responses and Mehrabi et al. (2021) have found representational harms in common sense resources. We acknowledge that the generated responses from our models might contain biases. All of the dialogue datasets and models are in English, which benefits English speakers more. We have conducted human evaluation using Amazon Mechanical Turks. We pay turkers around $15 per hour, well above the highest state minimum wage and engage in constructive discussions if they have concerns about the process. We also give each annotation instance enough time so that we do not pressure annotators.

A TBS Framework Details

A.1 Matching Detail

Hard-Matching This process follows that used in Zhou et al. (2021a). We first identify potential candidates for concepts in ConceptNet (Speer et al., 2017). For each utterance, we use a part-of-speech (POS) tagger to find the nouns, verbs, and adjectives that are not stopwords and then construct a set of potential concepts by including the lemmatized version of these words. The POS tagger, lemmatizer, and stopword list are from the Natural Language Toolkit (NLTK) package (Bird et al., 2009). This step results in a set of concept words for *each turn* of a dialogue.

With a set of concepts we extract for every dialogue turn, we then identify a list of candidate triples (e_1, r, e_2). We use the ConceptNet containing single-word concepts pre-processed by Zhou et al. (2018). For each concept we identified in a turn, we store all triples in ConceptNet that contain this concept, either as subject or object.

After getting a list of commonsense triples (e_1, r, e_2) containing concepts in a particular turn using ConceptNet, we next examine if any of the *other* entity in the triples appears in the concept set of the next turn. If we find such a match, we record this triple to be a commonsense assertion that might be implied in the response.

Soft-Matching We reuse the first several steps of hard-matching to find a set of candidate triples for each dialogue turn, then instead of searching for the exact words in the next turn, we use embedding similarity from SentenceBERT (Reimers and Gurevych, 2019) (specifically the "*all-MiniLM-L6-v2*" variant, which is claimed to be a "All-round model tuned for many use-cases. Trained on a large and diverse dataset of over 1 billion training pairs")[4].

To select the final matched knowledge, we choose the top 3 triples from ConceptNet with the highest similarity. After examining the distribution of embedding similarities from SBERT, we also require the similarity to be above 0.4 to be matched to ensure quality matching.

A.2 Mappings

We show complete mappings of relations from ConceptNet for both relation-converted NL and information-seeking QA pairs in Table 7.

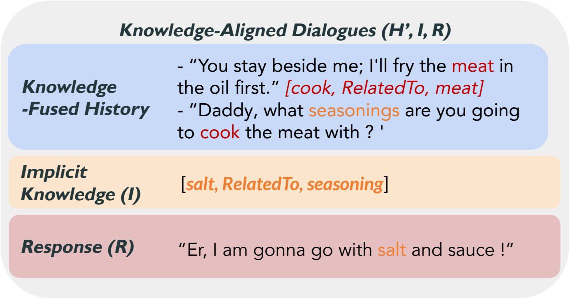

Figure 6: **Data example.** We align implicit knowledge from ConceptNet (Speer et al., 2017) between dialogue turns and form each instance in three components.

B Experimental Details

B.1 Implementation Details

We use base models from HuggingFace[5] and implement TBS based on TransferTransfo (Wolf et al., 2019)[6]. We fine-tune the model for 3 epochs with batch size 4 and set the learning rate to be 6.25e-5. We perform gradient accumulation for 8 steps and gradient clipping with a max norm of 1.0 and optimize using the Adam optimizer. For decoding, we use top-p nucleus sampling (Holtzman et al., 2019) with temperature T (p = 0.9 and T = 0.7), and a maximum decoding length of 300 tokens. Note that since we are also generating knowledge, this maximum length is larger than normal RG models. Our TBS models are mostly trained on 4 Quadro RTX 8000 GPUs and take around 5 hours. For automatic metrics, we use the nlg-eval package[7] and the GRADE repo[8].

B.2 Evaluation Detail

We present the MTurk interface we use for response quality and knowledge quality evaluation in Figures 7, 8, and 9 including instructions and examples. We require turkers to have at least 500 numbers of HITs approved, with approval rate higher than 95%, and from either Canada, UK, or US since our data is in English.

C Additional Results

C.1 Models Combining Variants

Table 8 presents the complete results considering all of our models' variants. We find that the best overall configuration is hard-symbol-QA.

C.2 CEDAR Probing: Do TBS models understand why a response makes sense?

We follow the CEDAR probing framework from Zhou et al. (2021b) that analyzes if RG models assign a higher probability to the response when provided with valid common sense in the form of explanations compared to corrupted explanations. Results comparing to an end-to-end RG model and a knowledge-selection model are shown in Table 9. We find that by TBS training, RG models become much more sensitive to commonsense explanations against complete corruptions but still fall short against more subtle logical corruptions that require deeper reasoning.

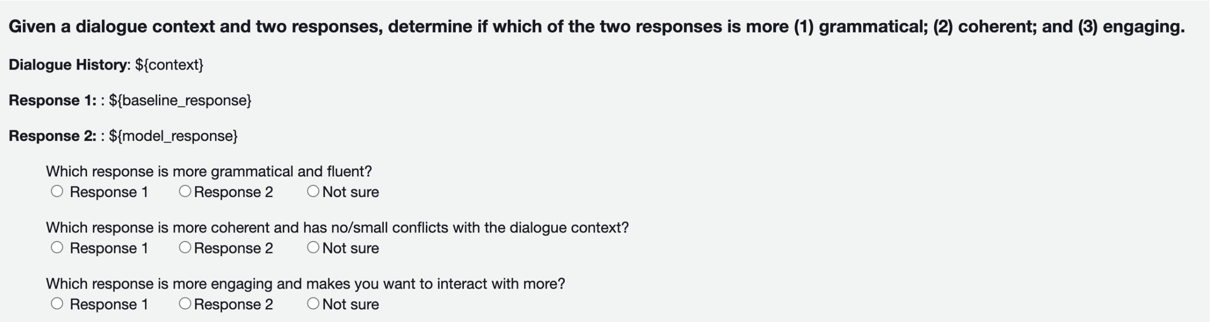
[6] `https://github.com/huggingface/transfer-learning-conv-ai`

[7] `https://github.com/Maluuba/nlg-eval`

[8] `https://github.com/li3cmz/GRADE`



Given a dialogue context and two responses, determine if which of the two responses is more (1) grammatical; (2) coherent; and (3) engaging.

Dialogue History: ${context}

Response 1: : ${baseline_response}

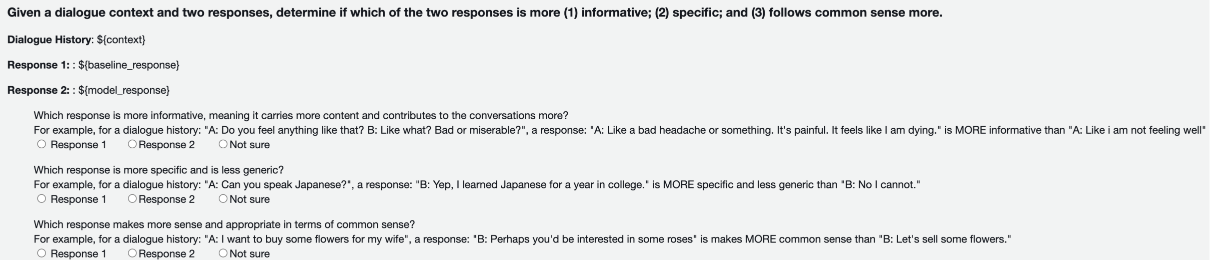
Response 2: : ${model_response}

Which response is more grammatical and fluent?
○ Response 1 ○ Response 2 ○ Not sure

Which response is more coherent and has no/small conflicts with the dialogue context?
○ Response 1 ○ Response 2 ○ Not sure

Which response is more engaging and makes you want to interact with more?
○ Response 1 ○ Response 2 ○ Not sure

Figure 7: **Human evaluation interface** for response quality on dimensions: grammar, coherence, and engagingness.



Given a dialogue context and two responses, determine if which of the two responses is more (1) informative; (2) specific; and (3) follows common sense more.

Dialogue History: ${context}

Response 1: : ${baseline_response}

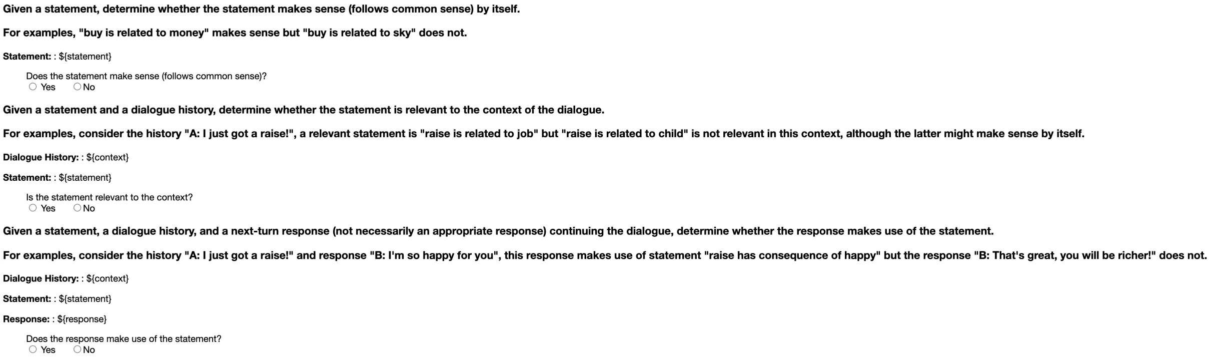
Response 2: : ${model_response}

Which response is more informative, meaning it carries more content and contributes to the conversations more?
For example, for a dialogue history: "A: Do you feel anything like that? B: Like what? Bad or miserable?", a response: "A: Like a bad headache or something. It's painful. It feels like I am dying." is MORE informative than "A: Like i am not feeling well"
○ Response 1 ○ Response 2 ○ Not sure

Which response is more specific and is less generic?
For example, for a dialogue history: "A: Can you speak Japanese?", a response: "B: Yep, I learned Japanese for a year in college." is MORE specific and less generic than "B: No I cannot."
○ Response 1 ○ Response 2 ○ Not sure

Which response makes more sense and appropriate in terms of common sense?
For example, for a dialogue history: "A: I want to buy some flowers for my wife", a response: "B: Perhaps you'd be interested in some roses" is makes MORE common sense than "B: Let's sell some flowers."
○ Response 1 ○ Response 2 ○ Not sure

Figure 8: **Human evaluation interface** for response quality on dimensions: informativeness, specificity, and common sense.



Given a statement, determine whether the statement makes sense (follows common sense) by itself.

For examples, "buy is related to money" makes sense but "buy is related to sky" does not.

Statement: : ${statement}

Does the statement make sense (follows common sense)?
○ Yes ○ No

Given a statement and a dialogue history, determine whether the statement is relevant to the context of the dialogue.

For examples, consider the history "A: I just got a raise!", a relevant statement is "raise is related to job" but "raise is related to child" is not relevant in this context, although the latter might make sense by itself.

Dialogue History: : ${context}

Statement: : ${statement}

Is the statement relevant to the context?
○ Yes ○ No

Given a statement, a dialogue history, and a next-turn response (not necessarily an appropriate response) continuing the dialogue, determine whether the response makes use of the statement.

For examples, consider the history "A: I just got a raise!" and response "B: I'm so happy for you", this response makes use of statement "raise has consequence of happy" but the response "B: That's great, you will be richer!" does not.

Dialogue History: : ${context}

Statement: : ${statement}

Response: : ${response}

Does the response make use of the statement?
○ Yes ○ No

Figure 9: **Human evaluation interface** for knowledge quality with 3 questions: does the knowledge make sense as a standalone fact, is the knowledge relevant to the context, and does the generated resposne use the knowledge?

Flow-Adapter Architecture for Unsupervised Machine Translation

Abstract

In this work, we propose a *flow-adapter architecture* for unsupervised NMT. It leverages normalizing flows to explicitly model the distributions of sentence-level latent representations, which are subsequently used in conjunction with the attention mechanism for the translation task. The primary novelties of our model are: (a) capturing language-specific sentence representations separately for each language using normalizing flows and (b) using a simple transformation of these latent representations for translating from one language to another. This architecture allows for unsupervised training of each language independently. While there is prior work on latent variables for supervised MT, to the best of our knowledge, this is the first work that uses latent variables and normalizing flows for unsupervised MT. We obtain competitive results on several unsupervised MT benchmarks.

1 Introduction

Recent advances in deep learning have boosted the development of neural machine translation (NMT). Typical NMT models leverage an encoder-decoder framework (Cho et al., 2014; Sutskever et al., 2014). However, NMT models have been shown to be data-hungry, as the number of parallel sentences significantly influences the performance (Zoph et al., 2016). Unfortunately, large-scale bilingual corpora are limited to a relatively small subset of languages (Al-Onaizan et al., 2002). In contrast to bilingual corpora, monolingual corpora are much easier to obtain.

Unsupervised NMT, compared with supervised NMT, aims to train a model without parallel data. Some early works (Irvine and Callison-Burch, 2016; Sennrich et al., 2016b; Cheng et al., 2016) used monolingual corpora to boost performance when parallel data is not abundant. Lample et al. (2018a) and Artetxe et al. (2018) explored the possibility of training a model relying only on monolingual corpora. They both leveraged a shared-encoder architecture in order to generate universal representations, trained with techniques such as initial word-by-word translation through bilingual dictionaries (Lample et al., 2018b; Artetxe et al., 2017), denoising auto-encoding (DAE) (Vincent et al., 2008) and iterative back-translation (BT) (Hoang et al., 2018). However, Yang et al. (2018) argued that it is a bottleneck in such shared-encoder models to use a shared encoder that maps pairs of sentences of different languages to the same shared latent space. They proposed to use two independent encoders sharing part of their weights and achieved better results. But all of those aforementioned approaches trained the translation models almost from scratch (with only some prior knowledge in the pre-trained embeddings) and therefore it is hard to further advance their performance.

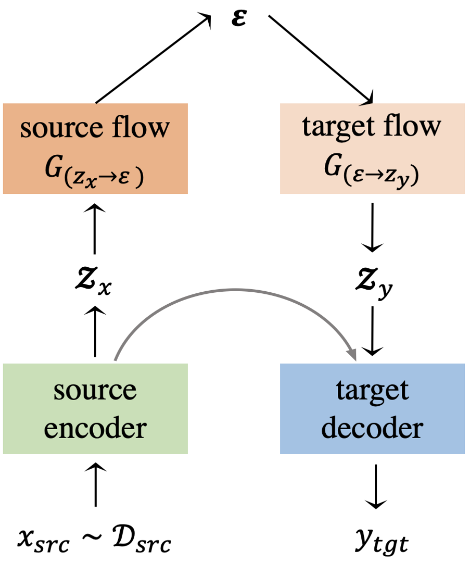

Figure 1: Inference pipeline of proposed flow-adapter based model for source-to-target translation. The decoder also uses the attentional input (shown as the gray arrow between the encoder and the decoder).

More recently, with the advance in pre-trained

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 1253 - 1266
May 22-27, 2022

models (Peters et al., 2018; Devlin et al., 2019), researchers have begun to explore the possibility of using pre-trained models for unsupervised NMT. Conneau and Lample (2019) extended the pre-training from a single language to multiple languages, referred to as cross-lingual pre-training. By using pre-trained cross-language models (XLMs) to initialize encoder and decoder, they achieved good unsupervised MT performance on multiple language pairs. In related work, Song et al. (2019) proposed masked sequence to sequence pre-training (MASS), which directly pre-trains a whole encoder-decoder model. Üstün et al. (2021) proposed a language-specific denoising-adapter architecture to increase the multilingual modeling capacity of the pre-trained model mBART (Liu et al., 2020) and used these adapters for multilingual unsupervised NMT. Although these adapters are trained with monolingual data only, the fine-tuning step relies on parallel data.

Current NMT frameworks rely heavily on the attention mechanism (Bahdanau et al., 2015; Vaswani et al., 2017) to capture alignments. However, attention-based context vectors can fail to extract sufficiently accurate sentence-level semantics and thus result in incorrect translations or translation ambiguity (Tu et al., 2016; Zhang et al., 2016). To tackle this issue, several variational frameworks for modeling the translation process have been proposed (Zhang et al., 2016; Eikema and Aziz, 2019; Setiawan et al., 2020). These approaches incorporate sentence-level latent representations into NMT. A latent representation, in the context of this paper, is a fixed-size continuous vector from an unknown distribution that captures the semantics of a source sentence. The target sentence is then generated from this latent representation using a simple transformation along with the attention mechanism commonly found in transformer architectures. In this way, when the attention mechanism learns incorrect alignments, the latent representation plays a complementary role in guiding the translation.

Prior work in this vein has only been conducted in supervised NMT. In this paper, we propose a flow-adapter architecture for unsupervised NMT. Similar to variational methods, we model the distribution of sentence-level representations. However, unlike variational methods, which model the distribution in an implicit way, we use a pair of normalizing flows to explicitly model the distributions of source and target languages. Secondly, different from some previous unsupervised NMT models that assume that the representations of source and target sentences share a common semantic space, we assume the representations are different because of language-specific characteristics. Hence they are modeled separately for each language. Subsequently a simple transformation converts source representations into target representations. This makes it possible to better capture sentence semantics in a language-specific manner. Lastly, instead of minimizing KL loss, the flows are directly trained by maximum likelihood estimation (MLE) of sentence-level latent representations. This gives the latent representations more flexibility.

Our main contributions:

(1) We propose a novel flow-adapter architecture. It uses normalizing flows to explicitly model the distributions of sentence-level representations and performs a latent representation transformation from source to target. To the best of our knowledge, this is the first work that uses latent variables and normalizing flows for unsupervised NMT.

(2) Experiments show the validity and effectiveness of our flow-adapter architecture. It performs very well in unsupervised NMT on several language pairs on the Multi30K dataset. When additionally using pre-trained models, we achieve results competitive with the state of the art on WMT datasets, especially for *en-fr* (WMT'14) and *en-ro* (WMT'16).

2 Background

2.1 Normalizing Flows

Normalizing flows (NFs) are a special type of deep generative model. Different from generative adversarial networks (GAN) (Goodfellow et al., 2014) and variational auto-encoding (VAE) (Kingma and Welling, 2014), NFs allow for not only sampling but also exact density estimation. Due to such desirable properties, in recent years, they have been successfully applied to fields such as image (Ho et al., 2019; Kingma and Dhariwal, 2018), audio (Esling et al., 2019; van den Oord et al., 2018) and video generation (Kumar et al., 2019). In addition to significant achievements in modeling continuous data, NFs have also been used for modeling discrete data, either by directly modeling the data in discrete space (Tran et al., 2019; Hesselink and Aziz, 2020) or by transforming the discrete data into continuous space (Ziegler and Rush, 2019; Tang et al., 2021).

NFs transform between two distributions based on the following change-of-variables formula (we follow the introduction of (Dinh et al., 2015, 2017)):

$$\log p_x(\boldsymbol{x}) = \log p_z(\boldsymbol{z}) + \log \left| \det \frac{\partial f_\theta(\boldsymbol{z})}{\partial \boldsymbol{z}} \right|^{-1} \quad (1)$$

where $\boldsymbol{z} \sim p_z(\boldsymbol{z})$ and $\boldsymbol{x} \sim p_x(\boldsymbol{x})$ denote two vectors from a simple latent distribution $p_z(\boldsymbol{z})$ and a complex distribution of the observed data $p_x(\boldsymbol{x})$, f_θ is an invertible and differentiable function (neural network with parameters θ), $f_\theta(\boldsymbol{z}) = \boldsymbol{x}$ and $\det \frac{\partial f_\theta(\boldsymbol{z})}{\partial \boldsymbol{z}}$ denotes the determinant of the Jacobian matrix of f_θ. The idea of NFs is to learn an f_θ such that f_θ and f_θ^{-1} transform between the latent space $p_z(\boldsymbol{z})$ and the observed space $p_x(\boldsymbol{x})$.

Constructing a single arbitrarily complex invertible and differentiable function is usually cumbersome. Therefore, a generally adopted approach is to stack multiple transformations f_i together, i.e., $\boldsymbol{x} = f_\theta(\boldsymbol{z}) = f_K \circ \cdots \circ f_1(\boldsymbol{z})$. Similarly, for the reverse direction we have $\boldsymbol{z} = f_\theta^{-1}(\boldsymbol{x}) = f_1^{-1} \circ \cdots \circ f_K^{-1}(\boldsymbol{x})$, whose Jacobian matrix is efficient to compute. Here K denotes the number of sequential flows (e.g., $K = 3$ in Table 1).

Normalizing flows are usually optimized by MLE of the parameters θ, i.e., $\log p(\mathcal{D}|\theta) = \sum_{n=1}^{N} \log p_x(\boldsymbol{x}^{(n)}|\theta)$, where N is the data size. By applying a variant of the change-of-variable formula in Equation (1), i.e., $\log p_x(\boldsymbol{x}) = \log p_z(f_\theta^{-1}(\boldsymbol{x})) + \log \left| \det \frac{\partial f_\theta^{-1}(\boldsymbol{x})}{\partial \boldsymbol{x}} \right|$, the MLE objective can be reformulated as follows:

$$\begin{aligned} \log p(\mathcal{D}|\theta) = \sum_{n=1}^{N} & \log p_z(f_\theta^{-1}(\boldsymbol{x}^{(n)})|\theta) \\ & + \log \left| \det \frac{\partial f_\theta^{-1}(\boldsymbol{x}^{(n)})}{\partial \boldsymbol{x}^{(n)}} |\theta \right| \end{aligned} \quad (2)$$

2.2 Latent-variable (variational) NMT

Compared with standard encoder-decoder based NMT models, latent-variable (variational) approaches (Zhang et al., 2016; Eikema and Aziz, 2019; Ma et al., 2019; Calixto et al., 2019; Setiawan et al., 2020; Shu et al., 2020) additionally leverage latent random variables.

Let $\boldsymbol{x}$ be a sentence from the source language and $\boldsymbol{y}$ be its translation in the target language. Then, the variational NMT framework introduces a continuous random latent variable $\boldsymbol{z}$ for the translation modeling, i.e., $p(\boldsymbol{y}|\boldsymbol{z}, \boldsymbol{x})$. With the introduction of $\boldsymbol{z}$, the conditional probability $p(\boldsymbol{y}|\boldsymbol{x})$ can then be reformulated as follows:

$$p(\boldsymbol{y}|\boldsymbol{x}) = \int_{\boldsymbol{z}} p(\boldsymbol{y}|\boldsymbol{z}, \boldsymbol{x}) p(\boldsymbol{z}|\boldsymbol{x}) d\boldsymbol{z} \quad (3)$$

In this way, $\boldsymbol{z}$ serves as a global semantic signal that is helpful to counteract incorrect alignments the model has learned and uses through attention. However, the integration of $\boldsymbol{z}$ poses challenges for inference. To address this problem, variational NMT adopts techniques from VAE (Kingma and Welling, 2014; Rezende et al., 2014), namely, neural approximation and the reparameterization trick.

Neural approximation leverages a neural network to approximate the posterior distribution $p(\boldsymbol{z}|\boldsymbol{x}, \boldsymbol{y})$ with $q_\phi(\boldsymbol{z}|\boldsymbol{x}, \boldsymbol{y})$, where ϕ denotes the parameters of the neural network. In most works, $q_\phi(\boldsymbol{z}|\boldsymbol{x}, \boldsymbol{y})$ is designed as a diagonal Gaussian $\mathcal{N}(\boldsymbol{\mu}, \mathrm{diag}(\boldsymbol{\sigma}^2))$, where the mean $\boldsymbol{\mu}$ and the variance $\boldsymbol{\sigma}^2$ are parameterized with neural networks.

Reparameterization means that the latent random variable $\boldsymbol{z}$ is parameterized as a function of the mean $\boldsymbol{\mu}$ and the variance $\boldsymbol{\sigma}^2$. In this way, the gradient with respect to the parameters $\boldsymbol{\mu}$ and $\boldsymbol{\sigma}^2$ can be computed. The reparameterization of $\boldsymbol{z}$ is often carried out in a location-scale manner: $\boldsymbol{z} = \boldsymbol{\mu} + \boldsymbol{\sigma} \odot \boldsymbol{\epsilon}$ where $\boldsymbol{\epsilon} \sim \mathcal{N}(0, 1)$

With these two techniques, the learning objective of variational NMT is the evidence lower-bound or ELBO of the conditional probability $p(\boldsymbol{y}|\boldsymbol{x})$:

$$\begin{aligned} \mathcal{L}(\theta, \phi; \boldsymbol{x}, \boldsymbol{y}) = & -\mathrm{KL}(q_\phi(\boldsymbol{z}|\boldsymbol{x}, \boldsymbol{y}) || p_\theta(\boldsymbol{z}|\boldsymbol{x})) \\ & + E_{q_\phi(\boldsymbol{z}|\boldsymbol{x}, \boldsymbol{y})}[\log p_\theta(\boldsymbol{y}|\boldsymbol{z}, \boldsymbol{x})] \end{aligned} \quad (4)$$

where $p_\theta(\boldsymbol{z}|\boldsymbol{x})$ is the prior distribution modeled by a neural network and $p_\theta(\boldsymbol{y}|\boldsymbol{z}, \boldsymbol{x})$ is modeled by the decoder given the input source sentence $\boldsymbol{x}$ and the latent variable $\boldsymbol{z}$. The KL term minimizes the discrepancy between the prior $p_\theta(\boldsymbol{z}|\boldsymbol{x})$ and the posterior $q_\theta(\boldsymbol{z}|\boldsymbol{x}, \boldsymbol{y})$. In the inference step, $\boldsymbol{z}$ can therefore be sampled from the prior, which only requires $\boldsymbol{x}$ instead of the posterior that requires both $\boldsymbol{x}$ and $\boldsymbol{y}$. Although this variational framework leverages latent variables, which are helpful for translation, it still has some flaws: **1)** training a variational NMT framework requires parallel corpora to construct the posterior $q_\phi(\boldsymbol{z}|\boldsymbol{x}, \boldsymbol{y})$ and such parallel corpora are not available for unsupervised MT; **2)** the distribution family of the latent variables, e.g., $p_\theta(\boldsymbol{z}|\boldsymbol{x})$, is pre-defined, e.g., a Gaussian, which might restricts the advantage of using a complex posterior; **3)** as variational NMT leverages $\boldsymbol{z}$

sampled from $p_\theta(\boldsymbol{z}|\boldsymbol{x})$ for inference, an underlying assumption is that $\boldsymbol{z}$ should be the same whether only $\boldsymbol{x}$ is considered or both $\boldsymbol{x}$ and $\boldsymbol{y}$ are considered. In other words, this framework assumes $\boldsymbol{z}$ is language-agnostic, which might not be true since language-specific characteristics can influence the generation of $\boldsymbol{z}$.

3 Flow-Adapter Based Framework

In this work, we want to reap the benefits of introducing latent variables into unsupervised MT while at the same time avoiding the flaws of variational NMT we just discussed. Therefore, we propose a flow-adapter based framework that uses two NFs to explicitly model the distribution of the sentence-level latent representations of the source and target sentences. In this way, we can take account of multilinguality in unsupervised MT and make use of language-specific sentence-level representations. During the translation process, a latent code transformation is performed to transform the source-language representation into the target-language representation so that the decoder can leverage them to generate a better target-language sentence. We will first introduce the sentence-level representation as well as the latent code transformation in Section 3.1, followed by the description of the flow-adapter based framework for unsupervised MT in Section 3.2.

3.1 Modeling Representation by NFs & Latent Code Transformation

As previously mentioned, variational methods such as (Zhang et al., 2016; Setiawan et al., 2020) assume that the semantics of the source sentence $\boldsymbol{x}$ and target sentence $\boldsymbol{y}$ are the same and thus the generated latent variable $\boldsymbol{z}$ is the same regardless of whether we only consider $\boldsymbol{x}$ or consider both $\boldsymbol{x}$ and $\boldsymbol{y}$. Unsupervised NMT methods such as (Lample et al., 2018a; Conneau and Lample, 2019) similarly assume that a shared encoder maps source and target sentences into a shared latent space.

In this work, however, we diverge from this assumption and follow Yang et al. (2018) in adopting the desideratum that the unique and internal characteristics of each language be respected. One could think that the semantics of a pair of sentences should theoretically be the same; but in reality, because of language-specific characteristics, the latent representations $\boldsymbol{z}$ obtained by an encoder can be different for source and target sentences. Differences in vocabulary, pragmatics and other linguistic properties all influence the generation of the latent representations. Therefore, we consider the latent representations from a different perspective as follows. We can view $\boldsymbol{z}_x$ and $\boldsymbol{z}_y$ as expressions of the sentence-level representations in two distinct languages based on the same semantics $\boldsymbol{\epsilon}$ where $\boldsymbol{\epsilon}$ is truly language-agnostic. $\boldsymbol{z}_x$ and $\boldsymbol{z}_y$ are obtained by applying parameter-free techniques such as pooling to the output of the encoder fed with source and target languages (see Section 3.2 for details).

Modeling by NFs. For our unsupervised scenario, we propose to explicitly model the distributions of the sentence-level representations of both source and target sentences – i.e., $p_{\boldsymbol{z}_x}(\boldsymbol{z}_x)$ and $p_{\boldsymbol{z}_y}(\boldsymbol{z}_y)$ – using NFs with K sequential flows:

$$p_{\boldsymbol{z}_x}(\boldsymbol{z}_x) = p_{\boldsymbol{\epsilon}}(\boldsymbol{\epsilon}) \prod_{i=1}^{K} \left| \det \frac{\partial f_x^{(i)}(\boldsymbol{z}^{(i)})}{\partial \boldsymbol{z}^{(i)}} \right|^{-1} \quad (5)$$

$$p_{\boldsymbol{z}_y}(\boldsymbol{z}_y) = p_{\boldsymbol{\epsilon}}(\boldsymbol{\epsilon}) \prod_{i=1}^{K} \left| \det \frac{\partial f_y^{(i)}(\boldsymbol{z}^{(i)})}{\partial \boldsymbol{z}^{(i)}} \right|^{-1} \quad (6)$$

where $p_{\boldsymbol{\epsilon}}(\boldsymbol{\epsilon})$ is a base distribution, e.g., the standard normal distribution; $f_x^{(i)}$ and $f_y^{(i)}$ are the i^{th} transformations for the source and target languages, respectively; and $\boldsymbol{z}^{(i)}$ is the intermediate variable where we define $\boldsymbol{z}^{(1)} = \boldsymbol{\epsilon}$ and $\boldsymbol{z}^{(K)} = \boldsymbol{z}_x$ or $\boldsymbol{z}_y$ for notational convenience. The base distribution can be viewed as the "true" underlying semantic space, abstracting away from language specifics.

Our transformation to the sentence-level representations is similar to (Li et al., 2020). They argued that BERT induces a non-smooth anisotropic semantic space of sentences, which can harm its accurate representation of semantic similarity. Therefore, they also used NFs to transform the anisotropic BERT sentence-level distribution to a standard Gaussian distribution that is smooth and isotropic and reported better performance on some sentence-level similarity tasks. By using this type of sentence-level representation, the semantics of sentences from different languages can therefore be aligned in a simple common space in an unsupervised way, which we show is effective for unsupervised MT.

For simplicity, we denote the NFs for transforming the distributions of source and target sentence-level representations to the base distribution as mappings $G_{(\boldsymbol{z}_x \to \boldsymbol{\epsilon})}$ and $G_{(\boldsymbol{z}_y \to \boldsymbol{\epsilon})}$. Because of the

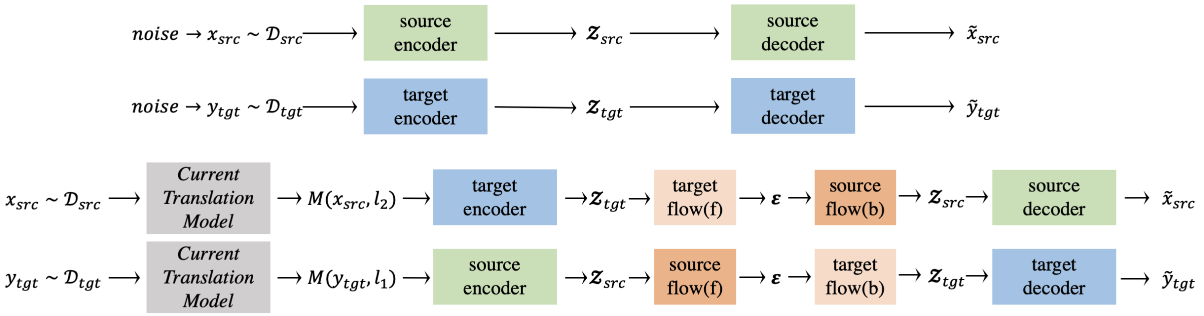

Figure 2: Top two diagrams: denoising auto-encoding for source and target sentences. Bottom two diagrams: iterative back-translation for source and target sentences. $M(\boldsymbol{x}, l_2)$ (resp. $M(\boldsymbol{y}, l_1)$) denotes the target-language (resp. source-language) sentence generated by applying the current translation model M to the source-language sentence $\boldsymbol{x}$ (resp. the target-language sentence $\boldsymbol{y}$). l_1 (the source language) and l_2 (the target language) are the parameters specifying the aim of the translation direction of M. $\tilde{\boldsymbol{x}}_{src}$ (resp. $\tilde{\boldsymbol{y}}_{tgt}$) is the reconstruction of $\boldsymbol{x}_{src}$ (resp. $\boldsymbol{y}_{tgt}$). (f) indicates the flow transforms forward from $\boldsymbol{z}$ to $\boldsymbol{\epsilon}$ while (b) for backward transformation, i.e., from $\boldsymbol{\epsilon}$ to $\boldsymbol{z}$.

invertibility property of NFs, these mappings are also invertible, and we have $G_{(\boldsymbol{\epsilon} \rightarrow \boldsymbol{z}_x)} = G^{-1}_{(\boldsymbol{z}_x \rightarrow \boldsymbol{\epsilon})}$ and $G_{(\boldsymbol{\epsilon} \rightarrow \boldsymbol{z}_y)} = G^{-1}_{(\boldsymbol{z}_y \rightarrow \boldsymbol{\epsilon})}$.

Latent Code Transformation. Inspired by AlignFlow (Grover et al., 2020), we consider the cross-domain transformation between $\boldsymbol{z}_x$ and $\boldsymbol{z}_y$. In this way, we can formulate a language-specific latent code for the decoder. We formalize the cross-language latent code transformation from the source to the target language as follows:

$$G_{(\boldsymbol{z}_x \rightarrow \boldsymbol{z}_y)} = G_{(\boldsymbol{\epsilon} \rightarrow \boldsymbol{z}_y)} \circ G_{(\boldsymbol{z}_x \rightarrow \boldsymbol{\epsilon})} \tag{7}$$

The target-to-source latent code transformation is then the composition of $G_{(\boldsymbol{\epsilon} \rightarrow \boldsymbol{z}_x)}$ and $G_{(\boldsymbol{z}_y \rightarrow \boldsymbol{\epsilon})}$. As $G_{(\boldsymbol{\epsilon} \rightarrow \boldsymbol{z}_y)}$ and $G_{(\boldsymbol{\epsilon} \rightarrow \boldsymbol{z}_x)}$ are the inverse mappings of $G_{(\boldsymbol{z}_y \rightarrow \boldsymbol{\epsilon})}$ and $G_{(\boldsymbol{z}_y \rightarrow \boldsymbol{\epsilon})}$, we can easily obtain them with normalizing flows, such as realNVP (Dinh et al., 2017) and Glow (Kingma and Dhariwal, 2018). We also note that $G_{(\boldsymbol{z}_x \rightarrow \boldsymbol{z}_y)}$ and $G_{(\boldsymbol{z}_y \rightarrow \boldsymbol{z}_x)}$ are both invertible since they are compositions of two invertible mappings. Moreover, $G_{(\boldsymbol{z}_x \rightarrow \boldsymbol{z}_y)}$ is the inverse of $G_{(\boldsymbol{z}_y \rightarrow \boldsymbol{z}_x)}$ and vice versa (see Appendix A.1 for details).

3.2 Flow-Adapter Based Unsupervised Machine Translation

The general architecture is shown in Figure 1. The transformer architecture (Vaswani et al., 2017) is used for both encoder and decoder. We use source encoder/decoder to denote the encoder/decoder for encoding/generating the source-language sentence. Similarly, target encoder/decoder refer to the encoder/decoder encoding/generating the target-language sentence. The decoders work in an autoregressive way. Source flow and target flow are NFs for modeling the sentence-level latent representations of the source and target language, respectively, as introduced in Section 3.1.

Encoding. The source encoder and the target encoder work in the same way; for brevity, we only describe the procedure of encoding the source sentence and how $\boldsymbol{z}_x$ is generated. The source encoder takes the source sentence $\boldsymbol{x} = \{x_0, \cdots, x_S\}$ as input and generates the hidden representations $\{\boldsymbol{h}_0, \cdots, \boldsymbol{h}_S\}$. These hidden representations will be used as encoder-decoder attentional inputs. In addition, we use the hidden representations to generate a sentence-level representation for the source sentence by applying max-pooling and mean-pooling to the token-level representations. After that, we sum up the results with the CLS representation $\boldsymbol{h}_0$, which usually encodes some global information. Finally, we use a projection matrix $\boldsymbol{W}$ to project the resulting vector to a latent space. The output is referred to as $\boldsymbol{z}_x$, i.e., the sentence-level representation of the source sentence (see Appendix A.2 for equation and illustration).

Cross-lingual Translation. We hypothesize that the decoder can better leverage language-specific latent representations (i.e., $\boldsymbol{z}_x$ for the source decoder and $\boldsymbol{z}_y$ for the target decoder) than indiscriminately using the same representational space for source and target, e.g., $\boldsymbol{z}_x$ for the target decoder. Therefore, we propose to perform a latent code transformation for cross-language translation as shown in Figure 1. If the model is performing the translation in the source-to-target direction, the source flow first transforms the source latent representation $\boldsymbol{z}_x$ into $\boldsymbol{\epsilon}$, which is a vector in the semantic base space. Then the target flow transforms $\boldsymbol{\epsilon}$ back into $\boldsymbol{z}_y$, which is in the target latent representation space. Then $\boldsymbol{z}_y$ is used in the target decoder for generating the target sentence.

Denoising Auto-Encoding (DAE) and Back Translation (BT) Processes. The DAE reconstructs a sentence from its noised version. For inducing noise, we use the same strategy which is used by (Lample et al., 2018a) (For more details, please refer to Appendix A.3). Since we train the DAEs separately for source and target languages, hence we don't need a latent code transformation there. For BT, however, such a latent code transformation is performed twice; taking BT for the source language as an example: first in the source-to-target direction, then in the target-to-source direction as shown in Figure 2.

Decoding. To enable the decoder to capture the global semantics and mitigate improper alignments, we use the procedure outlined in (Setiawan et al., 2020), and incorporate the latent representation $\boldsymbol{z}$ into the output of the last layer of the decoder $\{\boldsymbol{s}_0, \cdots, \boldsymbol{s}_T\}$:

$$\boldsymbol{o}_i = (1 - \boldsymbol{g}_i) \odot \boldsymbol{s}_i + \boldsymbol{g}_i \odot \boldsymbol{z} \tag{8}$$

where $\boldsymbol{g}_i = \sigma([\boldsymbol{s}_i; \boldsymbol{z}])$, $\sigma(\cdot)$ is the sigmoid function, $\odot$ denotes Hadamard product between two vectors, and $\boldsymbol{o}_i$ is the logit vector used to generate a prediction at the i^{th} position. The values in $\boldsymbol{g}_i$ control the contribution of $\boldsymbol{z}$ to $\boldsymbol{o}_i$. In case the dimension of the latent representation does not match the dimension of the decoder output, a linear projection maps $\boldsymbol{z}$ to the desired dimension.

Training. Our flow-adapter framework has three learning objectives: DAE, BT and MLE of the sentence-level representations. The description of DAE and BT is omitted here as they are well known from related work (Lample et al., 2018a; Artetxe et al., 2018). A single training iteration consists of a DAE step followed by a BT step as shown in Figure 2. MLE computation is integrated into the DAE step to calculate the likelihood of the sentence-level representations. Our MLE learning objective for the source monolingual dataset can be formulated as follows (similar for the target dataset, omitted):

$$\mathcal{L}_{MLE}(G_{(\boldsymbol{z}_x \to \boldsymbol{\epsilon})}) = E_{z \sim p_{\boldsymbol{z}_x}}[\log p_{\boldsymbol{z}_x}(z)] \tag{9}$$

where

$$p_{\boldsymbol{z}_x}(z) = p_{\boldsymbol{\epsilon}}(G_{(\boldsymbol{z}_x \to \boldsymbol{\epsilon})}(z)) \left| \det \frac{\partial G_{(\boldsymbol{z}_x \to \boldsymbol{\epsilon})}}{\partial \boldsymbol{z}_x} \right|_{\boldsymbol{z}_x = z} \tag{10}$$

by definition of the source NFs in Equation 5. $E_{z \sim p_{\boldsymbol{z}_x}}$ is approximated via mini-batches of sentence-level latent representations generated by the encoder in the training process. By training the source flow and the target flow with this MLE loss, the flows can therefore transform between the language-specific latent space of the representations and the base semantic space. In this way, the latent code transformations, i.e., $G_{(\boldsymbol{z}_x \to \boldsymbol{z}_y)}$ and $G_{(\boldsymbol{z}_y \to \boldsymbol{z}_x)}$ can be constructed.

4 Experiments

4.1 Datasets

Multi30K task1 dataset (Elliott et al., 2016, 2017).[1] This is a multi-modal dataset that has 30,000 images annotated with captions in English, German and French. Similar to (Lample et al., 2018a), we only use the caption of each image. The officially provided train, validation and test sets are used. We use this dataset as a small-scale test for validating the effectiveness of our methods.

WMT datasets.[2] Our experiments are run with the settings that were used for XLM (Conneau and Lample, 2019). XLM uses the monolingual data from the WMT News Crawl datasets[3]. We report results on *newstest2014 en-fr*, *newstest2016 en-de* and *newstest2016 en-ro*.

4.2 Setups

Preprocessing. We tokenize the sentences with the Moses script (Koehn et al., 2007). For the Multi30K dataset, we process it similar to Lample et al. (2018a). Specifically, the sentences are randomly divided into two parts. The source-language monolingual dataset is built from the source-language sentences in the first part and the target-language dataset from the second part. In this way, there will be no exact translations of any sentences in the datasets. For the WMT datasets, we use the preprocessing methods from (Conneau and Lample, 2019). For the English-Romanian dataset, we remove the diacritics as done by Sennrich et al. (2016a) to avoid their inconsistent usage in the Romanian part of the dataset.

Metric & Performance. We use BLEU as metric (Papineni et al., 2002) for all our experiments. Although Artetxe et al. (2020) recommended to use

Baseline: model without our proposed flow-adapter architecture. 3-scf or 3-glow models: baseline models with the flow-adapter architecture constructed by two realNVP NF models or Glow NF models, each of which consists of 3 sequential flows, for performing the latent code transformation in that translation direction.

unsupervised validation criteria for systematic tuning, we follow the setting of (Conneau and Lample, 2019; Song et al., 2019) and use the provided parallel validation sets for tuning hyperparameters. We report the results on the test sets of the models that achieve best performance on the validation sets.

Pre-trained Embeddings & Models. We use the pre-trained MUSE[4] (Lample et al., 2018b) embeddings for the multilingual unsupervised MT experiment (Table 1). We also leverage pre-trained cross-lingual models in the experiment of shared & separate decoder(s) (Table 2). Specifically, XLM models from HuggingFace[5] (Wolf et al., 2020) are used to initialize the encoder. Moreover, we also incorporate our flow-adapter architecture directly into the codebase of the original implementation of XLM[6] for the WMT dataset experiment (Table 3). In this case, the encoder and decoder are both initialized with pre-trained models. Details of these models can be found in Appendix A.3.

4.3 Results of Multilingual Unsupervised Machine Translation on Multi30K

As Multi30K provides parallel test data for English, French and German, we first conduct experiments to show the multilingual translation ability of our flow-adapter models. The results are shown in Table 1. The baseline model (without flow-adapter architecture) is trained with only DAE loss, while the flow-adapter based models (3-scf and 3-glow) are additionally trained with MLE loss for the NFs. 3-scf (resp. 3-glow) is the baseline model with two realNVP NF models (Dinh et al., 2017) (resp. Glow NF models (Kingma and Dhariwal, 2018)) , each of which consists of 3 sequential flows. Each NF model is used to model the sentence-level representations of one specific language, and two NF models then construct a flow-adapter for that translation direction (as shown in Figure 1). The flow-adapter based models additionally perform the latent code transformation to generate a language-specific representation while the baseline model does not perform such a transformation.

For this experiment, we use the pre-trained cross-lingual word embeddings (MUSE embeddings) and randomly initialize a shared encoder and a shared decoder for all three languages. It is worth noting that the training objective does not contain the iterative back-translation. For further research where there are far more languages accommodated, random online back-translation (ROBT) proposed by Zhang et al. (2020) could be considered.

Table 1 shows improvements over all six translation directions by using the flow-adapter architecture. Notably, our 3-scf and 3-glow models achieve 19.83 and 20.14 BLEU scores, respectively, on *de-en*, which is 0.52 and 0.83 higher than the baseline model. Similar improvements can also be seen on other translation directions. Our 3-scf model has BLEU scores that are 0.46 to 0.88 higher than the baselines while our 3-glow model has BLEU scores that are 0.04 to 0.83 higher than the baselines. The overall improvements show that the flow-adapter can generate more suitable sentence-level representations by performing the latent code transformation, which is helpful for the decoder to capture the semantics and generate more suitable translations.

We also find that the translation performance is closely related to the language pair and the translation direction for both the baseline models and flow-adapter models. Our models obtain very good performance on *en-fr*, with performances in both the *en-fr* or *fr-en* directions better by 16 BLEU points. For other language pairs (including *en-fr*), there is always one direction showing better performance than the other. Specifically, *de-en* achieves more than 19 BLEU points compared with 12 points for *en-de*, and *de-fr* achieves more than 11 BLEU points compared with 8.5 for *fr-de*.

4.4 Results of Shared-Decoder & Separate-Decoder Models on Multi30K

We present the performance of our flow-adapter models under the shared-decoder and separate-decoder settings on Multi30K. For this experiment, the encoder is initialized with the pre-trained XLM model and fixed; the decoder parameters are ran-

UNMT (Lample et al., 2018a)	22.74	26.26	32.76	32.07

Table 2: BLEU of the flow-adapter models and unsupervised SOTA model, i.e., UNMT (Lample et al., 2018a), on Multi30K. Baseline models use pre-trained XLMs from HuggingFace as the encoder and randomly initialized decoder(s) without the flow-adapter. (separate decoders): two independent and randomly initialized decoders are used, each for decoding a specific language. (shared decoder): a single shared decoder for decoding both languages is used. 3-scf and 3-glow (as defined in Table 1 and Section 4.3) denote the baseline models with the flow-adapter architecture. We report the results of UNMT from their original paper.

domly initialized and then trained. We also report the performance of a previous SOTA model, i.e., UNMT (Lample et al., 2018a).[7] The results are shown in Table 2. First, we notice that the shared-decoder baseline model obtains very low BLEU scores. By checking the translation generated, we find the model only copies the input as translation. This phenomenon shows that this baseline, which does not perform the latent code transformation, cannot model two languages simultaneously well, and thus cannot generate translations in the desired language domains. However, by incorporating the flow-adapter, the models will no longer have this limitation. Both shared-decoder models, i.e., 3-scf and 3-glow, achieve very good performance on all translation pairs. For example, the 3-scf model obtains BLEU scores of 25.80, 28.92, 39.26 and 36.84 on *en-de*, *de-en*, *en-fr* and *fr-en*, which are much higher than the baseline.

Compared with the shared-decoder scenario, the models under the separate-decoder setting do not suffer from the copying problem, because different decoders are used to specifically model and generate sentences in distinct language domains. The downside, however, is that using multiple decoders at the same time can substantially increase the number of trainable parameters. Within the separate-decoder models, the flow-adapter models generally perform better than the baseline model, with about 1 BLEU increase on *en-de* and *de-en* directions and relatively smaller improvements on *en-fr* and *fr-en*. Those improvements demonstrate that the model can benefit from the flow-adapter architectures as language-specific latent representations are used, thus advancing the translation quality.

We also observe that the separate-decoder models generally perform better than the shared-decoder models. The separate-decoder baseline is much better than its counterpart as it avoids the copying problem. For the 3-scf flow-adapter models, we find that the separate-decoder model outperforms the shared-decoder model by 2.44, 1.71, 0.38 on *en-de*, *de-en* and *en-fr*. However, on *fr-en*, the shared-decoder model achieves a BLEU socre that is by 0.39 BLEU points better. A similar phenomenon can also be seen for the 3-glow model. We conjecture this is due to the similarity between languages. As English and French share common vocabulary, some common features can therefore be captured by a shared decoder, thus improving its generalization.

Lastly, when compared with UNMT, our models show superiority, improving performance by more than 4 BLEU points in each direction. We attribute the improvements to the usage of the pre-trained model and incorporation of language-specific sentence-level representations obtained by our latent code transformation.

4.5 Results on WMT datasets

We further integrate our flow-adapter architecture into the original implementation of XLM (Conneau and Lample, 2019) and conduct experiments on the WMT datasets. To fully leverage the pre-trained models, we initialize both the encoder and decoder with XLM models and set them trainable. In contrast to the experiment in Section 4.4, a single shared decoder is used for this experiment, since the decoder is also initialized with the pre-trained model and has far more parameters compared with the randomly initialized transformer decoder we use in Section 4.4. We report the performance of the flow-adapter based models (5-scf and 5-

---

[7] UNMT did not use pre-trained models. The results are therefore not strictly comparable to ours.

Models	en-de	de-en	en-ro	ro-en	en-fr	fr-en
XLM (EMD + EMD) (Conneau and Lample, 2019)	21.30	27.30	27.50	26.60	29.40	29.40
XLM (MLM + MLM) (Conneau and Lample, 2019)	26.40	**34.30**	33.30	**31.80**	33.40	33.30
5-scf	**26.50**	32.63	**34.11**	31.69	**35.77**	**33.72**
5-glow	26.43	32.04	33.87	31.32	35.25	33.12
MASS (Song et al., 2019)	28.30	35.20	35.20	33.10	37.50	34.90
CSP and fine-tuning (Yang et al., 2020)	28.70	35.70	-	-	37.90	34.50

Table 3: BLEU of the flow-adapter models (5-scf and 5-glow) and SOTA models on WMT datasets. XLM (MLM + MLM) is the baseline in this table, as 5-scf and 5-glow use it as the base model for the flow-adapter architecture. We report the results of XLM, MASS and CSP from the original paper.

glow[8]) as well as the performance of the SOTA models, namely XLM, MASS and CSP.[9] The results are shown in Table 3. Noticeably, both of our flow-adapter models achieve remarkable performance on all language pairs. Compared with the results of XLM (EMD + EMD), which uses the pre-trained cross-lingual embeddings instead of pre-trained models, both 5-scf and 5-glow achieve overall better performance. For example, 3-scf achieves BLEU scores higher by 5.20, 5.33, 6.61, 5.09, 6.37 and 4.32 on *en-de*, *de-en*, *en-ro*, *ro-en*, *en-fr* and *fr-en*, respectively. While not being as good as 5-scf, 5-glow still shows superiority over XLM (EMD + EMD). These improvements can be contributed to (1) the usage of pre-trained models and (2) the introduction of the flow-adapter.

We further compare our flow-adapter based models with XLM (MLM + MLM), which is also initialized with pre-trained models. We find the performance of *x-en* directions is consistently lower than *en-x* directions for our models except for *en-de*. This pattern is not limited to our architecture but is consistently present in prior work. We, again, speculate this is relating to the complexity of languages as well as similarity between languages. We leave this finding for future investigation. Our flow-adapter based models, though achieving similar or relatively worse BLEU scores on *de-en* and *ro-en* compared with XLM (MLM + MLM), obtain higher scores on other directions, i.e., *en-de* and *en-ro*, suggesting that our models might be more helpful on specific translation directions, as the flow-adapter generates language-specific representations. Lastly, 5-scf achieves scores by 2.37 and 0.42 better than XLM (MLM + MLM) on *en-fr* and *fr-en*. As in the other experiments, the improvement due to flow adapters seems to be related to the languages involved in that language pair and the translation directions. We would like to investigate this phenomenon in future research.

Finally, out models are competitve with MASS and CSP, with only small differences in BLEU. In general, the experiments shows the validity and effectiveness of our flow-adapter architecture integrated into pre-trained models.

5 Conclusion

In this work, we propose a novel flow-adapter architecture for unsupervised NMT. The flow-adapter employs a pair of NFs to explicitly model the distributions of the sentence-level representations. A latent code transformation is performed in translation, which enables the decoder to better capture the semantics of sentences in certain language domains. Through extensive experiments, we show the flow-adapter can improve multilingual translation ability. Moreover, it can alleviate the copying problem. By integrating the flow-adapter into pre-trained XLM models, we achieve results competitive to state-of-the-art models on WMT datasets.

In the future, we would like to explore the possibility of pre-training the flow-adapter simultaneously when pre-training the language models so that the flows can learn more information. Moreover, we would like to extend normalizing flows to language generation. By using different flows for different languages, multilingual language generation of the same semantics can be performed.

Acknowledgements

We are grateful to Alex Fraser and Alexandra Chronopoulou for their insightful input. This work was funded by the European Research Council (ERC #740516).

---

[8] Preliminary experiments showed that using 5 flows provides slightly better results than 3 flows for WMT as WMT has many more sentences than Multi30K and therefore more powerful generative models (by adding more intermediate flows) are needed to model the sentence-level representations.

[9] We follow prior convention and compare directly with MASS and CSP even though dataset processing for MASS and CSP (e.g., filtering, sampling) are not strictly the same as for XLM. But the difference is small and results would not be much different as Yang et al. (2020) mentions.

A Appendix

A.1 Proof of the Invertibility

The following proof is based on the proof by Grover et al. (2020) and shows the source-to-target latent code transformation is the inverse of the target-to-source latent code transformation, and vice versa:

$$\begin{aligned} G^{-1}_{(\boldsymbol{z}_x \to \boldsymbol{z}_y)} &= (G_{(\boldsymbol{\epsilon} \to \boldsymbol{z}_y)} \circ G_{(\boldsymbol{z}_x \to \boldsymbol{\epsilon})})^{-1} \\ &= G^{-1}_{(\boldsymbol{z}_x \to \boldsymbol{\epsilon})} \circ G^{-1}_{(\boldsymbol{\epsilon} \to \boldsymbol{z}_y)} \\ &= G_{(\boldsymbol{\epsilon} \to \boldsymbol{z}_x)} \circ G_{(\boldsymbol{z}_y \to \boldsymbol{\epsilon})} \\ &= G_{(\boldsymbol{z}_y \to \boldsymbol{z}_x)} \end{aligned} \tag{11}$$

A.2 Generation of Sentence-level Representation

The following formula shows the process of how the sentence-level representation is generated:

$$\begin{aligned} \boldsymbol{z} = \text{Linear}(&\text{max-pool}([\boldsymbol{h}_0, \cdots, \boldsymbol{h}_S]) \\ &+ \text{mean-pool}([\boldsymbol{h}_0, \cdots, \boldsymbol{h}_S]) \\ &+ \boldsymbol{h}_0) \end{aligned} \tag{12}$$

where the pooling operation generates a vector that has the same dimension as $\boldsymbol{h}_0$, so the three vectors have the same shape and therefore are additive. An illustration can be seen in Figure 3.

A.3 Details of the Experiments: Models & Hyperparameters

A.3.1 Multi30K Experiment

For the multilingual machine translation tasks, we use the cross-lingual MUSE (Lample et al., 2018b). The embeddings were learned using fastText[10] (Bojanowski et al., 2017) on Wikipedia data and then aligned in a common space by the method proposed by Lample et al. (2018b). The results shown in Table 1 is the average over 10 runs on the test sets. Denosing auto-encoding is used to train the baseline model. The flow-adapter based (3-scf and 3-glow) models are additionally trained with MLE loss. We follow the denoising auto-encoding hyperparameter settings used by Lample et al. (2018a). Specifically, word drop and word shuffling are used. For word drop, every word in a sentence (except <bos> and <eos>) can be dropped with a probability p_{wd}, which we set 0.1 in our experiments. For word shuffling, a random permutation σ is applied to the input sentence, which satisfy the condition: $\forall i \in \{1, n\}, |\sigma(i) - i| \leq k$, where i is the index of a word in the sequence, n is the length of the sequence and k is a hyperparameter that controls the degree of the permutation which we set 3 in our experiments. The dimension of the pre-trained embedding is 300. The randomly initialized shared encoder and decoder use transformer architecture with 512 hidden units, 4 heads and 3 layers by default. We use separate embedding layers for each language and tie their weights with the output layers for each language. The size of the sentence-level latent representation is set to 100. And the weight of the MLE loss for the flows is set to 0.01. We use dropout (Srivastava et al., 2014) probability of 0.2 for the transformers and 0 for the flows. The batch size is set to 32. The whole model is trained in an end-to-end manner with Adam optimizer (Kingma and Ba, 2015) with an initial learning rate of 0.0001.

For the shared-decoder & separate-decoder experiments, we use the pre-trained language models *xlm-mlm-enfr-1024*, *xlm-mlm-ende-1024*, *xlm-mlm-enro-1024* from HuggingFace[11] (Wolf et al., 2020)

---

[11] https://github.com/huggingface

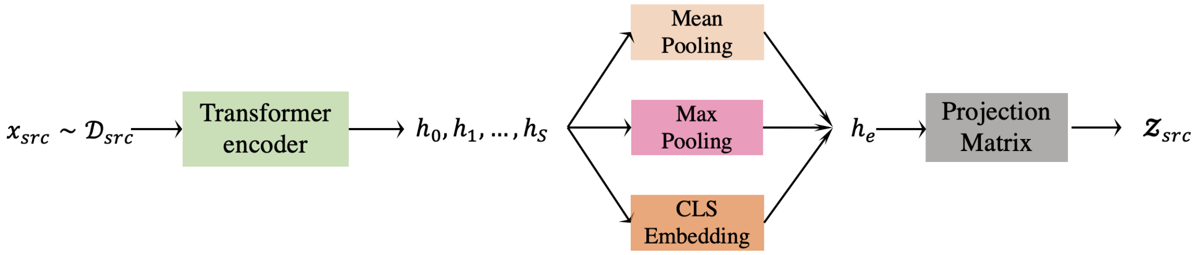

Figure 3: The illustration of generation of the sentence-level representations. CLS embedding refers to the first vector output by the transformer encoder, i.e., $\boldsymbol{h}_0$.

to initialize a shared encoder and randomly initialize the decoder(s).using pre-trained models. Densoing auto-encoding and iterative back-translation are used to train the baseline model. The flow-adapter based (3-scf and 3-glow) models are additionally trained with MLE loss. The same denoising auto-encoding hyperparameters as above are used. For iterative back-translation, greedy decoding is used to generate synthetic parallel sentences as well as the reconstructions. A single embedding layer (from the pre-trained model) is used for both the source and target languages and its weight is tied with the output layer. The parameters of the encoder are fixed except for its embedding layer which is also used by the decoder(s). The size of the sentence-level latent representation is set to 256. The pre-trained encoder uses 1024 as the embedding size and GELU activations (Hendrycks and Gimpel, 2016), and has 4096 hidden units, 8 heads and 6 layers. The randomly initialized decoder has 512 hidden units, 8 heads and 3 layers. The models are firstly trained with DAE loss (and MLE loss for flow-adapter models) for the first 3 epochs, then trained with all losses (including the iterative back-translation) for the rest epochs. The rest hyperparameters are the same as above.

A.3.2 WMT Experiment

We insert our implementation of flow-adapter architecture into the codebase of XLM[12] and use the pre-trained model of *en-fr*, *en-de* and *en-ro* from them. We also follow their recommended unsupervised training settings. For the flow-related hyperparameters, we use 256 as the size of the sentence-level latent representation. The weight of the MLE loss is set to 0.01.

Abstract

Sentence compression reduces the length of text by removing non-essential content while preserving important facts and grammaticality. Unsupervised objective driven methods for sentence compression can be used to create customized models without the need for ground-truth training data, while allowing flexibility in the objective function(s) that are used for learning and inference. Recent unsupervised sentence compression approaches use custom objectives to guide discrete search; however, guided search is expensive at inference time. In this work, we explore the use of reinforcement learning to train effective sentence compression models that are also fast when generating predictions. In particular, we cast the task as binary sequence labelling and fine-tune a pre-trained transformer using a simple policy gradient approach. Our approach outperforms other unsupervised models while also being more efficient at inference time.

1 Introduction

In general, the information content of text is correlated with its length. However, for a given text, a shorter version may still convey the essential information while preserving grammaticality (Siddharthan, 2014). The definition of *essential* can change depending on the downstream application, thus models for text compression must be able to adapt based on information about the downstream task.

Sentence compression models have been used as sub-modules of text and speech summarization (Banerjee et al., 2015; Shang et al., 2018), for headline generation (Dorr et al., 2003), subtitle generation (Vandeghinste and Pan, 2004), and summarizing emails (Zajic et al., 2008). Potential applications also include snippet generation and highlighting for social media, blog posts or search results.

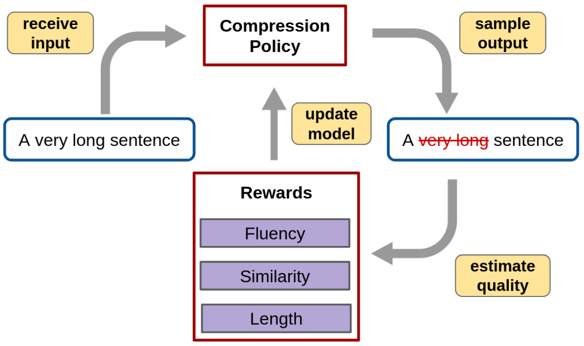

Figure 1: Reinforcement learning framework for sentence compression.

Given a particular text compression task, relevant evaluation metrics and auxiliary models of compression quality may not be straightforward to formulate as well-behaved differentiable objectives that can be used with standard backpropagation. In addition, ground-truth examples may be difficult to obtain because the annotation task is difficult to fully specify, and metrics which capture different facets of compression quality, such as fluency and optimal sentence length, may be negatively correlated. Even in the case where ground-truth examples are available, they are likely to represent only a subset of the possible outputs, so there is a risk of over-fitting or biasing models when relying solely upon a small amount of gold training data for optimization.

Recent unsupervised sentence compression approaches leverage powerful neural language models to directly optimize objectives such as fluency and faithfulness of compressed sentences, using discrete search strategies, without relying on ground-truth examples (Niu et al., 2019; Zhou and Rush, 2019; Schumann et al., 2020). However, these search-based methods are very inefficient at inference-time because the search must navigate through a large candidate space while recomputing expensive reward functions.

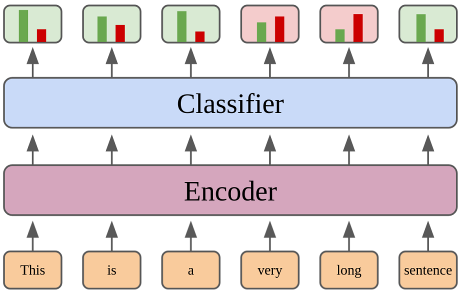

Figure 2: Model architecture for compressing sentences.

To allow for flexible reward specification, while also enabling efficient inference, we design a simple and effective reinforcement learning (RL) setup: our model is initialized as an unsupervised pre-trained language model with an untrained binary classification head (see Figure 2), and the sentence compression task is framed as sequence labeling, with optimization via policy gradient using a suite of reward functions. Sentences are compressed in an instantaneous, one-step fashion, similar to modern part-of-speech tagging or named entity recognition models. This approach simplifies the learning setup while also allowing for high throughput.

According to quantitative evaluation on several summarization benchmarks, our approach shows similar or superior performance compared to search-based methods, while also being much faster at inference time.

Our approach to unsupervised extractive sentence compression has the following benefits:

- **Unsupervised:** No labelled examples are required.
- **Fast inference:** At test time, the model only performs one-step sequence labeling.
- **Configurable:** Rewards can be tailored to specific use cases.

We review related work in Section 2. Section 3 formalizes the task. Section 4 gives a detailed description of the model and reward functions. Section 5 presents experimental results, and Sections 6 and 7 provide analysis and discussion of our findings.

2 Related Work

Unsupervised Sentence Compression

Early work on sentence compression casts the task as an optimization problem under linguistically motivated constraints (Hori and Furui, 2004; Clarke and Lapata, 2006, 2008). The objectives to be optimized include n-gram language model scores and frequency-based word relevance measures. Constraints are designed to ensure the grammaticality of compressions.

Some recent work follows the discrete optimization paradigm while leveraging powerful models as objective functions in place of hand-crafted constraints, while exploring different strategies for heuristic search: Zhou and Rush (2019) use beam search to optimize a fluency and a similarity objective. Schumann et al. (2020) use a greedy hill-climbing search to optimize fluency and similarity objectives. Niu et al. (2019) use a greedy search with a look-ahead mechanism, only optimizing fluency. All of these recent approaches use large neural language models to estimate fluency. While the approach presented in whis work does not involve discrete search, we consider it complementary and orthogonal to our RL-based approach (see Section 7 for more discussion).

Another commonly proposed unsupervised framework is to use autoencoders and reconstruction objectives (Miao and Blunsom, 2016; Févry and Phang, 2018; Malireddy et al., 2020). These approaches are based on the assumption that a good sentence compression is one from which the original sentence can be inferred.

Wang et al. (2018) is an example of prior work using reinforcement learning for unsupervised sentence compression. They use a Deep Q-Network to optimize a reward incorporating n-gram language model probabilities and grammatical constraints. This model repeatedly deletes a token until it terminates, as opposed to our one-step approach. Zhao et al. (2018) also use RL to optimize a syntax-focused language model score. However, their policy is initialized with a supervised sentence compression model, whereas ours is fully unsupervised.

Reinforcement Learning for Summarization

Reinforcement learning has become popular in the wider field of text summarization, finding applications in both extractive and abstractive sub-tasks. One use case of RL is in supervised scenarios, where rewards are computed based on ground-truth examples, e.g., ROUGE scores, to overcome issues with cross-entropy losses (Paulus et al., 2017; Narayan et al., 2018; Dong et al., 2018). BANDITSUM (Dong et al., 2018) in particular has a very similar RL setup to ours: they train in one-step episodes where a policy predicts extractive labels and immediately receives a reward. Scialom et al. (2019) augment a ROUGE-based reward with a reward based on question answering. Böhm et al. (2019) and Stiennon et al. (2020) learn reward functions from human quality ratings of summaries. Similar to our unsupervised approach, Laban et al. (2020) use RL for unsupervised abstractive summarization, optimizing reward functions representing fluency, coverage under a length constraint, and also use a policy gradient approach.

3 Task

We focus on the specific task of summarizing a sentence by extracting a subset of its tokens in their original order. Given an input sentence x consisting of n tokens $x = (x_0, x_1, ..., x_n)$, we aim to produce a sequence of binary labels $y = (y_0, y_1, ..., y_n) \in \{0, 1\}^n$, where each label indicates whether the corresponding input token should be included in the compressed version of a sentence.

We further assume an objective function, or *reward* function $R(x, y)$ that measures how well applying the labels y summarizes the original sentence x. For a particular x, the goal is to find $\operatorname{argmax}_y R(x, y)$, without access to any ground-truth examples.

In general, there are 2^n possibilities to shorten a sentence in this task. A fixed summary length L would reduce this to $\binom{n}{L}$ possibilities, peaking at $L = \frac{n}{2}$ (for even n). We do not constrain our approach to a fixed length, but we compare it to search-based techniques that are constrained to the $\binom{n}{L}$ search space.

4 Method

4.1 Training Procedure

We train a policy π_θ with parameters θ to produce binary labels. Given an input x, the policy π_θ predicts a binary keep/discard probability distribution for each token index in x. We use the notation $\pi_\theta(*|x)$ to refer to the collection of these distributions for all tokens in x. We obtain the probability $\pi_\theta(y|x)$ of a label sequence y given input sequence x as follows:

$$\pi_\theta(y|x) = \prod_i \pi_\theta(y_i|x), \tag{1}$$

where $\pi_\theta(y_i|x)$ is the probability of a token x_i being included if $y_i = 1$ or excluded if $y_i = 0$. To compress a sentence using π_θ, we select the higher scoring label for each token:

$$y^a = \{\operatorname*{argmax}_{y_i} \pi_\theta(y_i|x) \ \text{ for } y_i \in y\}. \tag{2}$$

We train our model using a policy gradient technique (Sutton et al., 1999). Unlike typical sequential reinforcement learning scenarios, our π_θ only performs one action for a given input, receiving the corresponding reward immediately, without transitioning through other intermediate states. Therefore, our setup is similar to a contextual multi-armed bandit problem (Langford and Zhang, 2008), where each "arm" corresponds to a particular label sequence $y = (y_0, y_1, ..., y_n) \in \{0, 1\}^n$. However, in our scenario, the policy is generally allowed to access rewards for multiple possible actions via sampling, which is different from typical bandit settings where only one $(action, reward)$ pair is available for each episode.

The training objective is to maximize the expected reward assigned to a predicted label sequence y for a given input x, computed by the reward function R:

$$J(\theta) = \mathbb{E}[R(x, y)] \tag{3}$$

The policy gradient theorem states that the gradient of this expectation can be expressed as follows (Sutton et al., 1999):

$$\nabla_\theta J(\theta) = \nabla_\theta \mathbb{E}[R(x, y) \log \pi_\theta(y|x)] \tag{4}$$

Since the above expectation is intractable for a large dataset and the corresponding action space, this gradient is estimated by sampling:

$$\nabla_\theta J(\theta) = \nabla_\theta r^s \log \pi_\theta(y^s|x), \tag{5}$$

where $y^s \sim \pi_\theta(*|x)$ is a sample from the current policy at a given step, consisting of binary token labels $y^s = ({y^s}_0, {y^s}_1, ..., {y^s}_n)$, and $r^s = R(x, y^s)$.

As is commonly done when using policy gradients, we subtract a baseline from the reward for variance reduction. We instantiate the baseline as $r^a = R(x, y^a)$, the reward given to the the most likely label sequence y^a according to the current policy. The gradient becomes:

$$\nabla_\theta J(\theta) = \nabla_\theta (r^s - r^a) \log \pi_\theta(y^s|x) \tag{6}$$

Accordingly, we train our model by minimizing the following loss function:

$$\ell_\theta = (r^a - r^s) \log \pi_\theta(y^s|x). \tag{7}$$

Using the baseline r^a allows the intuitive interpretation that a sample y^s is encouraged if its reward is higher than the current policy's prediction, i.e., when factor $(r^a - r^s)$ is negative, and discouraged otherwise.

Best-of-k Sampling

Prior work with a similar application of policy gradient (Dong et al., 2018; Laban et al., 2021) observed an advantage in sampling k times and taking the average loss over all samples rather than using a single sample. However, in our experiments, we observe that only using the sample with the *maximum* reward from a large number of samples works significantly better than taking the average or only sampling once. A large k improves the discovery of high-quality compressions – if we only use a single sample or a very small k, we observe a higher tendency of models to converge on simple behaviors with low reward improvements, such as only extracting the first-L tokens of a sentence. The choice of k controls a trade-off: with a higher k, we spend more time computing the rewards of samples and less on model updates, given a limited wall-time constraint for training. We determine k in an unsupervised manner using a validation set (details in Section 5.2).

4.2 Model Architecture

π_θ is initialized as a transformer encoder model with a linear classification head. In particular, we use the 6-layer DistilRoBERTa model (Sanh et al., 2019) due to its efficiency and smaller size compared to other BERT-like models, while retaining good results on the GLUE benchmark[1]. During training, the whole model is fine-tuned. For each token in the input, our model will determine whether it should be kept or filtered. Figure 2 visualizes the design. This architecture produces summaries in an instantaneous, non-autoregressive fashion, allowing for fast prediction (see Section 5.6).

4.3 Reward Functions

We do not have direct access to ground-truth training data in our setup, so we consider a suite of reward functions that may correlate with different aspects of sentence compression quality.

Fluency

This reward function is intended to ensure grammatically correct and well-written sentences. We use a masked language model (LM) to estimate the fluency of a compressed sentence. In particular, we compute fluency as the average logit of a token y_i in the compressed sentence y. We do this without masking y_i to reduce the running time during training, as masking would require to re-encode the sentence for each token. Based on our experiments, this simplification still produces good estimates of fluency.

$$R_{fluency}(y) = \frac{1}{|y|} \sum_{i=1} \text{LM}(y_i|y) \tag{8}$$

We normalize $R_{fluency}$ by dividing it by an empirically set constant, to keep its values in a similar range compared to the other rewards. The constant is an observed minimum value from a sample dataset. We argue that a masked language model is more appropriate in our setup compared to a left-to-right (causal) language model – when predicting or sampling a compressed sentence during training, the sentence is treated as a finished rather than an intermediate output, which is not captured by the auto-regressive inference of causal LMs. We confirm the advantage of a masked LM over a left-to-right LM in a comparison on a development set (Appendix A).

We note the precedent for using language models to measure fluency: Zhou and Rush (2019) and Schumann et al. (2020) use language models trained on a summarization target domain, e.g., headlines. Laban et al. (2020) uses a generic causal language model to estimate fluency. Niu et al. (2019) use a masked language model to score candidate compressions.

Similarity-to-Source

The similarity reward is intended to preserve the meaning of the source sentence in the compressed sentence. We experiment with several options to compute similarity, all using models from the `sentence-transformers` library[2] (Reimers and Gurevych, 2019):

- **Bi-Encoder Similarity**: A sentence encoder f separately computes embeddings for the source and the predicted summary. We calculate the cosine similarity between both embeddings: $R_{sim}(x, y) = cos(f(x), f(y))$

---

[1] https://huggingface.co/distilroberta-base

[2] https://www.sbert.net/

- **Cross-Encoder Similarity**: Output of a cross-encoder model f_{sim} measuring the semantic textual similarity between both sentences: $R_{sim}(x, y) = f_{sim}(x, y)$
- **Cross-Encoder NLI:** We also test a natural language inference (NLI) model f_{nli} to estimate how well a compressed sentence retains source information. The intuition is that the source should *imply* information in the output: $R_{nli}(x, y) = f_{nli}(y|x)$

Based on experiments on a development dataset, the bi-encoder similarity performs best in our setup.

Length and Compression Ratio

Because our model is non-sequential, we cannot easily employ a hard constraint to control the length of compressed sentences. Instead, we impose a soft length control using Gaussian reward functions. In particular, we either use a reward function for the length (token count) in a compressed sentence R_{len}, or one for the compression ratio between the source and prediction, in terms of token counts, R_{cr}. We choose one of these two depending on whether a consistent length or a consistent ratio is desired, which differs for different evaluation datasets. We set the distribution means of both rewards as the desired values for word count and compression ratio. We set the standard deviations as the mean times a factor s which we set to 0.4 for both reward functions (Equations 9, 10):

$$R_{len} = \mathcal{N}(\mu_L, (s \times \mu_L)^2), \tag{9}$$

$$R_{cr} = \mathcal{N}(\mu_{cr}, (s \times \mu_{cr})^2). \tag{10}$$

Reward Aggregation

The final reward function is an average of the reward functions $R_{fluency}$, R_{sim}, combined with either R_{len} or R_{cr}:

$$r_{total}(x, y) = \frac{1}{3} \sum_i R_i(x, y). \tag{11}$$

In practice, when the downstream task is known, reward functions may be designed and calibrated based upon insights and domain expertise, e.g., an optimal summary length for a specific application or different language models corresponding to different summary styles. In this work, we only use publicly available and commonly-used off-the-shelf models to construct reward functions.

5 Experiments

This section presents a detailed analysis and evaluation results for our proposed model. We name our model **SCRL (Sentence Compression with Reinforcement Learning)**. We make all code, model outputs and data available[3].

5.1 Datasets

5.1.1 Training Datasets

We use two datasets for training: Newsroom (Grusky et al., 2018) and Gigaword (Rush et al., 2015). For Newsroom, we extract the first three sentences from each article, only keeping sentences with a number of tokens between 15 and 60. Newsroom was chosen due to the large size and a variety of un-preprocessed news articles from different sources. Ground-truth summaries are not included in the training data, thus the two datasets are treated as large unlabeled text collections. We train a model for short headline-like summaries on Gigaword to evaluate it on the Gigaword test set, which comes in a specific preprocessed format[4]. Training on Gigaword allows to expose the model to the same preprocessing, for a fair evaluation.

5.1.2 Development Dataset

We constructed a small labelled validation dataset for model development: we automatically identified sentence-summary pairs in Newsroom, also including title-summary pairs, by extracting cases where the tokenized summary is contained in a tokenized sentence, with preserved order. We manually filter a subset of these examples based on grammaticality and informativeness and obtain 280 examples. This dataset was only used during initial development to compare the different reward function variants discussed in Section 4.3.

5.1.3 Evaluation Datasets

The evaluation includes five test sets – key statistics are listed in Table 1. L_{src}, L_{tgt} are the token counts in source and target sentences and $cr = L_{tgt}/L_{src}$ is the compression ratio. Following Schumann et al. (2020), we compare our models on Gigaword against baselines of comparable length brackets using ROUGE F1-scores[5]. For DUC2004 (Task

[4] Lowercased, pre-tokenized, rare words and digits replaced with special tokens.

[5] We only consider lengths similar to the ground-truth, i.e. 8-10 tokens.

Testset	**Type**	**Size**	L_{src}	L_{tgt}	cr
Gigaword	abs	1951	29.7	8.8	0.4
DUC2004	abs	500	32.9	11.9	0.41
Google	ext	1000	27	11	0.45
Broadcast	ext	1370	19.8	14.4	0.76
BNC	ext	1629	27.9	19.3	0.72

Table 1: Overview of the evaluation datasets. The *Type* column indicates whether the ground-truth is extractive or abstractive. *Size* gives the number of sentences.

1), following prior work, we truncate model outputs to 75 characters and compute ROUGE recall scores. While Gigaword and DUC2004 contain abstractive ground-truth summaries, the remaining three datasets have token-level extractive ground-truth summaries. The ground-truth compressions in the Google sentence compression dataset (Filippova and Altun, 2013) were automatically generated using grammatical constraints and distant supervision via headlines. The Broadcast and BNC datasets (Clarke and Lapata, 2008) contain manually created extractive sentence compressions which tend to be longer compared to the other evaluation datasets. Following previous work, we report a simple F1-score based on tokenized predicted and ground-truth summaries on the three extractive datasets, but also measure ROUGE F1 scores.

5.2 Model Development

We tune our approach in several phases. At first, we identify an optimal learning rate and batch size using a grid search with a fixed training duration. We compare different settings based on the average reward achieved on a unlabelled, held-out set of the training data. Next, we test different values of k (1, 5, 10, 50, 100), the number of samples per step, and pick the best k based on the average reward on the validation set. This method of hyperparameter tuning is fully unsupervised.

Using learning rate $1e-05$, batch size 4 and $k = 100$ identified in the previous runs, we next compare the different options for the similarity reward listed in Section 4.3 and pick the best (bi-encoder similarity) based on the F1-score on our labelled Newsroom-based validation set (see Appendix B).

5.3 Training

We initialize the encoder component of our model with the pretrained 6-layer DistilRoBERTa model (Sanh et al., 2019). The binary classifier module is initialized randomly. We train each model for 8,000 steps with a batch size of 4 on a Google Cloud virtual machine with one NVIDIA Tesla T4 GPU, using the AdamW optimizer (Loshchilov and Hutter, 2019). Our default reward combination contains masked-LM fluency and bi-encoder similarity combined with either R_{len} or R_{cr}. Table 2 gives an overview of the three models that are used in the evaluation. Note that the sample size of 100 is responsible for the long training durations. SCRL-L8 and SCRL-L11 are trained with R_{len} whereas SCRL-CR75 is trained with R_{cr}, with a compression ratio of 0.75. This is because the ground-truth summary lengths are approximated better by a fixed length rather than a fixed ratio in the Google and DUC2004 datasets, whereas a fixed ratio describes the Broadcast and BNC datasets better.

Name	Train data	Test Data	Time
SCRL-L8	Gigaword	Gigaword	9
SCRL-L11	Newsroom	DUC04, Google	9.5
SCRL-CR75	Newsroom	Broadcast, BNC	10

Table 2: Overview of trained models and training time in hours.

5.4 Baselines

We compare our model to the greedy stochastic hill climbing approach in Schumann et al. (2020) which obtained state-of-the-art ROUGE results for unsupervised baselines on the Gigaword and DUC2004 datasets. Because this method and SCRL do not have identical objective functions, we implement the hill climbing algorithm applied to our reward functions, which we will name HC throughout this work. This allows for a clearer comparison between RL and discrete search. HC optimizes $R_{fluency}$, R_{sim} under fixed length constraints instead of using R_{len} and R_{cr}. Different from Schumann et al. (2020), it runs for a fixed number of 2000 steps and restarts only when the search is stuck rather than in equal intervals (details in Appendix E). We analyze the performance of HC for different budgets to understand at what point search can surpass the learned policies. We also compare against Zhou and Rush (2019), Niu et al. (2019) and the RL-based method by Wang et al. (2018) on datasets where results are available.

5.5 Evaluation Results

Table 3 shows the evaluation results on all used test datasets. Results of methods apart from SCRL and HC are taken from previous works. We com-

Table 3: Results on evaluation datasets. ★ indicates supervised models. ROUGE F1-scores are shown for all dataset but DUC2004, where ROUGE recall is used. L_d: desired output length, L_o / cr_o: actual average length / compression ratio of the outputs.

pute ROUGE scores using the implementation from Google Research[6]. On Gigaword, SCRL outperforms all baselines, except Schumann et al. (2020) with a 10 token constraint in ROUGE-2. On DUC2004, SCRL remains behind the hill climbing methods, but outperforms other unsupervised baselines. On the Google dataset, SCRL obtains state-of-the-art results among unsupervised methods. On Broadcast and BNC, SCRL and HC obtain very similar scores, which are both higher than previously reported results. Figure 3 shows ROUGE-1 scores obtained by HC at different search budgets, compared to SCRL. The hill climbing strategy approaches or outperforms the trained model at different paces, depending on the dataset.

Interestingly, HC still achieves higher rewards than SCRL relatively early during its search (see Appendix F), which is inconsistent with the evaluation results. Potential reasons for this disparity are disadvantages through the hard length constraints, a mismatch between the heuristic reward functions and evaluation metrics, and beneficial biases induced through our training framework.

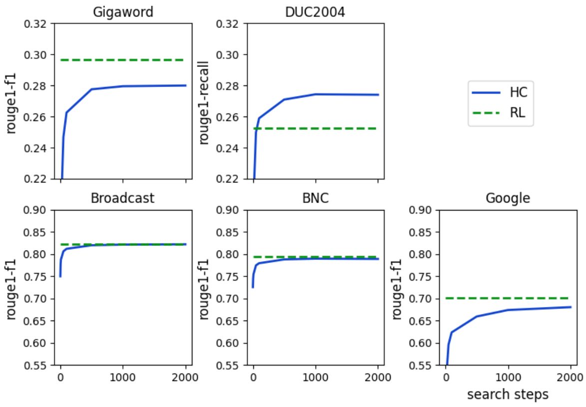

Figure 3: Evaluation scores of RL model compared to hill climbing algorithm (HC) at different search budgets.

5.6 Prediction Running Times

We compare the inference-time speed of SCRL with HC using different budgets of search steps[7]. The fastest batch size for both approaches is used. The *Inference Time* in Table 3 shows the average number of seconds per processed sentence, with the number of search steps set to $T = 2000$ for HC. SCRL is roughly $4000\times$ faster than HC with $T =$

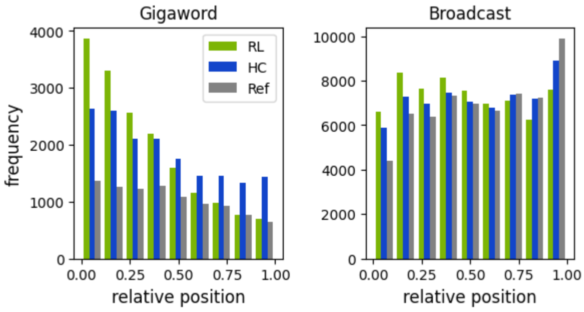

Figure 5: Distribution of relative positions from which tokens are extracted in source sentences.

2000, and $\sim 200\times$ faster when T is reduced to 100, for example. We believe that such a speed-up with a preserved evaluation performance is a critical factor when considering real-world applications of sentence compression.

6 Analysis

6.1 Summary Length and Extraction Regions

The length and compression ratio of summaries produced by SCRL is distributed around the desired values, with peakier distributions than in ground-truth summaries (examples in Figure 4). HC produces exactly the desired value whenever possible, due to the enforced constraint for length or ratio. Figure 5 shows how SCRL and HC extract tokens from different relative positions within source sentences. SCRL has a higher tendency to extract early tokens. We hypothesize that this is a reliable high-reward strategy discovered during training, considering that a milder form of the lead-bias also shows in HC. Note that neither method is inherently biased in its design to prefer tokens from certain regions.

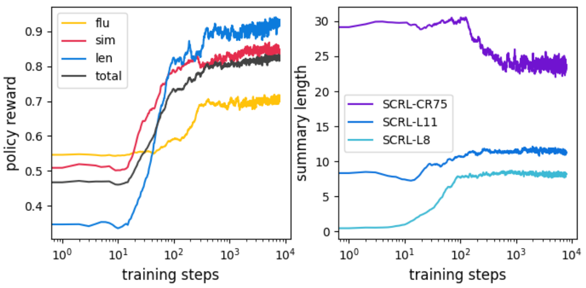

Figure 6: Development of reward functions (of SCRL-L11) and summary length during training (all models), from a moving average over 50 steps, using a log scale.

6.2 Training Dynamics

Figure 6 shows how rewards and summary length develop throughout training. The rewards generally increase quickly in the first few hundred training steps and then continue to grow very slowly. Fluency starts to increase later than the other reward functions, which is likely related to our observation that it is more sensitive to small changes in a summary. Interestingly, the summary lengths develop differently depending on the length or compression setting – SCRL-L8 and SCRL-L11 start with short summaries and increase the size over time whereas SCRL-CR75 starts with long summaries before settling on a shorter certain range.

6.3 Learned Summarization Techniques

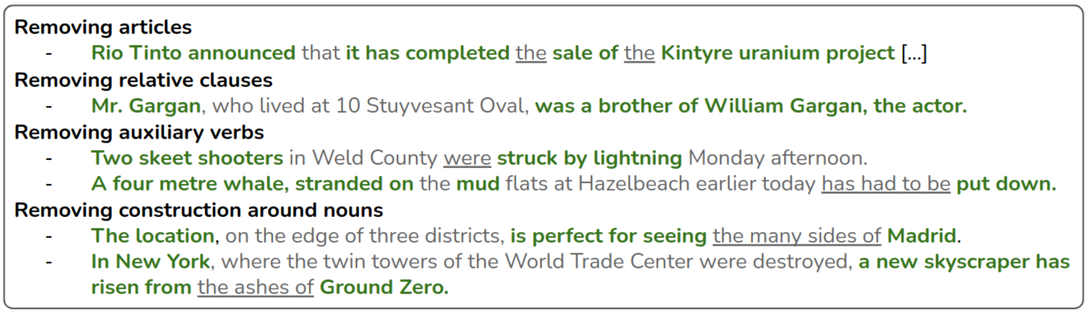
Our models learn a variety of behaviors to compress sentences, such as removing articles, auxiliary verbs, relative clauses and temporal expressions. Figure 7 shows some examples.

6.4 Error Analysis

Even though our models learn to produce grammatical sentences fairly well, grammatical errors do still appear, and are more common for the models with a short output length (SCRL-8, SCRL-11). In some cases, semantic errors occur where the original meaning is changed or made unintelligeble. Both SCRL and HC are susceptible of semantic and grammatical errors, as can be seen in some examples in Appendix G. A type of error that is specific to SCRL is the splitting or merging of tokens resulting from its operation on Byte Pair Encoding-based subword tokens (more details in Appendix C).

6.5 Customization via Reward Functions

To demonstrate that our approach is flexible for customization, we pick a simple example of re-



Removing articles
- **Rio Tinto announced** that **it has completed** the **sale of** the **Kintyre uranium project** [...]

Removing relative clauses
- **Mr. Gargan**, who lived at 10 Stuyvesant Oval, **was a brother of William Gargan, the actor.**

Removing auxiliary verbs
- **Two skeet shooters** in Weld County were **struck by lightning** Monday afternoon.
- **A four metre whale, stranded on** the **mud** flats at Hazelbeach earlier today has had to be **put down.**

Removing construction around nouns
- **The location,** on the edge of three districts, **is perfect for seeing** the many sides of **Madrid.**
- **In New York**, where the twin towers of the World Trade Center were destroyed, **a new skyscraper has risen from** the ashes of **Ground Zero.**

Figure 7: Examples of learned summarization techniques. Selected tokens are marked in green and common removal behaviors are pointed out with underlining.

programming model behavior using a hand-crafted reward function. We note that in some cases, the model unnecessarily keeps day references in compressed sentences, such as "Thursday" or "yesterday". We construct a simple reward function that returns zero if any day-like word from a small gazetteer appears in an output and a score of 1 otherwise. We fine-tune an existing model with this additional reward and observe that it successfully avoids including day-words that the previous model would include. Importantly, it additionally learned to remove other tokens attached to day-words, e.g. "on" in "on Monday", keeping the sentences grammatical. Table 4 shows some examples. Empirically, the new model's outputs contain words from the gazeteer in 1% of cases where they appear in the source, compared to 12% in the initial model.

Initial Model	Customized Reward
The burrito chain said **on Tuesday** that comparable sales fell 26.1% last month.	The burrito chain said that comparable sales fell 26.1%.
His car was found **last Thursday** alongside Rubyvale Road.	His car was found alongside Rubyvale Road.

Table 4: Example outputs of model with customized reward function to exclude mentions of days.

7 Discussion

We argue that RL offers the following advantages over discrete search strategies for sentence compression and similar text editing or generation tasks. The necessary search and exploration is moved into the training stage, allowing fast inference independently of how efficient objectives are to compute. Furthermore, discrete search unnecessarily spends time navigating through low-quality outputs that a trained model can quickly learn to avoid. Limitations of our approach compared to the search-based approach are its lesser flexibility in terms of on-the-fly customization and a sensitivity to disparities between training data and the application domain. Furthermore, the trained models show a lower capability to optimize the selected objectives compared to search, though this does not have a negative impact on the evaluation in most cases.

The fact that most of our training time is spent on estimating the quality of sampled compressions due to large sample size k, shows that our approach is somewhat similar to large-scale search strategies applied to a whole dataset, with the difference that the sampling behavior at each step changes over time and is informed by previous steps. This suggests that discrete search could support the RL training, similarly to the learning-from-search approach described by (Li et al., 2020).

8 Conclusion

This work presents a simple and effective approach for learning sentence compression models based on objective functions rather than ground-truth examples. Because it is unsupervised, it is well-suited for creating customized applications even when no gold training data is available, allowing for task-specific tuning based on arbitrary sets of reward functions, which do not need to be differentiable. Importantly, our approach is very fast at inference time compared to alternative discrete search-based methods. We are interested in several future directions related to this work: 1) systematic approaches to design reward functions for summarization, 2) RL-based summarization models with length control on the fly, 3) testing our approach on other languages, and 4) the design of curricula for different reward functions as they might pose varying difficulties at different stages of the training.

A Masked vs. Causal Language Model for Fluency

We compare the masked DistilRoBERTa[8] language model to the causal DistilGPT2[9] model on our development dataset. Both models have roughly the same number of parameters (82M). Table 5 shows the results.

LM	DistilRoBERTa	DistilGPT2
F1-Score	0.565	0.546

Table 5: Comparison of a masked and a causal language model to estimate fluency.

B Similarity Functions

Table 6 compares different variants of the similarity reward functions on our development dataset.

Similarity	Bi-Sim	Cross-Sim	NLI
F1-Score	0.624	0.598	0.564

Table 6: Comparison of similarity reward functions on our development dataset.

C Error Analysis: Split and Merged Tokens

One type of error is the splitting or merging of tokens from the source which results from the fact our model predicts labels at the level of BPE subword tokenization used in the pretrained language model that we finetune. While some of these occurrences are minor, e.g. 'St.' → 'St', or even useful compressions, e.g. '29th' → '29', many of these cases produce noisy outputs, e.g 'Perigord' → 'Perig'. Based upon analysis of prediction behavior, we estimate that 6% of output sentences contain some form of this phenomenon.

D Implementation Details

D.1 Pretrained Model IDs

Table 7 lists the model IDs of all open-source pretrained models used in this work, which can be found at `https://huggingface.co`.

Algorithm 1 Stochastic First-Choice Hill Climbing

```
input objective function $R(x, y)$, source sentence $x$, summary length $L$, number of steps $T$, initialization function $Init(x, L)$, sampling function $S(y)$
  $y^0 \leftarrow Init(x, L)$
  for $t = 1$ to $T$ do
    $y' \leftarrow S(y^{t-1})$
    if $R(x, y') \geq R(x, y^{t-1})$ then
      $y^t = y'$
    else
      $y^t = y^{t-1}$
  return $y_t$
```

D.2 Tokenization

We use the NLTK[10] Punkt Tokenizer for several purposes in this work:

- Obtaining the sentence length and compression ratio in R_{len} and R_{cr}.
- Compressing sentences by selecting tokens in our hill climbing implementation HC.
- Obtaining source and summary tokens to compute the F1-score in Table 3, except for source and reference tokens on the Gigaword, Broadcast and BNC datasets which are pretokenized.

The involved transformer models (SCRL, $R_{fluency}$, R_{sim}) internally tokenize sentences based on Byte Pair Encoding.

E Hill Climbing Baseline

Algorithm 1 shows the hill climbing search approach HC used in our experiments, which is based on Schumann et al. (2020). At the beginning, a binary label sequence y^0 is initialized by setting L randomly selected labels to 1 and the rest to 0. At each step t, $S(y)$ samples a new label sequence y' by randomly selecting a positive and a negative-valued label y_i and y_j and swapping their value. Note that this always keeps the number of tokens at L. The sampled y' is accepted if it obtains a higher or equal objective score than the previously best candidate y^{t-1}. We keep track of previously created sequences and skip these. If no new label sequence can be discovered at step t, we terminate the algorithm and restart it with $T - t$ remaining steps. In the end, the highest-scoring y found across different runs is returned. We generally set T to 2000 and keep track of intermediate results to evaluate HC also at fewer search steps. Due to this,

we decided restart the search dynamically rather in equal-paced intervals, which we believe should be tuned with respect to a known maximum budget T.

F Rewards Obtained by HC vs. SCRL

Figure 8 compares the $R_{fluency}$ and R_{sim} rewards of SCRL to HC with different search budgets. The length and compression ratio rewards are not included as these are enforced through a constraint by HC. Note that these figures need to be interpreted carefully as they assume that both approaches produce summaries of comparable lengths. For example, the similarity reward tends to increase with the summary length.

Abstract

Machine reading comprehension is a heavily-studied research and test field for evaluating new pre-trained language models (PrLMs) and fine-tuning strategies, and recent studies have enriched the pre-trained language models with syntactic, semantic and other linguistic information to improve the performance of the models. In this paper, we imitate the human reading process in connecting the anaphoric expressions and explicitly leverage the coreference information of the entities to enhance the word embeddings from the pre-trained language model, in order to highlight the coreference mentions of the entities that must be identified for coreference-intensive question answering in QUOREF, a relatively new dataset that is specifically designed to evaluate the coreference-related performance of a model. We use two strategies to fine-tune a pre-trained language model, namely, placing an additional encoder layer after a pre-trained language model to focus on the coreference mentions or constructing a relational graph convolutional network to model the coreference relations. We demonstrate that the explicit incorporation of coreference information in the fine-tuning stage performs better than the incorporation of the coreference information in pre-training a language model.

Context: ***Frankie Bono***, *a mentally disturbed hitman from Cleveland, comes back to his hometown in New York City during Christmas week to kill a middle-management mobster, Troiano. ...First* ***he*** *follows his target to select the best possible location, but opts to wait until Troiano isn't being accompanied by his bodyguards. ... Losing his nerve,* ***Frankie*** *calls up his employers to tell them he wants to quit the job. Unsympathetic, the supervisor tells him* ***he*** *has until New Year's Eve to perform the hit.*
Question: *What is the first name of the person who has until New Year's Eve to perform a hit?* Answer: he ->Frankie
Question: *What is the first name of the person who follows their target to select the best possible location?* Answer: he ->Frankie

Table 1: An example from QUOREF: coreference resolution is required to extract the correct answer. We highlight the supporting text in teal color and the related deictic expressions in **bold**.

1 Introduction

Machine reading comprehension (MRC), a task that automatically identifies one or multiple words from a given passage as the context to answer a specific question for that passage, is widely used in information retrieving, search engines, and dialog systems. Several datasets on MRC that limit the answer to one single word or multiple words from the passage are introduced, including TREC (Harman, 1993), SQuAD (Rajpurkar et al., 2018), NewsQA (Trischler et al., 2017), SearchQA (Dunn et al., 2017), and QuAC (Choi et al., 2018), and intensive efforts were made to build new models that surpass the human performance on these datasets, including the pre-trained language models (Devlin et al., 2019; Liu et al., 2019; Yang et al., 2019a) or the ensemble models that outperform the human, in particular on SQuAD (Lan et al., 2020; Yamada et al., 2020; Zhang et al., 2021). More challenging datasets are also introduced, which require several reasoning steps to answer (Yang et al., 2018; Qi et al., 2021), the understanding of a much larger context (Kočiský et al., 2018) or the understanding of the adversarial content and numeric reasoning (Dua et al., 2019).

Human texts, especially long texts, are abound in deictic and anaphoric expressions that refer to the entities in the same text. These deictic and anaphoric expressions, in particular, constrain the generalization of the models trained without explicit awareness of the coreference. The QUOREF dataset (Dasigi et al., 2019) is specifically designed to validate the performance

May 22-27, 2022

of the models in coreferential reasoning, in that "78% of the manually analyzed questions cannot be answered without coreference" (Dasigi et al., 2019). The example in Table 1 shows that the answers to the two questions cannot be directly retrieved from the sentences because the word in the corresponding sentence of the context is an anaphoric pronoun ***he***, and to obtain the correct answers, tracing of its antecedent ***Frankie*** is required. The reasoning in coreference resolution is required to successfully complete the task in machine reading comprehension in the SQuAD-style QUOREF dataset.

Pre-trained language models, including BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019) and XLNet (Yang et al., 2019b), that are trained through self-supervised language modeling objectives like masked language modeling, perform rather poorly in the QUOREF dataset. We argue that the reason for the poor performance is that those pre-trained language models do learn the background knowledge for coreference resolution but may not learn adequately the coreference information required for the coreference-intensive reading comprehension tasks. In the human reading process, as shown in the empirical study of first-year English as a second language students during the reading of expository texts, "anaphoric resolution requires a reader to perform a text-connecting task across textual units by successfully linking an appropriate antecedent (among several prior antecedents) with a specific anaphoric referent" and "students who were not performing well academically were not skilled at resolving anaphors" (Pretorius, 2005) and the direct instruction on anaphoric resolution elevated the readers' comprehension of the text (Baumann, 1986). In addition, the studies on anaphor resolution in both adults using eye movement studies (Duffy and Rayner, 1990; van Gompel et al., 2004) and children (Joseph et al., 2015) evidenced a two-stage model of anaphor resolution proposed by Garrod and Terras(Garrod and Terras, 2000). The first stage is "an initial lexically driven, context-free stage known as bonding, whereby a link between the anaphor and a potential antecedent is made, followed by a later process known as resolution, which resolves the link with respect to the overall discourse context" (Joseph et al., 2015). The pre-trained language models only capture the semantic representations of the words and sentences, without explicitly performing such text-connecting actions in the specific coreference-intensive reading comprehension task, thus they do not learn adequate knowledge to solve the complex coreference reasoning problems.

Explicitly injecting external knowledge such as linguistics and knowledge graph entities, has been shown effective to broaden the scope of the pre-trained language models' capacity and performance, and they are often known as X-aware pre-trained language models (Zhang et al., 2020; Liu et al., 2020; Kumar et al., 2021). It is plausible that we may imitate the anaphoric resolution process in human's two-stage reading comprehension of coreference intensive materials and explicitly make the text-connecting task in our fine-tuning stage as the second stage in the machine reading comprehension.

As an important tool that captures the anaphoric relationship between words or phrases, coreference resolution that clusters the mentions of the same entity within a given text is an active field in natural language processing (Chen et al., 2011; Sangeetha, 2012; Huang et al., 2019; Joshi et al., 2020; Kirstain et al., 2021), with neural networks taking the lead in the coreference resolution challenges. The incorporation of the coreference resolution results in the pre-training to obtain the coreference-informed pre-trained language models, such as CorefBERT and CorefRoBERTa (Ye et al., 2020), has shown positive improvements on the QUOREF dataset, a dataset that is specially designed for measuring the models' coreference capability, but the performance is still considerably below the human performance.

In this paper, we make a different attempt to leverage the coreference resolution knowledge and complete the anaphoric resolution process in reading comprehension. We propose a fine-tuned coref-aware model that directly instructs the model to learn the coreference information[1]. Our model can be roughly divided into three major components: 1) pre-trained language model component. We use the contextualized representations from the pre-trained language models as the token embeddings for the downstream reading comprehension tasks. 2) coreference resolution component. NeuralCoref, an extension to the spaCy, is applied here to extract the mention clusters from the context. 3)

coreference enrichment component. We apply three methods in incorporating the coreference knowledge: additive attention enhancement, multiplication attention enhancement, and relation-enhanced graph-attention network + fusing layer.

In this paper, we show that by simulating the human behavior in explicitly connecting the anaphoric expressions to the antecedent entities and infusing the coreference knowledge our model can surpass that of the pre-trained coreference language models on the QUOREF dataset.

2 Background and Related Work

2.1 Models and Training Strategies

Recent studies on machine reading comprehension mainly rely on the neural network approaches. Before the prevalence of the pre-trained language models, the main focus was to guide and fuse the attentions between questions and paragraphs in their models, in order to gain better global and attended representation (Huang et al., 2018; Hu et al., 2018; Wang et al., 2018).

After the advent of the BERT (Devlin et al., 2019), there were two trends in solving the machine reading comprehension. The first trend was to develop better pre-trained language models that captured the representation of contexts and questions (Liu et al., 2019; Yang et al., 2019a; Lewis et al., 2020), and more datasets on question answering were introduced to increase the difficulty in this task, including NewsQA (Trischler et al., 2017), SearchQA (Dunn et al., 2017), QuAC (Choi et al., 2018), HotpotQA (Yang et al., 2018), NarrativeQA (Kočiský et al., 2018), DROP (Dua et al., 2019), and BeerQA (Qi et al., 2021).

However, the raw pre-trained language models, being deprived of the in-domain knowledge, the structures and the reasoning capabilities required for the datasets, often perform unsatisfactorily in the hard datasets, being significantly below the human performance. Efforts had been made to boost the model performance by enriching the pre-trained language models with specific syntactic information (Ye et al., 2020) or semantic information. Another trend was to fine-tune the pre-trained language model and added additional layers to incorporate task-specific information for better representation, in particular, the coreference information (Ouyang et al., 2021; Liu et al., 2021). For some questions that have multi-span answers, in other words, a single answer contains two or more discontinuous entities in the context, the BIO (B denotes the start token of the span; I denotes the subsequent tokens and O denotes tokens outside of the span) tagging mechanism is used to identify these answers and improve the model performance (Segal et al., 2020).

Recent studies also explored the possibilities of prompt-based learning in machine reading comprehension, including a new pre-training scheme that changed the question answering into a few-shot span selection model (Ram et al., 2021) and a new model that fine-tuned the prompts with knowledge (Chen et al., 2021). The performance of the models using prompt-based learning is significantly higher than the baseline models, but is still below that of the fine-tuned models (Chen et al., 2021).

2.2 Graph Neural Network in Machine Reading Comprehension

Graph neural network (GNN) captures the relations among the entities in the text by modeling the entities as nodes in the graph and learning the weights via the message passing between the nodes of the graph (Kipf and Welling, 2017; Velickovic et al., 2018). As the dependencies in the natural language text, the relations among entities and knowledge-base triples can be relatively easily modeled in a graph structure, graph neural networks are used for numeric reasoning (Ran et al., 2019), for multi-document question answering by connecting mentions of candidate answers (De Cao et al., 2019), and for multi-hop reasoning by adding the edges with co-occurrence relations(Qiu et al., 2019), or with contextual sentences as embeddings (Tu et al., 2020), or with a hierarchical paragraph-sentence-entity graph (Fang et al., 2020), but none of them had attempted to connect the anaphoric expressions and their antecedents as a coreference resolution strategy in a graph neural network for machine reading comprehension.

3 Coreference-aware Machine Reading Comprehension

Our model, inspired by the anaphoric connecting behavior in the human reading comprehension process, consists of four parts, namely, a pre-trained language model, a coreference resolution component, a graph encoder and a fusing layer. Context in the machine reading comprehension task is first processed by a coreference resolution model to identify the underlying coreference clusters,

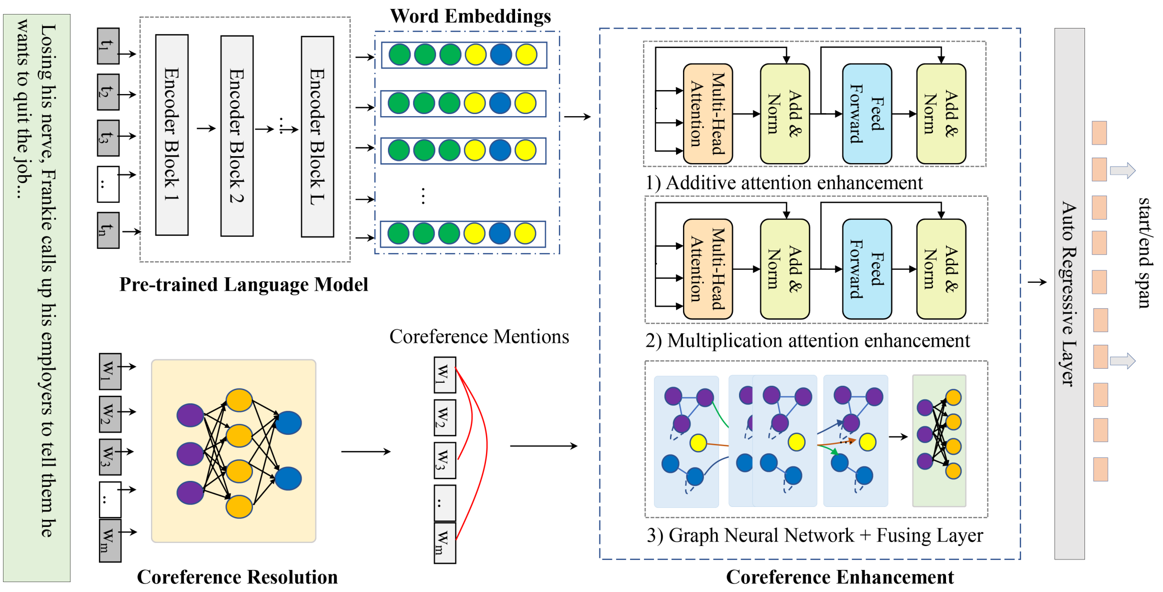

Figure 1: Coref-aware fine-tuning for machine reading comprehension. The text is tokenized and fed into a pre-trained language model to obtain the embeddings, and into a coreference resolution model to obtain coreference information. Both the embeddings and the coreference information are used in the fine-tuning stage to 1) enhance cross attentions with additive operations; 2) enhance cross attentions with multiplication operations, or; 3) construct a coreference graph neural network with the coreference relations as edges.

which are formed by dividing the entities and anaphoric expressions in the context into disjoint groups on the principle that the mentions of the same entity should be in the same group. Then we use the coreference clusters to construct a coreference matrix that labels each individual cluster and identifies each element in the same cluster with the same cluster number. Meanwhile, the context is tokenized by the tokenizer defined in the pre-trained language model and the embeddings for each token are retrieved from that model. We propose three methods for connecting the anaphoric expressions and their antecedent entity: 1) adding the coreference matrix with each attention head in the additional coreference encoder layer; 2) multiplying the coreference matrix with each attention head in the additional coreference encoder layer; 3) constructing a graph neural network based on the coreference matrix with the edges corresponding to the coreference relations and then fusing the graph representation in the graph neural network with the embeddings of the context, as shown in Figure 1. The final representations from either one of the three methods are fed into the classifier to calculate the start/end span of the question.

3.1 Coreference Resolution

Coreference resolution is the process that identifies all the expressions of the same entity in the text, clusters them together as coreference clusters, and locates their spans. For example, after coreference resolution for the text *Losing his nerve, Frankie calls up his employers to tell them he wants to quit the job.*, we obtained two mention clusters *[Frankie: [his, Frankie, his, he], his employers: [his employers, them]]*, where *Frankie* is the head entity and *his, Frankie, his, he* are all the expressions referring to this entity, as shown in Figure 2.

As pre-trained language models use subwords in their tokenization and the coreference resolution uses word in the tokenization, a mapping is required to establish the relations. For the input sequence $X = \{x_1, ...x_n\}$ of length n, the words $W = \{w_1, ..., w_m\}$ obtained from the coreference tokenization are mapped to the corresponding subwords (tokens) $T = \{t_1, ..., t_k\}$ from the tokenizer in the pre-trained language model, with one word contains one or more than one subwords. Then we constructed a coreference array with the

---

[2] Image generated from https://huggingface.co/coref/

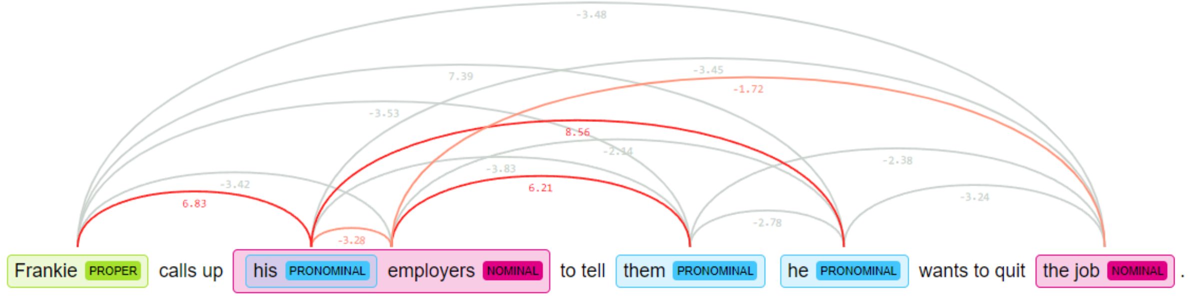

Figure 2: Coreference resolution: the red curves connecting the mentions of the same entity and marking the coreference relations. [2]

following rule:

$$coref(i) = \begin{cases} 0 & \text{if tokens[i]} \notin \mathrm{S_m}, \\ n & \text{if tokens[i]} \in \mathrm{S_m}, \end{cases} \tag{1}$$

where i is the position of the token in the token array, S_m is an array of all words in the coreference mention clusters, n is the sequence number of the mention cluster and $n \geq 1$. Tokens in the same mention cluster have the same sequence number n in the coreference array.

3.2 Graph Neural Network

We use the standard relational graph convolutional network (RGCN) (Sejr Schlichtkrull et al., 2018) to obtain the graph representation of the context enriched with coreference information. We use the coreference matrix and the word embeddings to construct a directed and labeled graph $\mathcal{G} = (\mathcal{V}, \mathcal{E}, \mathcal{R})$, with nodes (subwords) $v_i \in \mathcal{V}$, edges(relations) $(v_i, r, v_j)) \in \mathcal{E}$, where $r \in \mathcal{R}$ is one of the two relation types (1 indicates coreference relation and self-loop; 2 indicates global relation), as shown in Figure 3 .

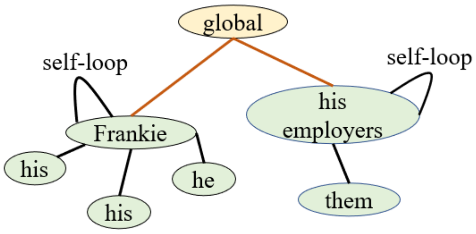

Figure 3: Coreference graph. We connect the entities with their coreference mentions to form a graph, and the nodes are connected to the global node to form global representations.

The constructed graph is then fed into the RGCN, with the differentiable message passing and the basis decomposition to reduce model parameter size and prevent overfitting:

$$\begin{gathered} h_i^{l+1} = \sigma\big(W_0^{(l)} h_i^{(l)} + \sum_{r \in R} \sum_{j \in N_i^r} \frac{1}{c_{i,r}} W_r^{(l)} h^{(l)}\big), \\ W_r^{(l)} = \sum_{b=1}^{B} a_{rb}^{(l)} V_b^{(l)}, \end{gathered} \tag{2}$$

where N_i^r denotes the set of neighbor indices of node i under the relation $r \in \mathcal{R}$, $c_{i,r}$ is the normalization constant, and $W_r^{(l)}$ is a linear combination of basis transformation $V_b^{(l)}$ with coefficient $a_{rb}^{(l)}$.

3.3 Coreference-enhanced Attention

In addition to the Graph Neural Network method, we also explore the possibility of using the self-attention mechanism (Vaswani et al., 2017) to explicitly add an encoder layer and incorporate the coreference information into the attention heads of that layer, so as to guide the model to identify the mentions in the cluster as the same entity.

We use two methods to fuse the coreference information and the original embeddings from the pre-trained language model: additive attention fusing and dot product attention fusing (multiplication). Given the coreference array $A = \{m_1, 0, m_1, m_2, 0, m_2, m_3, 0, m_3, m_1 ...\}$, where m_n denotes the nth mention cluster, and 0 denotes no mentions, the enriched attention for additive attention fusing is formulated as:

$$\begin{gathered} \text{Attention}(Q, K, V) = \text{softmax}(\frac{QK^T}{\sqrt{d_k}} + M_A)V, \\ head_i = \text{Attention}(QW_i^Q, KW_i^K, VW_i^V), \end{gathered} \tag{3}$$

where M_A is a coreference matrix constructed from the coreference array A with the element value in the matrix calculated by adding (for additive model) or multiplying (for multiplication model) the coreference hyper-parameter $coref_{weight}$ with the original attention weight if the element belongs to the coreference array, Q, K, V are the query, key and value respectively, d_k is the dimension of the keys, and W_i is trainable parameter. For dot product (multiplication) fusing, it is formulated as:

$$\text{Attention}(Q, K, V) = \text{softmax}(\frac{QK^T}{\sqrt{d_k}} \odot M_A)V,$$
$$head_i = \text{Attention}(QW_i^Q, KW_i^K, VW_i^V), \tag{4}$$

where we calculate the dot product of $\frac{QK^T}{\sqrt{d_k}}$ and a coreference matrix M_A constructed from the coreference array A.

3.4 Integration

A machine reading comprehension task expects the model to output the start and end positions of the answer. For the RCGN method, we fuse the hidden state of nodes v_i in the last layer of RCGN and the embeddings from the pre-trained language model with a fully-connected (FC) layer , and then calculate the start/end positions of the answer.

$$\begin{aligned} E &= FC(E_{prLM} || E_{gnn}), \\ P_s &= argmax(softmax(W_s S)), \end{aligned} \tag{5}$$

where E_{prLM} denotes the embeddings from the pre-trained language model, E_{gnn} denotes the embeddings from the graph encoder, P_s denotes the predicted start positions, W_s denotes the weight matrix and S denotes the text feature.

For the two methods that add one additional encoder layer for additive or multiplication attention enrichment, we directly used the output of that encoder layer for the follow-up processing.

Following the practice of CorefRoBERTa (Ye et al., 2020) in handling multiple answers for the same question, we use the cross entropy to calculate the losses for each answer if the question has multiple answers:

$$\begin{aligned} E_n &= FC(E_{prLM}, n), \\ L_s &= \sum_i^n H(p_s i, q_s i), \\ L_e &= \sum_i^n H(p_e i, q_e i), \\ L_{total} &= avg(L_s + L_e + L(E_n, n)), \end{aligned} \tag{6}$$

where n denotes the answer count as a hyper parameter for handling multiple answers, E_n denotes the results after the linear transformation of the embeddings for the answer count and then we obtains the predicted start positions and end positions from that embeddings, $L(E_n, n)$ denotes the cross-entropy loss between the transformed embeddings and the answer count, L_s denotes the total loss of the start positions, L_e denotes the total loss of the end positions and L_{total} denotes the combined total loss.

4 Experiments

4.1 Model Settings

We developed three models based on the sequence-to-sequence Transformer architecture. The pre-trained RoBERTa-large was used as the base model and then we used the following three methods to fine-tune it: 1) $\text{Coref}_{\text{GNN}}$: feeding the coreference information into a graph neural network and then fuse the representations; 2) $\text{Coref}_{\text{AddAtt}}$: adding the coreference weights with the self-attention weights; 3) $\text{Coref}_{\text{MultiAtt}}$: calculating the dot product of the coreference weights with the self-attention weights. We used the results from CorefRoBERTa (Ye et al., 2020) as our baselines.

4.2 Setup

Our coreference resolution was implemented in spaCy (Honnibal and Montani, 2017) and NeuralCoref. NeuralCoref is an extension for spaCy that is trained on the OntoNotes 5.0 dataset based on the training process proposed by Clark and Manning (Clark and Manning, 2016), which identifies the coreference clusters in the text as mentions. In particular, spaCy 2.1.0 and NeuralCoref 4.0 are used, because the latest spaCy version 3.0+ has compatibility issues with NeuralCoref and extra efforts are required to solve the issues.

The neural network implementation was implemented in PyTorch (Paszke et al., 2019) and Hugging Face Transformers (Wolf et al., 2020). We used the embeddings of the pre-trained language model $\text{RoBERTa}_{\text{LARGE}}$, with the relational graph convolutional network implemented in Deep Graph Library (DGL) (Wang et al., 2020). We used Adam (Kingma and Ba, 2015) as our optimizer, and the learning-rate was {1e-5, 2e-5, 3e-5}. We trained each model for {4, 6} epochs and selected the best checkpoints on the development dataset with Exact match and F1 scores. All experiments were run on

Model	Dev EM	Dev F1	Test EM	Test F1
QANet*	34.41	38.26	34.17	38.90

Table 2: Exact Match and F1 scores of baselines and our proposed models. Results with *, + are from Dasigi et al. (2019) and Ye et al. (2020) respectively.

two NVIDIA TITAN RTX GPUs, each with 24GB memory.

4.3 Tasks and Datasets

Our evaluation was performed on the QUOREF dataset (Dasigi et al., 2019). The dataset contains a train set with 3,771 paragraphs and 19,399 questions, a validation set with 454 paragraphs and 2,418 questions, and a test set with 477 paragraphs and 2,537 questions.

4.4 Results

We quantitatively evaluated the three methods and reported the standard metrics: exact match score (EM) and word-level F1-score (F1) (Rajpurkar et al., 2016).

As shown in Table 2, compared with the baseline model CorefRoBERTa, the performance of our models improves significantly. In particular, Coref$_{\text{AddAtt}}$ performs best with 5.08%, 4.42% improvements over the baseline model in Exact Match and F1 score respectively on the QUOREF dev set, and 3.05% (F1) and 3.31% (Exact Match) improvements on the QUOREF test set. Coref$_{\text{GNN}}$ and Coref$_{\text{MultiAtt}}$ also outperform the baseline model by 2.34% (F1) and 2.80% (Exact Match), and 2.46% (F1) and 2.72% (Exact Match) respectively on the test set. Compared with the RoBERTa$_{\text{LARGE}}$ that does not use any explicit coreference information in the training or the CorefRoBERTa$_{\text{LARGE}}$ that uses the coreference information in the training, the improvements of our model are higher, which proves the effectiveness of the explicit coreference instructions in our strategies.

5 Analysis

5.1 Model Efficiency

As shown in Table 2, compared with RoBERTa$_{\text{LARGE}}$, our methods added only one component that explicitly incorporates the coreference information, and the three methods we used all exhibit considerable improvements over the baselines. Compared with RoBERTa$_{\text{LARGE}}$ which has 354M parameters, Coref$_{\text{AddAtt}}$ and the Coref$_{\text{MultiAtt}}$ add an encoder layer, which adds over 12M parameters. For the Coref$_{\text{GNN}}$ method, we added one hidden layer in GNN and two linear layers to transform the feature dimensions, with around 68.7K parameters in total. Our predictions are that intuitively with more focuses on the coreference clues, the models perform better on the task that requires intensive coreference resolution, as we have explicitly increased the attention weights to connect the words in the same coreference mention clusters. However, the overall performance of the models is also limited by the performance of the coreference component we use, namely, NeuralCoref.

5.2 Case Studies

To understand the model's performance beyond the automated metrics, we analyze our predicted answers qualitatively. Table 3 compares the representative answers predicted by our models and CorefRoBERTa$_{\text{LARGE}}$. These examples require that the models should precisely locate the entity from several distracting entities for the anaphoric expression that directly answers the questions. Our model demonstrates that, after resolving the anaphoric expression with the antecedents in the context and enhancing with the coreference information by connecting the anaphoric expression with its antecedents, such as the connection from ***her*** to ***Henrietta*** in the first example and the connection from ***she*** to ***Rihanna*** in the second example, our model accurately locates the entity name among several names in the context, which the CorefRoBERTa$_{\text{LARGE}}$ fails to uncover.

We further explored the effects of the anaphoric connections on the attention weights by comparing the attention weights of the sample in the first row in Table 3 between our Coref$_{\text{AddAtt}}$ and CorefRoBERTa$_{\text{LARGE}}$ model, as shown in Figure 4. It is clear that the anaphoric expressions are not connected in the CorefRoBERTa$_{\text{LARGE}}$ model,

Coref-resolved Context (Abbreviated)	Question	Answers
Henrietta *take an immediate liking to her, and she asks if Luce can sit by* ***her*** *during the wedding. Rachel arrives with her father and the ceremony begins. As Rachel is walking down the aisle, her eyes wander and she makes eye contact with Luce.*	*Rachel makes eye contact with a woman sitting next to whom?*	*Henrietta* (Golden) Rachel (CorefR) Henrietta ($\mathrm{C}_{\mathrm{AddAtt}}$)
After the song was completed, they wanted to play it to ***Rihanna****, but Blanco was skeptical about the reaction towards the song because of its slow sound. After StarGate played it to her, they called Blanco from London and told him that* ***she*** *liked the song: "She's flippin' out.*	*Who liked a song?*	*Rihanna* (Golden) Blanco (CorefR) Rihanna ($\mathrm{C}_{\mathrm{AddAtt}}$)

Table 3: Comparison of the predictions for two questions in QUOREF dev set. The blue and bold words indicate the mentions in the same coreference cluster obtained from coreference resolution. In the Answers column, Golden indicates the golden answer; CorefR indicates the prediction made by CorefRoBERTa$_{\mathrm{LARGE}}$ model; $\mathrm{C}_{\mathrm{AddAtt}}$ indicates the prediction made by Coref$_{\mathrm{AddAtt}}$ model.

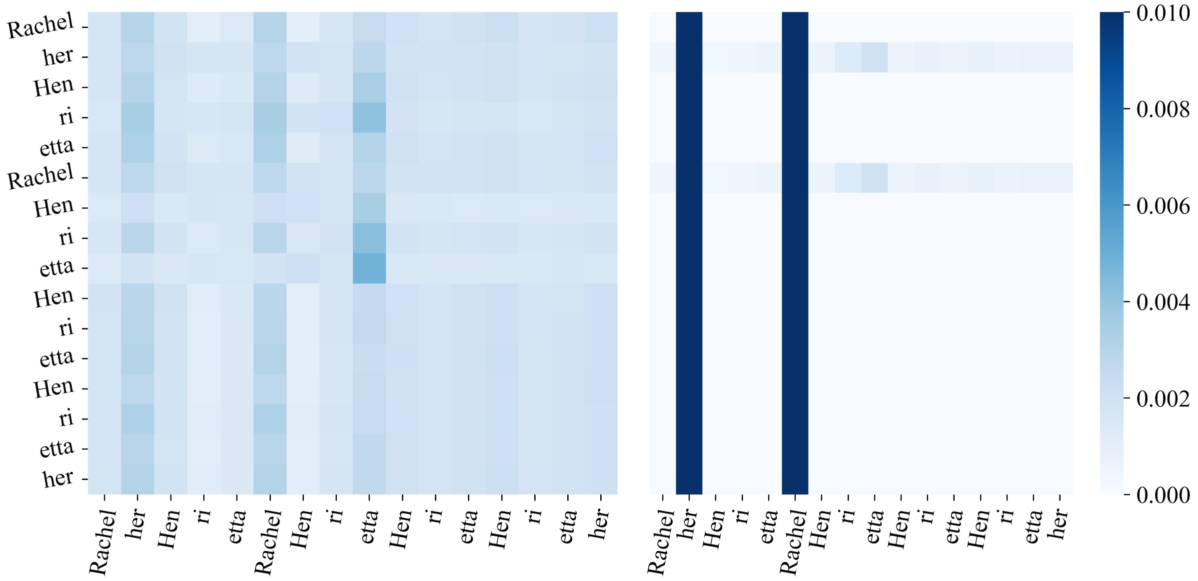

Figure 4: Sample average cross attentions for all heads from Coref$_{\mathrm{AddAtt}}$ model (left) and CorefRoBERTa$_{\mathrm{LARGE}}$ model (right). The cross attentions among the anaphoric expressions and the entities of our model (Coref$_{\mathrm{AddAtt}}$) are visibly much more distinctive than those of the baseline model (CorefRoBERTa$_{\mathrm{LARGE}}$).

as indicated by the obtrusive attentions on **Rachel** and **Her** in the heatmap on the right of the figure. For the Coref$_{\mathrm{AddAtt}}$, the varying colors on the left heat-map indicate the connection strength among the anaphoric expressions and evidence the effects of explicit coreference addition that smooth and strength the attentions for anaphoric expressions, which contributes to the higher performance of our models.

5.3 Error Analysis

Despite the improvements made by our model, it still fails to predict the correct answers for some questions. We analyzed and summarized several error cases as follows.

Table 4 shows three representative types of errors. The first type of errors is caused by the limitations of the coreference resolution component, NeuralCoref, as its performance had not reached 80% in F1 for MUC, B^3 or CEAF$_{\phi 4}$ (Clark and Manning, 2016), which is evidenced by the failure in resolving the antecedent of the anaphoric expression ***its*** as ***the academy*** in the first sample, and the failure in clustering the anaphoric expressions ***her*** with the entity ***Beyoncé*** in the second sample, despite the success in resolving the second ***Gilman*** to its antecedent ***Rockwell "Rocky" Gilman***. The second type of errors is more complicated, which involves multi-step reasoning that cannot be handled by simply adding the coreference information. To correctly answer the second question, the model should perform two successive tasks successfully: 1) it should understand that ***Mathew Knowles*** is the father

Coref-resolved Context (Abbreviated)	**Question**	**Answers**
West Point cadet ***Rockwell "Rocky" Gilman*** *is called before a hearing brought after an influential cadet, Raymond Denmore, Jr., is forced to leave the academy...Denmore's attorney, Lew Proctor, attacking* ***the academy*** *and* ***its*** *Honor Code system, declares that* ***Gilman*** *is unfit and possibly criminally liable.*	*Who's honor code system does Proctor attack?*	*the academy* (Golden) West Point ($\mathrm{C}_{\mathrm{AddAtt}}$)
Following a career hiatus that reignited ***her*** *creativity,* ***Beyoncé*** *was inspired to create a record with a basis in traditional rhythm and blues that stood apart from contemporary popular music...Severing professional ties with* ***father*** *and manager* ***Mathew Knowles****,* ***Beyoncé*** *eschewed the music of* ***her*** *previous releases*	*What is the last name of the person who went on a career hiatus?*	*Knowles* (Golden) Beyoncé ($\mathrm{C}_{\mathrm{AddAtt}}$)
When the prosecutor suggests that the crime would have still happened if the owner were a woman, ***Christine, Andrea****,* ***Annie****, Janine and the other women who witnessed the crime all laugh and exit the courtroom.*	*What are the names of the women Janine has to determine are sane or crazy?*	*Christine, Andrea, Annie* (Golden) Christine, Andrea ($\mathrm{C}_{\mathrm{AddAtt}}$)

Table 4: Errors in predictions for three questions in QUOREF dev set. The blue and bold words indicate the mentions in the same coreference cluster. The bold words in red or magenta indicate the failure of our model in making necessary reasoning. In the Answers column, Golden indicates the golden answer; $\mathrm{C}_{\mathrm{AddAtt}}$ indicates the prediction made by $\mathrm{Coref}_{\mathrm{AddAtt}}$ model.

of ***Beyoncé***; 2) it should understand the world knowledge that the last name of ***Beyoncé*** is the same as her father's, which should be ***Knowles***. This type of errors shows that our model performs poorly on the questions that require multi-step reasoning. The third type of errors is caused by the questions that have multiple items in an answer. A hyperparameter that limits the total number of items in an answer is used in our models and this parameter is set to 2 in the training, thus when the number of total items in the answer exceeds 2, our models fail to predict the exact items, and the third item ***Annie*** is ignored.

6 Conclusion

In this paper, we present intuitive methods to solve coreference-intensive machine reading comprehension tasks by following the reading process of human in which people connect the anaphoric expressions with explicit instructions. We demonstrate that all our three fine-tuning methods, including $\mathrm{Coref}_{\mathrm{GNN}}$, $\mathrm{Coref}_{\mathrm{AddAtt}}$ and $\mathrm{Coref}_{\mathrm{MultiAtt}}$, are superior to the pre-trained language models that incorporate the coreference information in the pre-training stage, such as $\mathrm{CorefRoBERTa}_{\mathrm{LARGE}}$. As the fine-tuning methods rely on the coreference resolution models supplied by other researchers, their performance is also constrained by the accuracy of those coreference resolution models. In addition, the questions that require multi-step reasoning, span multiple entities or contain multiple answer items also pose the challenges to our models. In the future, with more in-depth study on human reasoning in reading comprehension and more progress in graph neural networks, the GNN-based coreference graph can be enriched with more edge types and diverse structures to leverage more linguistic knowledge and gain better performance.

Abstract

We contribute a new dataset[1] for the task of automated fact checking and an evaluation of state of the art algorithms. The dataset includes claims (from speeches, interviews, social media and news articles), review articles published by professional fact checkers and premise articles used by those professional fact checkers to support their review and verify the veracity of the claims. An important challenge in the use of premise articles is the identification of relevant passages that will help to infer the veracity of a claim. We show that transferring a dense passage retrieval model trained with review articles improves the retrieval quality of passages in premise articles. We report results for the prediction of claim veracity by inference from premise articles.

1 Introduction

The rise of social media has led to a democratization of news, but it has also amplified issues related to fake news and misinformation. To that effect, many fact checking organizations (e.g., Politifact, Snopes, AFP Fact Check, Alt News, FactCheck.org, Africa Check, etc.) have emerged around the globe. They investigate debatable claims made by authorities, politicians, celebrities and the public. For each claim, they publish a review article with links to sources that support a verdict (e.g., true, partly true/false, false) about the veracity of the claim. Those reviews debunk false claims and mitigate the spread of misinformation. We consider a key NLP challenge in the context of automated fact checking: claim inference from premise articles. Note that determining the veracity of a claim without additional information is nearly impossible since claims are selected by professional fact checkers in part because their veracity is far from obvious and also because of their degree of controversy. To that effect, professional fact checkers invest a fair amount of time to research each claim by finding relevant sources and publishing a review article that explains their verdict of the claim. Hence there is a natural entailment problem, whereby anyone who reads a review article should be able to arrive at the same verdict as the professional fact checker regarding the claim. Unlike many entailment tasks that consist of short text (e.g., pairs of utterances) that may be artificially generated or extracted, this is a natural and challenging entailment task that involves an entire document (review article) with an utterance (claim) that requires a certain degree of reading comprehension. We note that this entailment problem has been tackled in some previous work (Augenstein et al., 2019; Shu et al., 2018; Nakov et al., 2021) and although it is a challenging NLP problem, it does not correspond to the problem that professional fact checkers need to solve.

In this paper, we focus on the harder problem of claim inference from premise articles. This is part of the challenge that professional fact checkers face. They find premise articles that contain relevant facts and then infer the veracity of the claim based on those facts. Unlike many existing inference tasks where it is sufficient to use one or a few facts in a few sentences (Storks et al., 2019; Schlegel et al., 2020), information from a set of premise articles must be distilled and combined in non trivial ways to infer the veracity of a claim.

We assembled a dataset of 33,697 claims made between December 1996 and July 2021 with associated review articles, premise articles and claim verdicts. Many other datasets for claim verification are listed in Table 1. However, most of them do not include premise articles needed for the inference task described above. We note two exceptions: PubHealth (Kotonya and Toni, 2020b), which is restricted to health claims and UKP

May 22-27, 2022

Snopes (Hanselowski et al., 2019), which is restricted to claims investigated by one fact checking organization (Snopes). In contrast, WatClaimCheck includes claims investigated by 8 fact checking organizations on any topic.

Since there are several premise articles for a given claim and each premise article may be long, a simple two-stage approach to identify relevant passages would consist of a lightweight retrieval technique in a first stage, followed by a heavyweight inference technique applied to those passages. When the first stage fails to retrieve key passages, then the inferred verdict will be negatively affected regardless of how good the second stage is. To that effect, several supervised dense passage retrieval techniques have been proposed for question-answering (Karpukhin et al., 2020; Qu et al., 2021; Ren et al., 2021). Unfortunately, we cannot directly apply those techniques since we do not have labels for the relevant passages. Instead, we show how to use the review articles to train a supervised dense retrieval technique that is then transferred to premise articles. The contributions of the paper can be summarized as follows:

- New dataset of claims with review and premise articles for claim inference in automated fact checking;
- Novel use of review articles to transfer a dense retrieval technique to premise articles;
- Experiments establishing the state of the art for claim inference.

The paper is organized as follows. Sect. 2 reviews previous work related to automated fact checking and claim verification. Sect. 3 describes the new dataset and summarizes the differences with previous datasets for claim verification. Sect. 4 describes a two-stage process to i) extract evidence sentences from premise articles and ii) infer the veracity of claims. This section also explains how to transfer a dense passage retrieval technique trained with review articles to premise articles. Sect. 5 reports the results for the claim veracity inference task. Finally, Sect. 6 concludes and discusses possible future work.

2 Related Work

There is an important line of work that focuses on claim verification (Kotonya and Toni, 2020a; Guo et al., 2022). This includes techniques that predict the veracity of a claim based on the text of the claim only (Rashkin et al., 2017), linguistic features (Popat et al., 2017), meta information about the claimant (e.g., name, job, party affiliation, veracity history) (Wang, 2017), review articles (Augenstein et al., 2019; Shu et al., 2018; Nakov et al., 2021), relevant articles returned by a search engine (Popat et al., 2018; Augenstein et al., 2019; Mishra and Setty, 2019) as well as premise articles (Aly et al., 2021; Kotonya and Toni, 2020b). There is an important distinction between articles returned by a search engine and premise articles. The techniques that use a search engine to find articles related to a claim query the search engine *after* a fact checking website has published a review article and therefore end up retrieving articles that include the review article as well as other articles that summarize and/or discuss the verdict of the fact checking website. Hence they are tackling an entailment problem. In contrast, the premise articles that we consider are the source articles used by a fact checker *before* publishing a review article. Those articles contain relevant facts, but not a summary or discussion of the review article since they are published before the review article and in fact serve as premises for the review article.

Closely related to claim verification is the problem of fake news detection. In this problem, the credibility of an entire news article is evaluated. The credibility can be estimated based on linguistic and textual features (Conroy et al., 2015; Reis et al., 2019; Li et al., 2019), discourse level structure (Karimi and Tang, 2019), network analysis (Conroy et al., 2015), knowledge graphs (Cui et al., 2020), inter-user behaviour dynamics (Gangireddy et al., 2020) or a combination of multiple modalities (Wang et al., 2020). Some techniques reorder the articles returned by a search engine based on their degree of credibility (Olteanu et al., 2013; Beylunioglu, 2020). An important task that can help the detection of fake news is stance detection (Borges et al., 2019; Jwa et al., 2019), i.e., does the content of an article agree or disagree with the title of the article? The following surveys summarize advances in fake news detection: (Kumar and Shah, 2018; Bondielli and Marcelloni, 2019).

3 Fact Checking Dataset

3.1 Data Collection

We collect claims, along with a review article, premise articles, and metadata from the following eight fact checking services: Politifact, Snopes, AFP Fact Check, Alt News, FactCheck.org, Africa Check, USA Today, and Full Fact. We utilize Google's fact check tool APIs[2] to collect the claims' metadata for all fact checking services except Politifact and Snopes. The claims' metadata collected from Google's fact check tool APIs include the claim review article URL, which is used to retrieve the claim review article. The claim review articles published by some of the fact checking services provide the premise article URLs in a separate section while others provide the URLs as inline links in the review article body. We parse the article body, retrieving the premise article URLs used in the review article to justify the claim veracity. Finally, the premise URLs are used to retrieve the premise articles. We try to directly retrieve the article where possible, but also use archive.org's API in case a premise article is no longer available online. We follow the same general procedure for data collection from Politifact and Snopes except that we directly crawl the respective websites instead of using Google's fact check tool APIs for collecting claims and associated metadata.

We perform some basic cleanup to the collected data before inclusion in the dataset. This includes removing articles behind paywalls, removing claims with less than two premise articles, and removing non-textual premise sources. We obtain premise article text from their HTML pages by loading the HTML files into a text based web browser (Links browser) and then dumping the web page text into a text file. This allows us to bypass the CSS styling and JavaScript code included in the HTML pages and obtain only the text displayed to end users. Admittedly, this does not eliminate auxiliary text such as navigation links, footer text, recommended links, etc. The premise articles include the source document of the claim when available as well as evidence articles used by fact checkers. We map the numerous claim veracity labels used by the fact checking websites into three broad labels: True, Partially True/False, and False.

3.2 WatClaimCheck Dataset

The contributed dataset contains a total of 33,721 claims. We split those claims into the following three sets: training set containing 26,976 claims, validation set containing 3,372 claims, and test set containing 3,373 claims. For each claim in the dataset, we provide the following data: *ID, Claimant, Claim, Claim Date, Reviewer Name, Reviewer Site, Review Article URL, Review Article Date, Review Article, Rating, Original Rating, Premise Articles* and *Premise Article URLs*. Here *Original Rating* refers to the rating assigned by a fact checking organization and *Rating* corresponds to our mapping of the original rating to true, partly true/false and false (see the dataset for the precise mapping). We provide the extracted text files for the review and premise articles.

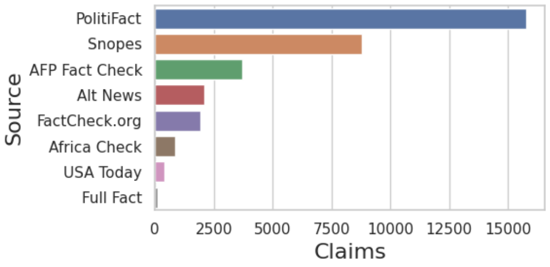

Figure 1: Number of claims from each source

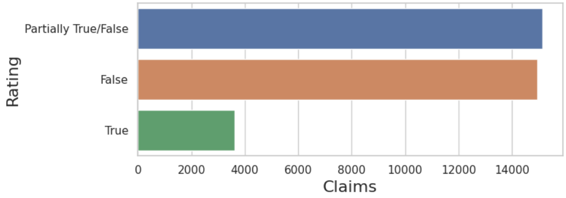

Figure 2: Dataset Claim Rating Counts

Fig. 1 shows the number of claims per fact checking services. Fig. 2 shows the claim rating distribution. Claims in the Partially True/False and False categories significantly outnumber the claims in the True category. In reality, the number of true claims is much larger than the number of partially true/false and false claims, but fact checking services focus on debunking controversial claims and therefore the majority of the claims they investigate are false or partially true/false. This imbalance poses an important challenge.

3.3 Comparison with existing Datasets

We compare our proposed dataset with other publicly available fact checking related datasets in Table 1. We can broadly classify the fact checking datasets into two different categories: (1) veracity detection datasets based only on claim text and some metadata, but without supporting evidence documents and (2) datasets that provide claim text along with supporting evidence and/or context doc-

---

[2] https://toolbox.google.com/factcheck/apis

uments. The datasets that provide some evidence or context documents can be further subcategorized: (1) datasets that provide social media posts and comments related to the claim (Mitra and Gilbert, 2015; Nakamura et al., 2020; Shu et al., 2018), (2) datasets that retrieve supporting evidence for the claims by performing a web search using queries obtained from lexical and semantic features of the claim text (Baly et al., 2018; Augenstein et al., 2019; Gupta and Srikumar, 2021), (3) datasets that provide Wikipedia pages as supporting evidence (Thorne et al., 2018; Fan et al., 2020; Aly et al., 2021), and (4) datasets that include premise articles used by professional fact checkers (Hanselowski et al., 2019; Kotonya and Toni, 2020b). Our proposed dataset provides the documents cited by the professional fact checkers in the claim review article to justify their claim rating. This reflects the real world task of automated veracity detection more truthfully due to the availability of the premise articles cited by the professional fact checkers in claim review articles. Although, social media posts and comments can sometimes be helpful in claim veracity detection they are rarely treated as authoritative sources of information. Using a web search to retrieve evidence documents *after* a fact checking service has verified a claim is problematic since multiple news agencies often publish articles referencing the original fact checking review article. Top-k web search results typically contain those articles which may indirectly leak the veracity label.

4 Models

We develop a two-stage system to perform evidence based veracity detection. The first stage selects relevant sentence level evidence from the premise articles associated with a claim and the second stage performs claim veracity inference using the claim text and selected evidence sentences. For the first stage, we evaluate two different approaches. The first approach is term frequency inverse document frequency (TF-IDF), which is typically used by fact checking methods for sentence based retrieval (Aly et al., 2021). For the second approach, we propose a novel way to adapt dense passage retrieval techniques using the review articles for evidence sentence selection. In our experiments, the aforementioned dense passage retrieval technique outperforms TF-IDF text retrieval and leads to overall system performance improvements. The second stage consists of training deep learning models to perform claim veracity inference using the claim text and selected evidence. We utilize multiple deep learning models to perform claim veracity inference ranging from basic bi-directional recurrent networks to state of the art transformers.

4.1 Problem Formulation

We represent a claim containing l tokens as $C_n = \{c_1, c_2, \ldots, c_l\}$, where $n \in [1, N]$ and N is the size of the dataset. Each claim is associated with multiple premise articles, we represent the k-th premise article associated with the n-th claim containing m sentences as $A_{n,k} = \{s^P_{n,1}, s^P_{n,2}, \ldots, s^P_{n,m}\}$ where $s_{n,i}$ represents the i-th sentence. Similarly, we represent the review article associated with the claim C_n containing m sentences by $R_n = \{s^R_{n,1}, s^R_{n,2}, \ldots, s^R_{n,m}\}$. For a given claim C_n, we represent its ground truth veracity label by $\mathbf{y_n}$. We cast the problem as a textual inference problem. Given a claim C_n and a set of associated premise articles $\mathbf{A}$, our goal is to predict the ground truth veracity $\mathbf{y_n}$ of the claim.

4.2 Stage-1: Evidence Sentence Extraction

A key step performed by professional fact checkers is examining the premise articles associated with a claim and extracting useful evidence from them to establish claim veracity. Our first stage seeks to perform a similar task. Each claim in our dataset has multiple associated premise articles with each article containing a large amount of text. Our goal in the first stage is to rank the evidence available in the associated premise articles at the sentence level and extract the ones which are most useful and impactful for veracity detection in the second stage. Our experiments show that an improvement in this stage directly contributes to an overall improvement in the veracity detection performance.

4.2.1 TF-IDF

We measure TF-IDF similarity between the claim text and the premise article sentences to rank the sentence level evidence. Top ranked sentences are used in the second stage to perform veracity detection. This approach is similar to the one used by Thorne et al. (2018) to extract evidence sentences from Wikipedia articles for fact checking.

4.2.2 Dense Passage Retrieval

We propose a novel way of adapting the dense passage retrieval method proposed by Karpukhin et al. (2020) for open domain question answering to the

Dataset	Claims	Labels	Review Article	Evidence	Sources

Table 1: Proposed WatClaimCheck dataset compared with other existing fact checking datasets. The "Labels" column indicates the number of veracity labels. For some datasets, there are several labeling schemes with different numbers of labels separated by commas. For instance, WatClaimCheck includes the original set of 86 fine grained labels from the fact checking organizations as well as a remapping into 3 coarse labels only.

task of retrieving evidence sentences from premise articles. Karpukhin et al.'s method uses a dual encoder architecture. Each encoder is implemented using BERT (Devlin et al., 2018). The question encoder E_Q and the passage encoder E_P embed question q and passage p into d-dimensional vectors. The similarity between the question and passage is defined as the dot product of their vectors:

$$\text{sim}(q, p) = E_Q(q)^T E_P(p) \tag{1}$$

The model is then trained to learn embeddings such that the similarity score between relevant question-passage pairs will be higher than irrelevant ones.

We adapt this method for our first stage by taking advantage of the fact that the review article published by fact checking websites (along with a claim) typically contains key evidence taken from the premise articles. The evidence is usually paraphrased in order to form a coherent argument in support of the claim veracity verdict.

To train the dense passage retrieval model for stage-1, we use the claims and the associated review articles in the training set of our dataset. We form positive pairs using the claim and the sentences from the associated review article. The negative pairs are formed using that same claim and sentences from review articles associated with other claims. This corresponds to the "gold" negative sampling technique in (Karpukhin et al., 2020).

Let $D = \{\langle C_i, s^{R+}_{i,j}, s^{R-}_{i,1}, s^{R-}_{i,2}, \dots, s^{R-}_{i,n-1}\rangle_{j=1}^{|R_i|}\}_{i=1}^{N}$ be the training data containing $\sum_{i=1}^{N} |R_i|$ instances where N is the number of claims in the training set, $|R_i|$ is the number of sentences in the review article associated with the i-th claim. Each instance is made up of a claim C_i with one positive sentence from the associated review article $s^{R+}_{i,j}$ and $n-1$ randomly chosen negative sentences $s^{R-}_{i,k}$. These negative sentences are positive sentences for other claims within the same batch. We train the model by optimizing the negative log likelihood of the positive sentences:

$$\begin{aligned} & L(C_i, s^{R+}_{i,j}, s^{R-}_{i,1}, s^{R-}_{i,2}, \dots, s^{R-}_{i,n-1}) \\ &= -\log \frac{e^{\text{sim}(C_i, s^{R+}_{i,j})}}{e^{\text{sim}(C_i, s^{R+}_{i,j})} + \sum_{k=1}^{n-1} e^{\text{sim}(C_i, s^{R-}_{i,k})}} \end{aligned} \tag{2}$$

For model evaluation, we use the top-k recall rate for retrieving the review article sentences corresponding to the claims in the validation and test set using the similarity score. The review article sentences are retrieved from the corpus formed by all the sentences from every review article in the corresponding set.

After training, we use the encoders to encode the claim text and the sentences of the associated premise articles. We compute the similarity score using the dot product between the encoded claim vector and the premise article sentences. We use the top scoring sentences as evidence sentences in the next stage to perform claim veracity inference.

4.3 Stage-2: Claim Veracity Inference

In this section, we describe how several popular sequence models are used to classify a claim as true, partly true/false or false based on the text of the claim, the claimant and the evidence sentences extracted in stage 1.

4.3.1 Bi-LSTM and Bi-GRU

We first consider bi-directional long short term memory (Bi-LSTM) networks and bi-directional gated recurrent units (Bi-GRUs). The evidence sentences of each premise article are concatenated with the claim and claimant, and then encoded by a Bi-LSTM or Bi-GRU into a latent vector. For N premise articles, the resulting N vectors are then averaged and passed through a softmax layer with 3 outputs corresponding to the predicted probabilities of true, partly true/false and false.

4.3.2 HAN

Instead of concatenating the evidence sentences of each premise article into a long sequence, we can also use hierarchical attention networks (HANs) (Yang et al., 2016; Mishra and Setty, 2019) to compute sentence level embeddings that are then combined into article level embeddings. A HAN is used to embed each premise article with the claim as follows. Each sentence (claimant with claim text or each evidence sentence of the premise article) is embedded as a sequence of hidden vectors (one per word) by a bi-directional recurrent network (Bi-LSTM or Bi-GRU). Then, a word-level attention layer computes a sentence level embedding. Next, those embeddings are fed to another bi-directional recurrent network (Bi-LSTM or Bi-GRU) that computes a sequence of hidden vectors (one per sentence) and a sentence level attention layer computes an embedding for the document-claim pair. Finally, the embeddings of the document-claim pairs are averaged and passed through a softmax over the labels true, partly true/false and false.

4.3.3 Transformer

We finetune a RoBERTa-base (Liu et al., 2019) model to perform claim veracity inference using the claim and the evidence sentences. We concatenate the claim text, the name of the claimant, and the evidence sentences extracted for that particular claim in the first stage to build a training data instance. The input sequence is encoded using the RoBERTa-base model and passed through a dense linear layer followed by a softmax to obtain the predicted claim veracity label distribution. We use the cross entropy loss function to train the model.

5 Experiments

We evaluate the two-stage process and the algorithms described in the previous section on the claim inference problem with our new dataset.

5.1 Stage-1 Results

In order to reduce the computational resources and memory requirements, we implement the encoders in the dense passage retrieval model using DistilRoBERTa (Dis). We use a batch size of 64 and the **in-batch negatives** technique as described in (Karpukhin et al., 2020).

We evaluate the stage-1 methods by comparing their performance using the top-k recall rate metric. The claim text is used to retrieve the ground truth review article sentences from the corpus containing all the sentences of all the review articles in the test set. The test contains a total of $114,290$ sentences and $3,373$ claims. We report the top-k recall rate for $k = 10, 25, 50, 100$ in Table 2. The results clearly show that the DPR (dense passage retrieval) method outperforms the method based on TF-IDF.

Top-k Recall	TF-IDF	DPR (DistilRoberta)
Top-10 Recall	18%	26%
Top-25 Recall	25%	38%
Top-50 Recall	30%	46%
Top-100 Recall	35%	54%

Table 2: Top-K recall performance for stage-1 methods

5.2 Stage-2 Results

To evaluate whether the inference models in stage-2 can do better with the inclusion of additional evidence sentences, we perform the experiments in stage-2 in two settings: Pooled and Averaged.

Pooled: In this setting, for each claim we pool all the sentences from every associated premise article and rank them using the similarity score. The evidence sentences are concatenated in the descending order of their similarity score. Afterwards, the claim text and evidence sentences are concatenated. The resulting text is then truncated to the maximum sequence length capability of the transformer model being used to perform claim veracity inference. For each claim, we get exactly one data instance.

Averaged: This refers to the setting where we generate one data instance per claim and associated premise article. So, if a claim has m premise articles, we get m data instances. For each premise article associated with a claim, we score the sentences from that article and extract the top scoring sentences to form a data instance. We concatenate the evidence sentences in the descending order of their similarity score. The evidence sentences are then concatenated to the claim text and truncated to the maximum sequence length capability of the transformer model being used to perform claim veracity inference. During training, each data instance for a claim is used independently, but during inference, we compute the average of the claim veracity prediction distributions of the data instances associated with a single claim. We show in our reported results that the inclusion of additional evidence in the form of m data instances per claim (instead of 1 data instance for the pooled setting) does improve the performance when the retrieval method of stage 1 is not very effective.

We use macro F1 as the evaluation metric. We report the results in Table 3. We report all the hyper parameters used in our experiments in the appendix. The best performance when doing the claim veracity inference is obtained by using the DPR model in the first stage and the RoBERTa-base model in the second stage. We also report results for claim entailment from the review articles as an upper bound on the accuracy that could be achieved for claim inference based on the premise articles.

5.2.1 Prequential Results

We note that the traditional experimental setup of dividing a dataset at random into train, validation and test does not reflect the streaming nature of claims. When new topics arise (i.e., election, covid-19), the nature of the claims and the premise articles changes. Randomly splitting the dataset into train/validation/test ensures that all claim topics are well represented across the train/validation/test splits, which would not be the case in practice. In reality, when a new topic arises, the test split may have new types of claims that are not well represented in the train/validation splits. To evaluate the effect of this distribution shift over time, we performed a prequential evaluation (Bifet et al., 2015). More precisely, we divide the dataset into subsets corresponding to periods of 6 months. We repeatedly evaluate the performance for each 6-month period by treating the claims in that period as the test set and the claims in previous periods as the train/validation sets. This corresponds to a realistic setting where a claim verification algorithm may be re-trained every 6 months on the data seen so far to predict the veracity of the claims for the next 6 months. Naturally, the time period between each re-training iteration may be shorter than 6 months in practice. We chose 6 months simply to ensure that the size of the test set would be large enough to obtain reliable results.

Fig. 3 shows the number of claims investigated in each 6-month period in our dataset. We note two peaks. The first one in 2016 corresponds to a sudden surge of claims investigated by some fact checking websites regarding India politics. The second peak in 2020 corresponds to the 2020 US presidential election and the start of the covid-19 pandemic. Fig. 4 shows the macro F1 results achieved by the top 4 algorithms with DPR evidence in each 6-month period. We note that the prequential results are significantly lower than the results in the DPR column of Table 3. This drop of accuracy is precisely due to the distribution shift of claims that naturally occurs over time. We also note a trend whereby the accuracy increases as time passes by. This is explained by the fact that more data is available for training in later time periods. We strongly recommend that future algorithms be evaluated in prequential mode since this evaluation setup is more realistic.

6 Conclusion

This paper introduces a new dataset for automated fact checking. WatClaimCheck includes premise articles used by professional fact checkers and therefore corresponds more closely to the task of claim veracity inference in automated fact checking. An important challenge is the extraction of relevant facts from the premise articles since it is not generally possible to apply heavyweight models on the entire content of all premise articles. To that effect, we described how to train the encoders of a dense passage retrieval technique with the review articles and then transfer the resulting retrieval technique to the premise articles. This increased the overall performance of the claim verification algorithms. We also performed a prequential evaluation that highlighted an important distribution shift that caused a significant drop in accuracy for all algorithms. We strongly recommend that future algorithms be evaluated in prequential mode. In fact, an important direction for future research would be to design algorithms based on transfer learning or domain generalization that can cope better with this distributional shift. We also note that the tech-

Algorithm	Review	Evidence(TF-IDF)	Evidence(DPR)
Bi-GRU	0.779±0.009	0.418±0.010	0.453±0.009
Bi-LSTM	0.777±0.008	0.421±0.011	0.454±0.010
HAN-Bi-GRU	**0.821±0.007**	0.445±0.010	0.471±0.009
HAN-Bi-LSTM	0.818±0.007	0.444±0.008	0.471±0.011
Roberta-base (pooled)	0.741±0.005	0.541±0.017	**0.580±0.009**
Roberta-base (averaged)	0.741±0.005	**0.563±0.010**	0.565±0.009

Table 3: Macro F1 score averaged over 10 runs with standard deviation

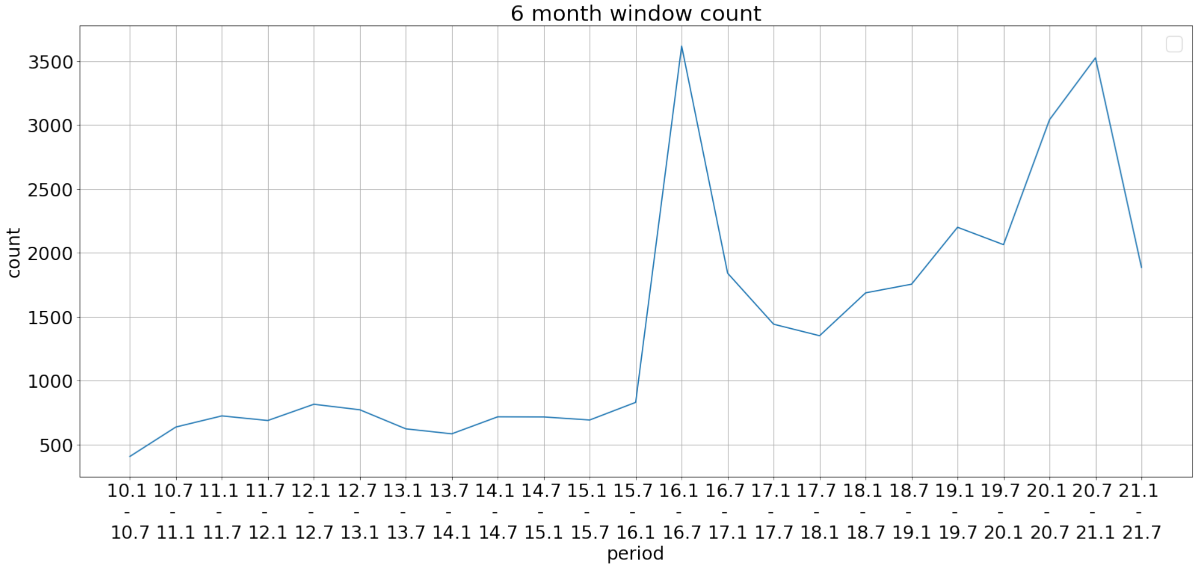

Figure 3: count of claims in each time window

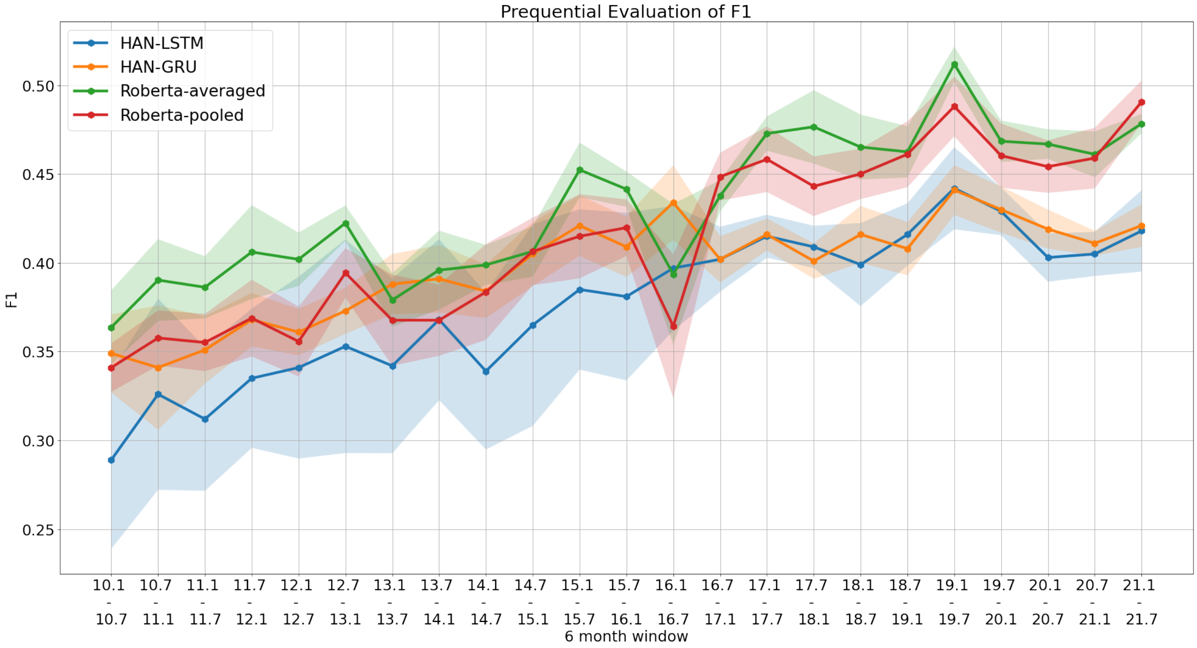

Figure 4: Prequential evaluation score based on macro F1 (average of 10 runs with standard deviation)

niques that we evaluated are black boxes and therefore it is not clear how they do inference. Hence, another direction for future research would be to develop inference techniques that are explainable in the sense that they could provide explanations to the users to justify their veracity prediction for a claim.

A Appendix

A.1 Dataset

Since the dataset is larger than the 200 Mb limit for the supplementary material, we include a sample corresponding to the data collected from March 15 to July 1, 2021 in the supplementary material. A link to the entire dataset will be made available once the paper is accepted.

A.2 Hyperparameters

The code will be made public once the paper is accepted. Table 4 lists the hyperparameters used for the Bi-LSTM, Bi-GRU and HANs. Table 5 describes the hyperparameters of the DPR technique in stage 1 and Table 6 lists the hyperparameters of RoBERTA-base in stage 2.

Parameter	Value
Max Sentence Length	20 words per sentence
Max Sentence Count	30 sentences per claim
Embedding Dimension	100
Batch Size	64
Learning Rate	0.01
Convergence Patience	6 epochs
Optimizer	Adam

Table 4: Hyperparameters used in Bi-LSTM/GRU and HAN

Parameter	Value
Max Sequence Length	512
Batch Size	64
Learning Rate	$1e^{-5}$
Epochs	500
Optimizer	AdamW

Abstract

Fast and reliable evaluation metrics are key to R&D progress. While traditional natural language generation metrics are fast, they are not very reliable. Conversely, new metrics based on large pretrained language models are much more reliable, but require significant computational resources. In this paper, we propose FrugalScore, an approach to learn a fixed, low cost version of any expensive NLG metric, while retaining most of its original performance. Experiments with BERTScore and MoverScore on summarization and translation show that FrugalScore is on par with the original metrics (and sometimes better), while having several orders of magnitude less parameters and running several times faster. On average over all learned metrics, tasks, and variants, FrugalScore retains 96.8% of the performance, runs 24 times faster, and has 35 times less parameters than the original metrics. We make our trained metrics publicly available[1] and easily accessible via Hugging Face, to benefit the entire NLP community and in particular researchers and practitioners with limited resources.

1 Introduction

Automatic evaluation metrics are the only way to monitor the training of, evaluate, and compare across models in a systematic, large-scale way, and are thus a critical component of the research and development ecosystem in machine learning. To get adopted in practice, evaluation metrics need to be both reliable and affordable, i.e., fast and easy to compute.

While some metrics meet these criteria, such as precision and recall in information retrieval, root mean square error in regression, etc., finding suitable metrics is still an open problem in the field of Natural Language Generation (NLG) (Novikova et al., 2017).

Indeed, historical n-gram matching metrics such as ROUGE (Lin, 2004) for summarization, BLEU (Papineni et al., 2002) and METEOR (Banerjee and Lavie, 2005) for translation, while affordable, are not very reliable, as they are based on surface-form matching only, i.e., lexical similarity, and have thus no sense of semantic similarity. For instance, it makes little sense to use ROUGE for the evaluation of abstractive summarization systems (which are becoming the norm), or whenever the generated text paraphrases the original text.

Following the advent of transfer learning in NLP, new NLG metrics based on large pretrained language models have recently been proposed, such as BERTScore (Zhang et al., 2019) and MoverScore (Zhao et al., 2019). By relying on contextual embeddings, these metrics capture semantics and are therefore much more reliable. However, due to the sheer size of the underlying models, these metrics pose environmental issues (Strubell et al., 2019), take time to compute, and require access to significant computational resources, so they are not accessible by everyone in the NLP community.

For example, we were not able to run some of the best variants of BERTScore[2], based on DeBERTa-Large and DeBERTa-XLarge (He et al., 2020) on a 12GB GPU. Even when enough GPU memory is available, relying on such large models is still associated with extended runtimes, which can impede the progress of experiments when used once or more per epoch for validation and monitoring purposes.

To address this problem, we propose in this paper FrugalScore, an approach to learn a lightweight version of BERTScore, MoverScore, and more generally any metric based on a large pretrained language model.

Our contributions can be summarized as follows: 1) Our compact models have several orders of magnitude less parameters than the original metrics and

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 1305 - 1318
May 22-27, 2022

run several times faster, while retaining most of their original performance. We even outperform the original metrics in some cases[3].
2) Our metrics are not only faster because of the much smaller amount of parameters, but also because they do not rely on any similarity function.
3) Regardless of how expensive the original metric is, querying our trained metrics always has the same low, fixed cost. This decoupling is a major advantage as the size of the pretrained language models has recently been growing tremendously (e.g., Brown et al. (2020)).

2 Background

Related work falls into two categories: unsupervised and supervised metrics.

2.1 Unsupervised metrics

To address the limitations of ROUGE and BLEU, variants based on static word embeddings (Mikolov et al., 2013) were developed, e.g., ROUGE-WE (Ng and Abrecht, 2015), BLEU2VEC (Tättar and Fishel, 2017), and MEANT 2.0 (Lo, 2017). While using word vectors is a progress over strict n-gram matching, static embeddings are still very limited as they do not capture polysemy, i.e., the fact that words have different meanings in different contexts.

More recently, the focus has shifted to harnessing the power of the contextualized embeddings produced by large pretrained language models. For instance, the Sentence Mover's Similarity (Clark et al., 2019) represents sentences as the average of their ELMo word embeddings (Peters et al., 2018) and measures the minimum cost of transforming one summary into the other, using a modified version of the Word Mover's Distance (Kusner et al., 2015). BERTR (Mathur et al., 2019) computes approximate recall based on the pairwise cosine similarity between the BERT embeddings (Devlin et al., 2018) of the words in automatic and reference translations. Mark-Evaluate (Mordido and Meinel, 2020) is a family of metrics that consider contextualized word or sentence embeddings derived from BERT as population samples, to evaluate language generation with population estimation methods used in ecology.

Finally, the recently introduced BERTScore (Zhang et al., 2019) and MoverScore (Zhao et al., 2019) are general-purpose NLG evaluation metrics that are becoming widely used. The main difference between BERTScore and MoverScore lies in the function used to compute the similarity between the representations of the two sequences $\mathbf{x} = \langle \mathbf{x_1}, ..., \mathbf{x_k} \rangle$ and $\mathbf{y} = \langle \mathbf{y_1}, ..., \mathbf{y_l} \rangle$. We experimented with these two metrics, so we provide more details about them in what follows.

BERTScore first computes the pairwise cosine similarity between the representations of the tokens in each sequence, and uses greedy matching to match each token to the most similar one in the other sequence. Given two pre-normalized vector sequences $\mathbf{x}$ and $\mathbf{y}$, BERTScore computes:

$$R_{BERT} = \frac{1}{|\mathbf{x}|} \sum_{\mathbf{x_i} \in x} \max_{y_j \in \mathbf{y}} \mathbf{x_i^T y_j} \tag{1}$$

and:

$$P_{BERT} = \frac{1}{|\mathbf{y}|} \sum_{\mathbf{y_i} \in y} \max_{\mathbf{x}_j \in \mathbf{x}} \mathbf{y_i^T x_j} \tag{2}$$

The F1-score is classically obtained as:

$$F_{BERT} = 2 \frac{P_{BERT} R_{BERT}}{P_{BERT} + R_{BERT}} \tag{3}$$

MoverScore uses an n-gram generalization of the Word Mover's Distance (WMD) (Kusner et al., 2015) as their (dis)similarity function. More specifically, they solve for the optimal transportation flow matrix $F \in \mathbb{R}^{|\mathbf{x}| \times |\mathbf{y}|}$ between the two weighted sequences of n-grams:

$$WMD(\mathbf{x}, \mathbf{y}) = min_F \langle C, F \rangle \tag{4}$$

$$s.t. \quad F\mathbf{1} = f_{\mathbf{x}}, \quad F^T\mathbf{1} = f_{\mathbf{y}}$$

Where C is the transportation cost matrix (C_{ij} is the Euclidean distance between x_i and y_j) and $f_x \in \mathbb{R}_+^{|\mathbf{x}|}$ and $f_y \in \mathbb{R}_+^{|\mathbf{y}|}$ are the n-gram weight vectors.

Note that by directly learning BERTScore's and MoverScore's full internal mapping (from sequence pairs to final scalar scores), FrugalScore internalizes their similarity functions. This does not only provide a speedup at inference time, but also improves performance, as shown in section 5.

---

[3] Hence the name FrugalScore, as frugal engineering is defined as "achieving more with fewer resources".

2.2 Supervised metrics

Related to our work are also supervised metrics, which are directly trained on human evaluations. ROSE (Conroy and Dang, 2008) is a linear combination model of different variants of ROUGE using canonical correlation. BEER (Stanojević and Sima'an, 2014) is a learning-to-rank approach using word and character n-gram matching, and token ordering, as features to maximize correlation with human rankings of machine translation systems. S^3 (Peyrard et al., 2017) trains a regression model that takes the evaluation scores of several existing metrics and many hand-crafted features as input, and learns the best combination of them to approximate human summary judgments. DPMFcomb (Yu et al., 2015) and Blend (Ma et al., 2017) are combined metrics incorporating a vast amount of lexical, syntactic and semantic based translation evaluation metrics using ranking and regression SVMs respectively. RUSE (Shimanaka et al., 2018) evaluates machine translation with a neural regressor based on universal sentence embeddings (e.g., InferSent (Conneau et al., 2017)). NUBIA (Kane et al., 2020) consists of three modules: a feature extractor based on RoBERTa (Liu et al., 2019) and GPT-2 (Radford et al., 2019) fine-tuned on language evaluation tasks, an aggregator trained to predict the quality of the hypothesis given the reference using the extracted features, and a calibrator mapping all predictions between 0 and 1.

Differences. Like the aforementioned efforts, FrugalScore is a learned metric. However, it does not rely on any intermediate or handcrafted features, and, most importantly, it does not require training on human annotations. Supervision in FrugalScore is conducted on a synthetic dataset, as a trick to expose and learn the internal mapping of the unsupervised metrics to be learned. Last but not least, unlike all aforementioned methods, compression is central to FrugalScore, which is based on miniature versions of the models used by the original metrics.

2.3 Knowledge distillation

Knowledge distillation (KD) (Hinton et al., 2015) is the process of transferring knowledge from a large teacher model to a smaller student model to accomplish model compression (Buciluă et al., 2006). It was originally proposed in the domain of computer vision and speech recognition, then successfully adapted to NLP (Sanh et al., 2019). Distillation can be accomplished in three ways: (1) offline, where a teacher is first pre-trained, then a student is trained under the guidance of the teacher (Hinton et al., 2015); (2) online, where the student and the teacher are trained simultaneously (Zhang et al., 2018); and (3) self, where the same model plays the role of student and teacher, e.g., transferring the knowledge of a later exit layer into an earlier one of the same multi-exit network (Phuong and Lampert, 2019). Previous studies on KD mainly focused on classification problems (Gou et al., 2021). A few attempts have been made on regression problems (Chen et al., 2017; Saputra et al., 2019; Takamoto et al., 2020), in which special losses were proposed to train the student with respect to both the teacher's regression outputs and ground truth scores. Different from conventional distillation, our work is more similar to *data-free* KD (Kang and Kang, 2021), where the student is trained in the absence of the dataset used to train the teacher. To transfer knowledge, we first create a synthetic dataset by annotating sequence pairs with a large model (teacher), and then train a miniature model (student) on that dataset, in an offline and regression setting.

2.4 Differences with BLEURT

A work closely related to ours is BLEURT (Sellam et al., 2020). However, there are a number of significant differences with our approach. First, BLEURT continues the pretraining of an already pretrained BERT-based model on a synthetic dataset in a self-supervised way, whereas FrugalScore is directly trained to learn the scores of the metric of interest, in a supervised fashion.

Also, BLEURT's synthetic dataset is made by perturbing Wikipedia sentences with mask-filling, backtranslation, and word dropping, whereas we use other data sources than Wikipedia such as summarization and translation datasets, and only NLG models to induce perturbations.

When creating its synthetic dataset, BLEURT automatically annotates the (original, perturbed) sequence pairs with numerical and categorical "signals": BLEU, ROUGE, BERTscore, backtranslation likelihood, textual entailment (probability of three labels: entail, contradict, and neutral, given by BERT fine-tuned on MNLI), and backtranslation flag. On the other hand, FrugalScore simply and directly annotates the sequence pairs with the metric to be learned.

After pretraining, BLEURT is fine-tuned on human judgments, in a way similar to the supervised metrics described in subsection 2.2. BLEURT does not learn to generate a scalar until that final fine-tuning phase, so it cannot be used as a metric before that. Conversely, FrugalScore is trained from the start to be a metric, and the fine-tuning phase is optional.

Also, BLEURT was designed for the evaluation of translation. The authors only test whether it can be applied to a different task by experimenting on the WebNLG (data-to-text) dataset (Gardent et al., 2017). Conversely, we focus on learning general text similarity metrics (e.g., BERTscore and MoverScore), so FrugalScore is task-agnostic by design.

Finally, and above all, the objective of FrugalScore is model compression, whereas that of BLEURT is metric learning.

3 Our approach

Developing FrugalScore requires three phases, one of which is optional.

Phase 1. We create a synthetic dataset (see subsection 3.1) by sampling pairs of more or less related sequences and annotating them with the expensive metrics to be learned. This is a one-time operation that does not need to be repeated regardless of the model used in Phase 2.

Phase 2. We continue the pretraining (see subsection 3.2) of a miniature pretrained language model on the synthetic dataset built by Phase 1. Here, the miniature model learns the internal mapping of the expensive metric, including any similarity function applied to the representations. Note that a different miniature is trained for each metric to be learned (we leave learning metric combinations as future work).

The miniature can then be used in inference mode to generate scores for any never-seen pair of sequences.

Phase 3 (optional). We fine-tune the miniature on human annotations, which, as shown in section 6, can boost performance.

3.1 Synthetic dataset

The objective here was to generate pairs of sequences mimicking the (reference, candidate) pairs found in NLG datasets, which are usually semantically related and in many cases paraphrasing one another. We sampled our sequences from a variety of data sources, listed next.

Summarization. For each document in the well-known CNN/DailyMail dataset (Nallapati et al., 2016), our goal was to generate several summaries differing in terms of structure and quality. To this purpose, we used different pretrained seq2seq summarization models: BART-base and BART-large (Lewis et al., 2019), mBART (Liu et al., 2020), and BARThez (Kamal Eddine et al., 2021). BART is a seq2seq autoencoder with a Transformer architecture.

The four models were fine-tuned for one epoch on 50k examples randomly sampled from the training set of CNN/DM, and were used to generate summaries for the whole training set of 287,112 documents, using greedy decoding.

Note that we kept the 50K documents used for fine-tuning in the final generation pool, in order to create quality differences among summaries. Indeed, models are expected to better summarize the documents used for training than never-seen documents.

We also used the human reference summaries, so that in the end, each document was associated with 5 summaries, resulting in 10 pairs of summaries per document.

Backtranslation. We also generated paraphrases with backtranslation, by sampling sentences from the OpenSubtitle English monolingual corpus (Lison and Tiedemann, 2016), and translating them to French, Arabic and German with OPUS-MT (Tiedemann and Thottingal, 2020), before translating them back to English. We used OPUS-MT because of its ready-to-use checkpoints available for many language pairs. We ended up with 4 variations for each sentence (including the original one), resulting in 6 paraphrase pairs per sentence.

Denoising. To avoid bias towards summarization and translation, we also generated pairs of related sequences such that the first element in the pair was a Wikipedia segment and the second element was a BART-denoised version of it (Lewis et al., 2019).

More precisely, we sampled 2M segments from Wikipedia such that the number of unigrams in these segments was uniformly distributed between 1 and 200. Our assumption was that enforcing variations in sequence length would help the learned metric to generalize.

We then applied BART's *text infilling* and *sentence permutation* perturbation strategies to each segment. That is, multiple text spans were sampled and replaced with a `[MASK]` special token. The lengths of the spans were sampled from a Poisson distribution ($\lambda = 3$). 50% of the tokens within the input segment were masked and 20% of the masked text was replaced with random tokens (creating pathological examples to increase the robustness of the learned metric). The sentences in the input segment were then shuffled.

We finally used a BART-Base checkpoint[4] from the Fairseq library (Ott et al., 2019) to try to reconstruct the perturbed versions of the original sequences, hence creating variants of them.

Annotating pairs. We sampled 4.5M sequence pairs uniformly from each aforelisted source. These pairs were then annotated with the metrics to be learned. Note that this is a one-time operation that does not need to be repeated regardless of which models are trained downstream.

In this work, we experimented with two recent expensive NLG metrics that rely on large pretrained language models, BERTScore (Zhang et al., 2019) and MoverScore (Zhao et al., 2019), presented in section 2. However, it is important to note that our method can be used with any other NLG metric.

Note that for BERTScore, we used the F-1 score F_{BERT}, as recommended by the authors (Zhang et al., 2019). For MoverScore, still following the authors (Zhao et al., 2019), we used the variant operating on unigrams and the IDF to compute the vectors of weights.

3.2 Metric learning

We continue the pretraining of three BERT miniatures[5] on our synthetic dataset: BERT-Tiny ($L = 2$, $H = 128$), BERT-Small ($L = 4$, $H = 512$) and BERT-Medium ($L = 8$, $H = 512$), where L is the number of layers and H is the dimension of the embedding space. These models have respectively 25 times, 3.78 times, and 2.64 times less parameters than BERT-base. The concept of BERT miniatures was introduced by Turc et al. (2019) to test whether pretraining small models from scratch was competitive to distilling very large models. The miniature models have already been pretrained on masked language model and next sentence prediction objectives.

We continue pretraining using the standard method introduced by Devlin et al. (2018). We concatenate the two sequences $x = \langle x_1, ..., x_k \rangle$ and $y = \langle y_1, ..., y_l \rangle$ in a given pair, separating them with a special `[SEP]` token. A special `[CLS]` token is also added at the beginning of the resulting sequence. The sequence of contextualised embeddings $\langle \mathbf{z_{[CLS]}}, \mathbf{x_1}, ...\mathbf{x_k}, \mathbf{z_{[SEP]}}, \mathbf{y_1}, ..., \mathbf{y_l} \rangle$ is then obtained. We finally add a fully connected layer on top, that linearly projects the $\mathbf{z_{[CLS]}}$ vector to a scalar s.

The model is trained to minimize the mean square error (MSE) loss between the learned metric s_i and the metric to be learned $\hat{s_i}$ (i.e., the annotation of the pair):

$$l = \frac{1}{N} \sum_{i=1}^{N} ||s_i - \hat{s_i}||^2 \tag{5}$$

When pretraining is over, the models can be further fine-tuned on smaller human-annotated datasets as shown in section 6, or directly used to generate scores for unseen examples as shown in section 4.

Setup. We use a batch size of 32 and the Adam optimizer (Kingma and Ba, 2014) with a learning rate of 3×10^{-5}, linear decay, and a warm-up for 6% of the total training steps, and we train the model for three epochs. We conducted the pretraining on a single TITAN RTX GPU (24GB). It took 10, 24 and 33 hours, respectively for the tiny, small, and medium miniatures. We rely on the Transformers library (Wolf et al., 2019) for all pretraining and fine-tuning experiments.

4 Experiments

In this section, FrugalScore is used in inference mode to generate scores directly after pretraining, i.e., no fine-tuning is performed (see section 6 for fine-tuning results).

We evaluate on two text generation tasks: summarization and translation. We use evaluation datasets containing (reference, candidate) sequence pairs annotated with human scores assessing the quality of the candidates given the references. We measure the effectiveness of FrugalScore by measuring the Pearson correlation of its scores with the human judgments and comparing it to that of the original metrics. We also take the number of parameters and the runtime into account.

Text summarization. We use 4 different multi-document summarization datasets from the Text Analysis Conference (TAC)[6]: TAC-2008, TAC-2009, TAC-2010 and TAC-2011.

Table 1: Scores are summary-level (TAC) and segment-level (WMT) Pearson correlations averaged over 2008 to 2011 for TAC (pyramid score/responsiveness) and over all source languages for WMT-2019. Runtimes include preprocessing. Subscripts refer to row labels and indicate which metric-model combination was used to annotate pairs (e.g., for FrugalScore$_d$, it is row d, i.e., BERTScore-BERT-Base).

These datasets respectively contain 48, 44, 46 and 44 clusters of documents and 58, 55, 43 and 51 systems are used to generate summaries. Each cluster forms a topic to be summarized and has 4 reference summaries. There are approximately 10k pairs in each dataset. Each pair is annotated with two human judgment scores: the *Pyramid Score* (Harnly et al., 2005) and the *Responsiveness* (Dang et al., 2008). The former measures the proportion of important semantic units (SCUs) in the reference summaries captured by the system summary, while the latter reflects the content coverage and the readability of each summary.

Machine translation. Our evaluation corpus is from the WMT-2019[7] shared task (Li et al., 2019). We consider all the to-English pairs: Chinese, Czech, German, Finnish, Russian, Lithuanian and Kazakh to English. For each language, we use the test set that contains several thousands of reference-candidate pairs annotated with human ratings that assess the translation quality.

5 Results

Table 1 reports the results averaged over the 4 TAC datasets and the 7 WMT to-English language pairs. Details are provided in Appendices A and B.

We benchmarked the metrics in terms of Pearson correlations with human scores, runtimes, and numbers of parameters. We used two approaches to compute the Pearson correlations: summary-level (or segment-level) and system-level.

In the former approach, a score is attributed to each of the output candidates, while in the latter approach, one single overall score is attributed to the system (by averaging its individual scores).

Rows `a` to `c` correspond to BERTScore with BERT miniatures as the underlying model. They are simple baselines added for the sake of comparison, to see what we get when BERTScore is used with the same number of parameters as FrugalScore.

Rows `d` to `g` correspond to the expensive metrics that are learned by FrugalScore (in the respective sections of the bottom half of the table). They

---

[7] http://www.statmt.org/wmt19/

are BERTScore and MoverScore metrics where the underlying model is a large pretrained language model: BERT-Base ($L = 12$, $H = 512$), RoBERTa-Large ($L = 24$, $H = 1024$) (Liu et al., 2019), and DeBERTa-XLarge ($L = 24$, $H = 1536$) (He et al., 2020).

Finally, rows `i` to `xii` correspond to FrugalScore. Subscripts refer to row labels and indicate which metric-model combination was used to annotate pairs. I.e., FrugalScore$_d$ learned the metric of row d, i.e., BERTScore with BERT-Base.

First, results show that all FrugalScores, regardless of which metric they learned, significantly outperform the BERTScores with miniature models. These results suggest that FrugalScore is a better approach than using an existing metric with a lightweight underlying model. The reason for this is probably that in FrugalScore, the knowledge of the original unsupervised metric (based on a large model) is explicitly transferred to the miniature via the continuation of its pretraining on the synthetic dataset. That is, the miniature is actually learning a metric. Whereas, on the other hand, plugging a compressed version of a general-purpose language model into the original unsupervised metric just makes it lose expressiveness and capacity.

Second, we can clearly see that FrugalScore retains most of the performance of the original metric, while running several times faster and reducing the number of parameters by several orders of magnitude. On average over all metrics, tasks, and miniatures, FrugalScore retains 96.8% of the original performance, runs 24 times faster, and has 35 times less parameters.

More precisely, on average across all metrics, FrugalScore-Tiny retains 97.7/94.7% of the original performance on TAC (pyramid score/responsiveness), while running 54 times faster and having 84 times less parameters. Its small and medium versions retain near full performance in terms of responsiveness (98 and 97.7%) and even slightly outperform the original metrics in terms of pyramid score, while at the same time reducing the runtime and the number of parameters by 32 (resp. 21) and 13 (resp. 9) times.

On WMT, FrugalScore-Tiny retains 88.58% of the performance of the original metrics, while running 14 times faster (and still having 84 times less parameters), while the small and medium versions of FrugalScore retain 95.71 % and 98.06% of the original performance while still offering a 32 times (resp. 21) speedup and having 13 times (resp. 9) less parameters, on average.

Interestingly, FrugalScore even improves the performance of the original metrics in some cases. For example, on TAC, FrugalScore$_g$ with BERT-Tiny (row `x`) improves the performance of the original MoverScore metric based on BERT-Base (row `g`) from 66.5 to 67.3 in terms of pyramid score, while reducing the number of parameters by 25 and running 50 times faster. Other examples, also for TAC with the pyramid score, include FrugalScore$_f$ with BERT-Small (row `viii`, +1.5 point) and FrugalScore$_f$ with BERT-medium (row `ix`, +1 point).

Finally, the results of FrugalScore for different miniature sizes show that, on WMT, using larger models always improves performance (e.g., row `x` $\rightarrow$ `xi` $\rightarrow$ `xii`). But interestingly, on TAC, this observation does not hold (e.g., row `vi` $\rightarrow$ `viii` $\rightarrow$ `ix`), and sometimes, FrugalScore with the smallest miniature (BERT-Tiny) is superior (e.g. rows `i` and `x`). This finding suggests that the impact of the pretrained language model size is task-dependent.

To sum up, results clearly show the effectiveness of FrugalScore in learning a cheaper, lighter, and faster version of the original metrics, while retaining most of their original performance. The system-level correlations, provided in Appendices C and D, corroborate these positive results.

We also provide the correlations between the original and the learned metrics in Appendices E and F. It is interesting to note that a greater correlation with the original metric is not always associated with a better performance. E.g., the tiny version of FrugalScore$_g$ is the best (row `x`), while it is the less correlated with the original metric.

6 Fine-tuning on human annotations

We test two hypotheses in this section: (1) whether fine-tuning on a human-annotated dataset is beneficial, and (2) when fine-tuning on human annotations, whether continuing pretraining on our synthetic dataset is useful.

Because we cannot use the same dataset for fine-tuning and evaluation, we fine-tune a BERT-Small on each year of TAC 2008-2011 for 4 epochs, using two other years as the validation set, and the remaining year as the test set. The best epoch is selected based on validation performance. We use a batch size of 32 and a learning rate of 2e-5 that linearly decreases to zero. Finally, we experi-

	Pretraining Continued	TAC-2008	TAC-2009	TAC-2010	TAC-2011	Average
TAC-2008	no	-	$67.7_{0.57}$	$66.1_{0.18}$	$63.6_{0.36}$	65.8
	yes		$74.4_{0.13}$	$71.3_{0.04}$	$67.3_{0.13}$	71.0

Table 2: Summary-level Pearson correlations with human judgments (Pyramid scores), averaged over 3 runs (standard deviation as subscript). Rows correspond to the training sets and columns to the test sets.

ment with two scenarios: fine-tuning the miniature directly without continuing its pretraining on our synthetic dataset, and fine-tuning it after the pretraining continuation (with annotations generated by BERTScore-BERT-Base).

Results. Results are reported in Table 2 in terms of summary-level Pearson correlations with human evaluations (Pyramid), averaged over 3 runs with different random seeds.

First, it is obvious that everywhere, continuing the pretraining on our synthetic dataset leads to a significant boost in performance. This is in accordance with Sellam et al. (2020), who found that pretraining was beneficial even in a supervised setting.

Second, even if a direct comparison is not possible, we can remark when looking at the TAC Pyramid score of row ii) in Table 1 (FrugalScore$_d$-BERT-Small) that fine-tuning after pretraining seems very beneficial too. Indeed, after fine-tuning, we reach on average 71, 67.5, 68.7, and 69.2 (depending on the split), which represents overall a gain of 4.4 points over the non-fine-tuned model (score of 64.7).

7 Impact of data sources

To test the importance of each data source introduced in subsection 3.1, we created a training set containing sequence pairs uniformly and equally sampled from each source. We annotated these pairs with the BERTScore-BERT-Base metric and we used them to continue the pretraining of a BERT-Small miniature.

We also considered pairs drawn at random from the pairs generated with the other strategies. The motivation for random pairs was to sample "negative examples", as seeing only "positive examples" (pairs of related sequences) could bias the learned metric towards considering any two unrelated sequences as similar.

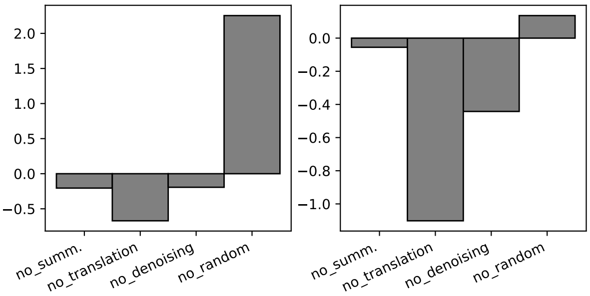

Figure 1: Relative improvement in Pearson correlation compared to a dataset covering all sources. Left: TAC. Right: WMT.

We then continued the pretraining of the BERT-Small miniature four times, excluding each time the pairs coming from a specific data source. We evaluated the learned metric on TAC-2008 to 2011 and on WMT-2019. Figure 1 shows the average improvements in the Pearson correlation with human judgments relative to training a model on all sources. Note that when training on all four sources, we sampled 30k pairs from each source (120k total), and when excluding a source, we sampled 40k pairs from each source (120k total).

We can clearly see that excluding the random pairs improves performance while excluding any of the other data sources decreases performance. In other words, all our data sources are beneficial, and it is not necessary to add "negative examples". We hypothesise that this is due to the fact that NLG datasets typically do not contain completely unrelated pairs of sentences. Interestingly, the pairs generated with the backtranslation strategy have the greatest impact on performance.

8 Conclusion

We proposed FrugalScore, an approach to learn a fixed, low-cost version of any expensive NLG evaluation metric. Experiments on summarization and translation tasks show that our FrugalScore versions of BERTScore and MoverScore retain most of the original performance in terms of the correlation with human judgments, while running several times faster and having several orders of magnitude less parameters. On average over all learned metrics, tasks, and variants, FrugalScore retains 96.8% of the performance, runs 24 times faster, and has 35 times less parameters than the original metrics.

Abstract

We propose Composition Sampling, a simple but effective method to generate diverse outputs for conditional generation of higher quality compared to previous stochastic decoding strategies. It builds on recently proposed plan-based neural generation models (Narayan et al., 2021) that are trained to first create a composition of the output and then generate by conditioning on it and the input. Our approach avoids text degeneration by first sampling a composition in the form of an entity chain and then using beam search to generate the best possible text grounded to this entity chain. Experiments on summarization (CNN/DailyMail and XSum) and question generation (SQuAD), using existing and newly proposed automatic metrics together with human-based evaluation, demonstrate that Composition Sampling is currently the best available decoding strategy for generating diverse meaningful outputs.

1 Introduction

In many NLG tasks, it is important to be able to generate multiple diverse outputs from a model. Tasks like summarization (Mani, 2001; Nenkova and McKeown, 2011) and question generation (Zhou et al., 2017) exhibit one-to-many relationships; there can be multiple semantically diverse summaries or questions for the same source, and it may be useful for a model to be able to generate multiple outputs. Yet, the primary focus of recent research in NLG has been on improving the quality of single-best outputs (Raffel et al., 2019; Lewis et al., 2019; Dong et al., 2019; Zhang et al., 2020a; Narayan et al., 2021), while diversity remains an unsolved problem (Hashimoto et al., 2019; Zhang et al., 2021). This is particularly challenging in conditional generation, where diversity in the target sequence should not come at the cost of correctness or faithfulness; for example, alternate summaries are not valuable if they are unfaithful to the input document(s) (Maynez et al., 2020; Kryscinski et al., 2020). In this work, we investigate decoding methods for generating semantically diverse text which is also faithful to its input focusing on two tasks, namely summarization and question generation.

Beam search (Li et al., 2016; Wiseman et al., 2017) has proven successful for single-best generation (Rush et al., 2015; Barrault et al., 2020; Meister et al., 2020), but struggles to generate diverse output (Vijayakumar et al., 2016). Stochastic sampling strategies, such as top-k sampling (Fan et al., 2018) and nucleus sampling (Holtzman et al., 2020), are better at generating diverse sequences but are not suitable for conditional generation as they degenerate,[1] producing output that is not faithful to the source. Figure 1 exposes degeneration in summary output using nucleus sampling.

To address these shortcomings, we propose *Composition Sampling*, a simple but effective hybrid decoding method for diverse *and* faithful conditional generation. It builds on recently proposed generation models (Narayan et al., 2021) that are trained to first *plan* a semantic *composition* of the target and then generate the text conditioned on the composition *and* the input. Composition sampling first samples a composition in the form of an *entity chain* and then uses beam search to generate the best possible sequence *grounded* to the sampled entity chain. Unlike top-k or nucleus sampling, it avoids degeneration by instilling diversity in composition, rather than directly on the surface form.

Our contributions can be summarized as follows: (a) we introduce Composition Sampling, a simple yet effective decoding method for diverse conditional generation, which combines planning with stochastic sampling; (b) we propose several metrics to compute semantic diversity in generated text; our metrics are complementary to lexical diversity

---

[1] Holtzman et al. (2020) use the term 'degeneration' to describe automatically generated text that is generic, repetitive, and awkward for story continuation. These issues are less common in conditional generation. In our case, 'degenerate' refers to text unfaithful or inconsistent to the input.

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 1319 - 1339
May 22-27, 2022

Haman Written Summary: Chelsea star Eden Hazard is set to make his 100th top-flight appearance. Santi Cazorla should hit the same milestone when Arsenal meet Burnley. Both players have impressed since moving to the Premier League in 2012. Hazard has more goals this season but Cazorla has one more assist. Sportsmail's reporters choose the player who has excited them the most.

Beam Search: Eden Hazard and Santi Cazorla are both set to make their 100th Premier League appearances this weekend. Both players have been hugely influential since they moved to London. Here, Sportsmail's reporters choose the player they most enjoy seeing in action.

Nucleus Sampling: Eden Hazard and Santi Cazorlag will each make their 100th Premier League appearance this weekend. nightstandapplication.com. Sportsmail's hovercraft reporters choose their man of the match countermeasures.

Nucleus Sampling: By making their 100th Premier League appearances this weekend, Eden Hazard and Santi Cazor halibut will set new records. Here, Anna Coren and Dominic King select their favourites.

Composition Sampling: (Eden Hazard | Santi Cazorla | Chelsea | Arsenal | Premier League ||| London | 2012 |||) Eden Hazard and Santi Cazorla are set to make their 100th appearances for Chelsea and Arsenal respectively in the Premier League this weekend. Both players have been hugely influential since they moved to London in the summer of 2012. But who has been the most exciting import to watch?

Composition Sampling: (Chelsea | Eden Hazard | Arsenal | Santi Cazorla ||| Sportsmail ||| London) Ch elsea's Eden Hazard and Arsenal's Santi Cazorla will both make 100th appearances this weekend. Sportsmail's reporters pick the player they most enjoy seeing in action. Both players have been hugely influential since moving to London.

Figure 1: Human written summary, single-best predicted summary using beam search (beam size 8), and diverse summaries with nucleus sampling ($p = 0.95$) and our composition sampling for a CNN/DailyMail article (shown in the Appendix, Figure 6). We highlight spans in orange that are not faithful to the input.

(e.g., Self-BLEU; Zhu et al. 2018; Alihosseini et al. 2019) and assess whether a set of diverse outputs are contextually dissimilar (*Self-BERTscore*; Zhang et al. 2020b) or non-entailing (*Self-Entailment*); and (c) finally, we introduce, EDNA, a novel metric aiming to "**E**valuate **D**iversity a**N**d f**A**ithfulness" for summarization by quantifying whether summaries in a diverse set are faithful to their input without entailing each other.

Evaluation on two popular summarization tasks, namely highlight generation (CNN/DailyMail; Hermann et al. 2015) and extreme summarization (XSum; Narayan et al. 2018), and question generation (SQuAD; Rajpurkar et al. 2016; Zhou et al. 2017), shows that composition sampling is most effective in generating diverse summaries or questions. When assessed by humans, composition sampled summaries are as faithful as the best summaries produced with beam search. In comparison, nucleus sampled summaries can be as diverse but far less faithful. Taken together our results demonstrate that Composition Sampling is currently the best available decoding strategy for generating diverse and meaningful output.[2]

2 Background

Conditional generation tasks such as summarization (See et al., 2017), data-to-text generation (Wiseman et al., 2017), and machine translation (Bahdanau et al., 2015), are typically modeled using attention-based encoder-decoder architectures (Bahdanau et al., 2015; Gu et al., 2016; Vaswani et al., 2017). The encoder first encodes the input text d and then the decoder predicts the output $s_{1:n}$ (e.g., the translation or summary of d) one token at a time as $p(s_i|s_1,\ldots,s_{i-1};d)$, where, n is the output length and s_i is the ith token in the output. Often these models benefit from large scale task-agnostic pretraining (Song et al., 2019; Radford et al., 2018; Lewis et al., 2019; Rothe et al., 2020; Raffel et al., 2019; Zhang et al., 2020a).

Plan-based Conditional Generation Narayan et al. (2021) develop a *plan-based* approach for neural summarization; their decoder generates a composition $c_{1:m}$ of target summary s as $p(c_j|c_1,\ldots,c_{j-1};d)$, and then the same decoder produces s as $p(s_i|s_1,\ldots,s_{i-1};c;d)$ conditioned on input d and composition $c_{1:m}$, with m being the composition length. Specifically, they adopt entity chains as the composition c of summary s, under the assumption that entities in the chain ought to be observed in the output summary. During inference, the model takes document d as input and generates $c;s$, the concatenation of composition and summary sequences, instead of generating s directly; c and s are prefixed with special markers "[CONTENT]" and "[SUMMARY]", respectively, as shown in Figure 2. If s consists of multiple sentences, markers"|||" denote sentence boundaries in composition c.

Nucleus Sampling
[CONTENT] Russian | Anna Pavlovna | William II | Netherlands
[SUMMARY] Anna Petrovna of Russia was wife of King William II of the Netherlands.

Beam Search
[CONTENT] Anna Pavlovna | Russia | Netherlands | king William II *[SUMMARY]* Anna Pavlovna of Russia was a queen consort of the Netherlands by marriage to king William II.

Figure 2: Illustration of composition sampling and other decoding strategies with vanilla and plan-based generation models. The term ‘composition’ is inspired from the quote “*A Well-Composed Painting is Half Done*” from French painter Pierre Bonnard. Images in black-and-white are early sketches or compositions of the painting in color. Nucleus or focus sampling often lead to hallucinations (highlight spans in red); corresponding color images are blurred to illustrate this. (Credit: The image of “Anna Pavlovna of Russia” is taken from Wikipedia.)

The approach allows to directly manipulate the content of summaries and their quality. For example, we might inspect the predicted chain during inference and drop entities which are not present in the input document, thereby controlling for hallucinations (Narayan et al., 2021). Outwith summarization, similar constraints can be easily adapted to other conditional generation tasks.

Maximization-Based Decoding In order to obtain the most likely output $\hat{s}$ from encoder-decoder models, we typically solve a maximization-based objective: $\hat{x} = \arg\max_x p(x|d)$, where x is either the predicted output text s (for models without planning) or the concatenation of the predicted composition and the output text $c; s$ (for models with planning). It is standard practice to use *beam search* (Tillmann and Ney, 2003; Li et al., 2016; Wiseman et al., 2017) as solving the objective for the optimal sequence with neural sequence models is not tractable (Chen et al., 2018).

Stochastic Sampling for Diverse Decoding Sampling-based strategies have been widely used to induce diversity in language models. Temperature sampling uses a temperature to skew the distribution towards high probability tokens at each decoding step (Ackley et al., 1985; Ficler and Goldberg, 2017; Fan et al., 2018), while top-k sampling truncates the distribution to k high probability tokens (Fan et al., 2018; Holtzman et al., 2018; Radford et al., 2019). Similarly to top-k sampling, *nucleus sampling* (Holtzman et al., 2020) also truncates the tail of the distribution but chooses k dynamically. At each decoding step, it samples high-probable tokens from a nucleus N defined as the smallest subset of tokens from the vocabulary V with cumulative probability $p' \geq p$, where p is the pre-specified mass of the nucleus.

Aralikatte et al. (2021) introduce *focus sampling* to promote diversity in summarization models. It constructs a subset $V_k \subseteq V$ by sampling k source-relevant and topical tokens from the vocabulary distribution. Standard beam search decoding is then used to generate a summary limited to V_k. However, the authors show that focus sampling is very sensitive to k; increasing it improves generation quality but at the cost of diversity.

3 Composition Sampling

Composition Sampling is a novel hybrid method which combines stochastic sampling with maximization-based decoding, whilst leveraging plan-based generation (Narayan et al., 2021). Specifically, we employ nucleus sampling to obtain diverse compositions c_{sample} from $p(c|d)$ where d is the input text and c are entity chains (prefixed with “[CONTENT]” in Figure 2). We first employ nucleus sampling to obtain diverse compositions from $p(c|d)$, where d is the input text. And then employ beam search to generate the most-likely diverse output s (prefixed with “[SUMMARY]” in Figure 2), given input d and composition c_{sample} as

$p(s|c_{\text{sample}}; d)$. We will experimentally show that composition sampling enables the generation of fluent, faithful and diverse texts for conditional generation.

Why Entity Chains? Unlike top-k or nucleus sampling, composition sampling avoids degeneration by introducing diversity in composition, rather than directly on the surface form. For this to effectively work, the choice of c needs to be well correlated with an underlying notion of "semantic composition", which we want to "diversify"; if c_1 and c_2 are two semantic compositions for input d such that $c_1 \neq c_2$, then two summaries $s_1 = \arg\max_s p(s|c_1; d)$ and $s_2 = \arg\max_s p(s|c_2; d)$ are bound to be diverse. In our work, we have chosen entity chains to model semantic compositions; entity chains have been widely studied to model entity-level lexical cohesion (Barzilay and Elhadad, 1997) and coherence (Halliday and Hasan, 1976; Azzam et al., 1999) in text. Also, entity chains are unique to d, and thus can be easily distinguished from compositions for other inputs. Moreover, entity chains provide a very effective knob for content control in abstractive generation, e.g., compositions can be constrained to entities only present in the input document, thereby avoiding hallucinations and entity degeneration.

Hypothesis 1: *If the semantic composition c of the output text s corresponds to entity chains, then learning $p(c|d)$ is much easier than learning $p(s|d)$; d is the input. Hence, we can sample from $p(c|d)$ with higher confidence than sampling directly from $p(s|d)$, and then compute* $\arg\max_s p(s|c; d)$.

We demonstrate the effectiveness of entity chains as a choice for c using the summarization example in Figure 3. The negative log likelihood of generating the summary s from scratch without planning ($-\log p(s|d)$) is 121.18, while the negative log likelihood of generating composition c with planning ($-\log p(c|d)$) is 46.95; hence, the model is much more confident when sampling from $p(c|d)$ than directly from $p(s|d)$.

Why Grounded Generation? The generation of s is inherently grounded to its entity composition c; following Narayan et al. (2021), the entity chains are extracted from their targets during training. Hence, once the hard part of planning the composition is done, the model is less perplexed during generation of the output.

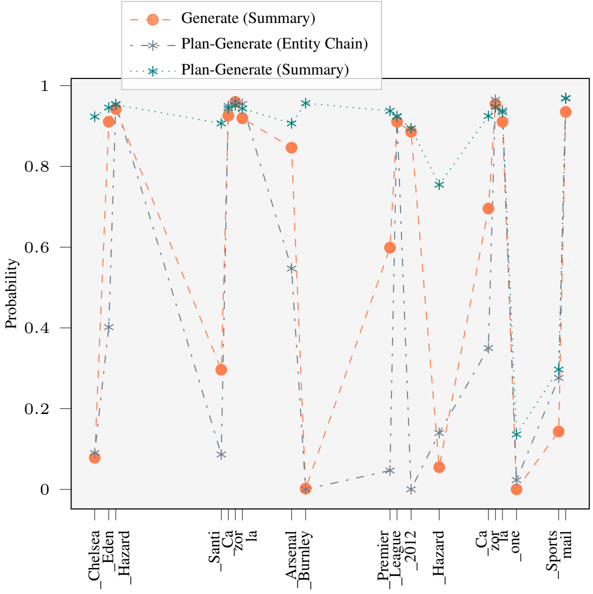

Figure 3: Probabilities of generating underlined entities in human written reference summary from Figure 1 (input article shown in Figure 6): when the summary is generated directly (Generate, Summary), when the entity chain "*Chelsea | Eden Hazard ||| Santi Cazorla | Arsenal | Burnley ||| Premier League | 2012 ||| Hazard | Cazorla | one ||| Sportsmail*" is predicted first during planning (Plan-Generate, Entity Chain), and when the entities are predicted in the summary after planning (Plan-Generate, Summary). All probabilities were computed with PEGASUS (Zhang et al., 2020a) finetuned models. The symbol '_' denotes start of token.

In Figure 3, the plan-based model is more confident in predicting entities than its counterpart without planning; perplexities of predicting entities in the summary with and without planning are 0.24 and 1.36, respectively, and perplexities of generating the whole summary with and without planning are 1.15 and 1.48, respectively. In fact, despite the increased length of the target in the plan-based model (i.e., $c_{1:m}; s_{1:n}$ instead of $s_{1:n}$), we find that the perplexity of predicting the longer sequence ($c_{1:m}; s_{1:n}$) is lower than predicting just the summary without any planning, due to grounding (1.16 vs 1.48). Overall, $p(c; s|d)$, the plan-based approach, learns a more confident distribution at each decoding step compared to no planing, i.e., $p(s|d)$. For the example in Figure 3, the average cumulative probabilities for the top 15 tokens in the vocabulary distribution at each decoding step are 0.283 for $p(s|d)$ and 0.433 for $p(c; s|d)$.

In the following we assess composition sampling for its ability to generate semantically diverse output for two tasks, namely summarization (Section 4) and question generation (Section 5).

4 Single Document Summarization

4.1 Datasets and Models

We evaluate our decoding strategy on two popular single document summarization datasets: CNN/DailyMail highlight generation (Hermann et al., 2015) and XSum extreme summarization (Narayan et al., 2018), using the original train/validation/test splits. Inputs and outputs were truncated to 512 and 128 for XSum, and, 1,024 and 256 for CNN/DailyMail.[3]

We conduct experiments with state-of-the-art pretrained models for summarization, namely PEGASUS (Zhang et al., 2020a) and FROST (Narayan et al., 2021). Our PEGASUS finetuned model generates summaries directly, whereas FROST generates the entity chain followed by the summary. In both cases we use large transformer architectures (Vaswani et al., 2017) with $L = 16$, $H = 1,024$, $F = 4,096$, $A = 16$ (568M parameters), where L denotes the number of layers for encoder and decoder Transformer blocks, H is the hidden size, F the feed-forward layer size, and A the number of self-attention heads. Since this paper is proposing a decoding strategy, there is no need to train new summarization models. We use the publicly available PEGASUS and FROST checkpoints. Training details and model hyperparameters can be found in Zhang et al. (2020a) and Narayan et al. (2021).

All models are decoded with a beam size of 8 and a length-penalty of 0.8. For nucleus sampling and composition sampling, we use nucleus probability p set to 0.95.[4] For focus sampling (Aralikatte et al., 2021), we use $k = 10,000$.

4.2 Evaluation Metrics

We assess our decoding strategy for likelihood, fluency, relevance, faithfulness, and diversity, using both automatic and human evaluation. FROST models predict a plan in the form of an entity chain, followed by a summary. All evaluations, except likelihood, are done on the summary, while the predicted entity chains are stripped out. For each *diverse* decoding strategy, we sample 5 times for each test document and report the average.

Sequence Likelihood We report the perplexity of the generated sequence (i.e., entity chains concatenated with their summaries for planning models and summaries only for the others) using various decoding strategies.

Lexical Fluency and Relevance We report ROUGE-L F1 scores (Lin and Hovy, 2003) against reference summaries.[5]

Semantic Relevance We report *BERTScore* (Zhang et al., 2020b) which computes the contextual similarity between a candidate and its reference.

Faithfulness We follow Maynez et al. (2020) and report on textual entailment (Pasunuru and Bansal, 2018; Falke et al., 2019; Kryscinski et al., 2020). In particular, we report the probability of a summary entailing (*Entailment*) its input document using a classifier trained by fine-tuning an uncased BERT-Large pretrained model (Devlin et al., 2019) on the Multi-NLI dataset (Williams et al., 2018).

We further assess faithfulness by humans. Our annotators, proficient in English, were tasked to read a document and then grade its summary on a scale of 1–4 (*entirely unfaithful*, *somewhat unfaithful*, *somewhat faithful*, and *entirely faithful*); a summary is "entirely faithful" if its content is fully supported or can be inferred from the document. We collected 3 ratings for each (document, summary) pair; we report average system ratings (across documents). With summaries deemed "somewhat unfaithful" and "somewhat faithful", annotators were asked to also specify what was faithful or unfaithful, to improve agreement.

Diversity We report the number of times (out of five samples), a decoding technique is able to generate a completely new summary (*Unique*). We also use *Self-BLEU* (Zhu et al., 2018; Alihosseini et al., 2019) to measure lexical diversity in the generated summaries. We consider all pairs of summaries out of 5 samples, and for each pair we compute the BLEU score (Papineni et al., 2002) considering one summary as a hypothesis and the other as a reference. We report the average BLEU score as the Self-BLEU of the document. The lower the Self-BLEU for a decoding strategy is, the better it is in generating a more diverse set of summaries.

---

[3] We also experimented with MultiNews (Fabbri et al., 2019), a multi-document summarization dataset. Results can be found in the Appendix (Table 7).

[4] Results with different temperatures and nucleus probabilities for random sampling, nucleus sampling, and composition sampling are in Figure 4.

[5] We lowercased candidate and reference summaries and used `pyrouge` with parameters "-a -c 95 -m -n 4 -w 1.2."

	Model	XSum			CNN/DailyMail		
		R1	R2	RL	R1	R2	RL
Single	GSum (Dou et al., 2020)	45.40	21.89	36.67	**45.94**	22.32	42.48
	CTRLsum (He et al., 2020)	—	—	—	45.65	**22.35**	**42.50**
	Fame (Aralikatte et al., 2021)	45.31	22.75	37.46	42.95	20.79	39.90
	Pegasus (Zhang et al., 2020a)	47.56	24.87	39.40	44.05	21.69	40.98
	Frost (Narayan et al., 2021)	**47.80**	**25.06**	**39.76**	45.11	22.11	42.01
	Frost$_{++}$ (Narayan et al., 2021)	44.94	21.58	37.20	45.08	22.14	41.99
Diverse	Focus (Fame)	42.76	19.89	34.97	—	—	—
	Nucleus (Pegasus)	38.49	16.57	30.99	36.27	15.10	33.46

	Composition (Frost)	**45.12**	**22.24**	**36.98**	41.76	18.94	38.69
	Composition (Frost$_{++}$)	43.82	20.35	35.89	**42.37**	**19.48**	**39.28**

Table 1: Comparison of decoding strategies with ROUGE: single-best vs diverse decoding (we report averages over 5 samples). Best results in each block are bold-faced. See Table 5 in the Appendix for more comparisons.

We propose two additional measures to capture semantic diversity in summaries: *Self-Entailment* and *Self-BERTScore*. Similar to Self-BLEU, we compute the Entailment score and BERTScore for each possible pair of summaries, respectively and report the average. A lower Self-Entailment value suggests that the generated summaries do not entail each other. Analogously, a low Self-BERTScore value indicates that the decoding technique is able to generate more contextually dissimilar summaries.

We further assess diversity by humans. Our annotators, proficient in English, again read two summaries (out of five samples) and then graded the pair on a scale of 1–4 (*identical*, *somewhat identical*, *somewhat diverse*, and *diverse*); the document was not shown in this assessment. Two summaries are "identical" if they are semantically equivalent, while the same information may be presented differently in the case of "somewhat identical". A "somewhat diverse" pair may introduce one or two new concepts or topics in one summary. A "diverse" pair should introduce new concepts or topics in each summary. We collected 3 ratings for each pair and report their average. This assessment was only done with single-sentence XSum summaries, in future work we will explore how to do this effectively for multi-sentence summaries.

Diversity and Faithfulness For summarization, diverse summaries are not meaningful if they are not faithful to the input. We propose Edna, a novel measure for "**E**valuating **D**iversity a**N**d f**A**ithfulness" in summaries. Edna is the harmonic mean of Entailment and (1−Self-Entailment); higher values of Edna imply more faithful and diverse summaries. The reason Edna relies on Self-Entailment to measure diversity is because the faithfulness metric is also based on Entailment. This means that both components will be mapped to a score in a similar output space (i.e., they both yield values between 0 and 1 obtained through the same trained model), making it more likely to be properly balanced when mixed.

4.3 Results

Table 1 presents ROUGE results on the XSum and CNN/DailyMail test sets. The top block includes results for models which employ maximization-based decoding. GSum (Dou et al., 2020) is a state-of-the art system which decodes summaries guided by an an extractive model at test time. CTRLsum (He et al., 2020) controls the summarization output trough keywords and automatically extracted sentences. Fame (Aralikatte et al., 2021) uses a focus attention mechanism to encourage the decoder to proactively generate tokens that are similar or topical to the input document. As mentioned earlier Frost (Narayan et al., 2021) first generates an entity chain and then a summary while Frost$_{++}$ is a constrained variant which restricts the predicted entities to those present in the document. We also show results for a vanilla Pegasus model (Zhang et al., 2020a) finetuned on our datasets.

The bottom block focuses on diverse decoding (we report averages across five samples). We show results with Focus sampling (Aralikatte et al., 2021) built on top of Fame, Nucleus sampling (Holtzman et al., 2020) with Pegasus and Frost, and our Composition sampling.

Table 2 presents more detailed faithfulness and diversity results, on challenge sets consisting of 50 documents for each XSum and CNN/DailyMail

		Models	ppl	With Ref.		Faithfulness		Diversity					Div+Faith

Table 2: Likelihood, faithfulness and diversity results on 50 documents sampled from XSum and CNN/DailyMail each. We report on perplexity (ppl), Entailment (Ent), Uniqueness (Uniq), Self-BLEU (S-BL), Self-Entailment (S-Ent), Self-BERTScore (S-BSc) and EDNA scores, along with ROUGE (RL) and BERTScore (BSc) for comparison. We also report on human judgements for faithfulness and diversity. Additional R1 and R2 numbers can be found in the Appendix (Table 6). Best results in the diverse block for each dataset are bold faced. Scores for single-best decoded summaries are also presented for comparison. Focus (FAME) diverse predictions on CNN/DailyMail are not available. The lower the Self-* metric is, the better the decoding method in generating diverse outputs.

summaries. We construct these challenge sets by randomly selecting documents whose reference summaries have non-extractive entity chains in them; an entity chain is extractive if all entities in it can be found in the input document. Narayan et al. (2021) have found that models struggle to generate faithful summaries for documents with data-divergence issues (Dhingra et al., 2019). The same challenge sets were used for our human evaluations of faithfulness and diversity.

Composition Sampling is not as Performance Diminishing as Nucleus Sampling Single-best decoding for FROST achieves 39.76 ROUGE (RL) on XSum,; nucleus and composition sampling fare worse showing an average drop of 7.27 and 2.78, respectively. Similarly, for CNN/DailyMail, ROUGE drops for nucleus sampling by an average of 6.51 points, compared to an average drop of 3.28 points for composition sampling (with FROST). Nucleus sampling is even more damaging for non-plan based models, such as PEGASUS; we see an average drop of 8.59 and 7.30 ROUGE points on XSum and CNN/DailyMail. These gaps are slightly larger for the challenging subsets in Table 2 which is expected due to the highly abstractive nature of the reference summaries therein.

On XSum, composition Sampling with FROST$_{++}$ performs slightly worse than with vanilla FROST in terms of ROUGE. This is due to the extreme abstractive nature of the XSum reference summaries (Maynez et al., 2020); as a result, a model is required to hallucinate factual content, that is not necessarily faithful to the input (see examples of XSum summaries in the Appendix, Figure 5). But Composition(FROST$_{++}$) only keeps supported entities in the sampled plans giving rise to summaries which diverge from their reference. This is not the case with CNN/DailyMail which is mostly extractive and we see that ROUGE performance improves with Composition(FROST$_{++}$) in Table 1.

Composition Sampling is more Confident in its Predictions than Nucleus Sampling Perplexity for FROST predictions increases from 0.31 to 0.83 for nucleus sampling, but only to 0.51 for composition sampling, on XSum. PEGASUS shows an even larger increment in perplexity (from 0.51 to 1.47) for nucleus sampling. Similar patterns are observed for CNN/DailyMail summaries.

Composition(FROST $_{++}$) is more perplexed when generating XSum summaries due to the reference summary divergence issue discussed earlier; perplexity increases from 0.51 to 0.74 compared to Composition(FROST). Interestingly, Composition(FROST$_{++}$) is almost as confident in generating diverse summaries as single-best beam decoding (FROST; perplexities of 0.71 vs 0.74 for XSum). Unsurprisingly, Composition(FROST$_{++}$) is more confident in generating CNN/DailyMail summaries than FROST (0.46 vs 0.52) due to their extractive nature.

Constrained Composition is Most Effective in Generating Meaningful Diverse Summaries It is no surprise that nucleus sampling is able to generate the most diverse summaries on both XSum and CNN/DailyMail (achieving best scores for Self-BLEU, Self-Entailment, Self-BERTScore, and diversity assessed by humans); however these summaries perform poorly on faithfulness measures. Composition(FROST$_{++}$) is most effective in generating faithful summaries, as demonstrated automatically (with best entailment scores on XSum and CNN/DailyMail) and by humans (with highest ratings on XSum and CNN/DailyMail); these summaries are also diverse achieving highest EDNA scores on both summarization datasets.

We also examined whether models differ in terms of faithfulness and diversity as rated by our participants. We carried out pairwise comparisons using one-way ANOVA with post-hoc Tukey HSD tests ($p < 0.01$). The difference between Nucleus(PEGASUS) and Nucleus(FROST) is not significant. Nucleus(PEGASUS) was also not significantly more faithful than Focus(FAME) for XSum summaries. All other pairwise differences were significant for both faithfulness and diversity.

In sum, our results demonstrate that composition sampling is a better alternative to nucleus or focus sampling for generating meaningful diverse summaries. Figure 1 presents summaries from different decoding strategies for a CNN/DailyMail article. Other example predictions for XSum and CNN/DailyMail articles can be found in the Appendix (Figures 5–9).

Faithfulness and Diversity Metrics Correlate with Human Judgements We estimate the extent to which automatic metrics of faithfulness and diversity correlate with human ratings (using Spearman's rank correlation coefficient) in Table 3. In line with previous work (Maynez et al., 2020; Kryscinski et al., 2019), we find that entailment scores are best correlated with faithfulness (moderate, $0.40 \leq r \leq 0.59$). Like Self-BLUE, Self-Entailment and Self-BERTScore are also strongly correlated with diversity ratings. Compared to other metrics which capture a single dimension, EDNA is positively correlated with both dimensions of diversity *and* faithfulness.

Metric	Faithfulness	Diversity
ROUGE-L	0.197	−0.164
BERTScore	0.209	−0.195
Entailment	0.588	−0.067
1 - Self-BLEU	−0.208	0.880
1 - Self-Entailment	−0.187	0.771
1 - Self-BERTScore	−0.198	0.873
EDNA	0.482	0.174

Table 3: Different automatic metrics and their correlation against human assessments using Spearman's rank coefficient.

Finally, in Figure 4, we plot faithfulness and diversity scores for different decoding strategies with varying temperatures and nucleus probabilities. We find that summaries sampled with Composition(FROST$_{++}$) are consistently more faithful than single-best Beam(FROST) summaries, but worse than summaries decoded with Beam(FROST$_{++}$). Summaries sampled with Composition(FROST$_{++}$) achieve the best EDNA score (with $p = 0.95$) amongst all diverse decoding strategies.

5 Question Generation

5.1 Dataset and Metrics

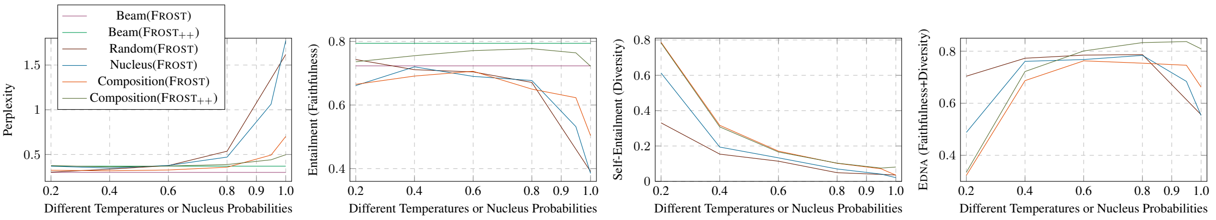
Question generation is often conceptualized as the task of generating a question from a passage-answer pair (Zhou et al., 2017). We experiment on SQuAD (Rajpurkar et al., 2016) and use the split of Zhou et al. (2017) consisting of 86,635, 8,965, and 8,964 source-target pairs for training, validation, and testing, respectively.[6] We follow Cho et al. (2019) and report BLEU-4 (Top-1, the single-best accuracy), Oracle (Top-5, the best accuracy among the 5-sampled hypotheses), and Self-BLEU (as defined in Section 4).

5.2 Results

For our question generation experiments we also compare models which employ single-best decoding against models which adopt diverse decoding techniques. The top block in Table 4 presents results for NQG++ (Zhou et al., 2017), a pointer generator-based model, CP+GSA (Zhao et al.,

---

[6] We also experimented with the split of Du et al. (2017). Results can be found in the Appendix (Table 8).



a. b. c. d.

Figure 4: Perplexity, entailment, self-entailment and EDNA scores on the CNN/DailyMail challenge set (Table 2) with varying temperatures (for random sampling) and nucleus Probabilities (for nucleus and composition sampling). For each diverse decoding strategy, we sample 5 times per document and report the average.

	Models	T1	T5	S-BL
Single	NQG++ (Zhou et al., 2017)	13.27	—	—
	MCP+GSA (Zhao et al., 2018)	16.85	—	—
	PEGASUS (Zhang et al., 2020a)	**22.17**	—	—
	FROST (Narayan et al., 2021)	21.04	—	—
Diverse	top-k Sampling	11.53	17.65	45.99
	Diverse Beam Search	13.38	18.30	74.80
	Mixture Decoder (Shen et al.)	15.17	21.97	58.73
	Mixture Selector (Cho et al.)	15.67	22.45	59.82
	Mixture Selector (Wang et al.)	15.34	21.15	54.18
	Nucleus (PEGASUS)	12.05	24.72	30.64
	Nucleus (FROST)	10.64	22.49	**25.50**
	Composition (FROST)	17.16	**27.04**	61.68
	Composition (FROST$_{++}$)	**18.77**	26.60	74.89

Table 4: Comparison of different decoding techniques on question generation. We report on BLEU-4 Top-1 accuracy (T1) and Top-5 (T5), and Self-BLEU (S-BL). Results for diverse decoding comparison models are taken from Wang et al. (2020). Best results in each block are bold-faced.

2018), a model which combines a pointer mechanism with a gated self-attention encoder, and fine-tuned PEGASUS and FROST models. The second block in the table contains several diverse decoding approaches including top-k sampling (Fan et al., 2018), diverse beam search (Vijayakumar et al., 2018), mixture decoding (Shen et al., 2019) and mixture content selection (Cho et al., 2019; Wang et al., 2020). We compare these models against nucleus sampling with PEGASUS and FROST, and composition sampling with FROST.

As in our summarization experiments, we observe that composition sampling is not as performance diminishing as nucleus sampling, in terms BLEU. FROST achieves a BLEU of 21.04 (top-1) in the single-best decoding setting; in comparison, BLEU drops for nucleus sampling by 10.40 points (on average), and 2.27 points only for composition sampling (FROST$_{++}$). Nucleus sampled questions achieve the best pairwise diversity scores (Self-BLEU of 25.50), but very low BLEU Top-1 score of 10.64. Composition sampled questions are less diverse then other methods, but outperform all baselines on Top-1 and Oracle metrics. Poor diversity (in terms of Self-BLEU) in composition sampled questions can be attributed to two limitations: (a) SQuAD questions are mostly extractive, and (b) questions are generated conditioned on the passage *and* the answer spans; leaving limited scope for models to generate diverse questions. An example in the Appendix (Figure 11) demonstrates the effectiveness of composition sampling in generating accurate and diverse questions compared to other sampling methods.[7]

6 Conclusion

We proposed Composition Sampling, a simple yet effective decoding method for faithful and diverse conditional generation. Our method is straightforward to implement and does not require any external system to augment the input during inference. Our experiments demonstrate that it is currently the best available decoding strategy for generating diverse and meaningful output. We also introduced Self-Entailment and Self-BERTScore, to automatically compute semantic diversity in summaries, and, EDNA, for jointly measuring faithfulness and diversity.

Acknowledgements

We thank the reviewers, the ARR action editor, and the senior area chair for their valuable feedback. We would like to thank Ryan McDonald, Ankur Parikh, and Slav Petrov for their insightful comments. Many thanks also to Ashwin Kakarla and his team for their help with the human evaluation.

---

[7] Detailed comparative error analysis to Cho et al. (2019) and Wang et al. (2020) was not possible as their predictions are not publicly available.

Ethical Considerations

The nature of text generation leads to multiple ethical considerations when considering applications. The main failure mode is that the model can learn to mimic target properties in the training data that are not desirable.

Faithfulness and Factuality Since models create new text, there is the danger that they may neither be faithful to the source material nor factual. This can be exacerbated when the data itself has highly abstractive targets, which require the model to generate words not seen in the source material during training. This often leads the model to generate content inconsistent with the source material (Maynez et al., 2020; Kryscinski et al., 2020; Gabriel et al., 2021).

Trustworthy Data If the data itself is not trustworthy (comes from suspect or malicious sources) the model will naturally become untrustworthy as it will ultimately learn the language and topics of the training data. For instance, if the training data is about Obama birther conspiracies, and the model is asked to generate information about the early life of Obama, there is a risk that false claims will be predicted by the model.

Bias in Data Similarly, biases in the data around gender, race, etc., risk being propagated in the model predictions, which is common for most NLP tasks. This is especially true when the models are trained from non-contemporary data that do not represent current norms and practices (Blodgett et al., 2020).

The above considerations are non-malicious, in that the model is merely learning to behave as its underlying source material. If users of such models are not aware of these issues and do not account for them, e.g., with better data selection and evaluation, then the generated text can be damaging.

Generation models can also be misused in malicious ways. These include generating fake news, spam, and other text meant to mislead large sections of the general population.

GOLD: Walsall have signed defender Luke Leahy on a two-year contract from Scottish Championship side Falkirk.

Input: Leahy, 24, scored 12 goals in 158 appearances with Falkirk, having joined the club from Rugby Town in 2012. The left-back made 38 appearances last season, helping the club finish second in the Scottish second tier before they lost to Dundee United in the play-offs. He joins Walsall on a free transfer after his contract expired and is the League One club's first summer signing. Find all the latest football transfers on our dedicated page.

Single-best summaries

Focus (PEGASUS) ($d \rightarrow t_d \rightarrow s$): Walsall have signed Falkirk defender Alex Leahy on a two-year deal.
PEGASUS ($d \rightarrow s$): Walsall have signed defender Paddy Leahy from Scottish Championship side Falkirk on a three-year deal.
FROST ($d \rightarrow c; s$):[CONTENT] Walsall | Falkirk | Liam Leahy | two [SUMMARY] Walsall have signed Falkirk defender Liam Leahy on a two-year deal.
FROST ($d \rightarrow c_{\text{drop}}; s$): [CONTENT] Walsall | Falkirk | Leahy [SUMMARY] Walsall have signed Falkirk defender Leahy on a free transfer.

Focus Sampling: FAME

$\mathbf{s_1} \rightarrow$ Welsall have signed defender Adebayu ” Adebayu ”eahy on a two-year deal following his departure from Scottish Championship club Falkiri.
$\mathbf{s_2} \rightarrow$ Welsall have signed defender Adebayu ” Adebayu ”eahy on a two-year deal from Scottish Championship club Falkock.

Figure 5: Example input article, its human written summary, and model predictions for the XSum dataset. We highlight spans in orange that are not faithful to the input. We use $c*$ and $s*$ to denote different compositions and their corresponding summaries.

Chelsea star Eden Hazard vs Arsenal playmaker Santi Cazorla: As duo prepare to reach 100 Premier League games, who has excited our experts the most since 2012?

Chelsea's Eden Hazard and Arsenal's Santi Cazorla are set to reach a Premier League milestone this weekend when they each make their 100th appearance.

Both players have been hugely influential since they moved to London in the summer of 2012, but who has been the most exciting import to watch?

Here, Sportsmail's reporters choose the player they most enjoy seeing in action.

Eden Hazard (L) and Santi Cazorla are both set to make their 100th Premier League appearance this weekend.

Lee Clayton.

Cazorla has wonderful balance. So does Hazard. Cazorla scores important goals. So does Hazard. Cazorla is two-footed. So is Hazard. Cazorla dances past opponents. So does Hazard.

So, while there is not a lot to choose between them and Hazard is likely to get the most picks in this article, I am going for Cazorla. It's a personal choice. He is a wonderful footballer. I have paid to watch them both (and I will pay to watch them both again), but the little Spanish magician edges it for me.

VERDICT: CAZORLA.

Cazorla, pictured in action against Burnley, has been an influential part of Arsenal's midfield this season.

Ian Ladyman.

I remember when Manchester City baulked at paying Hazard's wages when the Belgian was up for grabs in 2012. Back then City thought the young forward had a rather high opinion of his own worth for a player who was yet to play in a major European league.

In the early days of his time at Chelsea, it looked as though City may have been right. He showed flashes of brilliance but also looked rather too easy to push off the ball.

Roll forward to 2015, however, and the 24-year-old has developed in to one of the most important players in the Barclays Premier League. Brave, strong and ambitious, Hazard plays on the front foot and with only one thought in this mind.

Rather like Cristiano Ronaldo, he has also developed in to the type of player ever defender hates, simply because he gets back up every time he is knocked to the ground. He would get in every team in the Premier League and is one of the reasons Chelsea will win the title this season.

VERDICT: HAZARD.

Hazard controls the ball under pressure from Stoke midfielder Stephen Ireland at Stamford Bridge.

Dominic King. It has to be Hazard. I saw him play for Lille twice in the season before he joined Chelsea – once against St Etienne, the other was what proved to be his final appearance against Nancy. He scored two in the first match, a hat-trick the latter and played a different game to those around him.

He hasn't disappointed since arriving here and I love the nonchalance with which he takes a penalty, his low centre of gravity and the way he can bamboozle defenders. If there is such a thing as £32million bargain, it is Hazard.

VERDICT: HAZARD.

Hazard celebrates after scoring a fine individual goal in Chelsea's 3-2 win against Hull in March.

Nick Harris.

Now this is a tricky one because while Eden Hazard will frequently embark on a dribble or dink in a pass that will make you nod in appreciation, he'll also miss a penalty and make you groan. Whereas the older Cazorla, less flashy but no less of a technical master, is to my mind more of a fulcrum, more important relatively to the sum of Arsenal's parts than Hazard is to Chelsea.

You'll gasp at Hazard but Cazorla's wow factor is richer. That's not to dismiss either: both are brilliant footballers, contributing goals, assists and flair. Any neutral would bite your hand off to have either playing in your team.

Forced to pick though, it's Cazorla, for his consistency and crucially doing it in the biggest games. Exhibit A would be Manchester City 0 Arsenal 2 in January; goal, assist, all-round brilliance, against a big team, at an important time.

VERDICT: CAZORLA.

Cazorla scores from the penalty spot in Arsena's 2-0 away win at Manchester City in January.

Riath Al-Samarrai.

Eden Hazard for me. Cazorla is an utter delight, a little pinball of a man who is probably the most two-footed player I've seen. Put him in a tight space and then you see what makes him rare among the best. But Hazard is the top player in the Premier League, in my opinion.

This is the sixth of his eight seasons as a professional where he has reached double figures and yet he offers so much more than goals (36 in 99 in the Premier League for Chelsea). He can beat a man and, better still, you sense he likes doing it.

Technically, his passing and shooting are excellent and he also has a mind capable of sussing out the shapes and systems in front of him. That intelligence, more specifically.

Inside the Clegg kitchen: Over white wine and paella Nick reveals how Miriam put her foot down and refused to swap their family home for a grace-and-favour property

It is a conversation that will be familiar to couples across the country. What one spouse thinks is a 'discussion', the other understands they are being overruled.
In a joint interview with his high flying lawyer wife Miriam Gonzalez Durantez, Nick Clegg revealed the balance of power lies where many long suspected: with her.
After the last election, Mr Clegg was given the option of moving his family into a grace-and-favour government mansion - but the move was vetoed by his wife.
After controversies over David Cameron's large country kitchen and Ed Miliband's small second kitchen, the couple invited the cameras into the kitchen of their £1.5million family home in Putney, south west London for ITV's Tonight programme.
Scroll down for video.
Home: In a revealing joint interview, Liberal Democrats leader Nick Clegg (pictured) admitted his wife Miriam (right) makes the big decisions in their household.
Mr Clegg is seen in the documentary drinking wine as his wife explains why she chose not to move her family into a government property.
They revealed why they decided to remain with their three sons Antonio, Alberto, and Miguel, in the family home instead of making the move to Whitehall.
Miriam, who uses her maiden name Gonzalez Durantez, told ITV News Political Editor Tom Bradby:
'We had a lot of pressure at the time to go to one of the houses of the government. 'We discussed and thought the best thing would be for the children to stay here.
Revealingly, Mr Clegg quipped: 'Discussion's a rather grand word for Miriam basically saying no.'
But he quickly added: 'You were so right, you were so right.'
However, the couple believe that choosing to remain in their family home has stopped them from becoming cut off from the rest of the world.
Mrs Clegg said: 'If you look at it with perspective it has been the best decision for all of us and if I may, also for Nick as well because you can see how politicians sometimes can get in a bubble and be completely distant from normal society and I think if you're in your house in your neighbourhood, it's much easier really.'
The couple were asked why they decided to remain with their three sons Antonio, Alberto, and Miguel, in their £1.5million family home in Putney, south west London.
The couple believe that choosing to remain in their family home has stopped them from becoming cut off from the rest of the world.
Asked how they coped with the 'terrific kicking' given to her husband she said she didn't take it 'too seriously'. 'Just like any other marriage, we just stand together and it's not any more of a difficulty than what many others have to go through and you know. You should never take it too seriously.'
And if he wanted five more years Mr Clegg said: 'Ten, 15, 20 why not! In for a penny, in for a pound.'
He also insisted he felt more full of 'vim and vigour' than he did in the start of the coalition.
Focus groups conducted by the programme found Mr Clegg was characterised as the 'chihuahua in a handbag' of the government. When asked what kind of drink he was the participants settled on Babycham.
Asked how they coped with the 'terrific kicking' given to her husband, Mrs Clegg said she didn't take it 'too seriously'
The Cleggs were seen drinking white wine and cooking paella in the kitchen of their home as they chatted about their family life.
Honest: 'Discussion's a rather grand word for Miriam basically saying no,' Mr Clegg (left) joked during the interview.
Ed Miliband was widely mocked after he posed with wife Justine in this picture, which turned out to be a second kitchen in his north London home used for 'tea and snacks'
David Cameron invited the cameras into his Oxfordshire home, where he revealed he did not plan to stand for a third term.
Mr Clegg sought to explain why his relations with the Prime Minister always seemed to be so cordial. He said: 'If you know you disagree with someone, there's no tension. I suspect meetings between Tony Blair and Gordon Brown were so fractious because they kind of should have agreed but they didn't.
'When David Cameron and I sit in a meeting, as we do week in week out, we kind of know that our starting point is that we come from different vantage points...'
He claimed not to read all newspapers, and had learned how to ignore attacks form his opponents.
'It sounds glib but I actually think you can't take it too seriously otherwise you spend all your time reacting to stuff and you just have to laugh at it because some of it is faintly silly.'
Mrs Clegg added that their close bond as a family has protected from the political brickbats.
'From my point of view if I spend my time thinking about whatever a specific person may has said, I don't have any time to do what I want to do.

GOLD Question: What does the Premier of Victoria need to lead in the Legislative Assembly?

Context with Answer (in boldface): Answer: **most seats** <n> Context: The Premier of Victoria is the leader of the political party or coalition with the **most seats** in the Legislative Assembly. The Premier is the public face of government and, with cabinet, sets the legislative and political agenda. Cabinet consists of representatives elected to either house of parliament. It is responsible for managing areas of government that are not exclusively the Commonwealth's, by the Australian Constitution, such as education, health and law enforcement. The current Premier of Victoria is Daniel Andrews.

Synthetic Question Value Estimation for Domain Adaptation of Question Answering

Xiang Yue[1], Ziyu Yao[2], and Huan Sun[1]

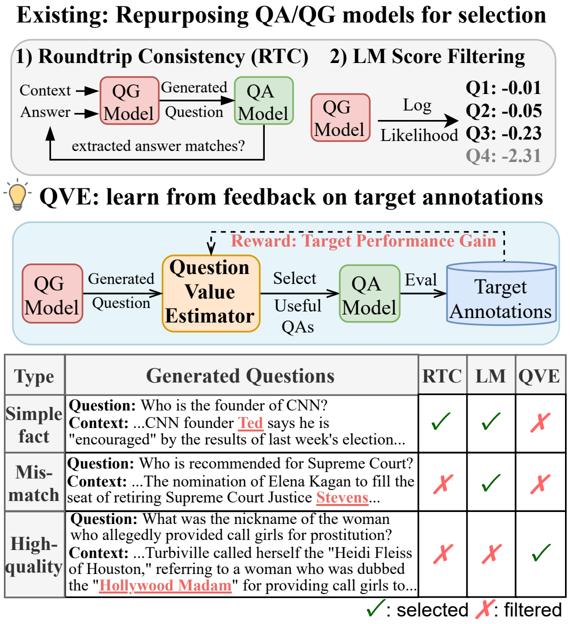
[1]The Ohio State University
[2]George Mason University
{yue.149, sun.397}@osu.edu ziyuyao@gmu.edu

Abstract

Synthesizing QA pairs with a question generator (QG) on the target domain has become a popular approach for domain adaptation of question answering (QA) models. Since synthetic questions are often noisy in practice, existing work adapts scores from a pretrained QA (or QG) model as criteria to select high-quality questions. However, these scores do not directly serve the ultimate goal of improving QA performance on the target domain. In this paper, we introduce a novel idea of training a *question value estimator (QVE)* that directly estimates the usefulness of synthetic questions for improving the target-domain QA performance. By conducting comprehensive experiments, we show that the synthetic questions selected by QVE can help achieve better target-domain QA performance, in comparison with existing techniques. We additionally show that by using such questions and only around 15% of the human annotations on the target domain, we can achieve comparable performance to the fully-supervised baselines.[1]

1 Introduction

Question answering (QA) systems based on pretrained language models such as BERT (Devlin et al., 2019) have recently achieved promising performance in machine reading comprehension. However, neural QA systems trained on one domain may not generalize well to another, leaving it challenging to deploy such systems on new domains that lack large-scale QA training data[2]. In this paper, we are interested in *semi-supervised domain adaptation*: we aim to build a target QA model with source-domain data and a small number of target-domain annotated QA pairs.



Type	Generated Questions	RTC	LM	QVE

✓: selected ✗: filtered

Figure 1: Existing work repurposes a pretrained QA (or QG) model to evaluate the quality of the generated questions, which is not directly associated with the target-domain QA performance and may select questions that are semantically-mismatched or ask about a simple fact. In contrast, our Question Value Estimator (QVE) learns to select useful questions with target-domain QA performance gain as direct feedback.

Due to high annotation costs, existing work (Golub et al., 2017; Dong et al., 2019; Wang et al., 2019; Puri et al., 2020; Chen et al., 2020; Yue et al., 2021) proposes to synthesize target-domain QA pairs via neural question generation (QG) models. The synthetic data are then used to train a QA model on the target domain. In practice, however, the generated questions are often of low quality, such as being semantically mismatched with their paired answers or asking about simple facts (Figure 1). Including all such questions for QA training is less likely to bring substantial improvements. This inspires us to study a crucial problem:

---

[1] Our source code is available at: `https://github.com/xiangyue9607/QVE`

[2] Large-scale training data are typically 60-100K in size.

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 1340 - 1351
May 22-27, 2022

Given a set of target-domain synthetic QA pairs, how to select high-quality ones that are useful to improve target-domain QA training?

To address the problem, Alberti et al. (2019) propose the Roundtrip Consistency (RTC) method, which filters[3] questions that cannot be correctly answered by a pretrained QA model. Other work (Shakeri et al., 2020) considers using the generation log likelihood by the QG model (LM Score) as a metric to filter noisy questions (Figure 1, top). Although these filtering techniques have been shown to improve the question quality to some extent (Rennie et al., 2020), they are not directly optimized for *selecting questions that can improve QA performance on the target domain*. For example, some useful but difficult questions (e.g., the last example in Figure 1) may be filtered by the Roundtrip method, since they cannot be answered correctly by the pretrained QA model. However, these questions are often crucial to further improving QA performance when added into training.

In this paper, we propose a *question value estimator (QVE)* (Figure 1, middle) to select questions that can improve QA performance on the target domain. QVE takes in generated QA examples and outputs real-valued scores (i.e., question values), which are expected to represent the usefulness of generated questions in terms of improving target-domain QA performance. However, training the QVE model towards this goal is challenging due to the lack of supervision (i.e., true question values).

To solve the problem, we propose to train the QVE with direct QA feedback from the target domain. Intuitively, if a batch of synthetic questions (when used for training) leads to increasing accuracy of the target-domain QA model, QVE should assign high values to them; the more the accuracy increases, the higher the question values should be. Thus, we optimize QVE with the *target-domain QA performance gain* after adding the selected questions into training. More formally, given the discrete and non-differentiable question selection process, we formulate the question selection of QVE as a reinforcement learning (Williams, 1992) problem (Figure 2). The QVE receives a batch of synthetic samples each time and learns to select high-quality ones based on their estimated values. The selected samples are then used to train the target-domain QA model, with the resulting performance gain (on the available target-domain annotations) as the reward. The reward guides the optimization of QVE such that it will eventually make proper question value estimation and selection.

To evaluate the QVE model, we instantiate the QG and the QA model based on the pretrained BART (Lewis et al., 2020) and BERT (Devlin et al., 2019), respectively. By carrying out comprehensive experiments on four commonly-used reading comprehension datasets (Trischler et al., 2017; Joshi et al., 2017; Yang et al., 2018; Kwiatkowski et al., 2019), we show that: (1) our QVE model trained with the target-domain QA feedback substantially outperforms the question selection techniques trained without direct QA feedback (Alberti et al., 2019; Shakeri et al., 2020). (2) When using our QVE model to select synthetic questions, QA models can achieve comparable performance to fully-supervised baselines while using only 15% of the full target-domain annotations, which indicates that our method can greatly alleviate human annotation effort in practice. (3) To understand why QVE brings superior improvement, we conduct human evaluation and find that QVE can better identify semantically-matched and difficult questions.

2 Related Work

Domain Adaptation of Question Answering. In this field, some work (Wiese et al., 2017; Chung et al., 2018; Hazen et al., 2019; Cao et al., 2020) assumes that target-domain annotated questions are available, however, manually creating questions is costly. Therefore, another line of research work (Golub et al., 2017; Wang et al., 2019; Lee et al., 2020; Shakeri et al., 2020) investigates a domain adaptation setting where annotated questions are not available on the target domain. A commonly-adopted approach of this line is to leverage a neural question generation (QG) model (Du et al., 2017; Zhou et al., 2017; Sun et al., 2018; Zhao et al., 2018; Nema et al., 2019; Tuan et al., 2020) to automatically synthesize questions given unlabeled contexts (Du and Cardie, 2018; Zhang and Bansal, 2019; Wang et al., 2019; Liu et al., 2020; Golub et al., 2017; Wang et al., 2019; Lee et al., 2020; Shakeri et al., 2020; Yue et al., 2021); see more discussions in Section 3. However, it is very challenging to achieve satisfying performance without any target annotations. In our work, we study *semi-supervised domain adaptation of QA*, and assume *a small number of target annotations are available*,

---

[3] We interchangeably use "filter" (noisy/low-quality questions) and "select" (useful/high-quality questions).

which can greatly help models adapt to the target domain while requiring minimal human effort.

Unsupervised and Semi-supervised QA are two other research topics relevant to our work (Fabbri et al., 2020; Li et al., 2020; Lewis et al., 2019; Dhingra et al., 2018). Unlike domain adaptation, these two settings do not assume the existence of the "source domain" and synthesize cloze-style questions via rule-based methods for building QA models. Since rule-based QG methods typically have much worse performance than neural ones (pretrained on the source data), we do not compare with these two lines of research in experiments.

Data Selection methods aim to select a useful subset from the (noisy) training data. Though (RL-based) data selection methods were explored in other NLP tasks (Ruder and Plank, 2017; Qu et al., 2019; Liu et al., 2019), none of them can be directly applied with trivial efforts to our QA scenario and semi-supervised setting. For example, (Ruder and Plank, 2017) and (Liu et al., 2019) reward or measure the selection with the distribution distance between the selected data and target data, while we reward the selection by measuring how large the improvement the selected data can bring for target-domain QA training, which is more aligned with the end goal. Our work is mostly inspired by recent research on data selection in machine learning community (Ghorbani and Zou, 2019; Jia et al., 2019), particularly (Yoon et al., 2020). However, the significant differences between our work and (Yoon et al., 2020) are as follows: 1) we study a very challenging task, domain adaptation of question answering, which was not studied in (Yoon et al., 2020). How to develop a method in a similar spirit for this task is unexplored. 2) In order to study the task, we begin our method by first proposing two data selection methods that are not covered in (Yoon et al., 2020) but achieve comparable results to existing baselines. We then introduce our RL-based method with a carefully-designed reward, which is well connected to the end goal of improving target-QA performance.

3 Background

3.1 Domain Adaptation of QA via QG

Semi-supervised Domain Adaptation. We study the semi-supervised domain adaptation of *extractive* question answering, where the source-domain and a small number[4] of target-domain QA annotations are provided. Formally, we denote the source-domain QA dataset as $D^{\mathsf{s}} = \{(c_i^{\mathsf{s}}, q_i^{\mathsf{s}}, a_i^{\mathsf{s}})\}_{i=1}^{N}$, where large-scale tuples of context c_i^{s}, question q_i^{s}, and answer a_i^{s} are available. For the target domain, only a small set of annotated QA pairs $D^{\mathsf{t}} = \{(c_j^{\mathsf{t}}, q_j^{\mathsf{t}}, a_j^{\mathsf{t}})\}_{j=1}^{M}$ are available ($M \ll N$). Since unlabeled contexts are easy to collect, we assume that they are largely available: $C^{\mathsf{t}} = \{c_l^{\mathsf{t}}\}_{l=1}^{L}$ ($L \gg M$). The task is to build a QA model that can accurately answer questions on the target domain, given D^{s}, D^{t}, and C^{t}.

Domain Adaptation via Question Generation. Given the lack of large-scale target-domain annotations, an intuitive approach to domain adaptation is first synthesizing target-domain QA data $D_{syn}^{\mathsf{t}} = \{(c_l^{\mathsf{t}}, q_l^{\mathsf{t}}, a_l^{\mathsf{t}})\}_{l=1}^{L}$ automatically from the unlabeled contexts C^{t}, and then training a target-domain QA model on the synthetic (D_{syn}^{t}) and the small-size annotated (D^{t}) target-domain data. In such an approach, a question generator (QG) g_ϕ is first pretrained on the source training data and further finetuned on the available target-domain annotated QA pairs. A well-trained QG model then takes target-domain context-answer pairs as input to generate a question: $q_l^{\mathsf{t}} = g_\phi(c_l^{\mathsf{t}}, a_l^{\mathsf{t}})$.

Although this approach has been shown promising, in practice, its effectiveness is restricted by the quality of synthetic questions. Thus, learning to select ones that can lead to a better target-domain QA model becomes a crucial problem.

With respect to how to obtain a_l^{t} for QG, in this paper, we assume an answer a_l^{t} (i.e., a text span in the context c_l^{t}) is given, following Du et al. (2017). When the answer a_l^{t} is not given, it can be extracted from the given context by using an entity recognition tool (Du and Cardie, 2018), a classifier (Puri et al., 2020) or a seq2seq model (Shakeri et al., 2020). Note that noise caused by such answer extraction tools will further lower the overall quality of the synthesized questions. In this paper, we focus on how to select useful synthetic questions in general (i.e., those questions can be synthesized by any QG process) and assume answers are given for simplicity.

3.2 Synthetic Question Selection

Given the synthetic target-domain QA data D_{syn}^{t}, the task is to select high-quality pairs from D_{syn}^{t}

---

[4] In our experiments, we assume 1,000 target annotations available, which is around 1-1.5% of the original training data.

that are useful to improve target-domain QA training. Such a selection decision is often made based on some scores that can indicate the quality of the pairs. For example, Roundtrip filtering (Alberti et al., 2019) selects questions based on the extracted answer's correctness by a pretrained QA model. Similarly, LM filtering (Shakeri et al., 2020) selects questions with high log-likelihood scores in the generation. However, these scores do not directly serve the goal of improving target-domain QA training. Inspired by recent research on data selection in the machine learning community (Ghorbani and Zou, 2019; Jia et al., 2019; Yoon et al., 2020), we propose a new idea of training a *question value estimator*, which predicts the usefulness of a synthetic question for target-domain QA.

4 Question Value Estimator (QVE)

Formally, we design a question value estimator (QVE), e_γ, which takes in a synthetic QA example (c_l, q_l, a_l) (for simplicity, we omit the superscript t) and outputs a score indicating its "value," i.e., $v_l = e_\gamma(c_l, q_l, a_l)$. The "value" can imply "the potential for improving the target-domain QA performance when being used as a training sample". With this score, one can select most useful synthetic examples for the target-domain QA training.

We use a BERT model as the backbone of the QVE. Specifically, we concatenate the context, question and answer as input to the QVE, and use BERT to encode the sequence (Devlin et al., 2019).

$$\mathbf{h} = \texttt{BERT}\ [\texttt{<CLS>}\ q\ \texttt{<ANS>}\ a\ \texttt{<SEP>}\ c]$$

where q, a, c represent the question, answer, and context, respectively. $\mathbf{h} \in \mathbb{R}^H$ denotes the hidden representation of the input sequence derived from the "`<CLS>`" token. `<ANS>` and `<SEP>` are two special tokens used as delimiters.

In our preliminary experiments, we find that adding the answer (start index and end index) probabilities (p_s, p_e) by a pretrained QA model as additional features to the hidden representation $\mathbf{h}$ can accelerate the QVE training convergence and lead to better performance. Thus, we add these two features (p_s, p_e) followed by linear transformations of the original hidden representation, and then build a linear classifier to output the question value.

$$\mathbf{h}' = \sigma(W_2\sigma(W_1\mathbf{h} + b_1) + b_2)$$
$$\mathbf{h}'' = \sigma(W_3(\mathbf{h}' \oplus p_s \oplus p_e) + b_3)$$
$$v_l = W_4\mathbf{h}'' + b_4$$

where $W_1 \in \mathbb{R}^{H_1 \times H}, W_2 \in \mathbb{R}^{H_2 \times H_1}, W_3 \in \mathbb{R}^{H_3 \times H_2}, W_4 \in \mathbb{R}^{H_3}$, $b_1 \in \mathbb{R}^{H_1}, b_2 \in \mathbb{R}^{H_2}, b_3 \in \mathbb{R}^{H_3}, b_4 \in \mathbb{R}$ are trainable parameters of linear layers. σ is the activation function `tanh`.

Learning such a question value estimator is challenging because we do not have direct supervision on the true value or usefulness of a synthetic question. We discuss two straightforward baselines to train QVE in Section 4.1, and a more advanced one based on reinforcement learning in Section 4.2.

4.1 QVE Training: Two Baselines

Binary Classifier: One straightforward solution is to treat QVE as a binary classifier and train it based on the human-annotated (positive) and the machine-synthesized (negative) QA pairs. Given the scarcity of target-domain data, we first pretrain the classifier on the source domain and then finetune it on the target domain. More specifically, we train a QG model on 70% of the source training data and generate synthetic questions on the remaining 30% of the source training contexts. The generated questions and the source-domain annotated questions are used to train this binary classifier. The classifier is then finetuned based on the small set of target-domain annotations (positive) and the samples synthesized on the same target-domain contexts (negative).

However, not all of the generated questions are bad. Simply treating all synthetic samples as negatives may mislead the classifier. Thus, we loose this assumption and introduce a ranking baseline.

Ranking Baseline: We assume that the quality of human-annotated questions is not inferior than that of machine-synthesized ones. Thus, we train QVE based on a ranking triplet loss defined as follows:

$$L_r = \sum \max(0, m + v_s - v_h)$$

where v_s, v_h are the estimated question values of the machine-synthesized sample and human-annotated sample. m is set to 0.15 as the margin.

The two baseline methods have two obvious drawbacks: (1) they are trained to differentiate between human-annotated and machine-synthesized samples, which is mismatched with our goal of selecting high-quality samples *among machine-synthesized data*; (2) similar as (Alberti et al., 2019; Shakeri et al., 2020), the two baselines are *not* trained with direct signals that can represent the usefulness of a synthetic question. In the next section, we will introduce a task-specific training

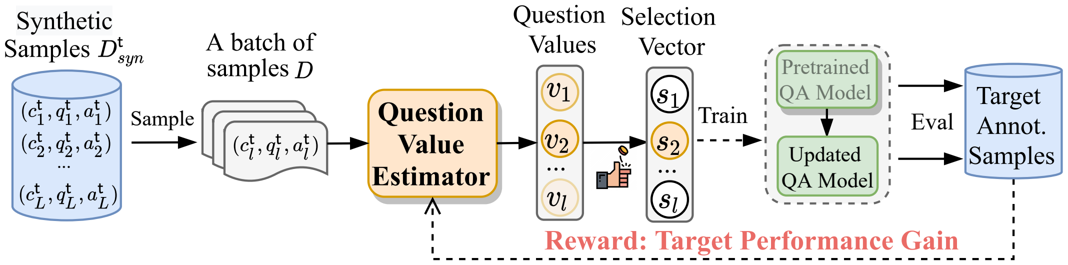

Figure 2: Illustration of QVE training based on the direct feedback from QA. Specifically, in the forward pass, QVE estimates the question values of a batch of synthetic questions and draws a Bernoulli sampling to select questions. The selected questions are then used to finetune a pretrained QA model. The performance gain (before and after the QA finetuning) on the target annotations is calculated as the reward for REINFORCED QVE training.

Algorithm 1 QVE REINFORCED Training

Input: pretrained QA model f_θ; target synthetic QA pairs D^t_{syn}; small target annotations D^t.
Hyperparameters: outer iterations I_o, outer batch size B_o, inner iterations I_n, inner batch size B_n, QVE learning rate α_o, QA learning rate α_n.
Output: QVE e_γ.

```
 1: Randomly initialize $e_\gamma$
 2: Store $\theta_0 \leftarrow \theta$ (pretrained QA checkpoint)
 3: for outer iteration $= 1$ to $I_o$ do
 4:     ▷ ① Sample a batch of synthetic QA pairs:
 5:     Sample $\mathcal{D} = \{(c_l, q_l, a_l)\}_{l=1}^{B_o}$ from $D^t_{syn}$
 6:     ▷ ② Estimate question values:
 7:     $\mathcal{V} = e_\gamma(\mathcal{D})$
 8:     ▷ ③ Sample selection vector:
 9:     $\mathcal{S} \sim \texttt{Bernoulli}(\mathcal{V})$
10:     ▷ ④ Update QA on selected samples:
11:     for inner iteration $= 1$ to $I_n$ do
12:         Sample $\{(c_l, q_l, a_l)\}_{l=1}^{B_n} \sim \mathcal{D}$
13:         $\theta \leftarrow \theta - \frac{\alpha_n}{B_n} \sum_{l=1}^{B_n} s_l \cdot \nabla_\theta \mathcal{L}_{qa}$
14:     end for
15:     ▷ ⑤ Calculate QA gain as QVE reward:
16:     $r_{qve} = \texttt{reward\_fn}(f_{\theta_0}, f_\theta, D^t)$
17:     ▷ ⑥ Update QVE based on Eq. 1:
18:     $\gamma \leftarrow \gamma - \alpha_o \cdot \nabla_\gamma \mathcal{L}_\gamma$
19:     Reset $\theta \leftarrow \theta_0$
20: end for
21: return $e_\gamma$
```

method, which directly uses the target-domain QA feedback to optimize QVE.

4.2 QVE Training: Direct Feedback from QA

A well-trained QVE is expected to assign high values to synthetic questions that can improve the target-domain QA performance. Therefore, an intuitive way to measure the value of a synthetic question is to consider the downstream QA performance gain (on the available target annotations) before and after this question is included in the training set. However, this "leave-one-out" formulation is computationally expensive and time-consuming, given that it can estimate the value of only one single synthetic question in each forward pass. In light of this challenge, we instead estimate question values in a *batch-wise* fashion. Algorithm 1 and Figure 2 describe the learning process.

Generally speaking, we frame the QVE model learning as a reinforcement learning problem (Williams, 1992), and stimulate QVE to assign higher values to more useful questions by using performance-driven rewards. Specially, for a batch of synthetic examples $\mathcal{D} = \{(c_l, q_l, a_l)\}_{l=1}^{B_o}$ in the outer training iteration (Line 4-5), the QVE model *selects a subset of examples* that are most likely to boost the QA performance on the target domain, based on its judgment on their values.

Mathematically, the decision-making outcome is represented by the selection vector $\mathcal{S} = (s_1, s_2, ..., s_{B_o})$, where $s_l \in \{0, 1\}$ $l = 1, ..., B_o$ (Line 6-9). The whole batch-level decision making policy π_γ is described as follows:

$$v_l = e_\gamma(c_l, q_l, a_l)$$

$$s_l \sim \texttt{Bernoulli}(v_l)$$

$$\pi_\gamma(\mathcal{S}|\mathcal{D}) = \prod_{l=1}^{B_o} [v_l^{s_l} \cdot (1 - v_l)^{1-s_l}],$$

where the selection of a certain example (c_l, q_l, a_l) is formulated as sampling from a Bernoulli distribution of probability v_l (i.e., its estimated question value). We adopt the Bernoulli sampling based on the estimated value v_l instead of setting a hard threshold to encourage the policy exploration.

The model is rewarded based on how much performance gain the selected examples could bring when they are used to train the target-domain QA model. To this end, we finetune the QA model f_θ on the selected batch samples based on $\mathcal{L}_{qa}$, which typically is a cross-entropy loss:

$$\mathcal{L}_{qa} = -\sum_{l}^{B_o} \log P(a_l|q_l, c_l; \theta)$$

In practice, to stabilize the QVE training, we choose a large outer batch size B_o in each outer training iteration. For finetuning the QA model, we pick a relatively smaller inner batch size B_n and repeat the training for I_n times, such that the QVE-selected samples are fully utilized (Line 10-14).

The reward r_{qve} is defined as the QA performance gain on the target-domain annotations D^{t} before (f_{θ_0}) and after (f_θ) finetuning (Line 15-16),

$$r_{qve} = \texttt{reward\_fn}(f_{\theta_0}, f_\theta, D^{\mathrm{t}})$$

where `reward_fn` is Exact Match (EM) gain[5].

Given the discrete and non-differentiable question selection process, we update the QVE model using the REINFORCE algorithm (Williams, 1992). Mathematically, we aim to minimize:

$$\mathcal{L}_\gamma = - \mathop{\mathbb{E}}_{\mathcal{S} \sim \pi_\gamma(\cdot|\mathcal{D})} [r_{qve}].$$

The gradient of the loss function is derived as:

$$\begin{aligned} \nabla_\gamma \mathcal{L}_\gamma &= - \mathop{\mathbb{E}}_{\mathcal{S} \sim \pi_\gamma} [r_{qve} \nabla_\gamma \log \pi_\gamma(\mathcal{S}|\mathcal{D})] \\ &= - \mathop{\mathbb{E}}_{\mathcal{S} \sim \pi_\gamma} [r_{qve} \nabla_\gamma \sum_{l=1}^{B_o} \log [v_l^{s_l} (1 - v_l)^{1-s_l}]]. \end{aligned} \tag{1}$$

Notably, to mitigate the instability in reinforcement learning, we reset the QA model to its pretrained checkpoint at the end of each outer iteration (Line 19), and keep the pretrained QG model unchanged.

After training QVE, we can use it to calculate the question value for all the synthetic questions on the target domain. Then we can select top $K\%$ synthetic QA pairs as the training corpus to train the target-domain QA model.

5 Experimental Setup

5.1 Datasets

We use datasets in the MRQA 2019 Shared Task (Fisch et al., 2019), a popular challenge focusing on generalization in reading comprehension. Specifically, following Shakeri et al. (2020), we use **SQuAD 1.1** (Rajpurkar et al., 2016) as the *source-domain* dataset. For the *target-domain* datasets, we consider **NewsQA** (Trischler et al., 2017), **Natural Questions (NQ)** (Kwiatkowski et al., 2019), **HotpotQA** (Yang et al., 2018) and **TriviaQA** (Joshi et al., 2017) as they are commonly used and have sufficient contexts for the QG model to generate synthetic samples. Since there is no test set available for each dataset, we use the original dev set as the test set. Detailed descriptions of each dataset are in Appendix A.

For the target-domain datasets, we assume all the contexts and n annotated QA pairs in the original training sets are available for training. We set $n = 1000$ (about 1%-1.5% of original training sets) as default and discuss the impact of n in Section 6.2.

5.2 Implementation Details

We implement models using the Hugging Face transformers (Wolf et al., 2020) library. We instantiate the QA model with `BERT-base-uncased` (Devlin et al., 2019), and the QG model with `BART-base` (Lewis et al., 2020). For training QVE (Algorithm 1), we use `BERT-base-uncased` model and set $H_1 = H_3 = H = 768$ and $H_2 = 64$ for linear layers. To enable a large batch size B_o, we use gradient checkpointing (Chen et al., 2016), a technique used for reducing the memory footprint when training deep neural networks. We set $I_o = 2000$, $B_o = 80$, $I_n = 20$, $B_n = 4$, and $\alpha_o = \alpha_n = 3e^{-5}$. To select the best QVE checkpoint, we pick the one that achieves the highest reward on the target annotations or the one that leads to the lowest QA training loss. When training (finetuning) QA and QG models (either on source or target domain), we set training epochs as 2 and 3 respectively. Other hyperparameters are set as default in the transformers library.

5.3 Compared Baselines

We evaluate the following QA models built on different training data:

(1) Source Only Baseline: we train a QA model on the source-domain data.

(2) Source + Target Annotations Baseline: we further finetune the "(1) Source Only Baseline" on the available target annotated QA pairs.

(3) QG Baseline (no filtering): we first pretrain a QG model on the source-domain data and finetune it on the available target annotations. The

---

[5] We also tried F1 gain and loss drop as the `reward_fn` and the EM gain is slightly better than the other two.

	Different Filtering Methods			
Dataset	NoFilter	RTC	LM	QVE
NewsQA	74,160	33,756	44,485	44,485
NQ	104,071	62,888	62,443	62,443
HotpotQA	72,928	46,273	43,757	43,757
TriviaQA	61,688	26,361	37,013	37,013

Table 1: Number of synthetic examples selected by different methods. NoFilter: QG baseline (no filtering); RTC: Roundtrip Filtering; LM: LM Filtering.

QG model is then used to generate synthetic QA samples on the target contexts. We finetune a QA model sequentially on all available data with the order of "source→target synthetic→target annotated" for all the datasets except TriviaQA[6]. The same QA finetuning strategy will also be used for (4)-(8).

(4) RoundTrip Filtering (Alberti et al., 2019): we use the "(2) Source + Target Annotation Baseline" to extract answers for target synthetic questions and select the ones, whose extracted answers are correct, as the target synthetic training corpus.

(5) LM Filtering (Shakeri et al., 2020): we use the log likelihood scores of synthetic questions produced by the QG model in (3) as the filtering criterion. We select top K% samples as the target synthetic training corpus.

(6) QVE (binary classifier): we train QVE as a binary classifier (Section 4.1) and then use it to select top K% target synthetic samples.

(7) QVE (ranking baseline): we train QVE based on a ranking function (Section 4.1), and then use it to select top K% synthetic samples.

(8) QVE (RL): we train QVE based on the direct feedback from target annotations using RL (Section 4.2), and then use it to select top K% target synthetic samples.

(9) Fully-supervised Baseline: we train a QA model on the original target training data. Note that we report the fully-supervised performance here only as the reference and (1)-(8) are not directly comparable to this.

The number of the selected synthetic examples of RoundTrip Filtering is determined by the QA model and varies for each dataset. For LM Filtering and QVE, we select top K% (K=60) samples among all synthetic ones and discuss the impact of the synthetic dataset size in Appendix B. We show the statistics of filtered datasets in Table 1.

6 Results

6.1 Overall Results

We first discuss the domain adaptation results on the 4 target-domain QA datasets under semi-supervised setting where $n = 1,000$ target-domain QA examples are available. Table 2 shows the overall results of different methods. We summarize key findings as follows:

(1) Compared with RoundTrip and LM Filtering, our QVE (RL) achieves the best performance. This is because both baselines are not specifically trained to select useful examples for improving QA performance on the target domain. Our QVE, on the contrary, is trained with a signal that directly reflects the QA performance, which can more accurately estimate the question value and select useful pairs for target-domain QA.

(2) Two QVE baselines (binary classifier and ranking baseline) can select some useful questions and achieve comparable performance with RoundTrip and LM Filtering. However, due to the lack of direct QA evaluation feedback, they underperform QVE (RL), which demonstrates the usefulness of the QA feedback during training QVE.

6.2 How many target QA pairs do we need?

In Table 2, we showed that with n (n=1,000) target annotated QA pairs and the selected high-quality synthetic QA pairs, we can finetune a better QA model on the target domain. In this section, we discuss the influence of n on the target-domain QA performance. The results are shown in Figure 3, and interesting findings include:

(1) In general, the performance of all models improves as more target annotations are used. This is intuitive as more annotated pairs can improve both QA and QG training. With a better QG model, the quality of the synthetic questions is improved, which could also lead to better QA models.

(2) Our QVE model can often outperform the QG baseline and the filtering baselines. With an optimization objective considering the downstream QA performance, QVE can select more useful questions for improving target-domain QA.

(3) The improvement of our QVE compared with baselines is usually larger when more annotated QA pairs are available. This is because our QVE training (with RL) relies on the QA feedback based on the available annotated pairs. With more annotated pairs, the feedback can be more accurate, thus

---

[6] For the TriviaQA dataset, we merge the target synthetic and target annotated dataset into one training file since directly finetuning on the target annotated dataset would hurt the QA performance based on our preliminary experiments.

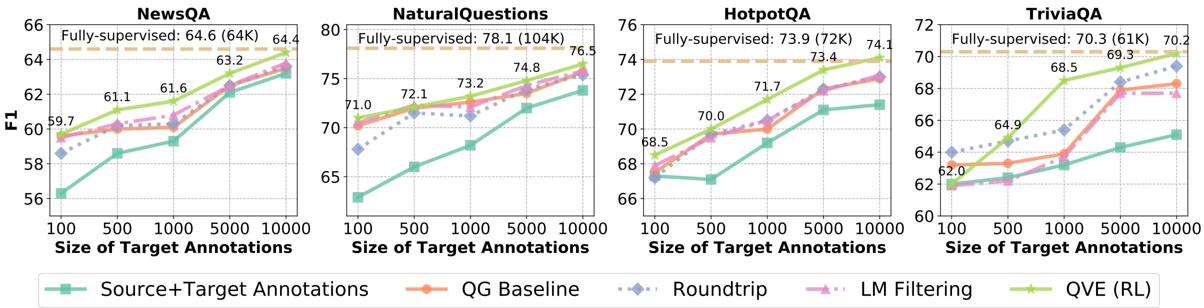

Figure 3: Impact of the number of target annotated QA pairs. We also show the fully-supervised performance (and #train) as the reference. With 10K target annotations (around 15% of the full training set), our method can achieve comparable performance to the supervised ones (as shown at the top of each sub-figure).

leading to a better QVE for selecting more useful synthetic questions.

(4) With 10,000 (around 15% of the original training set) target annotations and the synthetic questions selected by QVE, we can achieve comparable performance with the fully-supervised baseline. This indicates that one can save more annotation budgets when building a target-domain QA model based on our QVE in practice.

6.3 Experiments with Larger Models

The results presented in the previous sections are based on `BERT-base` and `BART-base`. In this section, we test whether our QVE can still be effective when working with larger models, and select `BERT-Large` and `BART-Large` as QA and QG model respectively. When changing the QA (QG) model to its larger alternative, we keep the other one as the base model to better show the difference. We use NaturalQuestions (NQ) and HotpotQA as representative datasets, and show results on them (with 1,000 target annotations). As shown in Table 3, our QVE model can still help improve the performance for larger instantiations of QG/QA.

6.4 Human Study: Why can QVE help QA?

In this section, we aim to gain a better understanding of why QVE helps QA and verify that QVE selects more semantically matched and non-trivial questions, thus benefiting downstream QA.

Since automatic metrics cannot often reflect the actual quality of the question selections, we sample 50 generated examples from each target-domain dataset (200 in total), and ask three human annotators to label whether a generated QA pair is semantically matched (i.e., can be selected to train QA) and (if yes) whether it asks about a simple fact. To lower the annotation bias in determining

Table 4: Two synthetic questions labeled by human and different question selection models.

whether a generated question asks about a simple fact or not, we provide the ground-truth question (the question in the original dataset created by humans) as a reference. If the generated question is simpler than the ground truth, then it would be marked as "trivial"; otherwise, it is a "non-trivial" one. Three annotators work independently and we adopt the majority vote for deciding the final labels of a generated QA pair (if disagreement appears).

We calculate the precision, recall and F1 between predictions[7] by each filtering method and human labels (for both "semantically matched" and "non-trivial"). As shown in Table 5, though three methods obtain a similar precision on all sampled questions, our method has a better recall, especially on the "non-trivial" questions. This means that our method can select more semantically matched and non-trivial questions, which explains why it leads to better QA performance. We also show some real cases in Figure 1 and Table 4 to further illustrate this point. For example, our QVE selects *"What was the nickname given to the woman who allegedly provided call girls for prostitution?"* while the baselines do not pick this semantically matched and non-trivial question. For another example, *"Who is the founder of CNN"*, both baselines select it while our QVE filters it out since such a simple question would probably not help further improve QA.

Methods	Semantically-Matched			Non-trivial		
	P	R	F1	P	R	F1
RoundTrip	87.9	60.0	71.2	82.6	47.5	60.3
LM Filtering	85.7	64.6	73.6	78.9	51.7	62.5
QVE(RL)	**88.2**	**70.0**	**78.0**	**83.3**	**59.3**	**69.3**

Table 5: Agreement with question selection by humans.

7 Conclusion

We propose a question value estimator to estimate the usefulness of synthetic questions and select useful ones for improving target-domain QA training. We optimize QVE with the target-domain QA performance gain after adding the selected questions into training. Our comprehensive experiments demonstrate the superiority of QVE compared with other question selection methods. Additionally, using the synthetic questions selected by QVE and only around 15% of the human annotated data on each target domain, we can achieve comparable performance to the fully-supervised baselines.

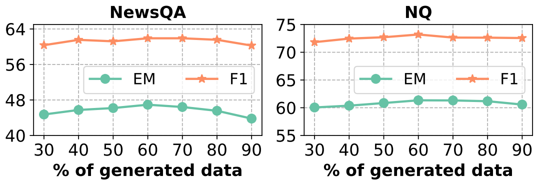

Figure A1: Impact of synthetic dataset size.

A Details of Datasets

Specifically, following Shakeri et al. (2020), we use **SQuAD 1.1** (Rajpurkar et al., 2016), a large reading comprehension dataset that consists of 100k questions on more than 500 articles from Wikipedia, as the *source-domain* dataset. For the *target-domain* datasets, we consider the following 4 datasets since they are commonly used and have sufficient contexts to train the models.

NewsQA (Trischler et al., 2017) consists of questions and answers based on a set of over 10k news articles from CNN News.

Natural Questions (NQ) (Kwiatkowski et al., 2019) contains questions extracted from Google user search queries and passages from Wikipedia.

HotpotQA (Yang et al., 2018) is a multi-hop question answering dataset based on Wikipedia passages.

TriviaQA (Joshi et al., 2017) includes QA pairs authored by trivia enthusiasts, as well as evidence documents independently gathered from Web search results and Wikipedia articles.

B Impact of Synthetic Dataset Size

In Figure A1, we show how the synthetic dataset size (i.e., the number of selected QA pairs) impacts the QA performance, based on our QVE (RL) filtering. As we expect, at the beginning, the target QA performance improves when more synthetic data is added to the training set. However, the performance reaches the peak at 60-70% and then goes down. This is reasonable since adding less valuable QA pairs from the noisy synthetic data will hurt the QA model training. We suggest 60%-70% (50K-70K QA pairs) for setting the synthetic data size in practical.

Better Language Model with Hypernym Class Prediction

Abstract

Class-based language models (LMs) have been long devised to address context sparsity in n-gram LMs. In this study, we revisit this approach in the context of neural LMs. We hypothesize that class-based prediction leads to an implicit context aggregation for similar words and thus can improve generalization for rare words. We map words that have a common WordNet hypernym to the same class and train large neural LMs by gradually annealing from predicting the class to token prediction during training. Empirically, this curriculum learning strategy consistently improves perplexity over various large, highly-performant state-of-the-art Transformer-based models on two datasets, **WikiText-103** and ARXIV. Our analysis shows that the performance improvement is achieved without sacrificing performance on rare words. Finally, we document other attempts that failed to yield empirical gains, and discuss future directions for the adoption of class-based LMs on a larger scale.

1 Introduction

Over the course of the past decades, language modeling (LM) has transitioned from n-gram to neural models (Bengio et al., 2003; Mnih and Hinton, 2007; Devlin et al., 2019; Brown et al., 2020). Performance improvement of today's neural LMs is often achieved at the cost of increased computational resources. For example, to capture long-term dependencies, various extensions of Transformer-based LMs have been proposed (Dai et al., 2019; Rae et al., 2020). These modifications bring about significant improvements on held-out perplexity, but training cost also increases significantly due to large GPU memory consumption and more computations at each training step.

Original Text:

A final **torch** used to enter Empire **Stadium** that was made of **stainless steel** and powered by a **magnesium candle**

Replaced with hypernym class:

A final **instrumentality.n.03** used to enter Empire **structure.n.01** that was made of **alloy.n.01 alloy.n.01** and powered by a **metallic_element.n.01 instrumentality.n.03**

Figure 1: An example of word prediction training text and hypernym class prediction training text.

In parallel, alternative training strategies have also been proposed (Guu et al., 2020; Ziegler and Rush, 2019; Deng et al., 2020). In this paper, we explore the effectiveness of class-based language models (CLMs, Brown et al. 1992) in the context of neural LMs. CLMs group individual words into coarser-grained classes and has proven effective in alleviating context sparsity in n-gram LMs (Dagan et al., 1999). It has been also used to improve computational efficiency in neural LMs (Morin and Bengio, 2005; Grave et al., 2017a). More recently, Levine et al. (2020) pretrain masked LMs (Devlin et al., 2019) by predicting WordNet supersense labels. However, the work focuses on word-sense disambiguation tasks and doesn't provide clear evidence of gains in terms of perplexity.

In this paper, we revisit CLM and assign words to classes by leveraging hypernym relations from the WordNet (Miller, 1995). Our proposal, dubbed Hypernym Class Prediction (HCP) is simple and effective: for each batch, we substitute a subset of the tokens with their WordNet hypernyms (see Figure 1). Then, we train an autoregressive LM on the resulting sentences using a mixed vocabulary composed of hypernyms and tokens. Crucially, we anneal the substitution rate during training, i.e., we gently switch from hypernym prediction to token prediction, following a curriculum learning approach. Note that this approach does not require WordNet information at inference time nor

---

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 1352 - 1362

increases training time.

Our approach is motivated by two hypotheses. Firstly, mapping words to their hypernyms gives rise to a natural gradation of difficulty in the prediction task. Prior work has shown that LM benefits from training on instances of increasing difficulty (Bengio et al., 2009; Press et al., 2021). We thus postulate that, when coupled with the right curriculum, HCP can improve LM training and perplexity. Secondly, we hypothesize that HCP can improve rare word generalization through implicit context sharing. Neural models still struggle to learn reliable representations for rare words (Schick and Schütze, 2020). With CLM-based models, data sparsity for rare words can be abated, e.g., when the representation of their contexts are potentially drawn closer to those of their more frequent siblings by way of label (hypernym) sharing.

Empirically, the proposed method consistently yields about 0.6–1.9% relative reduction in perplexity over baselines on the **WikiText-103** dataset (Merity et al., 2016), and 1.3–3.1% on the ARXIV dataset (Lazaridou et al., 2021). These improvements are observed with respect to memory-augmented (Dai et al., 2019) and segment-aware (Bai et al., 2021) LMs. Importantly, the proposed method improves performance for both rare and frequent words. We also observe that this is in contrast with performance improvements in regular LMs, which seem to be achieved at the cost of worsened performance on rare words.

To the best of our knowledge, this is the first work that shows how perplexity of Transformer LMs can be improved by leveraging hypernymy relationships. We provide an extensive ablation study highlighting crucial elements of HCP. Amongst those, we found particularly important to adopt a curriculum learning approach, rather than multi-objective learning or adaptive-softmax, and excluding frequent words from the hypernym prediction task. We highlight the simplicity and effectiveness of the proposed method as our main contribution, and hope this study would facilitate further exploration in this line of research.

2 Related Work

Transformer-based models are now popular language models. Dai et al. (2019) propose Transformer-XL by extending the vanilla Transformer (Vaswani et al., 2017) with a memory segment, which can encode more context tokens to predict the next token. Rae et al. (2020) extend Transformer-XL with a compressed memory segment to further encode long-time context memory. Other works explore different sparse Transformers to encode much longer sequences for LM (Beltagy et al., 2020; Roy et al., 2021). Bai et al. (2021) propose a segment-aware Transformer (Segatron) to encode more positional information for language modeling. Despite their effectiveness, neural models still struggle to learn reliable representations for rare words. Some approaches have been proposed to tackle this challenge by way of morphology (Luong et al., 2013), lexical similarity (Khassanov et al., 2019), context similarity (Schick and Schütze, 2020; Khandelwal et al., 2020) and tokenization (Kudo and Richardson, 2018).

In addition to the model modifications, other work investigated curriculum learning to train LMs. Bengio et al. (2009) first find that curriculum learning could benefit LM training by training with high-frequency tokens first and low-frequency tokens later. Wu et al. (2021) find that curricula works well when the training data is noisy or the training data is too large to iterate multiple epochs. Press et al. (2021) find that training Transformer-based LMs with short sequences first could improve convergence speed and perplexity.

Related work aimed at integrating WordNet information into pretrained language models. Levine et al. (2020) propose SenseBERT by adding the word sense (WordNet supersense) prediction as an additional task during BERT (Devlin et al., 2019) pre-training. SenseBERT outperforms BERT on both word supersense disambiguation (Raganato et al., 2017) task and word in context (Pilehvar and Camacho-Collados, 2019) task. Recently, Porada et al. (2021) use WordNet hypernymy chains as input to a Roberta (Liu et al., 2019) model to predict the plausibility of input events. In this work, our focus is to improve performance of auto-regressive LMs. We show that a multi-task strategy harms performance in this setting, and give a successful recipe to consistently boost LM performance with class-based predictions.

3 Method

Coupling class-based LM (CLM) and curriculum learning, HCP is to gradually anneal class prediction to token prediction during LM training. In this section, we first describe how we instantiate word classes by leveraging hypernym relation from the

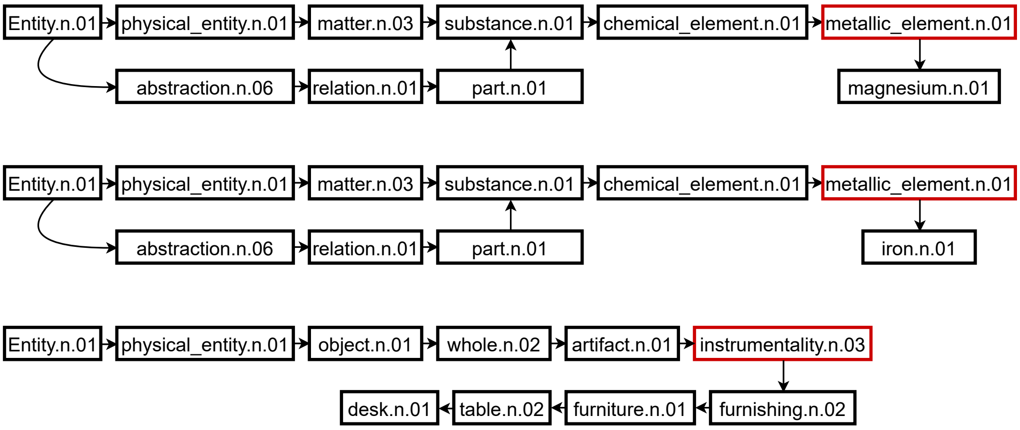

Figure 2: Hypernym-paths of synsets “magnesium.n.01”, “iron.n.01”, and “desk.n.01”, corresponding to the word *magnesium*, *iron*, and *desk* respectively.

```
def token2class(token2freq, d, f):
    # token2freq is a dictionary whose key is the token and
        value is the tokens' occurrences)
    # d is the depth, f is the occurrence threthold
    rtn = {}
    for token, freq in token2freq.items():
        if freq > f:
            continue
        for synset in wordnet.synsets(token):
            for path in synset.hypernym_paths():
                if len(path)>=d and 'noun' in path[d-1]:
                    rtn[token] = path[d-1]
                    break
            if token in rtn:
                break
    return rtn
```

Code 1: Pseudocode for token to class mapping.

WordNet. We then present how to incorporate the proposed Hypernym Class Prediction task into LM training via curriculum learning.

3.1 Hypernymy as Word Classes

WordNet (Miller, 1995) is a lexical database that groups words into sets of cognitive synonyms known as synsets, which are in turn organized into a directed graph by various lexical relations including the hypernymy (*is-a*) relation. As shown in Figure 2, each vertex is a synset, labeled by the text within the box, and each edge points from the hypernym (supertype) to the hyponym (subtype). Note that a word form (spelling) may be associated with multiple synsets – each corresponding to a different sense of the word, which are sorted by the frequency of the sense estimated from a sense-annotated corpus. For example, *iron* has 6 synsets, among which “iron.n.01” is the most common one.

Hence, if two words share the same hypernym at a certain level in their hypernym-paths (to the root in WordNet), we could say they are similar at that level. Here we use "Depth" to quantify the hypernym-path level. In Figure 2, for example, at Depth 6, *iron* and *magnesium* are mapped to the same group named “metallic_element.n.01”, while *desk* is mapped to “instrumentality.n.03”. At Depth 2, all these three words share the same (indirect) hypernym “physical_entity.n.01”.

In this work, we map each token in our training set into its hypernym class if this token (1) has a noun synset in the WordNet, (2) with a hypernym-path longer than a given depth d, and (3) has frequency below a given threshold f in the training corpus. We only consider nouns because it is not only the most common class in the WordNet but also a difficult class for LMs to learn (Lazaridou et al., 2021). For tokens with multiple synsets, we iterate over the synsets in the order of sense frequency and break the loop once found. We select the most frequent synset no less than the required depth. The mapping pseudocode is illustrated in Code 1, which is a data pre-processing algorithm conducted only once before the training and takes no more than 5 minutes in our implementation.

3.2 Hypernym Class Prediction

We first partition the vocabulary into $\mathbf{V_x}$ and $\mathbf{V_{\neg x}}$ based on whether or not a token has a hypernym in the WordNet, and $\mathbf{V_h}$ denotes the set of all hypernyms. The original task in a Transformer-based LM is then to predict the token w_j's probability with the output $\mathbf{x}$ from the last layer:

$$P(y = w_j|\mathbf{x}) = \frac{\exp(\mathbf{x}^\mathsf{T}\mathbf{v}_{w_j})}{\sum_{w_k \in \mathbf{V_x} \cup \mathbf{V_{\neg x}}} \exp(\mathbf{x}^\mathsf{T}\mathbf{v}_{w_k})} \qquad (1)$$

where w_k is the k_{th} word in the original vocabulary and $\mathbf{v}_{w_k}$ is its embedding. Here we assume the output layer weights are tied with the input em-

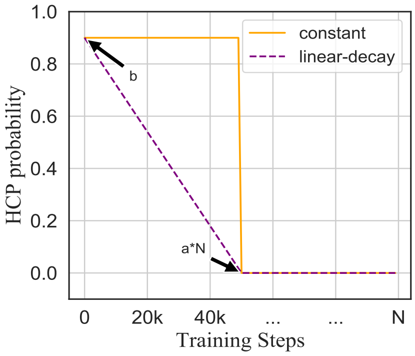

Figure 3: Probabilities of HCP step over training process with different pacing functions.

beddings. We call any training step predicted with Eq. 1 a token prediction step.

To do the Hypernym Class Prediction step, we replace all tokens in $\mathbf{V_x}$ in a batch of training data with their corresponding hypernym classes in $\mathbf{V_h}$. After the replacement, only hypernym classes in $\mathbf{V_h}$ and tokens in $\mathbf{V_{\neg x}}$ can be found in that batch. Then, the LM probability prediction becomes:

$$P(y = w_j|\mathbf{x}) = \frac{\exp(\mathbf{x}^\mathsf{T}\mathbf{v}_{w_j})}{\sum_{w_k \in \mathbf{V_h} \cup \mathbf{V_{\neg x}}} \exp(\mathbf{x}^\mathsf{T}\mathbf{v}_{w_k})} \quad (2)$$

where w_j could be either a token or a hypernym class. We called this batch step is a Hypernym Class Prediction (HCP) step.

Note that Eq. 2 is different from the multi-objective learning target, where the hypernym class would be predicted separately:

$$P(y = w_j|\mathbf{x}) = \frac{\exp(\mathbf{x}^\mathsf{T}\mathbf{v}_{w_j})}{\sum_{w_k \in \mathbf{V_h}} \exp(\mathbf{x}^\mathsf{T}\mathbf{v}_{w_k})} \quad (3)$$

where w_j is a hypernym class. We will elaborate on this difference in the experiment results part.

3.3 Training Method

We train a LM by switching from HCP to token prediction. For the example in Figure 2, our target is to teach a model to distinguish whether the next token belongs to the metallic element class or instrumentality class during the earlier stage in training, and to predict the exact word from magnesium, iron, and desk later.

Inspired by Bengio et al. (2009), we choose curriculum learning to achieve this. Curriculum learning usually defines a score function and a pacing function, where the score function maps from a training example to a difficulty score, while the pacing function determines the amount of the easiest/hardest examples that will be added into each epoch. We use a simple scoring function which treats HCP as an easier task than token prediction. Therefore, there is no need to sort all training examples. The pacing function determines whether the current training step is a HCP step, i.e. whether tokens will be substituted with their hypernyms.

Our pacing function can be defined as:

$$P(y = c|t) = \begin{cases} b & t < a * N \\ 0 & t \geq a * N \end{cases} \quad (4)$$

or

$$P(y = c|t) = \begin{cases} b - b * \frac{t}{a*N} & t < a * N \\ 0 & t \geq a * N \end{cases} \quad (5)$$

where $P(y = c|t)$ is the probability that the current step t is a hypernym class prediction step. N is the total training steps. a and b are hyper-parameters. So, Eq. 4 is a constant pacing function in the first $a * N$ steps, while Eq. 5 is a linear decay function. We plot these two functions in Figure 3. According to our experimental results Tab. 5, these two functions are both effective in improving the language model.

4 Experiments

We conduct experiments on two datasets. **WikiText-103** (Merity et al., 2016) is a large word-level dataset with long-distance dependencies for language modeling. There are 103M tokens and 28K articles (3.6K tokens per article on average). The original vocabulary size is 271121, among which we find 3383 hypernym classes for 71567 tokens with $d = 6$ and $f = 6000$ (Section 3.1). **ARXIV** (Lazaridou et al., 2021) is collected from publicly available arXiv abstracts[1] with an average of 172 words per abstract and partitioned into training (1986–Sept 2017), evaluation (Aug–Dec 2017), and test (2018–2019). Following Lazaridou et al. (2021), we use the BPE (Sennrich et al., 2015) tokenization for this dataset. The final vocabulary size is 48935, and we find 1148 hypernym classes for 5969 tokens among the vocabulary with $d = 6$ and $f = 1000$.

Several variants of the Transformer model have been used for our experiments:

- small model: 12 layers, 10 heads, hidden size 300, batch size 256, training steps 100k;
- base model: 16 layers, 10 heads, hidden size 410, batch size 64, training steps 200k;

---

Table 1: Results on **WikiText-103** dataset with different models.

- large model: 18 layers, 16 heads, hidden size 1024 batch size 128.

The input lengths are 150 for the base model and 384 for the large model. The memory length is equal to the input length for both training and testing. The hyper-parameters used for the ARXIV dataset are as same as the **WikiText-103**, except the ARXIV base model's input length is 384. The number of training steps varies greatly for the large model in previous work, so we experiment on both the lower (80k) higher (350k) ends.

4.1 Main results

Our main results are shown in Table 1. We can see that all architectures could benefit from HCP: Transformer-small improved 0.6 ppl, Transformer-base improved 0.5, Segatron-XL base improved 0.4, Transformer-large improved 0.5, and Segatron-XL large improved 0.1. We also plot the validation perplexities of small and large models trained with and without HCP in Figure 4. In the beginning, the perplexity of the HCP models is higher due to the mixed training steps from the two tasks, but we can see that HCP perplexity goes down faster than the baseline method. And after fully switching to token prediction, HCP outperforms the baseline method quickly and the gap between these two methods remains stable. These results suggest that HCP is indeed effective in improving LM training.

For experiments on the ARXIV dataset, we first compare the Segatron-XL base model trained with and without HCP. The results are shown in Table 2. The improvements over the validation set and test set are 0.6 and 0.75 respectively. For the large model, we use the same model architecture and

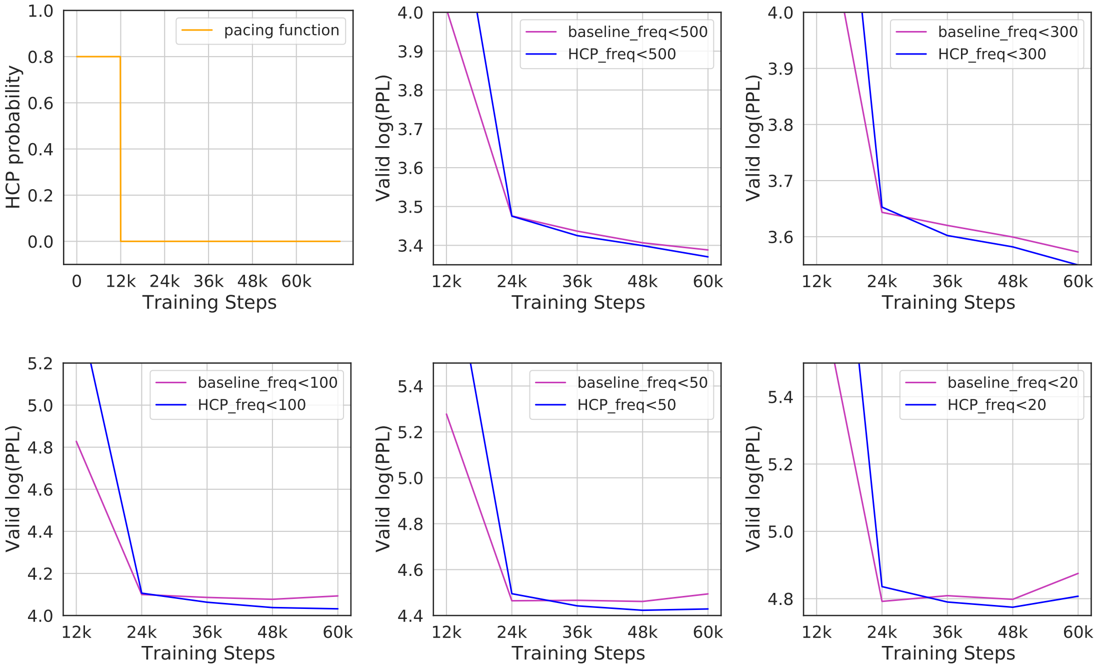

Figure 5: Frequency-stratified validation log(perplexity) of baseline model (Transformer-small) and HCP model (Transformer-small-HCP) with **WikiText-103**.

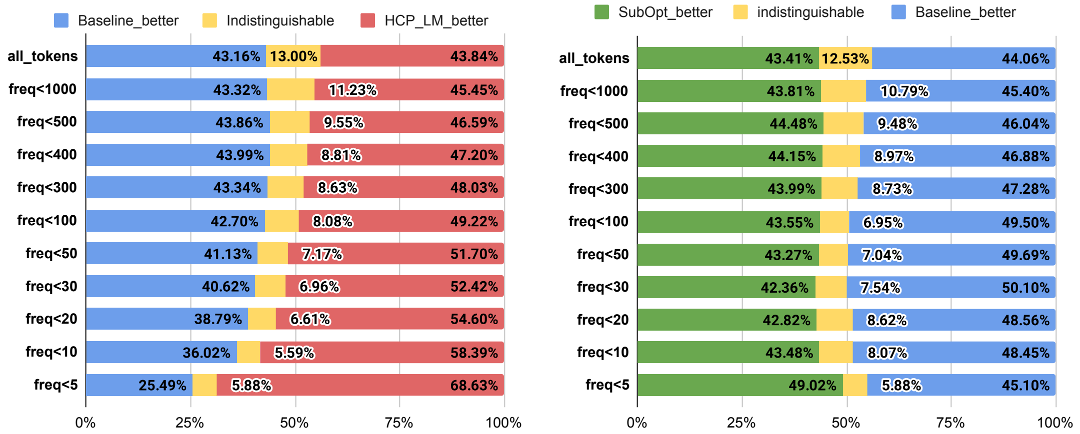
hyper-parameters as the **WikiText-103** large model but change the vocabulary to BPE sub-tokens. The final perplexity outperforms its counterparts about 0.4 and outperforms a larger model trained with 1024 input sequence length over 0.47, while our model length is 384.

4.2 Generalization on Rare Tokens

In addition to the overall perplexity comparison, we also conduct comparisons with frequency-stratified validation subsets, to show the perplexity of tokens that has been replaced with the hypernym classes during training. Results are shown in Figure 5. We can see that, after the first 12k hypernym class prediction steps, there is a large gap between our HCP model and the baseline model as the HCP model only learn to predict the hypernym class instead of the token itself. After that, in the next 12k steps, HCP's PPL decreases faster, achieves similar PPL at 24k steps, and finally outperforms the baseline method in all frequency groups. The results show that our proposed training method can benefit the learning of the replaced tokens in various frequencies. Strikingly, we observe that, for the baseline, more training steps lead to a *degradation* of performance for rare tokens, a behavior that deserves investigation in future work.

We further conduct pairwise model comparisons with tokens that have been replaced during HCP training on the **WikiText-103** test set. Given two models, we compare the prediction probabilities for each occurrence of a target token, and register a "win" for the model with a higher probability. We then calculate the percentage of winnings (as well as ties) for each model by tallying over all occurrences of the token. The results are then stratified by token frequency and plotted in Figure 6. The better model is placed on the right in both



(a) Baseline model and HCP model

(b) Baseline model and sub-optimal model

Figure 6: Pairwise comparison results. The baseline model and HCP model are trained without and with hypernym class prediction respectively. The sub-optimal model is trained without HCP and trained with different hyper-parameters, whose perplexity is increased by 0.9 compared with the baseline model.

sub-figures.

In Figure 6(a), we see that HCP outperforms the baseline model on all frequency strata. Interestingly, *the performance gap widens as frequency decreases*, indicating that HCP is beneficial in modeling rare tokens. In Figure 6(b), we compare the baseline model against an under-optimized model of identical architecture but slightly different hyper-parameters.[2] Here, the (optimal) baseline outperforms the sub-optimal model on all but the least frequent stratum, suggesting the possibility that perplexity reduction (resulting from hyperparameter tuning in this case) might be achieved by improving frequent word prediction *at the expense of rare words*. This is inline with observations made recently in vision tasks (Sagawa et al., 2020).

4.3 Ablation study

We conduct ablation studies with **WikiText-103** dataset and Transformer small model to investigate how to map words to hypernym classes, how to select curriculum learning pacing functions and to show why we use curriculum training.

4.3.1 Hypernym-path Depth

The hypernym classes are chosen from the hypernym-paths in WordNet. Considering that a hypernym-path consists of multiple hypernyms, it is not straightforward to tell which layer is the best. But the best depth d should be some layer in the middle. Because a small depth might map multiple distant words into the same class, while a large depth will result in too many classes which are hard for a model to learn. The extreme examples could be $d = 1$ and $d = \infty$, corresponding to mapping all candidate words into the class "Entity.n.01" and mapping each word into itself respectively. In Table 3, we show evaluation results among different depth selections. We find that depth 6th is the best choice, with the lowest valid perplexity. The results also confirm our assumption that the best one would be some middle layer.

Depth	Valid PPL	#Classes
Baseline	34.5	0
$d = 4$	34.54	145
$d = 5$	34.29	1169
$d = 6$	**34.05**	3383
$d = 7$	34.37	6604
$d = 8$	34.25	9063

Table 3: Clustering words into classes with different layer's hypernym parents. The average depth is 8.03. #Classes denotes the total number of hypernym classes.

4.3.2 Filter Frequency

In addition to the hypernym-path depth, we also investigate how to select frequency threshold f. As we mentioned above, our target is to map similar

---

[2] The sub-optimal model has batch size 128 instead of the optimal 64, and the perplexity gap between these two models is observed to be slightly larger than that between HCP and the baseline (0.9 vs 0.5).

FilterFreq.	Valid PPL	#Rep.
Baseline	34.5	0
$f = 3000$	34.14	70859
$f = 5000$	34.50	71735
$f = 6000$	**34.05**	71971
$f = 7000$	34.32	72153
$f = 8000$	34.35	72291
$f = \infty$	40.10	73067

Table 4: Ignoring words whose frequency more than a threshold f during hypernym class clustering. #Rep. denotes the number of tokens in the vocabulary that will mapped.

words into the same class, where predicting a hypernym class might be easier than predicting multiple different words. After the mapping process, low-frequency words can be clustered into hypernym classes with higher frequency. Table 4 shows the results of different f. We can see that $f = 6000$ achieves the best results while $f = \infty$ (without filter) is the worst. We hypothesize this might be due to two reasons. First, for some high-frequency common words, the model can learn them well already, while mapping them into hypernym classes may be superfluous or even harmful. Second, including frequent words skews the marginal distribution over hypernym classes, causing hypernym prediction to be more class-imbalanced, which in turn might lead to collapsed representation in the resulting LM (Fang et al., 2021). This hypothesis deserves further investigation. It should be noted that although the difference of #Rep.Tokens looks minor, the difference in the token's appearance is significant. For example, $f = \infty$ maps only 776 additional tokens compared with $f = 8000$, but each token's appearance is more than 8000, which explains the different perplexities in Table 4.

4.3.3 Pacing Function

Table 5 shows the results of models trained with various curriculum pacing functions. We also report the validation perplexities of the tokens that have ever been replaced with hypernym class (Rep.PPL) during training and tokens without hypernym class (NonRep.PPL).

For the constant pacing function, we fix $b = 1$ and change the value of a, In this case, the models are always training with HCP in the first $a * 100k$ steps and then switch to the token prediction training, which is a pre-training pacing function. We can see that all models outperform the baseline model over the validation perplexity. Rep.PPL improves from 348 to 339. The perplexity of NonRep.PPL between baseline model and HCP models are similar, except the model trained with $a = 4$, which indicates the pre-training should not take up too many steps.

For the linear pacing function, we choose some specific a and b to achieve the same HCP steps as the constant functions above. For simplicity, we also set $a = b$. In Table 5, we can see that the overall perplexity of the linear functions is similar to the corresponding constant functions, where the NonRep.PPL is slightly decreased while the Rep.PPL is slightly increased. We conduct a grid search over different pacing functions with Transformer small model and **WikiText-103**, and finally, use the constant function with $a = 0.12$ and $b = 0.8$ for all base models and large models.

Curriculum hyper-parameters could be transferred to the ARXIV dataset successfully. However, we tune the frequency threshold f on each dataset, because different tokenization methods change the frequency distribution. All HCP models in Table 2 are using $d = 6$, $f = 1000$, and the constant pacing function with $a = 0.12$ and $b = 0.8$.

4.3.4 Other Training Objectives

We also experimented with two other methods to incorporate hypernym information into LM training. Although neither method has yielded any empirical gain, we nonetheless report these methods and offer possible explanations for their failure.

Multi-objective Training Multi-objective (or multi-task) training consists in a weighted sum of token and hypernym prediction losses. We set the weight of the hypernym prediction loss to 0.2. The prediction of a token is calculated with Eq. 1. The prediction of a hypernym class is calculated with Eq. 3, where $\mathbf{x}$ can be the output vector from any layer in the Transformer LM. Table 6 lists the results using the last layer and the 8th layer. Using the last layer significantly undermines the original token prediction results. Using the 8th layer is better but the final perplexity is still no better than the baseline model. Simply forcing the language model to predict the hypernym class for each token is harmful to LM performance. We also tried to replace Eq. 3 with Eq. 2, by mixing $\mathbf{V_h}$ and $\mathbf{V_{\neg w}}$ together when predicting the hypernym classes (mix vocab). This significantly improves multi-objective

Constant Func.	HCP steps	Valid PPL	NonRep.PPL	Rep.PPL
a=0 b=0	0	34.5	22.07	348.87
a=0.1 b=1	10k	34.18	22.08	339.30
a=0.2 b=1	20k	**34.15**	22.07	339.34
a=0.3 b=1	30k	34.26	22.07	338.14
a=0.4 b=1	40k	34.39	22.26	338.31
Linear Func.				
a=0.45 b=0.45	10k	34.14	22.04	340.55
a=0.64 b=0.64	20k	**34.05**	21.96	341.33
a=0.78 b=0.78	30k	34.26	22.05	346.77
a=0.90 b=0.90	40k	34.56	22.12	354.40

Table 5: Training N steps hypernym class prediction among 100k training steps with different pacing functions. NonRep.PPL denotes non-replaced tokens' perplexity, and Rep.PPL denotes replaced tokens' perplexity.

	Valid PPL	Test PPL	NonRep.PPL	Rep.PPL
Baseline	34.50	36.46	22.07	348.87
Adaptive Softmax	36.32	38.16	22.48	435.93
Multi-obj				
last layer	46.06	48.49	27.81	627.23
8th layer	43.42	45.37	26.13	597.66
8th layer + mix vocab	35.97	38.02	22.98	365.27
Hypernym Class Prediction	**34.05**	**35.87**	**21.96**	**341.33**

Table 6: Results obtained by alternative strategies for integrating hypernymy information into the LM: adaptive softmax and multi-objective training. Both under-perform the proposed HCP method.

training. Learning to predict the hypernym class from a mixed vocabulary $\mathbf{V_h} \cup \mathbf{V_{\neg w}}$ is better than only hypernym classes $\mathbf{V_h}$.

Adaptive Softmax Another method is the adaptive-softmax (Grave et al., 2017a), where the model first predict the hypernym probability among $\mathbf{V_h} \cup \mathbf{V_{\neg w}}$ and then predict the token probability among the tokens with the same hypernym class. In Table 6, we can see that the adaptive-softmax is no better than the multi-objective trained model. By looking into the poor perplexity of Rep.PPL, we find this method cannot improve the prediction of tokens in $\mathbf{V_w}$. We believe this is due to the noise of hypernym class mapping, where we choose the first synset path as the token's hypernym synset without considering the context. Such noise will affect the adaptive-softmax prediction but is not an issue for curriculum training as the final training stage is fully trained with the original text.

5 Conclusion

In this work, we propose a new LM training strategy with WordNet's super-subordinate relation and curriculum learning. Although WordNet is an external resources, it's not clear how to get lower perplexity using WordNet before this work. Consistent perplexity reduction can be observed over various models. Both rare and frequent tokens can be modeling better with our proposed method while other optimization method may sacrifice the performance on rare tokens.

We'd like to address the limitations of this work: other methods to map words to classes; LM experiments with other languages; pre-training LM with our proposed method and testing on downstream tasks. We hope to investigate these directions in the future.

Tackling Fake News Detection by Continually Improving Social Context Representations using Graph Neural Networks

Nikhil Mehta, Maria Leonor Pacheco, Dan Goldwasser

Purdue University
West Lafayette, IN, USA
`{mehta52, pachecog, dgoldwas}@purdue.edu`

Abstract

Easy access, variety of content, and fast widespread interactions are some of the reasons making social media increasingly popular. However, this rise has also enabled the propagation of fake news, text published by news sources with an intent to spread misinformation and sway beliefs. Detecting it is an important and challenging problem to prevent large scale misinformation and maintain a healthy society.

We view fake news detection as reasoning over the relations between sources, articles they publish, and engaging users on social media in a graph framework. After embedding this information, we formulate inference operators which augment the graph edges by revealing unobserved interactions between its elements, such as similarity between documents' contents and users' engagement patterns. Our experiments over two challenging fake news detection tasks show that using inference operators leads to a better understanding of the social media framework enabling fake news spread, resulting in improved performance.

1 Introduction

Over the last decade an increasing number of people access news online (Amy Mitchell, 2016), and use social networking platforms to engage, consume and propagate this content in their social circles. Social networks provide easy means to distribute news and commentary, resulting in a sharp increase in the number of media outlets (Ribeiro et al., 2018), representing a wide range of perspectives and ideologies. However, despite this diversity, content is often shared only among people that hold similar beliefs and ideologies, leading to the formation of highly segregated information communities, often referred to as *"echo chambers"* (Gentzkow and Shapiro, 2011; Quattrociocchi et al., 2016; Dubois and Blank, 2018; Garimella et al., 2018). An unfortunate consequence of this process is the rapid proliferation of "fake news" (Lazer et al., 2018), content which resembles news in form but lacks the journalistic standards ensuring its quality. Social media platforms are now flooded with inaccurate, incomplete, and intentionally misleading information, which propagates at lightning speed between users sharing an echo-chamber. According to a recent study (Vosoughi et al., 2018) false stories spread six times faster compared to real news stories. Given the volume and speed of fake news spread, manual fact checking organizations cannot be used in real-time to stop it. An alternative, which is arguably easier to scale, is to jointly model the claims and their source and ask *who and what can you trust?*

Answering this question requires modeling the complex information landscape on social media, consisting of news sources, the articles they release and their social context, corresponding to social media users engaging and sharing information in their networks. Similar to previous work (Baly et al., 2020b, 2018) we formulate the problem as associating a discrete factuality level (*high, low*, or *mixed*) with news content and news sources. These works treat news factuality level assessment as a traditional classification problem, using features based on social media data.

Our goal in this paper is to explore a different approach, driven by the principal of *social homophily* (McPherson et al., 2001), referring to the tendency of individuals to form social ties with others who share their views and preferences. We follow the observation that the political perspectives and biases expressed in the text will be reflected in the behavior of users engaging with it. Together they form *information communities*, connecting users with each other based on their content preferences, and with sources that provide that content. In this highly connected structure, even a little evidence connecting users' preferences to false narratives can be propagated and help inform the judgements about the sources they follow and

May 22-27, 2022

engage with. Fig. 1 demonstrates the interactions between users, articles and their sources.

Unfortunately, much of this rich social information is not directly observed, or due to the volume of these interactions, cannot be fully sampled. To help alleviate this problem and capture this knowledge, we propose a set of *inference operators*, each augmenting the information graph with different relationships beyond what was initially seen. By iteratively applying these inference operators, we are able to capture more of the hidden relationships that enable the spread of fake news through social media, and are crucial for detecting it.

From a technical perspective, we view fake news detection as a reasoning problem over information graphs. We use the evidence provided by our existing knowledge of high vs. low factuality content (i.e., the training data), to assess the factuality of unknown content based on observed and predicted links capturing their connections. This transductive process is done using a Relational Graph Neural Net (R-GCN) (Schlichtkrull et al., 2018), which creates distributed representations of nodes contextualized by the graph structure, allowing us to transfer information from observed evidence nodes to unknown source nodes using graph embedding tasks. We use inference operators, which build on the similarity metric defined by the learned graph embedding, to increase the number of edges connecting the two node types. These two interdependent steps are done iteratively.

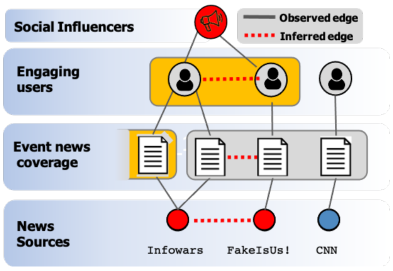

Figure 1: Information Graph capturing interactions between sources, articles, engaging users, and influencers. Dashed lines correspond Inference Operators outputs

For example in Fig. 1, observed user relationships are shown with black lines, such as users interacting with articles that are published by sources. Based on the observed data in the information graph, we can create an initial *graph-contextualized* representation for each node via graph embedding training. We can see that based on the current trained model, there are three articles that are similar in content and embedding, and are represented in the figure by sharing a gray background. Two are "fake news" articles, published by red background low-factuality news sources (*"FakeIsUs"* and *"InfoWars"*), while the right most one is published by a high-factuality source. Assuming the model is not familiar with their source factuality level, *then based on the observed graph information, it may not be able to distinguish between them*. Thus, in this work, we propose to augment the graph based on learned knowledge, via inference operators. Intuitively, the goal of our inference operators is to provide additional graph edges (shown as dashed red lines), such that the graph-contextualized embeddings would capture the similarity between the two low-factuality articles and the difference compared to the high-factuality one. For example, users engaging with the left two articles follow the same social influencer, who is a high activity user. In the initial graph training, this observed relationship would increase these users' learned node similarity (yellow background) allowing our inference operators to connect them into a strong information community of like-minded users, that was not initially observed, and thus not easily represented by the graph embedding. This newly inferred relationship can be propagated through the information graph, allowing us to have more strong information about other articles/sources/users these newly connected users interact with, thus detecting fake news better. In summary, we make the following contributions:

- We formulate fake news detection as a reasoning problem over an information graph.
- We suggest an inference-based graph representation learning approach, which incrementally augments the graph with inferences about users' social information and content preferences.
- We perform extensive experiments in source-level (Baly et al., 2020a) and content-level (Nguyen et al., 2020) settings, demonstrating our inference-based graph representation approach leads to performance improvements in both cases, even in weakly supervised settings.

2 Related Work

Fake News Detection: Detecting fake news using social media has been a popular research topic recently. It's typically studied as a supervised learning task, in which a classifier is trained using representations of news and their social context to predict factuality of the content (Hassan et al., 2017; Shu et al., 2017; Shao et al., 2018; Pérez-Rosas et al., 2017; Volkova and Jang, 2018; Shu et al., 2019a; Kim et al., 2019). Unfortunately, these methods cannot capture the interactions between the users and sources that share fake news on social media, which is necessary to better understand the way fake news propagates, and ultimately detect it.

Due to the above mentioned limitations, researchers have recently started using Graph Neural Networks (GNNs) (to model graphs), for this task. As they contain social media entities as nodes and link them through edges based on their observed interactions, graphs are able to better capture social context. More specifically, through edge interactions, nodes in graphs can reinforce other nodes' representations, strengthening the overall information quality. Shu et al. was one of the early works, and more recently, Han et al. utilized continual learning with GNNs to capture the propagation cascade of fake news on Twitter. However, unlike our work, these and other graph models do not uncover or model hidden relationships in the data.

Most similar to us, Nguyen et al. proposed the Factual News Graph (FANG) also modeling the relationship between sources, articles, and users in a graph framework, by training the model to better capture social context. However, rather than iteratively adding new explicit edges to uncover hidden interactions in the graph as we do by using inference operators, FANG (Nguyen et al., 2020) modified the loss function they used when training the graph to better capture user-user and user-article interactions that already exist. Despite this being effective, it does not model graph interactions that were not observed in the original data, while our approach can uncover these hidden relationships as well, and thus more strongly capture the fake news propagation landscape on social media (the information communities we make explicit can help model other content better). Moreover, our framework allows the graph to be continually enhanced, so we can capture more relationships than were built into the original graph (like source-source), and this leads to us achieving performance improvements over their work.

Iterative Graph Learning: Recently, there has also been work on learning to augment graphs, such as by using end-to-end neural models optimized for the final task (Jiang et al., 2019; Chen et al., 2020). While these works do iteratively augment the graph similar to us, by doing it end-to-end they can be prone to be task specific (edges may be created solely for achieving higher classification accuracy), rather than learning a high quality social media representation. This may lead to issues at test time or in inductive settings. In our case, as we are adding edges based on learned graph similarities, we are strengthening the information communities that already exist, while uncovering hidden ones. Further, we can easily control for the relations and amounts of them that are added.

3 Model

We view fake news detection as reasoning over the relations between sources, articles, and engaging users in an information graph. We hypothesize that due to the principle of homophily, social ties leading to the formation of online communities will capture similarities and differences in content preferences within and across communities.

We capture the interaction between social information and news content using a heterogeneous graph defined in Sec. 3.1, and use a Relational Graph Convolutional Network (R-GCN), to create vectorized node representations for factuality prediction. The R-GCN defined in Sec. 3.2 allows our model to capture the different social communities, by creating contextualized node representations. For example, an article node is represented using its contents, source, and relationships with users engaging with it (which are also represented using their relationships to other nodes).

The success of us capturing the social communities through the R-GCN hinges on having strong social information (i.e., graph edges) to characterize them. Providing this information might not be straight-forward, as collecting social information at scale can be costly and noisy. Instead, we propose inference operators, defined in Sec. 3.3, which augment the graph with new edges, using the similarity between learned nodes representation to assess their compatibility. This allows the R-GCN to enrich each newly connected nodes' contextualized representation, improving factuality classification. In Sec. 3.4 we describe a reasoning framework, which iteratively enriches the graph using inference operators and computes the updated node representations based on the updated graph. The framework is depicted in Fig. 2.

3.1 Graph Creation using Social Context

Our graph consists of the following nodes: (1) S, the news *sources*. Each sources' (s_i) vec-

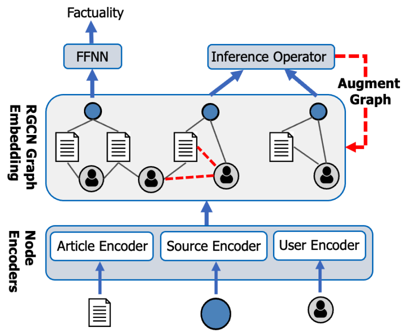

Figure 2: Factuality Prediction as Graph Reasoning

tor consists of its Twitter and YouTube profiles embeddings (numerical + LM features - details in App. A.2.1). Prior work (Baly et al., 2020b) showed that these features provide a strong signal. (2) A, the *articles* published by these sources. An article a_i vector captures its contents using a SBERT (Reimers and Gurevych, 2019) RoBERTa (Liu et al., 2019) model, as it provides strong, meaningful sentence embeddings. (3) U, the Twitter *users* that interact with articles and sources, and provide the social context for them. The description is applicable to the source-level (Baly et al., 2020a) and content-level (Nguyen et al., 2020) settings, where elements in S or A, res., are our classification targets. The user vector is identical to the Twitter embedding mentioned above.

The graph is formed by first adding the sources as individual nodes. Then, connecting each source with up to 300 articles ($e = \{s_i, a_j\}$). Next, we add social context to the graph via Twitter users that interact with sources: **(1) Following Sources:** We add up to 5000 users that follow sources, connecting each user to new sources they follow ($e = \{s_i, u_j\}$). These are likely to indicate a positive relationship. **(2) Discussing Articles:** We connect each article with users that tweet its title/link within a 3 month period of publication ($e = \{a_i, u_j\}$). These users provide the means for fake (and real) news spread, allowing us to model this process. Finally, social interactions, a crucial component for analyzing fake news propagation, are captured by scraping up to 5000 followers of each Twitter user, and connecting existing users with edges if they one follows another.

3.2 Graph Embedding

Given the observed interactions in the graph, we train a GNN to learn an embedding function, which will be used by the inference operators (Sec 3.3).

As a node embedding function, we utilize Relational Graph Convolutional Networks (R-GCNs) (Schlichtkrull et al., 2018), that generalize traditional GCNs to handle different relationship types, thus allowing us to better capture their interactions and improve their representation. Intuitively, R-GCNs create contextualized node representations by considering the graph structure through graph convolutions and learn a composition function:

$$\mathrm{h}_i^{l+1} = ReLU\left(\sum_{r\in R}\sum_{u\in U_r(v_i)} \frac{1}{z_{i,r}} W_r^l h_u^l\right),$$

where h_i^l is the hidden representation for the i-th node at layer l and $h_i^0 = v_i$ (output of the node encoder); $U_r(v_i)$ represents v_i's neighboring nodes connected by the relation type r; $z_{i,r}$ is for normalization; and W_r^l represents trainable parameters.

To obtain meaningful node representation used for capturing factuality, we optimize the Node Classification (NC) objective of Fake News Detection. After obtaining the source representations from the R-GCN, we pass them through the softmax activation function and then train using categorical cross-entropy loss, where the labels are factuality.

3.3 Inference Operators

We define multiple *inference operators* that enable the creation of new edges based on learned information graph inferences. The different operators capture our intuition about how connecting node pairs of different types would contribute to trustworthiness propagation. For example, pairs of users that are not explicitly connected in the graph (i.e., do not follow each other) but share articles with similar factuality levels may have similar levels of non-trustworthiness. Connecting them would provide more information to the nodes they connect to. One of our inference operators - adding user-user edges based on their node similarity in the embedding space - captures this situation.

For each inference operator type discussed below, we make edge connections based on the node representations we have learned, by computing similarity scores between all pairs of nodes (using the graph node embedding - efficiently with FAISS (Johnson et al., 2017)), and connecting the nodes with the top k similarity scores based on our model.

3.3.1 Social Information Based Operators

The first broad inference operator type adds edges between graph entities, in a similar way as a recommendation engine, suggesting entities to interact with each other, based on their graph relationships.

User-Source: We add edges between users and sources ($e = \{u_i, s_j\}$), using the top k most similar source/user pairs in the embedding space.

User-User: Pairs of users that interact with news in a similar way are connected ($e = \{u_i, u_j\}$). These users are likely to have the same beliefs and may even want to follow each other if they became aware of each others' profiles.

User-Article: We add edges between articles and users likely to be interested them ($e = \{u_i, a_j\}$)). This inference can be based on the target users' interactions with similar articles, or with other users sharing these articles.

3.3.2 News Content Based Operators

The second broad type connects entities based on content similarity. Unlike the previous set, these types of edges are not initially observed in the graph, which is one of the benefits of our setup, *allowing us to add inferences about latent relationships that underlie how information propagates*, such as coordination between different sources, information flooding by publishing similar content in multiple articles and "bad influencers", consistently propagating low-quality content.

Sources-Sources Sources likely to publish similar content at an equivalently factual level are connected ($e = \{s_i, s_j\}$).

Articles-Articles Articles that could be similar to each other in content are connected ($e = \{a_i, a_j\}$). To do this effectively, we first identify articles pairs that discuss the same event, approximated using the publication date and entity mentions overlap (using Flair (Akbik et al., 2018)) in their title. Second, we use an entailment model (Parikh et al., 2016; Gardner et al., 2017) to only connect articles that entail each other, as they are more likely to be talking about similar content.

Influencers Fake news is often spread by "bad influencers" that have a large following. Over the years, Twitter has launched campaigns intended to reduce fake news spread by suspending such users. This inference operator aims to do the same, by following these steps: (1) Using the training data, we label users by counting the paths to sources with a given factuality label. (2) Identify users without significant label variation in their followers group, as potential "news influencers". We avoid users with mostly highly factuality followers. (3) At inference time, we connect new users to influencers in this initial set, with a special edge type, indicating similarity to an influencer. We add the top k users, experimentally set to 500 (App. A.2.5).

Model	**Performance**		
	Acc	**Macro F1**	**# Edges**
`M1` : Majority class	52.43	22.93	-
`M2` : (Baly et al., 2018)	66.45	61.08	-
`M3` :(Baly et al., 2020b)	71.52	**67.25**	-
`M4` : Replication of (Baly et al., 2020b)	69.38	63.63	-
`M5` : Node classification (NC)	68.90	63.72	-
`M6` : `InfOp` Best Model	**72.55**	66.89	32K

Table 1: Results on (Baly et al., 2020b). Our best model (`M6`) achieves a 3.17% acc improvement compared to our re-implementation (which uses the same data -> `M4` vs `M6`), and the state-of-the-art on this dataset (which used different data - outside of train/test source labels - that was not released). Further, applying the inference operators (`InfOp` with 32K added edges) improves acc by 3.65% compared to Node Classification

3.4 Joint Inference and Representation

The inference operators we defined use the graph embedding function to identify new relationships that would potentially improve the embedding quality and allow for better information propagation during learning. The two steps are clearly interdependent. Now, we describe our iterative graph learning framework that builds on this dependency, and continually learns better social context representations in the graph by applying the inference operators, and then retraining the graph. It can be seen in Algorithm 1 and runs the following steps:

(1) **Initial Representation** In this step, we train the graph G using the framework described in Sec 3.2 to get an initial graph representation.

(2) **Inference Step** Apply inference operators (Sec 3.3) based on the learned representation.

(3) **Learning Step** After, we continue the training process for the graph.

We continually apply the two steps until convergence, based on development set performance. Additional details about the process are provided in Appendices A and C. When done, we retrain the model based on the final graph uncovered by applying the inference operators. Through this iterative approach, we continually improve our representation of the social media framework that enables fake news propagation, and reveal hidden relationships critical to understanding fake news spread.

4 Experiments

We evaluate our model's ability to predict fake news better on two challenging tasks: Fake News

Algorithm 1 *Joint Representation Learning and Reasoning for Characterizing Information Sources*

```
Input: $G_0 = S, A, U$
Output: $L_s$ (labels of sources), R-GCN parameters $\phi$
Initialization: $\phi_0 \leftarrow L_{final}$ over $G_0$
    Initial graph embedding uses Node Classification (NC)
while not converged do
    Infer: $G_i = G_{i-1} \cup \texttt{InferOperators}(G_{i-1}, \phi_{i-1})$
        Use inference operators to augment the graph
    Learn: $\phi_i \leftarrow L_{nc}$ over $G_i$
        Retrain R-GCN over new graph
end while
Final Training: $\phi_{final} \leftarrow L_{nc}$ over $G_{final}$
    Reset parameters and train final graph using NC
return $L_s \leftarrow \phi_{final}$ over $G_{final}$
    Predict unknown sources, using the final R-GCN
```

Source Classification, and Article Classification.

4.1 Dataset and Collection

To evaluate our model's ability to predict the factuality of news medium, we used the Media Bias/Fact Check dataset (Baly et al., 2018, 2020b). The public dataset consists of 859 sources, each labeled on a 3-point factuality scale: *low*, *mixed*, and *high*. Using the Twitter API[1], we gather an average of 27 user engagements for each articles (Sec 3.1). Our final graph consists of 69,978 users, 93,191 articles, 164,034 nodes, and 7,196,808 edges. Details about the setup we used when training our graph (chosen using the dev set), and our scraping protocol are in Appendix A. Our code is available[2].

To evaluate fake news article detection, we used the dataset released by (Nguyen et al., 2020), put together from Twitter data using related work on rumor classification (Kochkina et al., 2018; Ma et al., 2016) and fake news detection (Shu et al., 2018). For each article, the dataset provides its source and a list of engaged users. We also collected the followers for each user, leading to a graph with 48,895 users, 442 sources, and 1,050 articles.

4.2 Fake News Source Classification

Table 1 shows our results on source classification. We evaluate our models on the average of all 5 data splits released by (Baly et al., 2020b), using 20% of the training set sources as a development set. We report results on accuracy and Macro F1-score. We compare to (Baly et al., 2020b, 2018) (`M2,3`), who to the best of our knowledge achieve the strongest performance on this dataset. As (Baly et al., 2020b) did not release the article and social media data they used, we replicate their setup using the data we scraped (and their code), and compare to that as well (`M4`). Despite us optimizing their model, our results are worse than their released performance, so we hypothesize that their data on our setup may lead to better overall performance.

Model	Split	Performance	
		AUC	# New Edges
FANG	90%	75.18	-
SVM	90%	75.89	-
NC	90%	83.48	-
`InfOp`	90%	**85.89**	10,000
FANG	70%	72.32	-
SVM	70%	59.18	-
NC	70%	73.15	-
`InfOp`	70%	**77.76**	10,000
FANG	50%	71.66	-
`InfOp`	50%	**73.88**	10,000
FANG	30%	70.36	-
`InfOp`	30%	**72.63**	10,000
FANG	10%	66.83	-
`InfOp`	10%	**67.51**	10,000

Table 2: On (Nguyen et al., 2020), we achieve the SOTA on all data splits (% of data used for training). Our model beats the strong FANG model (Nguyen et al., 2020), SVM, and the Node Classification (NC).

When training our initial graph with only observed data using the Node Classification (NC) fake news loss and the *same data* as our replication of (Baly et al., 2020b), we obtain similar performance to their approach (`M5` vs `M4`). When we apply our inference operators, and then train the graph identically (as in `M5`), we notice a 3.65% acc. improvement (`M5` vs `M6`), showing the *clear benefit of our inference operator setup on this task*, and answering our research question that the added information helps. Further, this setup achieves the state-of-the-art on (Baly et al., 2020b), exceeding both our replication with the same data (by 3.17% acc.) and their published results (by 1.03% acc.).

4.3 Fake News Article Classification

Our results for article classification are in Tab 2. We compare to (Nguyen et al., 2020) (FANG), who to the best of our knowledge have the best performance, and compared to several competitive baselines in their work (Ruchansky et al., 2017). Nguyen et al. are also the most similar to us (as said in Sec 2, they also train GNN's), but they do not make unobserved interactions explicit, rather they modify the loss function they used when training to better capture them. Our setup is identical to the strong (Nguyen et al., 2020) setup (we use their

---

[1] https://developer.twitter.com/en/docs

[2] `https://github.com/hockeybro12/FakeNews_Inference_Operators`

released data and data splits) except we use different Twitter and Article representations, and we also consider Twitter follower edges. In addition, FANG (Nguyen et al., 2020) considered temporal aspects of how tweets propagate, which we do not, and we hypothesize that this may improve our performance. For this reason, we are using *less data* compared to FANG, apart from the fact that we consider Twitter user followers. For proper comparison, we also evaluate our representations by training a SVM, and in App. Tab 8, we evaluate our model with the same representations as FANG. We evaluate all of their data splits in Tab 2 (90% -> 90% of data for training, 10% for test, etc.). NC evaluates our model performance on the observed data. We show the best results (extended results and details in the App. C), and as can be seen, applying inference operators also improves performance on fake news article classification on all data splits (as much as 4.61% AUC), reinforcing that explicitly learning and creating unobserved relationships in the graph enables us to detect fake news content better. Also, we achieve SOTA by average 4.26%.

5 Discussion

In this section, we analyze our best model with inference operators (Table 1 `M6`) for fake news source detection (Baly et al., 2020b) by answering the following research questions:

(1) *Ablation study: What is the contribution of each inference operator?*

(2) *Can our model learn on limited data? Does our inference-based representation help?*

(3) *Can we learn meaningful user communities?*

(4) *What type of inferences does our model make for each inference operator?*

(5) *Can we detect the factuality of new content?*

(6) *What embeddings do we learn?* (App. B.1)

(7) *How many edges should we add for each inf. operator?* (App. B.2)

(8) *How long does running inference operators take?* (App. B.3)

5.1 Ablation Study

In Table 3, we evaluate each of our inference operators, trained using our joint learning and inference algorithm for up to two iterations. To evaluate the accuracy of the edge connections we make when applying the inference operators ("Inf. Acc"), we compare the labels of the two nodes connected by an inferred edge (i.e., accurate decisions connect nodes with similar labels). Since labels are only associated in our data with sources, we define a heuristic for computing labels for article and user nodes based on the most common gold label in all the sources they were directly connected to in the initial graph (ex: a user that follows 3 high factuality sources is assigned a high factuality label). We also report the number of edges connected in each setup (dev set for all params).

We note that almost all of our models with inference operators result in performance improvements over the baselines (Tab 1 `M4,5`), showing that capturing these hidden relations and making them explicit with new edges helps in fake news detection. Moreover, several of our inference operators (users-users/sources-sources) achieve high accuracy, while all perform better than random, showing that we can make useful edge connections after learning the initial information graph. Furthermore, applying multiple inference operators in multiple iterations through our setup (`InfOp` Users-Users and Users-Articles) leads to the strongest performance on this task. To evaluate the potential of our approach, we also evaluate our performance if we had no inaccurate edge predictions (i.e. 100% Inf. Acc), and see significant improvements. Note that this is a potential of our setup, as it involves using all the data (including the training set) to determine the user labels and then filtering out inaccurate edge predictions.

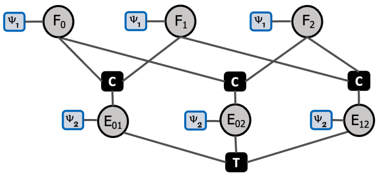

Figure 3: Inf. over Social and Factuality Information

Global Inference Operators An interesting direction for future work is to capture the interdependency between inference operators applications. We suggest a first step, based on probabilistic inference (Pacheco and Goldwasser, 2021), described in the factor graph in Fig. 3, applied to the Users-Users operators. We define two decision variable types, F associated with a user's factuality prediction, and E associated with the inference operator outcome on a user pair. Each is associated with a scoring function, ψ_1 scoring users factuality assignments, and ψ_2 scoring user pairs based on embedding similarity. The assignments are con-

nected using two sets of constraints: **C**, ensuring factuality label consistency in users connected via a predicted edge, and **T**, ensuring transitivity across pairs of edges, sharing a node. We use MAP inference to identify the solution edge set. The results in Tab. 3, show a modest improvement (72.17) compared to local inference (71.97), obtained using significantly less edges (6.7K compared 30K). This experimentally shows a benefit of using global probabilistic inference to more intelligently determine edges to connect, rather than only using embedding similarity as we did before (here we also considered user factuality, and other decision variables/scoring functions can be added in the future). Details and other potential benefits of this setup are provided in Appendix D.

5.2 Weakly Supervised Training

Next, in Table 4 we evaluate our model on using limited training data for fake news source classification, by training on a smaller set of sources (still using the entire graph and full test set). Here, we see the ability of our inference operators to strongly improve performance (NC vs *InfOp*), as they reveal relationships the model could not learn otherwise in the weakly supervised setting, which shows how our system could be useful for detecting recently published news.

Model	**k=17**	**k=55**	**k=200**
`B1` : User Trained	33.3, 50.9	35.4, 54.4	44.9, 60.1
`B2` : User *InfOp*	33.3, 51.8	38.2, 57.2	47.5, 62.9
`C1` : PF RoBERTa	33.98	34.03	36.21
`C3` : PF Connect	34.21	39.02	50.76
`C3` : PF *InfOp*	34.38	41.22	52.03

Table 5: Cluster purity of users (factuality, bias) and PolitiFact (PF) (factuality)

5.3 Learned Information Communities

Now, we analyze how well our user-user inference operator allows us to learn information communities of users (Tab 5). To do this, we cluster (K-means, Tab 5 shows different values of K) users before (`B1`) and after the inference operators are applied (`B2`), and evaluate the cluster purity based on user labels. To compute purity, each cluster is assigned to the class which is most frequent in the cluster, and then the accuracy of this is measured. We assigned labels to users using the same heuristic described in Sec. 5.1. We see that the users cluster better after the inference operators are applied (even via bias labels), showing our ability to use them to form information communities.

5.4 What Does our Model Learn to Connect?

Here, we analyze the inference operators by analyzing specific edge connections that are made. We see that the model makes smart choices in connecting nodes that may be part of the same information community. For example (more in Appendix B.4), a low factuality article discussing Democrats as 'dangerous open border fanatics' was connected to a user with bio 'BuildtheWall ... DEMONRATS'.

5.5 Incorporating New News Content

Finally, we evaluate how well our model can incorporate unseen news content, by clustering (like before) 1500 fact-checked claims from PolitiFact[3]. In Table 5, we first cluster the initial RoBERTa em-

---

[3] https://www.politifact.com

beddings of these claims (`C1`) and then add them into the graph by connecting them to five graph articles that have similar embeddings to them (`C2`). Next, we use our user-article inference operator to connect each of these articles to users (`C3`). It's clear that the RoBERTa embeddings statements don't cluster well by factuality. However, once they are added into the graph (`C2`) and after they are connected via inference operators (`C3`), they do. This further shows how our framework, especially through inference operators, allows the better detection of unseen news content (in this case claims). Not only can we determine its factuality, but we can also determine what other users are likely to interact with it.

6 Summary and Future Work

We propose an approach for tackling fake news detection by continually improving social context representations. To achieve this, we developed an iterative representation learning and inference framework that learns an initial graph embedding, and then applies different *inference operators* to reveal hidden relationships in the graph. We continually capture more knowledge about the social dynamics that allow fake news to propagate. We showed strong performance on fake news detection, across several datasets and settings.

Our current work looks at increasing the accuracy of the inference operators by adding external knowledge. We began exploring this direction by using an entailment model to infer article relationships using content similarity. We also explore additional ways to jointly model inference operators and capture the dependencies between them.

We believe this work helps pave the way for further research connecting text analysis along with its social context (Pujari and Goldwasser, 2021; Hovy and Yang, 2021; Pacheco and Goldwasser, 2021; Yang et al., 2016), a natural fit for many NLP tasks.

We thank the anonymous reviewers of this paper for all of their vital feedback. This work was partially supported by an NSF CAREER award IIS-2048001.

7 Ethics Statement

To the best of our knowledge no code of ethics was violated throughout the experiments done in this paper. We reported all hyper-parameters and other technical details necessary to reproduce our results, and release the code and dataset we collected. We evaluated our model on two different datasets and tasks (source and article fake news classification), but it is possible that results may differ on other datasets. However, we feel our methodology is solid and applies to any social media fake news setting. For space constraint we moved some of the technical details and discussion to the Appendix section. The results we reported supports our claims in this paper and we believe it is reproducible. Any qualitative result we report is an outcome from a machine learning model that does not represent the authors' personal views. For any results that we discuss on the data we use, we will not include account information and all results will be anonymous.

In our dataset release for (Baly et al., 2020b), we include sources, users, and articles. Sources are public information provided in (Baly et al., 2020b), and we map each to an ID. We scraped up to 300 articles for each source (as many as we could), which we map to an ID. We also scraped users that interact with articles, which we also release. Each user is given by their Twitter ID (which may be invalid or not provided if the user deleted their profile), and their graph ID. The Twitter ID of the Tweet the user propagates about the article is also given. We also scraped users that follow sources, and this information is released by providing the user ID's that interact with each source ID's. Finally, we provide the representations for each user, article, and source we used as our initial embedding in the graph. Our data is meant for academic research purposes and should not be used outside of academic research contexts. All our data is in English.

Our framework in general does not create direct societal consequence and is intended to be used to defend against fake news. While our model could be used to build better fake news spreaders, our approach of identifying information communities through inference operators, could also prevent against that.

A Supplemental Material: Fake News Source Detection

In this section, we provide implementation details for our models for fake news source detection. The dataset we use has 859 sources: 452 *high* factuality, 245 *mixed*, and 162 *low*, and was released publicly by (Baly et al., 2020b)[4]. The dataset does not include any other raw data (articles, sources, etc.), so we must scrape our own.

A.1 Data Collection

For each source, we attempted to scrape news articles using public libraries (Newspaper3K [5], Scrapy [6], and news-please [7] (Hamborg et al., 2017)). In the cases where the web pages of the source news articles was removed, we used the Wayback Machine [8]. We attempted to scrape up to 300 articles for each source, but this was not always possible. Overall, our sources have an average of 109 articles with a STD of 36.

For Twitter users, we used the Twitter API[9] to scrape 5000 followers for each Twitter account we could find (72.5% of the sources, identical to (Baly et al., 2020b). In addition, we used the Twitter Search API to search articles on Twitter and find any Tweets that mention the article title or URL within 3 months of the article being published. We then downloaded the users that make these Tweets as well, and added them to our graph, linking them to the respective article they tweeted about. Finally, to increase the connectivity of the graph and accurately capture the interactions between the users, we also scraped the followers of every Twitter user. We then filtered the users to only add to our graph ones that either interact with multiple sources (through source or article connections) or another user, so that every node would be interconnected.

We did not scrape YouTube accounts, but rather used the same ones as the released (Baly et al., 2020b). They found YouTube channels for 49% of sources and published this information.

A.2 Experimental Settings

A.2.1 Initial Embeddings

Our initial Twitter embedding for each source and engaging user was a 773 dimensional vector consisiting of the SBERT (Reimers and Gurevych, 2019) (RoBERTa (Liu et al., 2019) Base NLI model) representation of their bio (up to the first 512 tokens) concatenated with the following numerical features: a binary number representing whether the source is verified, the number of users a source follows and the number that follow it, the number of tweets it makes, and the number of favorites/likes its' tweets have received. For, YouTube, the embedding we used was the average of the number of views, dislikes, and comments for each video the source posted. For articles, we used the SBERT RoBERTa model to generate an embedding for each article, which was a 768 dimensional vector representing the article text, up to the first 512 tokens.

A.2.2 Model Setup

Our models are built on top of PyTorch (Paszke et al., 2019) and DGL (Deep Graph Library) (Wang et al., 2019) in Python. The R-GCN we use consists of 5 layers, 128 hidden units, a learning rate of 0.001, and a batch size of 128 for Node Classification. Our initial source and article embeddings have hidden dimension 768, while the user one has dimension 773. We use a final fully connected layer for classification, of size 3 for (Baly et al., 2020b).

For our Joint Inference and Representation Learning framework, we choose parameters using the development set (20% of training sources) for one of the training data splits, and then apply them uniformly across all the splits, when training the final models. We ended up running all the inference operators for 2 iterations (except users-sources, articles-articles, and users-articles) before they converged (we determined convergence using the dev set), although we hypothesize that a higher accuracy of choosing the edges to connect would allow us to run this process longer. The number of edges shown in Table 1 were also chosen based on the development set.

When applying inference operators, we make sure that at least 50% of the nodes that are being connected are connected to sources that are not in the train set. For example, to be considered linked to a non-train set node, if we were connecting two

---

[7] https://github.com/fhamborg/news-please

[8] https://archive.org/web/

[9] https://developer.twitter.com/en/docs

users, at least one of those users would need to be linked to a non-train set node directly (either by following a non-train set source or interacting with an article from a non-train set source). Not only does this setup simulate a real-world scenario when the model is deployed and inference operators are connecting new articles/sources to existing nodes, but it also makes sure that the graph does not only connect nodes that are learned better as they are closer to training set nodes, which helps performance.

Our models were trained on a 12GB TITAN XP GPU card and training each data split for Node Classification takes approximately 4 hours. The user-user inference operator phase to add 20,000 edges took 997.8724 seconds, or approximately 16 minutes.

A.2.3 Replication of Prior Work

To replicate (Baly et al., 2020b) (`M4`), we used their released code with our features. Specifically, we used our article, Twitter profile, Twitter Follower, and YouTube embeddings. This setup consists of all the data in our graph, and also provided the best performance in (Baly et al., 2020b).

A.2.4 Explanation of 100% Inf. Acc Approach

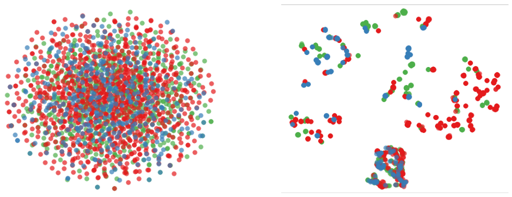
In Sec 5.1, we had mentioned results where we ran our approach with 100% Inf. Acc, and said this was a potential of our approach. Here, we explain that setup in further detail.

For our 100% accurate edges, we needed labels for the users, articles, and sources. We computed those using all the data (train, dev, and test set), which is cheating. The labels for the articles were computed based on the source they were directly connected to (even if it was a test set source), and the labels for the users were computed based on sources they interacted with or articles they followed (again, even if it was a test set). This is why we consider this a potential of our approach, because in practice we do not have access to the test set labels and thus cannot do this inference process with 100% accuracy.

A.2.5 Explanation of News Influencers

In Sec 3.3.2, we mentioned one of our inference operators as news influencers. Here, we explain how we choose those:

To choose influencers, we first looked at each user in the graph and determined how many followers it had. Then, using just the training set, we determined the labels of each user (based on the articles/sources they connect to, and what is the most common label). We consider influencers as users who mostly have one label of people following them. For example, a user with predominantly low factuality users following them is likely an influencer of low factuality information.



(a) (b)

Figure 4: TSNE plots of our article embeddings before and after the model is trained. (a) shows the embeddings before the model is trained, when we used SBERT (Reimers and Gurevych, 2019) RoBERTa (Liu et al., 2019) to encode the articles. In this case, the articles are not well separated based on factuality. In (b), after the graph model is trained and inference operators are applied, they are, showing that factuality in our graph propagates to articles as well.

Thus, now that we have the user labels and we know who follows each user, we can determine a distribution for each potential influencer. If the gap between the most common label (of all the people who follow them) and the next most common is larger than a threshold (which we experimentally set to 3000 for high/mixed factuality and 100 for low since there were less of those), then we consider a user an influencer. We added 500 influencers to begin with, and through the inference operator in Table 3, added 1000 more. When a user is connected to an influencer, it is done with a special edge type in the R-GCN.

B Fake News Source Detection Analysis

In this section, we build upon Sec 5 by providing extra analysis experiments and further detailing the ones already discussed.

B.1 Extra Analysis: Graph Embeddings

In this sub-section, we present a new analysis that attempts to answer the question of how meaningful our models embeddings are. To do this, we analyze article embeddings before (a) and after the model is trained (b), and plot them in Fig 4 (red=high factuality, blue is low, green is mixed). The embeddings show that our inference operators enable factuality to propagate to the representation of the articles, as the articles are more cleanly clustered after the graph is trained.

B.2 Extra Analysis: Inference Operator Edge Count Experiment

Now, we provide details on how the performance changes for each of our inference operators based on how many edges we add for each. The number of added edges is a hyper-parameter, as we can decide when to stop adding edges (we added edges based on the top k similarity scores, and that k is the hyperparameter). The results are shown in Tab 6. For each inference operator, we evaluate three different number of added edges hyperparameter settings, showing results on the test and a development set (20% of sources in the train set).

B.3 Extra Analysis: How Long Does Running Inference Operators take?

Now, we evaluate how long running our inference operators take, showing that our procedure is efficient. We timed our users-user inference operator when it added 20,000 edges. This is the most amount of edges of any of our single inference operators. Thus, this is is the most computationally expensive inference operator, except for articles-articles - which did not perform well.

We timed it on a single GPU GeForce GTX 1080 Ti GPU, with 6 Intel Core i5-8400 CPU @ 2.80 GHz processors over 5 runs (all data splits averaged). The inference operator took 997.8724 seconds (just over 16 minutes).

Thus, we believe that our procedure does not involve huge computational and memory costs. This is partly because we used FAISS (Johnson et al., 2017) to do the embedding similarity search efficiently, as we mentioned in Sec 3.3. Other inference operators and cases where less edge connections need to be made will take less time, especially on stronger machines. This is also an interesting direction for future work, where we can find the right balance between the number of edges that should be added, while taking into account the impact they would have on performance.

B.4 Continued Analysis: Inference Operator Specific Example Analysis

Next, we continue our analysis discussion from Sec 5 by analyze the inference operators by analyzing specific edge connections that are made. We see that the model makes smart choices in connecting nodes that may be part of the same information community.

(1) A low factuality article discussing Democrats as ‘dangerous open border fanatics’ was connected to a user with bio ‘BuildtheWall ... DEMONRATS‘.

(2) A user with a bio containing ‘Held Hostage by the Environmentalist Movement‘ that was connected to predominately low factuality sources was connected to an article talking about Democrats wanting to destroy fun through the ‘green movement’.

(3) A user with bio containing ‘Lets save our Republic‘ was connected to an article mentioning a celebrity tweeting a photo of a well known Democrat leader killing the President.

(4) A user with bio ‘makes memes for the masses’ was connected to another user with bio ‘here to have fun‘.

(5) Two articles talking about the Presidents first week in office were connected.

Overall, these examples show that our model can make decisions based on information communities that could exist on social media, as it connects users/articles that are talking about similar content, which is what we are trying to capture.

B.5 Continued Analysis: Learned Information Communities

Here, we provide the technical details behind our analysis in Sec 5.3. When clustering users, we evaluated purity based on user labels. The labels were computed for each user based on the most common label of the source it was directly connected to in the initial graph (ex: a user that follows 3 high factuality sources is assigned a high factuality label). We also evaluated how users clustered with respect to bias labels (second number in each cell of the first two rows of the table), using the bias labels from (Baly et al., 2020b).

B.6 Continued Analysis: Incorporating News Content

In our analysis in Sec 5.5, we wanted to see how well our model can incorporate news content that was not seen before. For this, we scraped 1500 fact-checked statements from the popular fact-checking website PolitiFact. Each statement was labeled by experts on a 1-5 scale in order of increasing

Model	Performance				
	Dev Acc	Dev Macro F1	Test Acc	Test Macro F1	Edges
`InfOp` Users-Sources	66.66	58.28	69.49	63.63	2,500

`InfOp` Users-Articles	67.53	61.13	68.09	60.90	2,500

Table 6: Experimental results on (Baly et al., 2020b) of our `InfOp` models for different hyper-parameter settings of number of edges added. For each inference operator evaluated, we show the performance on the development set and test set. We used the development set to select the hyper-parameter value to use in our final models. Results are averaged across all five data splits

level of factuality, which we converted to high (top two), low (bottom two) and mixed (other - # 3), to match our source labels. Then, we incorporated the statements into our graph by computing the similarity of each statements' RoBERTa embeddings to all of the graph article RoBERTa embeddings. We connected each PolitiFact statement to it's top 5 similar graph articles, generated graph embeddings for each statement, and then clustered this in Table 5 `D2`. Then, we applied our user-article inference operator, where each article was now a PolitiFact statement, and clustered them again in `D3`. When doing this, we found improved clustering at all values of k, showing that the inference operators allowed us to better capture the factuality of the PolitiFact statements. Further, the inference operator had an Inference Accuracy of 51.45% (user label inferred from user source connections matching PolitiFact statement label), showing that the graph was able to make good decisions when choosing what to connect.

C Supplemental Material: Fake News Article Detection

For Fake News Article detection, we used the dataset released publicly by (Nguyen et al., 2020). However, in our graph setup for the initial node embeddings, we use RoBERTa (Liu et al., 2019) article embeddings (See Sec 3.1) and Twitter Profile embeddings (see Sec A.2.1), which (Nguyen et al., 2020) did not. Thus, we downloaded the article text from the links released by (Nguyen et al., 2020), and encoded it using RoBERTa, with the first line of the article being the claim text (Nguyen et al., 2020) used, if it was available. As before, we encode up to the first 512 tokens. Further, we downloaded the Twitter profiles, but the users we have in our graph are the same as (Nguyen et al., 2020). Later in this section, we will also evaluate a version of our model where we use the same initial representations as (Nguyen et al., 2020), instead of the RoBERTa SBERT ones.

In addition to the initial embeddings, we also scraped followers of each social media user (Nguyen et al., 2020) used, and connected users where at least one follows the other in the graph. As mentioned in Sec 3.1, this process enables us to capture the social media landscape that enables fake news propagation, and is helpful for us to build information communities via our inference operators.

(Nguyen et al., 2020) also incorporated temporal information to their graph, which we do not. We hypothesize that adding temporal information to our setup will lead to further improvements, and leave it for future work.

Apart from these differences, our work is identical to (Nguyen et al., 2020) (FANG), except we utilize inference operators. Our graph is the same as described above in Appendix (albeit with different data), with sources, users, and articles with the same node/edge types. We train the same RGCN with the same parameters, using the same inference operator connection process.

U-A + U-U 10%	67.06	20,000

Table 7: Extended Final results on (Nguyen et al., 2020). From the results, it is clear that applying inference operators leads to performance improvements. Key: FANG = (Nguyen et al., 2020), NC = Node Classification, 90% = percentage of data used for training, the rest was for test/validation, SVM = support vector machine trained on our article + Twittere user features, U-U = Inference Operator connecting users to users, U-A = inference operator connecting users to articles, Iter. 2 = running the inference operator for 2 iterations.

Our extended experimental results below (Table 7) show how our different inference operators (connecting users to users -> U-U and connecting users to articles -> U-A, doing them in multiple iterations -> Iter 2, doing both at once -> U-A + U-U) enable performance improvements even on fake news article classification. As before, we use the dev set to judge convergence. For a complete evaluation, we also include results on our model trained without adding inference operators (just on Fake News Article Node Classification (NC)), and us using our article and social media features in a SVM (we trained a SVM using grid-search parameter optimization where the features for each article were the RoBERTa embedding we used in the graph plus the average of all the user profiles the article was connected to in the final graph). The SVM allows us to evaluate how much performance improvements we get from our Twitter/Article embeddings/other data compared to (Nguyen et al., 2020) FANG, and we can see that the embeddings do not lead to strong performance. Thus, it can be seen from the results that our graph setup, and on top of that applying inference operators, always leads to performance improvements compared to (Nguyen et al., 2020) (FANG), showing that our setup is useful for fake news article detection. Moreover, applying inference operators on top of our initial setup (NC), always leads to further performance improvements, achieving the best results on this task (to our knowledge). This shows the benefit of using our inference operator based framework for fake news article detection. Results can be seen in Table 7.

For further analysis on the initial representations, in Table 8, we evaluate our model performance with and without inference operators when we use the same node representations as (Nguyen et al., 2020) for articles, sources, and users. Nguyen et al. released these representations publicly with their paper, and each of them is 100 dimensional (articles are TFIDF + semantic from GLOVE, sources are TFIDF + GLOVE semantic of homepage and about us, users are TFIDF + GLOVE Semantic of profile bio). Everything else in our graph framework stays the same. Thus, our setup is now even weaker compared to (Nguyen et al., 2020), as we still do not include the temporal information that they used and we do not capture stance of Twitter users with respect to articles. Even in this case, we see that inference operators enable performance improve-

Model	Performance	
	AUC	Edges

Table 8: Results on (Nguyen et al., 2020) using the same representations as (Nguyen et al., 2020). In this setup, we use the same article (TFIDF + semantic from GLOVE (Pennington et al., 2014) of the text), source (TFIDF + semantic of homepage and about us), and user (TFIDF + semantic of profile bio) representations as (Nguyen et al., 2020), that they released online.

ments when compared to the node classification graph baseline, showing that inference operators can help models even with weak initial node representations. Further, the inference operator models compete with the best results from Nguyen et al.. We hypothesize that when inference operators are combined with the extra information Nguyen et al. used (stance prediction/temporal data), overall performance would be higher and exceed Nguyen et al. even with the same embeddings as them, and leave this for future work.

D Supplemental Material: Improved Inference

D.1 Inference Process

In Sec 5.1 we discussed a potential extension of our user-user inference operator based approach, where instead of adding the top k edges based on only embedding similarity search, we used a global probabilistic inference approach. Here, we explain that process in more detail.

In our current approach in Sec 3, we had considered similarity scores between all pairs of nodes for each inference operator, and chosen the top k to connect, where k was determined from the development set. While successful, this process may not always connect the best set of edges. For example, consider a situation when there are three users: *A, B, C*. Assume the inference operators decided to connect *A* and *B* with an edge, and likewise *B* and *C*. In this case, it's clear that *A* and *C* are likely in the same information community, as they are both connected to *B* (by the property of transitivity). However, in our current approach, we may not connect *A* and *C*, if their graph embeddings are not similar enough. At the same time, if *A* and *C* are very dissimilar, or they have a very different level of factuality (as determined by the training set), then we likely don't want to connect them (despite them both being connected to *B*. Thus, having a setup that allows all these decisions to be made jointly, would be beneficial.

For this reason, we explore how we can take advantage of global relational learning, to determine what edges to connect. In this work, we used a framework called DRaiL (Pacheco and Goldwasser, 2021). DRaiL is a probabilistic learning framework for learning a relational model using weighted logical rules. We described the settings as a factor graph in Fig 3 in Sec 5.1.

In the factor graph, we define two decision variable types, F associated with a user's factuality prediction, and E associated with the inference operator outcome on a user pair. Each is associated with a scoring function, ψ_1 scoring users factuality assignments, and ψ_2 scoring user pairs based on embedding similarity (similarity comes from FAISS, as before). The assignments are connected using two sets of constraints: **C**, ensuring factuality label consistency in users connected via a predicted edge, and **T**, ensuring transitivity across pairs of edges, sharing a node (explained above). DRaiL then uses MAP inference to identify the solution edge set. The results in Tab. 3, show a modest improvement (72.17) compared to local inference (71.97), obtained using significantly less edges (6.7K compared 30K).

Each scoring function (ψ_1, ψ_2) is given a weight in the MAP inference problem. For us, as factuality is important, we weighted ψ_1 (user factuality) with weight 5000 and ψ_2 (user-user similarity scores) with weight 1.0. Each constraint (**C**, **T**) is weighted equally. We determined all the weights experimentally, using the development set.

The factuality score for each user in the graph is probabilistic, spanning across the three values

- high, low, and mixed. We determined factuality labels for users using the training set, where users that follow training set sources or interact with training set articles are assigned the label of the respective source (if there are multiple, then this determines the probability - for example a user following 5 sources, 3 of which have a high factuality label in the training set, would have a 0.6 probability of being high factuality). For users that don't interact with training set articles, we look at all their indirect connections in the graph up to two hops away (a directly connected node is one hop away) and assign the label that way (for example, a user that interacts with another user that interacts with an article would be given the label of that article). Users that aren't assigned labels to this process are ignored, but as our graph is well connected, there are only 21 of these out of 69K. In the future, if new sources were added that were not in the training set and we wanted to use them to compute user labels (for example if their users weren't connected to anything in the training set), then we could also use the model source predictions to approximate their labels.

After receiving the top k similarity scores from the model based on FAISS, which we call candidates (30,000 candidates in the case of users-users), DRaiL solves the constrained MAP problem of deciding which edges to add based on the weighted scores and constraints provided (and discussed above). Through experimental testing, we decided to add a minimum of 5,000 candidates, and then DRAIL can further add edges based on which ones solve the optimization problem. In total, on average across the data splits for (Baly et al., 2020b) and the user-user inference operator, we added 6,732 edges.

D.2 Inference Benefits

Using a system like DRaiL for global inference has several benefits, some of which we discuss here.

Theoretically, through weighted scoring functions and constraints, DRaiL allows more knowledge to be incorporated into the node connection decision making process, which can eventually improve fake news detection performance. Here, we began to explore the users-users case, where we considered model similarity score, user factuality labels, and the transitivity constraint. However, more scoring functions and constraints can also be added in the future, such as increasing the likelihood of connecting users that talk about the same events. In this case, a semantic model could be used to determine the likelihood that two users are talking about the same event, and that could be passed in as an additional scoring function to a system like DRaiL. Similarly, there could also be additional constraints.

From an experimental perspective, by using DRaiL we saw performance improvements similar to our initial approach (slightly better in Table 3) by using significantly less edges (6,732 for DRaiL vs 30,000 for our similarity score approach). Adding less edges has several benefits, such as introducing less noise, being faster (which could also help in early detection of fake news), and not making the graph too large.

In the future, as more scoring functions and constraints are added, and more inference operator types are explored via an optimization system like DRaiL, we may see further performance improvements on fake news detection. Exploring this further is a very interesting direction for our future work.

Understanding Gender Bias in Knowledge Base Embeddings

Abstract

Knowledge base (KB) embeddings have been shown to contain gender biases (Fisher et al., 2020b). In this paper, we study two questions regarding these biases: how to *quantify them*, and how to *trace their origins in KB*? Specifically, first, we develop two novel bias measures respectively for a group of person entities and an individual person entity. Evidence of their validity is observed by comparison with real-world census data. Second, we use influence function to inspect the contribution of each triple in KB to the overall group bias. To exemplify the potential applications of our study, we also present two strategies (by adding and removing KB triples) to mitigate gender biases in KB embeddings.

1 Introduction

Gender biases have been shown to have noticeable presence in a wide range of NLP models. For example, we can observe that the word embedding of "engineer" is closer to "he" than "she" (Bolukbasi et al., 2016), and co-reference systems associate "surgeon" more with masculine pronouns than with feminine ones (Rudinger et al., 2018). These biases are brought to our models from training data by our algorithms. Hence, besides revealing the existence of gender biases, it is important to quantify them and explain their origins in data.

Knowledge bases (KB, e.g. Freebase, Bollacker et al., 2007) provide accessible organizations of human knowledge by the form of triples. Each triple consists of a head entity, a relation, and a tail entity. For example, the fact that *Marie Curie is a chemist* is represented as ⟨`Marie Curie`, `people.person.profession`, `chemist`⟩. KB embeddings encode these knowledge into dense vector representations. It is important to understand gender biases in KB embeddings for two major reasons. First, KB embeddings serve as sources of prior knowledge in many downstream NLP models (e.g. pre-trained language models, Zhang et al., 2019). Clearly, if biases exist in KB embeddings, they can easily propagate into these models, and drive these models more biased. Second, Garg et al. (2018) observe that word embeddings reflect biases in the training corpora, and hence our society. Likewise, we suspect KB embeddings to reflect biases encoded in KBs, as also suggested by Radstok et al. (2021).

In this paper, we **propose two novel gender bias measures** for KB embeddings, one for a group of person entities (*group bias*) and the other for an individual person entity (*individual bias*). Furthermore, with *influence function* (Koh and Liang, 2017), we **explain the origins of group bias** at the fact triple level (i.e. how each triple in KB contribute to group bias). In practice, we use TransE (Bordes et al., 2013) to demonstrate our methods, for its popularity and simplicity. Nevertheless, most of our study can generalize to other embedding algorithms. Specifically, we make four contributions.

First, regarding **a group of person entities** with a shared relation-tail pair (e.g. of the same occupation), using **correlation analyses**, we measure their gender biases by the differences between different genders' link prediction errors.

Second, to understand the origins of the group bias, we use influence function to find its highly-influential triples in KB (i.e. triples that will change the bias most if being removed during training).

Third, regarding **a single person entity**, using **counterfactual analyses**, we develop a bias measure by measuring the change of the link prediction error when we keep everything else the same and perturb its gender. To avoid the intractable computational cost of re-training, we propose to use influence function to approximate the results.

Fourth, to further facilitate large-scale influence function based analyses, we derive a closed-form approximation of the Hessian matrix of TransE loss.

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 1381 - 1395

We therefore improve the time complexity of computing influence function from $\mathcal{O}(n)$ (stochastic approximation) to $\mathcal{O}(1)$.

Moreover, in further analyses, we show that both group and individual bias correlate well with real-world biases. We argue that this suggests the validity of our bias measures. We also show the accuracy of our influence function approximation by comparing with the brute-force strategy (i.e., leave-one-out re-training). Finally, to exemplify the applications of our study, we propose two simple de-biasing strategies, and demonstrate their effectiveness.

2 Preliminaries

Knowledge Base KB is a set of structural human knowledge represented by triples $\mathcal{G} = \{\langle h, r, t\rangle\}$, where h is a head entity, r is a relation type, and t is a tail entity. Moreover, these triples form a graph with entities as nodes (denoted by E, where $e \in E$ is an entity) and relations as edges. In this work, since we are particularly interested in person entities and their gender, we use $\langle s, r_g, m\rangle$ or $\langle s, r_g, f\rangle$ to represent a person s with gender male or female, where r_g is the relation of gender.[1]

TransE The entities and relations in KB can be represented with embedding vectors. These embeddings can serve in many NLP task as a source of prior knowledge. In this work, we focus on the widely used TransE (Bordes et al., 2013).

Given a triple $\langle h, r, t\rangle$, the key idea of TransE is to make vectors of h, r and t close to each other in the sense of small *link prediction* error. Concretely, TransE embeddings are learned by minimizing a margin-based ranking loss,

$$\mathcal{L} = \sum_{\langle h,r,t\rangle \in \mathcal{G}} [m + \psi(h,r,t) - \psi(h',r,t')]_+, \quad (1)$$

where m is a scalar margin and ψ is a distance measure. The lower $\psi(h,r,t)$ is, the more likely $\langle h,r,t\rangle$ forms a fact. h' and t' are two randomly sampled entities. The triple $\langle h', r, t'\rangle$ is called a *negative* sample because it is not in $\mathcal{G}$. This loss function basically says that the dissimilarity of a positive triple $\langle h,r,t\rangle$ should be smaller than a negative sample by a margin m.[2] Specifically, in this paper, we take ψ to be the L_2-norm distance $\psi(h,r,t) = \|\mathbf{h} + \mathbf{r} - \mathbf{t}\|_2^2$, where $\mathbf{h}, \mathbf{r}, \mathbf{t} \in \mathbb{R}^d$ are the embeddings of h, r and t, respectively.

In this paper, we use Freebase's (Bollacker et al., 2007) subset **FB5M** (Bordes et al., 2015) as the KB for training TransE embeddings and performing our analyses. See Appendix A for detailed setup.

Influence Function (Cook and Weisberg, 1982; Koh and Liang, 2017) provides an efficient way to approximate each training sample's impact on correctly predicting a test sample.

Formally, let $L(z, \theta)$ be a convex loss function on a training set $\{z_i\}_{i=1}^n$ with parameters θ. The empirical risk minimizer (ERM) is given by $\hat{\theta} = \arg\min_\theta \frac{1}{n}\sum_{i=1}^n L(z_i, \theta)$. We are interested in a training sample z's impact on $\hat{\theta}$, with a weight of ε. In this case, the new ERM is given by $\hat{\theta}_{z,\varepsilon} = \arg\min_\theta \frac{1}{n}\sum_{i=1}^n L(z_i, \theta) + \varepsilon L(z, \theta)$ (Note that if $\varepsilon = -\frac{1}{n}$, it equals to removing z).

Influence function provides an efficient method of approximating the difference between $\hat{\theta}_{z,\varepsilon}$ and $\hat{\theta}$, without retraining the model,

$$\hat{\theta}_{z,\varepsilon} - \hat{\theta} \approx \varepsilon \mathcal{I}_{\text{up,param}}(z), \quad (2)$$

where $\mathcal{I}_{\text{up,param}}(z) \overset{\text{def}}{=} -H_{\hat{\theta}}^{-1} \nabla_\theta L(z, \hat{\theta})$. $H_\theta = \frac{1}{n}\sum_i \nabla^2 L(z_i, \theta)$ is the Hessian matrix of the original loss function.

Moreover, we are interested in the change of the test performance, which is a function F of the test sample z_{test} and the model parameter (LHS). By applying chain rule to F and Equation 2, we can obtain the difference of test performance. Formally,

$$F(\hat{\theta}_{z,\varepsilon}, z_{\text{test}}) - F(\hat{\theta}, z_{\text{test}}) \approx \varepsilon \mathcal{I}_{\text{up},F}(z, z_{\text{test}}), \quad (3)$$

where $\mathcal{I}_{\text{up},F}(z, z_{\text{test}}) \overset{\text{def}}{=} \nabla_\theta F(z_{\text{test}}, \hat{\theta})^\top \mathcal{I}_{\text{up,param}}(z)$.

Similarly, by splitting perturbation to first remove then add, we can also inspect the change of F when a training sample z is perturbed to z'. Denote $\theta_{-z,z',\varepsilon} = \arg\min_\theta \frac{1}{n}\sum_{i=1}^n L(z_i, \theta) - \varepsilon L(z, \theta) + \varepsilon L(z', \theta)$, and apply Equation 3 twice, we obtain

$$\begin{aligned} & F(\hat{\theta}_{-z,z',\varepsilon}, z_{\text{test}}) - F(\hat{\theta}, z_{\text{test}}) \\ \approx\, & \varepsilon \mathcal{I}_{\text{up},F}(z', z_{\text{test}}) - \varepsilon \mathcal{I}_{\text{up},F}(z, z_{\text{test}}) \\ \overset{\text{def}}{=}\, & \varepsilon \mathcal{I}_{\text{pert},F}(z, z', z_{\text{test}}). \end{aligned} \quad (4)$$

Finally, besides single sample estimation, we are also interested in inspecting the influence of removing a group of training samples. In these cases,

---

[1] We operate with binary gender here, because it is naturally encoded in KB.

[2] For simplicity, we consider only linear loss in the rest of this paper. This is a feasible choice both empirically and theoretically in our analyses. Empirically, in experiments we observe that the link prediction errors of all triples converge at a larger-than-margin value. Theoretically, when link prediction errors converge at values smaller than the margin, the gradients become 0. Its influence thus becomes 0, too.

Occupation	$\mathcal{B}_{\text{gr}}$	#male	#female
soldier	8.65×10^{-2}	3110	78
engineer	6.26×10^{-2}	3761	113
singer	1.46×10^{-2}	17260	13155
animator	-1.70×10^{-2}	1342	235
model	-3.11×10^{-2}	1595	5876
nurse	-9.77×10^{-2}	36	466

Table 1: A gallery of group bias ($\mathcal{B}_{\text{gr}}$) results. **#male** and **#female** are the numbers of male and female person entities in KB with this occupation respectively.

following Koh and Liang (2017), we simply add up the influence of each removed training sample. However, as noted by Koh and Liang (2017), when handling a group of samples, although influence function approximation still holds a strong correlation with the ground truth change of the parameters, the estimation can suffer from larger errors.

3 Gender Bias Measures

In this section, based on link prediction, we take two views to quantify gender biases in KB embeddings. First, using correlation analysis, we take a macro view to inspect gender biases of a group of person entities (e.g., how gender influences the overall occupation prediction accuracy of a group of engineer entities). Second, under the framework of counterfactual analysis, we take a micro view to assess gender biases of an individual person entity (e.g., how a specific engineer entity's gender influences its occupation prediction accuracy). Afterwards, we build connections between them.

In this following, we adopt occupation prediction as our running example. The reason is two fold. First, among all of the relations connected with person entities, occupation relation has the highest coverage rate (i.e. connect with the most person entities). Second, most previous relevant studies also focus on occupation. Our choice makes it easier to perform comparative studies (Garg et al., 2018; Fisher et al., 2020b).

3.1 Gender Biases of a Group

To see whether a group of entities exhibits bias, one direct solution is to deploy methods analog to those applied to analyze bias in word embeddings (Bolukbasi et al., 2016). For example, we can compute the projection of the TransE embedding of an occupation $\mathbf{o}$ to the difference between male and female entities (Bourli and Pitoura, 2020),

$$\mathcal{B}_{\text{wo}} = \mathbf{o}^{\top}(\mathbf{m} - \mathbf{f}),$$

where $\mathbf{m}$ and $\mathbf{f}$ are the embeddings of `male` and `female` entity respectively. However, we argue that because TransE follows a different type of learning objective (link prediction style objective instead of the vector-similarity-based ones in word embedding algorithms), directly adopt existing settings may not fully explore the semantics of TransE embeddings.

Therefore, we propose to detect group bias based on the correlation between genders and link prediction errors. Intuitively, given an occupation o, person entities of o's privileged gender will link to o with lower errors than those of unprivileged gender. Formally, we define the group bias of o as

$$\mathcal{B}_{\text{gr}} = \frac{1}{|F|}\sum_{s\in F}\psi(s, r_p, o) - \frac{1}{|M|}\sum_{s\in M}\psi(s, r_p, o),$$

where M and F are the sets of all male and female person entities with o respectively, and r_p is the relation `people.person.profession`. The higher $\mathcal{B}_{\text{gr}}$ is, the more o's embedding is biased towards male. Table 1 lists $\mathcal{B}_{\text{gr}}$ of some occupations, as well as the gender frequency of this occupation in KB. We make two observations.

First, we observe the existence of gender biases in KB embeddings, and note their consistency with real-world biases. For example, *engineer* and *nurse* have more extreme bias scores respectively towards male and female, while *singer* and *animator* have more moderate ones (quantitative analyses in §4).

Second, although the gender ratio of person entities has a great impact on $\mathcal{B}_{\text{gr}}$, it is not the only decisive factor. For example, *animator* has a gender ratio of 5.7:1, but its $\mathcal{B}_{\text{gr}}$ is biased towards female.

Inspecting the Origins of Biases The second observation motivates us to trace the origins of biases. More concretely, in the context of KB: *how do different triples contribute to $\mathcal{B}_{gr}$?* To answer this question, we apply influence function (Equation 3) with $F = \mathcal{B}_{\text{gr}}$ and observe how removing a training triple changes the overall group bias score.

One appealing property of TransE is that we are able to derive a closed-form Hessian matrix. Moreover, by further analyses, we can directly obtain a *diagonal approximation* of the Hessian matrix, and thus the Hessian inverse $\mathcal{I}_{\text{up, param}}$. Taking advantage of this, we can reduce the computation of $\mathcal{I}_{\text{up},\mathcal{B}_{\text{gr}}}$ to constant time complexity (w.r.t. training set size), which is much faster than the LiSSA algorithm (Agarwal et al., 2017) applied in (Koh and Liang, 2017), which requires $\mathcal{O}(n)$ time complexity to obtain a Hessian inverse approximation.

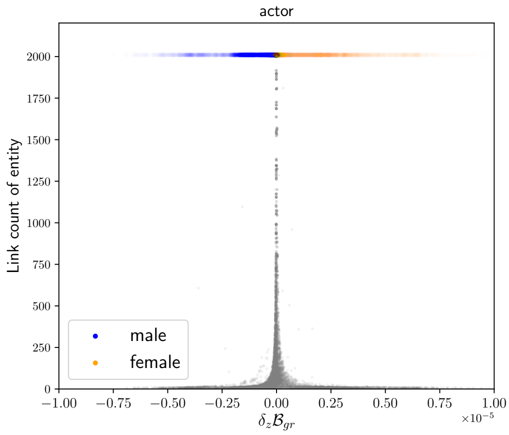

Figure 1: The relationship between different triples' $\delta_z\mathcal{B}_{\text{gr}}$ (i.e. the change of group bias $\mathcal{B}_{\text{gr}}$ if we re-train the KB embedding model without this triple) w.r.t. the occupation of *actor* and their person entities' attributes (i.e. the number of links of the entities and the gender information). Gender information is shown by blue and orange points, and node degrees is exhibited by grey points. We can observe that triples with positive (negative) $\delta_z\mathcal{B}_{\text{gr}}$ mostly contain person entities of female (male) gender. Moreover, triples contain high degree person entities are likely to have close-to-zero $\delta_z\mathcal{B}_{\text{gr}}$.

Concretely, using basic calculus, we have the following lemma and remarks. We include their detailed proof and derivations in Appendix B.

Lemma 1. *Suppose we generate the corresponding negative sample of a positive sample $\langle h, r, t\rangle$ by randomly choosing h or t and corrupting it to a random entity in E, we can derive the closed-form Hessian matrix of TransE with entries*

$$\mathbb{E}H_{\hat{\theta}} = \begin{array}{cc} & \begin{array}{ccccc} & e & e' & r & r' \end{array} \\ \begin{array}{c} \\ e \\ e' \\ r \\ \\ \end{array} & \left[\begin{array}{ccccc} \ddots & \vdots & \vdots & \vdots & \vdots \\ \cdots & \alpha_{ee}I_d & \alpha_{ee'}I_d & \alpha_{er}I_d & \vdots \\ \cdots & \alpha_{ee'}I_d & \alpha_{ee}I_d & \alpha_{er}I_d & \vdots \\ \cdots & \alpha_{er}I_d & \alpha_{er}I_d & 0 & 0 \\ \cdots & \vdots & \vdots & \vdots & \ddots \end{array}\right] \end{array},$$

where e, e' and r, r' are different entities and relations, α_{ee}, α_{er}, $\alpha_{ee'}$ are three different coefficients dependent on the frequencies of the corresponding entities and relations, and I_d is the identity matrix of $\mathbb{R}^{d\times d}$.

Remark 2. *In practice, we approximate the closed-form Hessian from Lemma 1 with its diagonal elements,*

$$\mathbb{E}H_{\hat{\theta}} \approx \mathrm{diag}\{\underbrace{\cdots, \alpha_{ee}I_d, \cdots}_{\text{entities}}, \underbrace{\cdots, 0, \cdots}_{\text{relations}}\}.$$

Remark 3. *α_e could be zero or negative, which breaks the positive definiteness of $H_{\hat{\theta}}$. Following Koh and Liang (2017), we add λI ($\lambda > 0$) to $H_{\hat{\theta}}$ (i.e., $\alpha_{ee} \leftarrow \alpha_{ee} + \lambda$), which equals adding an L_2 regularization on parameters.*

Following Equation 3 ($\varepsilon = -1/|\mathcal{G}|$), we can compute the change of group bias (denoted by $\delta_z\mathcal{B}_{\text{gr}}$) after removing a training triple $z = \langle h, r, t\rangle$,[3]

$$\delta_z\mathcal{B}_{\text{gr}} = \frac{1}{|\mathcal{G}|}\nabla_\theta\mathcal{B}_{\text{gr}}^\top\left(\mathbb{E}H_{\hat{\theta}}^{-1}\nabla_\theta L(z, \hat{\theta})\right).$$

A triple z with positive $\delta_z\mathcal{B}_{\text{gr}}$ means that re-training without it will increase $\mathcal{B}_{\text{gr}}$ (i.e., towards "masculine") and vice versa. We note that due to the diagonal Hessian, z will have a non-zero influence iff it is reachable from o in two hops (i.e., entities of z take part in the computation of $\mathcal{B}_{\text{gr}}$). In practice, we calculate $\delta_z\mathcal{B}_{\text{gr}}$ of each triple in KB regarding $\mathcal{B}_{\text{gr}}$ of each occupation, and make three observations.

First, regarding relations in KB, we find most of the highly-influential triples (i.e. triples with highest absolute $\delta_z\mathcal{B}_{\text{gr}}$ values) to be of the profession relation (i.e., r_p) and its inverse[4]. For example, regarding the occupation of *singer*, these two relations occupy 74% of the top 1% positive triples and 78% of the top 1% negative triples. It suggests that compared with indirectly (i.e. two-hop) connected triples, triples directly connect with an entity have larger impact on it, which matches our intuitions.

Second, regarding gender, we find that most person entities in triples with high positive $\delta_z\mathcal{B}_{\text{gr}}$ are of female gender, and vice versa. Figure 1 take the occupation of *actor* as an example to illustrate this.[5] This observation agrees with previous observation: triples with person entities of male gender will drive the overall biases towards masculine, and removing them will reverse this effect.

Third, regarding graph substructure, we find that if a triple contains a high degree person entity, it usually has a nearly zero $\delta_z\mathcal{B}_{\text{gr}}$ (i.e. has small impact on other triples, see Figure 1), We suspect the reason to be as follows: the more neighbors

---

[3] More precisely, z is a pair of triples $(\langle h, r, t\rangle, \langle h', r, t'\rangle)$. To handle randomness of negative samples, we adopt two strategies in our implementation. First, we freeze negative samples in training epochs to get consistent results. Second, we use $\mathbb{E}H_{\hat{\theta}}$ to replace random $H_{\hat{\theta}}$ in influence functions.

[4] i.e. `people.person.people_with_this_profession`

[5] Similar patterns are observed in other occupations for both this observation and the next one.

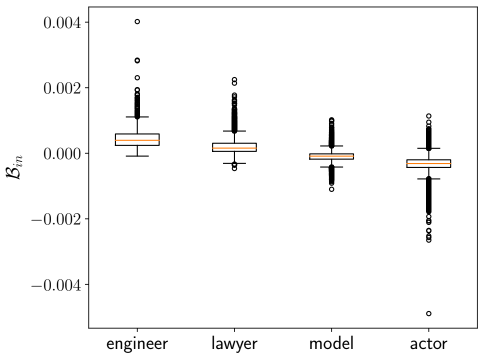

Figure 2: Distributions of $\mathcal{B}_{\text{in}}$. A positive value means the corresponding person entity's embedding is more biased towards male and vice versa. We can observe that for each occupation they are tightly distributed and consistent with real-world stereotypes.

an entity has, the more constraints its embedding needs to put on others (by link prediction). It makes the embedding less optimal to represent each constraint, and hence less influential to each triple.

3.2 Gender Biases of an Individual

Group-level correlation analyses offer us a coarse portrayal of biases. However, we are also interested in finer characterization (for each group member). Moreover, because of the complexity of KB structures, there very likely exist confounders between person entities and occupations (e.g. if two person entities of the same occupation are connected themselves, they are confounders of each other). In this case, **correlation does not imply causation**. In other words, gender differences are not guaranteed to be the only cause of $\mathcal{B}_{\text{gr}}$. Therefore, in this section, we study a further question: can we perform analyses on a specific person entity and measure its gender biases based on *how its gender change its link prediction error* (i.e. causality)?

By virtue of the structured knowledge in KB, we are able to conduct this individual-level analysis in a tractable way. The key idea is, *what if we keep everything else identical and* ***perturb*** *only the gender?* Intuitively, given an occupation o, if flipping a person entity's gender from female to male will make it easier to connect the person with o, $\mathbf{o}$ should be biased towards male. Formally, we define individual bias $\mathcal{B}_{\text{in}}$ of $\langle s, r_p, o\rangle$ as

$$\mathcal{B}_{\text{in}} = \psi(s, r_p, o)|_f - \psi(s, r_p, o)|_m,$$

where $\psi|_f$ ($\psi|_m$) is ψ computed on a version of TransE where s's gender is female (male). A high $\mathcal{B}_{\text{in}}$ means that, it is more difficult to predict s's occupation if s is female. We would thus argue that $\langle s, r_p, o\rangle$ is biased toward male. Because we keep all other attributes identical, this counterfactual definition naturally offers us causation.

The practical issue of $\mathcal{B}_{\text{in}}$ is the computation of the counterfactual: for each triple, this definition naively requires the re-training of the entire embedding model. This is intractable for large-scale analyses because of the extremely high computational cost. To avoid this issue, we apply influence function (Equation 4) for a fast evaluation of $\mathcal{B}_{\text{in}}$. Indeed, using Lemma 1 and Remark 2, we can obtain a closed-form $\mathcal{B}_{\text{in}}$ (proof in Appendix B).

Corollary 4. *Assume that for each person entity s, we have the same negative sample for $\langle s, r_p, f\rangle$ and $\langle s, r_p, m\rangle$, then*

$$\mathcal{B}_{in} \approx -\frac{4}{\alpha_s|\mathcal{G}|}\left(\mathbf{s}+\mathbf{r}_p-\mathbf{o}\right)^\top(\mathbf{m}-\mathbf{f}), \quad (5)$$

One important observation of $\mathcal{B}_{\text{in}}$ is that it is essentially a mixture of *local* graph substructure information (α_s, the degree of s in KB), and a projection of link prediction residual ($\mathbf{s}+\mathbf{r}_p-\mathbf{o}$) onto the gender difference ($\mathbf{m}-\mathbf{f}$, a reminiscence of word embedding gender subspace proposed in Bolukbasi et al., 2016). Compared with directly projecting $\mathbf{o}$ onto $\mathcal{B}_{\text{wo}}$ (a hard generalization of word embedding bias measure), the link prediction residual is more compatible with the TransE learning objective.

Figure 2 exhibits the distributions of $\mathcal{B}_{\text{in}}$ of several occupations. We make two observations from the results. First, although there are a number of outliers, most $\mathcal{B}_{in}$ are tightly distributed. It shows the consistency of the individual bias scores among different triples. Second, the bias scores correlate well with real-world gender stereotypes: *engineer* and *lawyer* lean more towards male, while *model* and *actor* lean more towards female. It suggests the validity of $\mathcal{B}_{\text{in}}$ in describing biases in KB.

Differences with Fisher et al. (2020b) A similar definition of bias is proposed in Fisher et al. (2020b) (denoted as $\mathcal{B}'_{\text{in}}$). $\mathcal{B}'_{\text{in}}$ is defined as follows: After training the embedding model to convergence, they perform one extra step of updating on the gender direction. The bias score is defined as the difference of the link prediction error before and after the update. We would like to note here the two aspects of differences between $\mathcal{B}_{\text{in}}$ and $\mathcal{B}'_{\text{in}}$.

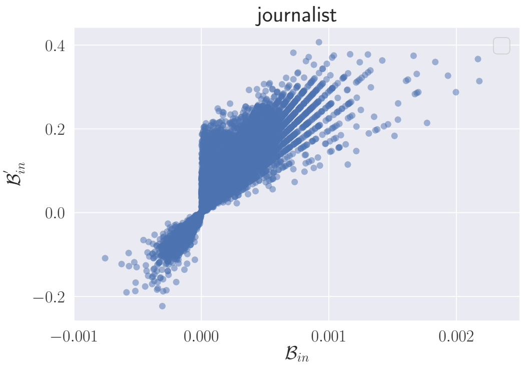

Figure 3: Relationship between $\mathcal{B}_{\text{in}}$ and $\mathcal{B}'_{\text{in}}$. We observe that these two bias measures align well. Nevertheless, there exist a substantial amount of data points with positive $\mathcal{B}_{\text{in}}$ but near zero $\mathcal{B}'_{\text{in}}$.

First, compared with $\mathcal{B}'_{\text{in}}$, $\mathcal{B}_{\text{in}}$ offers better interpretability. Concretely, in our definition, we approximate a purely counterfactual setting: flip the gender and re-train the entire model until convergence. In contrast, Fisher et al. (2020b) update the embedding after the convergence, which may not happen in real-world training.

Second, $\mathcal{B}_{\text{in}}$ takes more structural information into account. Under the case of TransE, $\mathcal{B}'_{\text{in}}$ can be expanded into the form (details in Appendix B),

$$\mathcal{B}'_{\text{in}} \propto -(\mathbf{s} + \mathbf{r}_p - \mathbf{o})^\top (\mathbf{m} - \mathbf{f}). \qquad (6)$$

Compared with Equation 6, Equation 5 (approximation of $\mathcal{B}_{\text{in}}$) has an additional graph information term α_s. Intuitively, α_s serves as a normalization term: entities with more connections will be less affected by a single perturbation. In other words, the more connections an entity has, the less its link prediction error relies on one of them (i.e. gender).

Again, take the occupation of journalist as an example, we show the relationship between $\mathcal{B}_{\text{in}}$ and $\mathcal{B}'_{\text{in}}$ in Figure 3 and make two observations. First, there is a strong correlation between these two bias measures: points are approximately distributed along the diagonal. Second, we notice that there exist a substantial number of data points with positive $\mathcal{B}'_{\text{in}}$ but near zero $\mathcal{B}_{\text{in}}$. This suggests that the normalization term α_s can prevent the over-estimation of biases of person entities with many connections. This also corresponds to our third observation regarding the distribution of $\delta_z \mathcal{B}_{\text{gr}}$ (§3.1).

3.3 Connections between $\mathcal{B}_{\text{gr}}$ and $\mathcal{B}_{\text{in}}$

After obtaining $\mathcal{B}_{\text{in}}$, a remaining question is: given a group of person entities, *how to use individual biases to characterize the group's overall bias?* The rationale behind is that, if we can accurately measure biases of individuals, we should be able to aggregate them to represent biases of the group.

A natural solution to this question is to directly average $\mathcal{B}_{\text{in}}$. However, in practice, we find that the averaged $\mathcal{B}_{\text{in}}$ of all occupations align poorly with $\mathcal{B}_{\text{gr}}$ ($r \approx 0.27$). We suspect this inconsistency to originate from the mismatches among different person entities' contexts in KB (i.e. different connections and local substructure). In other words, without controlling backdoor variables, simply averaging associations observed from each individual may not be suitable for representing association of the entire group (Pearl et al., 2016).[6]

In our analyses, because of the complexity of KB, it is infeasible to control all factors. Nevertheless, we can control some of them to alleviate this issue. Here, we focus on controlling gender for two reasons. First, occupations in KB are often of very imbalanced gender ratios (e.g., *nurse* connects with more female entities than male entities). At the same time, different genders usually have different distributions of $\mathcal{B}_{\text{in}}$: female entities mainly have above zero $\mathcal{B}_{\text{in}}$, while $\mathcal{B}_{\text{in}}$ of male entities distributes in a wider range.[7] Therefore, controlling gender should be able to effectively reduce the context mismatch. Second, because we treat the average link prediction error of each gender equally in group bias (§3.1), controlling gender can help us to obtain more comparable results.

We thus propose to average scores of each gender separately to calibrate this mismatch (*weighted averaging* instead of *vanilla averaging*). Formally,

$$\frac{1}{|F|}\sum_{s \in F} \mathcal{B}_{\text{in}}(\langle s, r_p, o \rangle) + \frac{1}{|M|}\sum_{s \in M} \mathcal{B}_{\text{in}}(\langle s, r_p, o \rangle).$$

We find weighted averaging align much better with $\mathcal{B}_{\text{gr}}$ ($r \approx 0.50$) and real-world biases (§4.1).

4 In-depth Analyses

4.1 Comparison with Real-world Biases

One method of inspecting the validity of a bias measure is to analyze its connection with real-world statistics (e.g. gender ratios of occupations). However, most existing datasets fail to meet our needs,

---

[6] Other examples of this phenomenon include *Simpson's Paradox* and *ecological fallacy*.

[7] We show $\mathcal{B}_{\text{in}}$ distribution of the occupation of *journalist* as an example in Figure 5 in Appendix C, and find similar trends in other occupations.

	vanilla		*weighted*	
	r	p	r	p
$\mathcal{B}'_{\text{in}}$	0.470	**.003**	0.590	$<\mathbf{10^{-4}}$
$\mathcal{B}_{\text{in}}$	0.480	**.002**	0.610	$<\mathbf{10^{-4}}$
$\mathcal{B}_{\text{gr}}$	–	–	0.668	$<\mathbf{10^{-5}}$

Table 2: Alignment results with census data. *Vanilla* and *weighted* denotes for vanilla averaging and weighted averaging, respectively. Note that because $\mathcal{B}_{gr}$ is not applicable for averaging strategies, we simply put its score into *weighted*. Significant p values $(< .01)$ are shown in bold font.

Occupation	$\mathcal{B}_{\text{gr}}$	**de-biased** $\mathcal{B}_{\text{gr}}$
architect	7.30×10^{-2}	4.32×10^{-2}
physicist	2.16×10^{-2}	0.22×10^{-2}
actor	-7.67×10^{-2}	-6.53×10^{-2}
nurse	-9.80×10^{-2}	-9.16×10^{-2}

Table 3: Examples of $\mathcal{B}_{\text{gr}}$ before and after adding dummy entities. We observe that this strategy can effectively mitigate bias, although the extent differs among different occupations.

because they have different occupation categories with FB5M (e.g. Garg et al., 2018; Du et al., 2019).

Accordingly, we take the following steps to build a new dataset. First, we collect the gender distributions of occupations in 2018 by the U.S. census data (Ruggles et al., 2020). Afterwards, we calculate their log proportions[8] and manually pair up them with occupations in KB.[9] We use it as our validation data and refer it as *census data*.

Table 2 shows the Pearson's r values and p values between census data and all five bias measures described in §3 ($\mathcal{B}_{\text{gr}}$, $\mathcal{B}_{\text{in}}$ and $\mathcal{B}'_{\text{in}}$ with both averaging strategies). Our observations are two fold.

First, both $\mathcal{B}_{\text{gr}}$ and $\mathcal{B}_{\text{in}}$ exhibit significant correlations (especially under *weighted averaging*) with census data ($p < .01$), indicating their validity of measuring gender biases in KB embeddings.

Second, individual bias measures ($\mathcal{B}_{\text{in}}$ and $\mathcal{B}'_{\text{in}}$) align better with census data under weight averaging than under vanilla averaging. This backs up our suspicion regarding contexts' mismatches, as well as our solution strategy (weighted averaging).

4.2 Accuracy of the Group Influence Approximation

Because the Hessian matrix we derived for the calculation of influence function is a diagonal approximation, and influence function of a group of training samples is only an approximation of the test performance change after re-training, one may concern the accuracy of our influence function. Therefore, in this section, we perform a validation experiment to address this concern. Specifically, for each occupation o, we first remove k triples with highest $\delta_z\mathcal{B}_{\text{gr}}$, then re-train the TransE model from scratch, and calculate their $\mathcal{B}_{\text{gr}}$ regarding o. Afterwards, we compare the sum of $\delta_z\mathcal{B}_{\text{gr}}$ with the ground truth changes in $\mathcal{B}_{\text{gr}}$. In practice, we take ks to be a arithmetic progression from 500 to 5000, with a common difference of 500.

We show a few occupations' alignment results as examples in Figure 4a-4c. We observe strong correlations between our approximation and the ground truth ($r > 0.95$ for all occupations). It suggests the accuracy of our approximation (some additional results in Appendix C).

4.3 Application: De-biasing KB Embeddings

Our study can broadly benefit relevant future research regarding societal biases and KB. As examples of such applications, based on our study in §3.1, we explore two strategies for de-biasing KB embeddings. We note that these two strategies aim to exemplify the potential impacts of our previous study, and are not necessarily the best method to de-bias KB embeddings.[10] Instead, we highly encourage future studies to build better de-biasing methods on the basis of our findings.

Strategy 1: De-biasing by Adding In Table 1, we observe that gender ratio has a substantial impact on $\mathcal{B}_{\text{gr}}$. Based on this, one natural idea of de-biasing is to balance gender proportion by adding dummy triples. The advantage of this strategy is that, because we do not remove triples, we are able to keep the information of the original KB intact.

Specifically, suppose an occupation o with M male entities and F female entities, where M is larger than F. To alleviate bias, we create $c(M - F)$[11] dummy entities and connect them with only the female gender and o. Afterwards, we re-train TransE and observe the $\mathcal{B}_{\text{gr}}$ regarding o.

Table 3 lists a few examples of the results. We find that this de-biasing strategy overall works well.

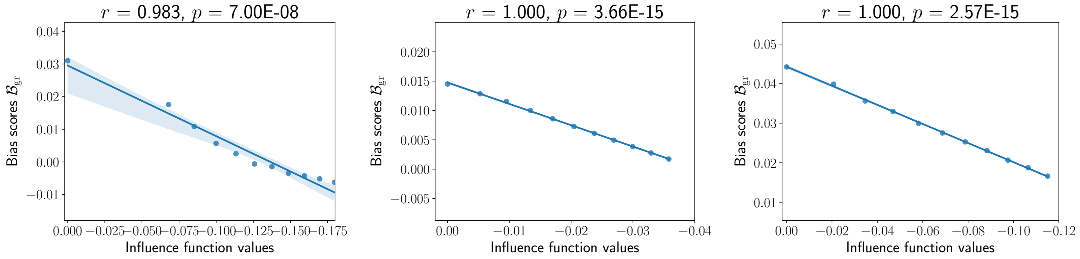
---

[8] log-prop $= \frac{p}{1-p}$, where p is % of men in occupation.

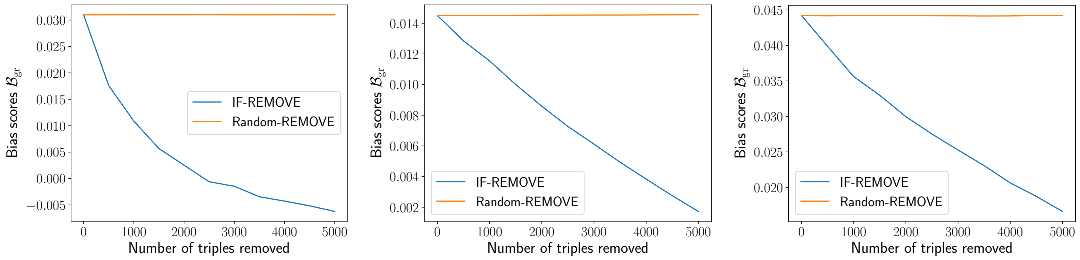
[9] We apply a *many to many* pairing to match the occupation categories in census data and KB.

[10] For example, Fisher et al. (2020a) and Arduini et al. (2020) adopt adversarial loss for de-biasing KB embeddings.

[11] In practice, we set c to be 0.5, and limit the number of total added entities of each occupation to be < 10000.



(a) Mathematician (b) Singer (c) Artist



(d) Mathematician (e) Singer (f) Artist

Figure 4: 4a - 4c are the correlations between approximated influence and ground truth results (obtained by removing triples and re-training). The titles list the Pearson's r and significance p values of the alignments. 4d-4f show the $\mathcal{B}_{gr}$ of influence-function-based triples removing (IF-REMOVE) and random removing (Random-REMOVE). Compared with Random-REMOVE, IF-REMOVE reduces $\mathcal{B}_{gr}$ much more significantly.

It is worth noting that the changes of biases of some occupations (e.g. *nurse*) are smaller, which matches our previous observation: gender ratio is not the only decisive factor of $\mathcal{B}_{gr}$.

Strategy 2: De-biasing by Removing Based on our study on the origins of biases, and inspired by the validation results in §4.2, we investigate a straightforward de-biasing strategy: we simply remove the top k most influential triples based on the approximation of influence function (IF-REMOVE). Again, we take ks to be $[500, 1000, 1500, ..., 5000]$. Besides, for the purpose of controlling variable, we compare it to a naive baseline method, in which we randomly delete triples of all entities (Random-REMOVE).

Figure 4d-4f exhibit some examples of the results. We observe that comparing with the baseline, where $\mathcal{B}_{gr}$ rarely change, this de-biasing strategy is able to mitigate biases very effectively. Several additional examples are included in Appendix C.

5 Related Work

Various measures have been proposed to quantify gender biases in word embeddings (Bolukbasi et al., 2016; Caliskan et al., 2017; Swinger et al., 2019). Many of them are based on vector similarity (e.g. cosine similarity) between words, which matches the training objective of most word embedding algorithms (maximize the vector similarities between similar words, Mikolov et al., 2013; Pennington et al., 2014). Moreover, Garg et al. (2018) suggest that word embedding can reflect biases in the training corpora and hence our society.

Recently, a few studies have explored gender biases in KBs and their embeddings. A pioneer study by Klein et al. (2016) investigates gender gap in Wikidata across time, space, culture, occupation and language. A following study (Shaik et al., 2021) further analyzes the race and country of citizenship bias in KB regarding STEM representation. Moreover, Janowicz et al. (2018) analyze the potential bias issues in KBs from both data and schema viewpoints. Fisher et al. (2020b) propose a KB embedding bias measure based on the change of link prediction error after a one-step update towards male. Fisher et al. (2020a) and Arduini et al. (2020) propose to use adversarial training objective to mitigate biases in KB embeddings.

Influence function is a commonly used technique in robust statistics (Cook and Weisberg, 1982). Koh and Liang (2017) first use it to inspect each training point's influence on a neural network's prediction. A following study by Koh et al. (2019) investigate the accuracy of influence function on measuring the effect of removing a group of training samples, and show that its approximation has strong correlations with actual effects. Afterwards, Brunet et al. (2019) apply influence function as a differential bias measure to study gender bias in word embedding. Moreover, Pezeshkpour et al. (2019) use an simplification of influence function to perform adversarial attack on link prediction.

6 Conclusion and Discussion

In this paper, we study the gender biases in KB embeddings. First, we develop two bias measures to quantify biases: one from the group level and the other from the individual level. Evidence of their validity are obtained in comparison with real-world biases. Second, to understand the origins of biases, we adopt influence functions for triple-level analysis and develop an efficient method for fast evaluation. The accuracy of this method is validated by comparing our approximation with group-truth changes after re-training. Moreover, as examples of the potential applications of our findings, we propose two de-biasing strategies for KB embeddings and obtain promising performance.

Although we focus on Freebase (FB5M) and TransE in this paper, we note that our analyses are theoretically generalizable to other commonly-used KBs and embedding training algorithms. For instance, Wikidata, another commonly-used KB, uses a different hierarchical structure to organize its data (Vrandečić and Krötzsch, 2014; Tanon et al., 2016; Wang et al., 2021). However, it still loosely follows the triple structure used in Freebase, and therefore can be pre-processed to fit in our analyses. Also, because our bias measures and bias tracing methods are built on simple and generalizable definitions (i.e., differences between link predictions errors and influence function), they can naturally be adapted to other KB embedding algorithms (Lin et al., 2015; Yang et al., 2015; Peng et al., 2021).

However, we recognize that such generalizations are not trivial efforts. Take Wikidata again for an instance, although a simple transformation is adequate for running the embedding algorithm, it is far from fully eliminating the differences between Freebase and Wikidata. For example, Wikidata does not have an inverse predicate for each relation, and has a much smaller number of overall relations (Azmy et al., 2018; Diefenbach et al., 2017). Such differences might have a large impact on the final results. Also, to perform the same analyses with other embedding algorithms, we will need to develop algorithms to facilitate the computation of their influence function (as Lemma 1), too. Therefore, we consider such generalizations to be promising future directions but out of the scope of our work.

Ethical Statement

Intended Usage Our work intend to provide insights of gender biases in KB and its embeddings, on how to measure these biases and how to trace the origins of them. Moreover, as discussed in §4.3, future studies can build better de-biasing methods based on our findings. In this way, our framework can contribute to the development of models that are less biased and hence potentially less harmful.

Limitations In this study, we use gender information already encoded in KB to measure and trace gender biases. However, because only binary gender is recorded in the KB that we use (Freebase), we take a narrow view of binary gender in our analyses. We hope to see more future studies on gender biases in KB embeddings that consider non-binary gender identities as well as intersectional identities.

A Experimental Setup

Choices of datasets Freebase (Bollacker et al., 2007) is one of the largest publicly available KBs, with over three billion triples covering a wide range of real-world facts. Due to time and hardware constraints, in this work, we use its subset FB5M (Bordes et al., 2015) as the KB for our experiments. In practice, we find that although FB5M only holds 0.5% of the triples from Freebase, it covers a much higher percentage of human type entities and their related facts. Regarding professions, we select ones with ≥ 400 person entities and contain both male and female in FB5M.

TransE training We use DGL-KE 0.1.0 (Zheng et al., 2020) to train TransE embeddings. To get deterministic results across different training runs, we fix the random seeds and restricted the training process to run under a single thread.

Due to that TransE involves negative sampling in its training objective, we save all negative samples from the final epoch to make sure that influence function can output accurate results.[12] Regarding hyper-parameters, we use a number of dimensions of 200, a batch size of 8000, and stop training after 120000 updating steps. It takes approximately 40 minutes with a single GTX TITAN X GPU.

B Proofs and Derivations

Proof of Lemma 1. We use E and R to denote the full set of entities and relations, and N_e and N_r to denote the times of occurrence of entity e and relation r in KB. Also, we use $|\mathcal{G}|$, $|E|$, and $|R|$ to respectively denote the number of triples in KB, and the number of different entities and relations. Moreover, we define a counting function C to denote the times of occurrence of certain triples,

$$C(e_0, r_0, e_1) = \sum_{\langle h,r,t\rangle \in \mathcal{G}} \mathbb{1}(h = e_0, r = r_0, t = e_1),$$

where $\mathbb{1}$ is the indicator function. Also, we use $*$ as a wildcard element. For example,

$$C(*, r_0, e_1) = \sum_{e_0 \in E} C(e_0, r_0, e_1),$$
$$N_r = C(*, r_0, *) = \sum_{e_0, e_1 \in E} C(e_0, r_0, e_1),$$
$$C(*, *, *) = |\mathcal{G}|.$$

For the TransE loss on a single triple $\langle h, r, t\rangle$, $\varphi(h, r, t)$, it is easy to derive the second-order derivatives,

$$\begin{aligned}&\nabla^2_{\mathbf{h},\mathbf{h}}\varphi(h,r,t) = \nabla^2_{\mathbf{r},\mathbf{r}}\varphi(h,r,t) \\ &= \nabla^2_{\mathbf{t},\mathbf{t}}\varphi(h,r,t) = \nabla^2_{\mathbf{h},\mathbf{r}}\varphi(h,r,t) \\ &= \nabla^2_{\mathbf{r},\mathbf{h}}\varphi(h,r,t) = -\nabla^2_{\mathbf{h},\mathbf{t}}\varphi(h,r,t) \\ &= -\nabla^2_{\mathbf{t},\mathbf{h}}\varphi(h,r,t) = -\nabla^2_{\mathbf{r},\mathbf{t}}\varphi(h,r,t) \\ &= -\nabla^2_{\mathbf{t},\mathbf{r}}\varphi(h,r,t) = 2I_d,\end{aligned} \tag{7}$$

where I_d is the identity matrix of $\mathbb{R}^{d\times d}$. We observe that *the value of the second-order derivative is independent of the triple*.

The expectation of Hessian matrix of the overall loss function $\mathcal{L}$ (Equation 1) consists of five parts: $\mathbb{E}\nabla^2_{e,e}\mathcal{L}$, $\mathbb{E}\nabla^2_{e,e'}\mathcal{L}$, $\mathbb{E}\nabla^2_{r,r}\mathcal{L}$, $\mathbb{E}\nabla^2_{r,r'}\mathcal{L}$, and $\mathbb{E}\nabla^2_{e,r}\mathcal{L}$, where e, e' and r, r' denotes two different entities and relations. Because we only have a single relation in each triple, we can immediately see that $\mathbb{E}\nabla^2_{r,r'}\mathcal{L}$ is always zero. Moreover, because we train TransE embeddings with negative sampling, and the relation r is the same for positive and negative samples, we know that $\mathbb{E}\nabla^2_{r,r}\mathcal{L}$ is zero as well.

We consider two types of training samples to calculate the remaining terms: e and e' appear in a positive triple (denoted as $\nabla^2\mathcal{L}_{\text{pos}}$), and e and e' are sampled to corrupt a sample ($\nabla^2\mathcal{L}_{\text{neg}}$).

For the first case, when e appears in a positive triple $\langle h, r, t\rangle$, there will be a corresponding negative sample, with 0.5 probability to be $\langle h', r, t\rangle$, where $h' \neq h$, and 0.5 probability of $\langle h, r, t'\rangle$, where $t' \neq t$. Using Equation 7, we obtain

$$\begin{aligned}&\mathbb{E}\nabla^2_{e,e}\mathcal{L}_{\text{pos}} \\ &= C(e,*,*)(\nabla^2_{\mathbf{h},\mathbf{h}}\varphi(h,r,t) \\ &-0.5\nabla^2_{\mathbf{h},\mathbf{h}}\varphi(h',r,t) - 0.5\nabla^2_{\mathbf{h},\mathbf{h}}\varphi(h,r,t')) \\ &+C(*,*,e)(\nabla^2_{\mathbf{t},\mathbf{t}}\varphi(h,r,t) \\ &-0.5\nabla^2_{\mathbf{t},\mathbf{t}}\varphi(h',r,t) - 0.5\nabla^2_{\mathbf{t},\mathbf{t}}\varphi(h,r,t')) \\ &= (C(e,*,*) + C(*,*,e))I_d = N_e I_d,\end{aligned}$$

$$\begin{aligned}&\mathbb{E}\nabla^2_{e,e'}\mathcal{L}_{\text{pos}} \\ &= C(e,*,e')(\nabla^2_{\mathbf{h},\mathbf{t}}\varphi(h,r,t) \\ &-0.5\nabla^2_{\mathbf{h},\mathbf{t}}\varphi(h',r,t) - 0.5\nabla^2_{\mathbf{h},\mathbf{t}}\varphi(h,r,t')) \\ &+C(e',*,e)(\nabla^2_{\mathbf{t},\mathbf{h}}\varphi(h,r,t) \\ &-0.5\nabla^2_{\mathbf{t},\mathbf{h}}\varphi(h',r,t) - 0.5\nabla^2_{\mathbf{t},\mathbf{h}}\varphi(h,r,t')) \\ &= -2(C(e,*,e') + C(e',*,e))I_d,\end{aligned}$$

---

[12] To ensure the results from influence function are accurate, we only use the negative samples when the embeddings are close to convergence.

and

$$\begin{aligned}
&\mathbb{E}\nabla^2_{e,r}\mathcal{L}_{\text{pos}}\\
&= C(e,r,*)(\nabla^2_{\mathbf{h},\mathbf{r}}\varphi(h,r,t)\\
&-0.5\nabla^2_{\mathbf{h},\mathbf{r}}\varphi(h',r,t) - 0.5\nabla^2_{\mathbf{h},\mathbf{r}}\varphi(h,r,t'))\\
&+C(*,r,e)(\nabla^2_{\mathbf{r},\mathbf{t}}\varphi(h,r,t)\\
&-0.5\nabla^2_{\mathbf{r},\mathbf{t}}\varphi(h',r,t) - 0.5\nabla^2_{\mathbf{r},\mathbf{t}}\varphi(h,r,t'))\\
&= (C(e,r,*) - C(*,r,e))I_d.
\end{aligned}$$

For the second case, since we corrupt a triple by uniformly sampling all entities, an entity is expected to be sampled as the head entity and the tail entity with the same probability of $1/2|E|$. Using Equation 7, we obtain

$$\begin{aligned}
&\mathbb{E}\nabla^2_{e,e}\mathcal{L}_{\text{neg}}\\
&= -2C(*,*,*)\nabla^2_{\mathbf{h},\mathbf{h}}\varphi(h,r,t)/2|E|\\
&= (-2|\mathcal{G}|/|E|)I_d,
\end{aligned}$$

$$\begin{aligned}
&\mathbb{E}\nabla^2_{e,e'}\mathcal{L}_{\text{neg}}\\
&= -C(*,*,e')\nabla^2_{\mathbf{h},\mathbf{t}}\varphi(h,r,t)/2|E|\\
&-C(e',*,*)\nabla^2_{\mathbf{t},\mathbf{h}}\varphi(h,r,t)/2|E|\\
&-C(e,*,*)\nabla^2_{\mathbf{h},\mathbf{t}}\varphi(h,r,t)/2|E|\\
&-C(*,*,e)\nabla^2_{\mathbf{t},\mathbf{h}}\varphi(h,r,t)/2|E|\\
&= (N_e/|E| + N_{e'}/|E|)I_d,
\end{aligned}$$

and

$$\begin{aligned}
&\mathbb{E}\nabla^2_{e,r}\mathcal{L}_{\text{neg}}\\
&= -C(*,r,*)\nabla^2_{\mathbf{h},\mathbf{r}}\varphi(h,r,t)/2|E|\\
&-C(*,r,*)\nabla^2_{\mathbf{t},\mathbf{r}}\varphi(h,r,t)/2|E|\\
&= 0.
\end{aligned}$$

Putting $\mathcal{L}_{\text{pos}}$ and $\mathcal{L}_{\text{neg}}$ together, we obtain

$$\begin{aligned}
&\mathbb{E}\nabla^2_{e,e}\mathcal{L} = (N_e - 2|\mathcal{G}|/|E|)I_d = \alpha_{ee}I_d,\\
&\mathbb{E}\nabla^2_{e,r}\mathcal{L} = (C(e,r,*) - C(*,r,e))I_d = \alpha_{er}I_d,\\
&\mathbb{E}\nabla^2_{e,e'}\mathcal{L} = (N_e/|E| + N_{e'}/|E|\\
&-2C(e,*,e') - 2C(e',*,e))I_d = \alpha_{ee'}I_d,\\
&\mathbb{E}\nabla^2_{r,r}\mathcal{L} = 0,\\
&\mathbb{E}\nabla^2_{r,r'}\mathcal{L} = 0.
\end{aligned}$$

□

Derivations of Remark 2. Clearly, the magnitude of non-zero diagonal terms of the Hessian (i.e. $\nabla^2_{\mathbf{e},\mathbf{e}}\mathcal{L}$) are much larger than those of the non-zero non-diagonal terms (i.e. $\nabla^2_{\mathbf{e},\mathbf{r}}\mathcal{L}$ and $\nabla^2_{\mathbf{e},\mathbf{e}'}\mathcal{L}$), because the former only requires the occurrence of e (mostly hundreds or thousands of times for human entities), while the latter requires the co-occurrence of two terms (usually once or much smaller than the number of occurrences of the corresponding entity). We therefore propose to *approximate the Hessian matrix with its diagonal elements*. With such approximation, we estimate the expectation of the Hessian matrix as

$$\mathbb{E}H_{\hat{\theta}} \approx \text{diag}\{\underbrace{\cdots, \alpha_{ee}I_d, \cdots}_{\text{entities}}, \underbrace{\cdots, 0, \cdots}_{\text{relations}}\},$$

where $\alpha_{ee} = N_e - 2|\mathcal{G}|/|E|$. □

Proof of Corollary 4. We consider the case that the TransE parameter $\hat{\theta}$ is learned with $\langle s, r_p, f\rangle$ in KB and we perturb it to $\langle s, r_p, m\rangle$. The other direction is identical. Following Equation 4 by setting $F = \psi(s, r_p, o)$, $z = \langle s, r_g, f\rangle$, $z' = \langle s, r_g, m\rangle$ and $\varepsilon = -1/|\mathcal{G}|$, we have

$$\begin{aligned}
\mathcal{B}_{\text{in}} \approx \tfrac{1}{|\mathcal{G}|}&\nabla_\theta\psi(s,r_p,o)^\top H^{-1}_{\hat{\theta}}\\
&\left(\nabla_\theta L(z,\hat{\theta}) - \nabla_\theta L(z',\hat{\theta})\right).
\end{aligned}$$

Let $\mathbf{d}_1 = 2(\mathbf{s} + \mathbf{r_p} - \mathbf{o})$, $\nabla_\theta\psi(s, r_p, o)^\top$ equals

$$\begin{array}{ccccccccc}
 & & s & & r_p & & o & & \\
\big[& .. & \mathbf{d}_1^\top & ... & \mathbf{d}_1^\top & ... & -\mathbf{d}_1^\top & .. & \big].
\end{array}$$

On the other side, $\nabla_\theta L(z,\hat{\theta}) - \nabla_\theta L(z',\hat{\theta}) = \nabla_\theta\psi(s, r_g, f) - \nabla_\theta\psi(s, r_g, m)$ by cancelling negative samples. Let $\mathbf{d}_2 = 2(\mathbf{f} - \mathbf{m})$, $\mathbf{d}_3 = 2(\mathbf{h} + \mathbf{r}_g - \mathbf{f})$ and $\mathbf{d}_4 = 2(\mathbf{h} + \mathbf{r}_g - \mathbf{m})$, its transpose equals

$$\begin{array}{ccccccccccc}
 & & s & & r_g & & f & & m & & \\
\big[& ... & \mathbf{d}_2^\top & ... & \mathbf{d}_2^\top & ... & \mathbf{d}_3^\top & ... & -\mathbf{d}_4^\top & ... & \big].
\end{array}$$

Finally, by approximating $H_{\hat{\theta}}$ using $\mathbb{E}H_{\hat{\theta}}$ (Lemma 1), we see that only the product of $\mathbf{d_i}$ and $\mathbf{d}_2$ is non-zero. □

Derivations of Fisher et al. (2020b). To measure gender biases in KB embeddings, Fisher et al. (2020b) first define a function m to be the difference between link prediction error of male and female entity,

$$m(\theta) = \psi(s, r_g, m) - \psi(s, r_g, f).$$

Afterwards, the bias score of a person entity regarding an occupation o is the change of the link prediction error after updating the entity embedding using the gradient of m (i.e., updating $\mathbf{s}$ to make m larger),

$$\begin{aligned}\mathcal{B}'_{\text{in}} &= \psi(s', r_p, o) - \psi(s, r_p, o),\\ \text{where } \mathbf{s}' &= \mathbf{s} + \eta \frac{\mathsf{d}m}{\mathsf{ds}}.\end{aligned}$$

For L_2 TransE loss, the gradient equals to

$$\begin{aligned}\frac{\mathsf{d}m}{\mathsf{ds}} &= 2(\mathbf{s} + \mathbf{r_g} - \mathbf{f}) - 2(\mathbf{s} + \mathbf{r_g} - \mathbf{m})\\ &= 2(\mathbf{f} - \mathbf{m}).\end{aligned}$$

Therefore,

$$\begin{aligned}\mathcal{B}'_{\text{in}} &= \psi(s', r_p, o) - \psi(s, r_p, o)\\ &= (\mathbf{s} + 2\eta(\mathbf{f} - \mathbf{m}) + \mathbf{r}_p - \mathbf{o})^2 - (\mathbf{s} + \mathbf{r}_p - \mathbf{o})^2\\ &= (\mathbf{s} + \mathbf{r}_p - \mathbf{o})^2 + 4\eta(\mathbf{s} + \mathbf{r}_p - \mathbf{o})^\top(\mathbf{m} - \mathbf{f})\\ &+ 4\eta^2(\mathbf{m} - \mathbf{f})^2 - (\mathbf{s} + \mathbf{r}_p - \mathbf{o})^2\\ &= k + 4\eta(\mathbf{s} + \mathbf{r}_p - \mathbf{o})^\top(\mathbf{m} - \mathbf{f})\end{aligned}$$

Omitting the constant part $k = 4\eta^2(\mathbf{m} - \mathbf{f})^2$, we can find that $\mathcal{B}'_{\text{in}}$ is essentially the projection of link prediction error $\mathbf{s} + \mathbf{r}_p - \mathbf{o}$ onto gender subspace $\mathbf{m} - \mathbf{f}$, which is similar to $\mathcal{B}_{\text{in}}$. ☐

C Additional Results

More Figures are in the next page.

Abstract

South Asia is home to a plethora of languages, many of which severely lack access to new language technologies. This linguistic diversity also results in a research environment conducive to the study of comparative, contact, and historical linguistics—fields which necessitate the gathering of extensive data from many languages. We claim that data scatteredness (rather than scarcity) is the primary obstacle in the development of South Asian language technology, and suggest that the study of language history is uniquely aligned with surmounting this obstacle. We review recent developments in and at the intersection of South Asian NLP and historical–comparative linguistics, describing our and others' current efforts in this area. We also offer new strategies towards breaking the data barrier.

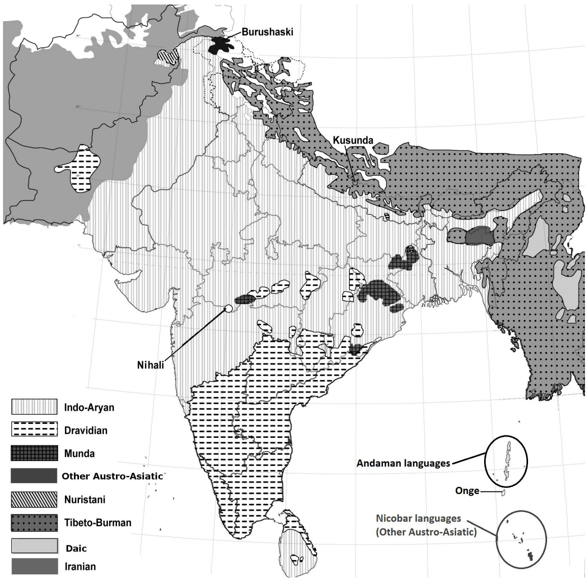

Figure 1: The major language families of South Asia (Kolichala, 2016).

1 Introduction

South Asia[1] is home to one-quarter of the world's population and boasts immense linguistic diversity (Saxena and Borin, 2008; Bashir, 2016). With members of at least four top-level major linguistic families[2] and several putative linguistic isolates, this region is a fascinating arena for linguistic research. The languages of South Asia, moreover, have a long recorded history, and have undergone complex change through genetic descent, sociolinguistic interactions, and contact influence.

Nevertheless, South Asian languages for the most part remain severely underdocumented (van Driem, 2008), and several languages with even official administrative status (e.g. Sindhi) are low-resource (if not data-scarce) for the purposes of all natural language processing tasks (Joshi et al., 2020). This data scatteredness persists despite long native traditions of linguistic description, continued language vitality with active use on the internet, and vast numbers of speakers (Rahman, 2008; Groff, 2017).

We argue that the most basic problem in NLP/CL work on South Asian languages is not data scarcity, but **data scatteredness**. There is much data to be extracted for even the most endangered languages (e.g., Burushaski, a language isolate of the northwest), from annotated corpora and grammatical descriptions compiled by linguists, *if only* one is willing to wrangle idiosyncratic data formats and digitise existing texts. Thus far, commercial interests and scientific agencies have only intermittently supported the development of language technology for the region—taking a new approach, we propose a research programme from the perspective of computational historical linguistics, outlining current data gathering initiatives in this discipline and potential benefits to other work across NLP.

0: Left-Behinds	(several hundred languages)

Table 1: A brief overview of NLP/CL research progress on South Asian languages grouped by Joshi et al. (2020)'s categories.

2 Background

Narrowing the low-resource category. Low-resource languages have recently gained attention in NLP/CL research, both due to the engineering problems of a data-scarce context and also in recognition of the historical focus on English in the field to the detriment of other languages (Hedderich et al., 2021; Ranathunga et al., 2021). This has been accompanied by debate on what languages the label encompasses (e.g. Hämäläinen, 2021).

In the South Asian context, even Hindi has been labelled low-resource in some recent work. While it is true that for certain tasks a large institutionally-backed language like Hindi can be low-resource, we propose that 'low-resource' languages can be better described with two kinds of situations:

- **Data scatteredness**: Data is available (perhaps even abundant), but due to issues in digitisation, cataloguing, and labelling and annotation it has not been leveraged to its full potential.
- **Data scarcity**: Data is not available or very limited to begin with, and without collecting or creating new data we do not have enough to work with.

The state of NLP in South Asia. So far, initiatives for improving language technology in South Asia have largely focused on data-scattered (not data-scarce) languages with official status and some degree of standardisation. These include cross-lingual projects such as IndicNLPSuite (Kakwani et al., 2020), the EMILLE corpus (McEnery et al., 2000), and iNLTK (Arora, 2020), and workshops like DravidianLangTech (Chakravarthi et al., 2021) and WILDRE (Jha et al., 2020). As table 1 shows, only a select few languages benefit from NLP research—even fewer benefit from (commericialised) products like Google Translate or OCR tools. Truly data-scarce langauges (e.g. Kangri, Tulu) lack instituational status and have been largely unstudied because the challenges are different and harder to surmount.

NLP/CL has proven to be an expansive field as of late. Computational historical linguistics is inextricably linked with computational approaches to fundamental linguistic tasks: corpus building, POS tagging and dependency parsing, morphological analysers, and lexical databases. Work on these has progressed fast for the big languages. For example, Hindi, the highest-resourced South Asian language, has massive hand-annotated dependency treebanks (Bhatt et al., 2009), state-of-the-art neural distributional semantic transformer models (Jain et al., 2020; Khanuja et al., 2021), and machine translation models to and from English (Saini and Sahula, 2018).

This is not to say that there are no resources at all for the languages Joshi et al. (2020) terms "the Left-Behinds". Linguists, for example, have compiled rudimentary treebanks for many languages, simply waiting to be digitised and converted to a multilingual format like Universal Dependencies; these include Palula (Liljegren and Haider, 2015) and Toda (Emeneau, 1984), which are yet to be the subject of any NLP research work. There are also new treebanks in Universal Dependencies for Kangri, Mandeali, Bhojpuri (Ojha and Zeman, 2020), and Magahi.

Historical/comparative linguistics. Historical linguistics is concerned with describing change of all kinds (phonological, morphological, syntactic, etc.) in language over time and the factors (social, cognitive, evolutionary) that contribute to that change. Comparative linguistics aims to use this historical study to relate languages and reconstruct earlier stages and common ancestors of related languages (Campbell, 2013).

The study of historical and comparative linguistics has a long history in South Asia, beginning well before similar threads of inquiry in the Western linguistic tradition, with grammarians like Pāṇini (c. 5th century BCE) and Hēmacandra (1088–1173) analysing historical and dialectal language from a comparative perspective.

Following the recognition by Western philologists of an Indo-European language family that includes Sanskrit, comparative study of the languages of South Asia began in earnest. As a result, several comprehensive comparative grammars featuring the Dravidian (Caldwell, 1856; Andronov, 2003; Krishnamurti, 2003) and Indo-Aryan families (Beames, 1872; Hoernlé, 1880; Bloch, 1934; Masica, 1993) have appeared in the years since. Emeneau (1956) was the first to posit a South Asian zone of language contact and convergence spanning multiple families. Subsequent work on micro-areal zones has yielded many insights into the nature of linguistic interactions in the region (Peterson, 2017; Liljegren et al., 2021; Toulmin, 2006).

The sole South Asia-wide linguistic data collection effort ever be undertaken was the **Linguistic Survey of India**, completed about a century ago (Grierson, 1903–1928). To date, there has been no comparable centralised data resource on South Asian languages of its magnitude–covering typological features, the lexicon, and sociolinguistic phenomena.

Data in the earliest comparative works was frequently sourced from high-prestige standard varieties like Delhi Hindi, with progress on studying and collecting data from more localised lects largely proceeding in isolation. Compilation of comparative data continued sporadically throughout the 20th century, resulting in works such as the *Comparative Dictionary of the Indo-Aryan Languages* (Turner, 1962–1966) and the *Dravidian Etymology Dictionary* (Burrow and Emeneau, 1984) which attempt at a more diverse spectrum of language data. Meanwhile, progress on documentation and comparative analysis of the Austroasiatic (Anderson, 2008), Sino-Tibetan, and isolate languages (e.g. Burushaski, Nihali, Kusunda) of South Asia is still in its infancy. As a consequence, studies drawing upon their data for purposes such as substrate analysis often lack nuance and family-internal consistency.

3 Ongoing work

Having established the issue of data scatteredness, the mutual benefit inherent to data collection (for historical/comparative linguistic work and other NLP tasks), as well as possible interesting avenues for future research, we present a compilation of our ongoing projects in this direction, most involving languages that have not been studied in NLP before.

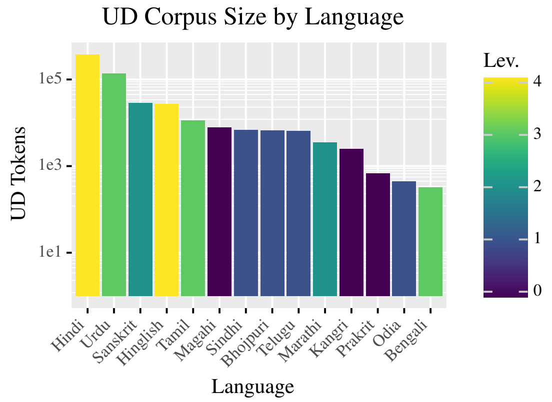

Figure 2: Universal Dependencies corpus sizes, in tokens, for all South Asian languages available thus far. Colors correspond to Joshi et al. (2020)'s level categorization.

3.1 Dependency treebanks

Structured, syntactically-parsed corpora are not only essential for (1) **downstream NLP tasks** such as information extraction (Gamallo et al., 2012) and semantic role labelling (Li et al., 2019), but also have the potential to (2) aid quantitative **comparative and historical linguistic study**. Parsing according to several formalisms is possible, though dependency formalisms in particular are better equipped to handle the flexible word-order characteristic of many South Asian languages (assuming the parsing algorithm used adequately handles non-projective dependency trees[3]) (Palmer et al., 2009).

Multilingual dependency formalisms such as Universal Dependencies (UD) (Nivre et al., 2016) have established consistent guidelines for the annotation of binary dependency relations, morphology, and other linguistic features, resulting in the recent appearance of treebanks for several data-scarce languages of the region (Bhojpuri, Kangri, etc.) as well as their older diachronic stages (Vedic and

---

[3] For vertex set V, weighted edge set $E \subseteq \{i \xrightarrow{w} j \mid i,j \in \mathbb{R}, w \in \mathbb{R}\}$, and root $\rho \in V$, let $G = (\rho, V, E)$ be a rooted weighted directed graph. A **dependency tree** is a spanning subgraph $D = (\rho, V, E')$, $E' \subseteq E$ subject to the following well-formedness constraints (Zmigrod et al., 2020):

(C1) Each non-root vertex of D has one incoming edge
(C2) D is acyclic
(C3) Root ρ of D has exactly one outgoing edge

In other words, dependency trees are *arborescences* (directed, rooted trees) equipped with the root constraint (C3). Graph-based parsing algorithms find the optimal dependency tree D^*, that is, the dependency tree D with maximum total edge weight in the set of all possible dependency trees $D(G)$, for a given sentence (maximum weight spanning arborescence). A **treebank** is a corpus of such dependency trees.

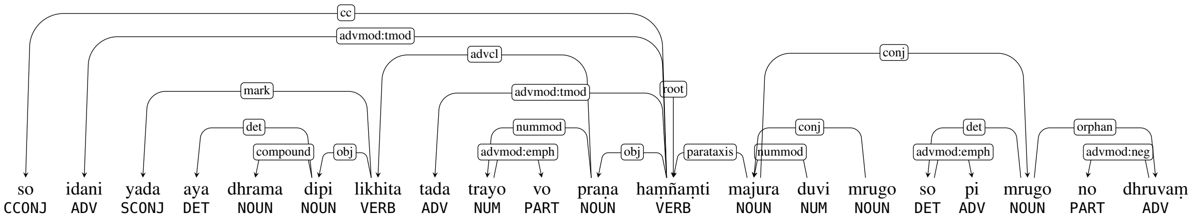

Figure 3: A sample dependency-parse from the Ashokan Prakrit UD treebank (Shahbazgarhi dialect)

Classical Sanskrit).

Towards the second goal listed above, Farris and Arora (2022) compiled a UD treebank for the Ashokan Prakrit dialect continuum–a parallel corpus of 14 pillar/rock inscriptions in six Middle Indo-Aryan (MIA) dialects dating back to the 3rd c. BCE. As the first study of MIA from a computational perspective, this work calls for an analysis of Indo-Aryan regional fragmentation through dialectometry, approaching contentious linguistic issues with statistical arguments curated using treebank data.

In a similar vein, we are currently working towards filling other chronological gaps in corpora (e.g. the Old Sinhala Sīgiri Graffiti of the Early New Indo-Aryan stage) through treebanking *in parallel* with their modern stages (e.g. Sinhala). To the best of our knowledge, we are unaware of any studies involving such **diachronic transfer** frameworks, where knowledge transfer between two historically-separated stages of the same language can be used to dependency-parse a given stage using resources from the other. Other historically-attested langauges we plan to include in this pipeline include Old Kashmiri, Old Maldivian, and Old Tamil.

In terms of modern South Asian languages, there has been recent diversification from combined efforts, such as an upcoming dependency parsing shared task at the WILDRE 2022 workshop based on new treebanks (Nallani et al., 2020; Ojha and Zeman, 2020).

Multilingual dependency parsing. More broadly, we are interested in cross-lingual transfer models (Duong et al., 2015; Guo et al., 2015; Schuster et al., 2019) as a means of expediting dependency parsing for data-scarce South-Asian languages. A similar approach for Uralic languages is (Lim et al., 2018). They propose a dependency-parsing model for North Saami and Komi using annotated corpora and bilingual word-embeddings from high-resourced genetically related (Finnish) and typologically similar (Russian) languages, without the requirement of extensive parallel texts for training. They conclude that while genetically related pairs (Komi–Finnish, North Saami–Finnish) allow for highly efficient parsing, pairs of unrelated languages in contact (Komi–Russian) also provide valuable input for further correction. Given the languages of South Asia exhibit common typological features by virtue of sharing a linguistic area, treebanking efforts will undoubtedly beneft from a multilingual dependency parsing approach. Languages like Sindhi, Punjabi, and Sinhala, which have genetic relatives and contact languages that are comparatively more resourced, are our immediate targets for such efforts.

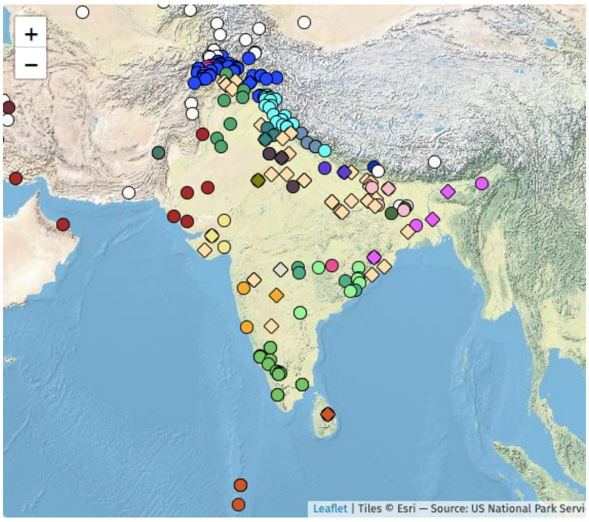

Figure 4: A map of languages included in Jambu, colour-coded by subfamily designation with point-geometry variation by diachronic stage.

3.2 *Jambu* etymological database

One of our major efforts in data-collection for the region has been the **Jambu** project. Jambu is a compiled cognate lexicon of all South Asian languages, cutting across phylogenetic groupings and historical language stages. It has a web interface online at `https://neojambu.glitch.me/`. It includes data parsed and compiled from the Uni-

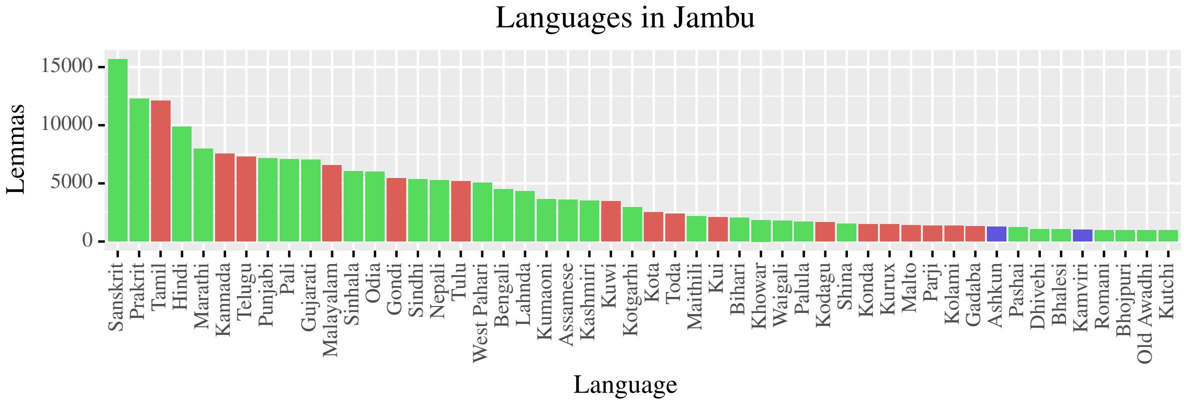

Figure 5: Top 50 languages by number of lemmas included in the Jambu database, colour-coded by language family (green = Indo-Aryan, red = Dravidian, blue = Nuristani).

versity of Chicago's Digital Dictionaries of South Asia project (Turner, 1962–1966; Burrow and Emeneau, 1984), existing web databases (Liljegren et al., 2021; Strand, 1997–2021), and individual articles and theses (Toulmin, 2006; Jouanne, 2014), totalling 294 lects and 202,653 lemmas. Some of these sources have been used in previous work on South Asian historical linguistics, e.g. Cathcart and Rama (2020); Cathcart (2019b,a, 2020)—this is the first attempt to consolidate them. Note some previous work in this direction: while the SARVA project (Southworth, 2005) did not reach fruition, a searchable database of Dravidian cognates was developed by Suresh Kolichala under its auspices.[4]

Past etymological research in South Asian languages was primarily focused on internal comparisons within linguistic families. Unknown etyma was often blindly attributed to Dravidian or Munda without comprehensive cross-linguistic analyses.[5] In fact, we find a large number of common words in languages of several families with uncertain origin, possibly substrate loans from undocumented languages.[6] In order to provide reliable data for the robust reconstruction of the history of the ancient linguistic contact, a comprehensive South Asia-wide linguistic data is desideratum.

Consolidating Indo-Aryan data. While Turner (1962–1966) and its supplements remain the undisputed gold standard for Indo-Aryan comparative etymologies, many later works on individual languages have considerably expanded our knowledge of cognate relations in underdocumented languages; e.g. Liljegren et al. (2021); Toulmin (2006); Zoller (2005). Inclusion of data from these newer works is ongoing. We also expanded coverage of the isolated and linguistically archaic Nuristani lects (Strand, 1997–2021), which are contended not to be Indo-Aryan—comparative lexical data will help cement their exact phylogenetic status.

Updates to Dravidian data. A *Dravidian Etymological Dictionary* published by Burrow and Emeneau (1984) (2nd edition; abbreviated DEDR) remains the latest effort to gather etymological data on Dravidian. Although Krishnamurti (2003) provides reconstructions for about 500 entries, systematic historical reconstruction for all known cognates of Dravidian is still pending. Subrahmanyam (2011) published an update to the DEDR utilizing new data on several non-literary languages that became available after 1984.

Recent fieldwork on several non-literary languages have produced grammars with new vocabulary lists, providing rich data to be updated in DEDR. In addition, several dictionaries with attempted etymologies for many literary languages have appeared since 1984, and can become a source for the realignment of cognates as well as new additions.

Cognate databases in NLP. The obvious benefit of cognate databases for upstream NLP tasks is for

---

[4] `http://kolichala.com/DEDR/`

[5] Recent comparative work on Munda and Indo-Aryan contact such as Ivani et al. (2020) in general find very limited influence of Munda, restricted primarily to the (eastern) Indo-Aryan languages in close proximity with them. Prior work had a tendency to exaggerate the impact of Munda to explain unusual features of other Indo-Aryan languages; notably, Witzel (1999), who advocated for a historical 'Para-Munda' family that influenced Indo-Aryan as far as in the northwest, the historical location of Rigvedic Sanskrit.

[6] Dr. Felix Rau (p.c.) terms these unattested substrate(s) 'the **big X** of South Asian linguistic history', and other (possible same) substrate(s) responsible for words reconstructable to Proto-Munda without secure cognates in other Austroasiatic branches 'the **big Y**'.

data-scarce languages that lack adequate corpora on the web. Similar work in this area is the panlingual CogNet (Batsuren et al., 2019), and also earlier WordNets (Miller, 1995). Cognate data can be used for transfer learning, where a data-scarce language can map onto existing models for higher-resource languages, such as a distributional semantic model which generally requires massive corpora to train (Sharoff, 2017). Typological data in general offers modest improvements in performance on a variety of NLP tasks (Ponti et al., 2019).

Unified transcription. Since many languages of South Asia are unwritten or are lacking standardised orthographies (even in their respective linguistics works), we developed a preliminary system for phonemic transcription of all South Asian languages, which all our cognate data will be converted to. For cognate identification and reconstruction work (both by humans and using NLP tools), a unified phonemic representation is important. This system combines features of the International Alphabet of Sanskrit Transliteration (IAST)[7] with IPA and Americanist phonetic transcription systems. Future work will outline it in depth, along with examples of its focus on cross-family diacritical consistency.

3.3 Historical linguistic analyses

One of our main objectives for building extensive comparative lexical and grammatical databases is to ensure credible data from up-to-date, modern sources are available to researchers working on comparative and diachronic linguistics in the South Asian linguistic area. Historical linguistics work needs data, and in South Asia too much work has progressed without including data from non-standardised (even if documented) languages, to the detriment of our understanding of South Asian linguistic history post-Sanskrit (Pystenen, 2022).

Below, we highlight two such projects we are currently engaged in involving three data-scarce languages of northern Pakistan: Burushaski, Gawri, and Torwali (Torwali, 2018).

3.3.1 Gawri tonogenesis and UniMorph

The languages of northern Pakistan have been synchronically analyzed to have phonemic tonal contrasts. Baart (2003) has classified such tonal languages into three broad groups based on the type of tonal contrast displayed:

- *Shina-type*: Shina varieties, Palula, Indus Kohistani (all Indo-Aryan), Burushaski (isolate) etc.
- *Punjabi-type*: Punjabi, Hindko, some Gujari varieties, extending into the Himachali languages of northern India, as well as Kishtwari,[8] which is usually classified as a divergent dialect of Kashmiri (all Indo-Aryan).
- *Kalami-type*: Gawri (Kalami), Kalkoti and Torwali (all Indo-Aryan) and possibly other undiscovered varieties of the area.

To these, one may also add the simpler accentual systems of Kalasha-mon (Heegård-Petersen, 2015) and Khowar (Liljegren and Khan, 2017), which we term *Chitrali-type*.

The tonal system and the historical mechanism of tonogenesis is broadly understood for Punjabi proper and some Hindko varieties (Shackle, 1980; Bashir and Conners, 2019; Bhatia, 2013), but specifics for individual varieties further east (Kishtwari and Himachali) remain underdescribed (Hendriksen, 1986; Jouanne, 2014). This system arises primarily from the disappearance of phonemic breathy voice, but the phonetic specifics differ from language to language. The Shina-type tonal system is both the best described and the best understood diachronically. It continues the Vedic (hence Indo-European) pitch-accent system subject to later changes necessitated by regular apocope (Liljegren, 2008, 2016; Kümmel, 2015). Vedic pitch-accent is also partly continued by the Chitrali-type accentual system (Heegård-Petersen, 2012), though less conservatively.

The tonal diachrony of the Kalami-type system, on the other hand, has not yet been fully understood. Part of the reason is that this system is considerably more complex than the other three accentual systems, contrasting as many as five distinct tonemes (Baart, 1997; Lunsford, 2001; Liljegren, 2013). In ongoing work, based on the Gawri data compiled from Baart (1997, 1999); Baart and Sagar (2004); Baart et al. (2004), we are investigating the origin of the system, and will be appended in the future by Torwali data we are now collecting.

Morphology in NLP. In addition to working out the history of the Kalami-type tonal system, we intend to incoporate our annotated lexical dataset into the **UniMorph** database (Kirov et al., 2018). The morphology of Gawri and Torwali marks gender,

[7] `https://en.wikipedia.org/wiki/International_Alphabet_of_Sanskrit_Transliteration`

[8] Not mentioned in Baart (2003), but independently identified by one of the present authors.

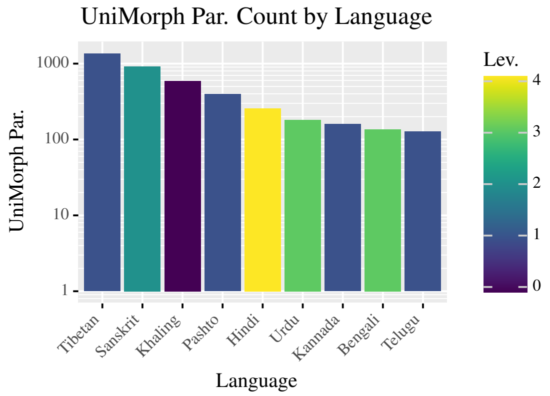

Figure 6: UniMorph paradigm counts for all South Asian languages available thus far. Colors correspond to Joshi et al. (2020)'s level categorization.

number and case for nouns and adjectives primarily by tonal changes and vowel alterations (historical umlaut) unlike other Indo-Aryan languages which use suffixation, though they still encode much the same categories and do not behave any different syntactically either. This makes them prime targets for testing out computational methods for morphological analysis, especially to compare performance vis-à-vis a related language like Hindi that has a similar grammar but different morphological profile.

UniMorph has only a few South Asian languages thus far, as shown in figure 6—this is part of a broader project to expand coverage in the region, using existing morphological data stored in analysers (e.g. for Sindhi, Motlani et al., 2016) and grammars (e.g. for Palula, Liljegren et al., 2021). In this vein, we also mention that UniMorph has only a handful of languages that signal morphological alterations tonally. So, our contribution will also improve typological diversity in the database to a considerable extent.

3.3.2 Proto-Burushaski reconstruction

Our understanding of the linguistic pre-history of South Asia is heavily reliant on disciplined studies of the histories of the non-Indo-European languages of the subcontinent. This is primarily because while we do have reliable estimates on the time-frame of Indo-European migration into the subcontinent, for the families endemic to the region (including isolates) analogous dating is not possible.

Burushaski, spoken in a few mountain valleys of the Karakoram, is among these endemic languages of South Asia. It has attracted quite a bit of scholarly attention since its academic discovery as it stands out both typologically and genealogically in its current neighborhood (cf. the latest descriptive grammars Berger (1974, 1998); Munshi (2018); Yoshioka (2012)). The history of the language and its speakers is virtually unknown until the first linguistic documentation in the mid-nineteenth century. The first secure pre-modern attestation of Burushaski speakers is in Tibetan chronicles dating from the ninth century where a people *bru-ža* or *bru-śa* to the west of Tibet find mention (Jäschke, 1881).[9,10]

As of now, both major varieties of Burushaski are well-documented, but there has been precious little comparative work done. The dictionaries in Berger (1974, 1998) lay the foundation of comparative studies by identifying several layers of potential loans in the language, cf. also Rybatzki (2010). Conversely, potential Burushaski interaction with and influence on the older stages of Indo-Iranian have been explored in Tikkanen (1988); Kümmel (2018), the former mainly dealing with how Burushaski broadly fits into the South Asian linguistic zone. A handful of Burushaski loans in Purik Tibetan are identified in Zemp (2018), not all of them convincing, and Steblin-Kamenskij (1999) contains shared lexemes with Wakhi. More speculative are the claimed Burushaski loans in (Proto-)Romani collected in Berger (1959), believed to be borrowed before the Roma migrated westward toward Europe (presumably) through Burushaski territory.

However, all these studies share a common drawback in that we do not yet have a principled way of identifying Burushaski lexemes or grammatical features. A first step toward this goal is Holst (2014), where the author attempts an internal reconstruction of Burushaski through a comparative lexical and morphological study of the two main dialect groups of Yasin and Hunza–Nager. Holst's work, though, is still just a preliminary investigation and there is much to be added and improved on. In particular, the book does not undertake a systematic study of loanwords to and from neighboring languages as previous areal studies involving Burushaski have, nor does it exhaustively utilize the

---

[9] We are grateful to Dr. Diego Loukota (p.c.) for informing us that a short text in the *bru-śa* language is also attested in Tibetan records with translation in Sanskrit. We are, however, not aware of any scholarly attempt to interpret said text through modern Burushaski.

[10] It is also possible that an older ethnonym recorded as Sanskrit *mūja-*, *maujavata-* and Avestan *muža-* refer to the same people but that is harder to establish.

descriptive literature available resulting in a few avoidable but significant errors of interpretation (Munshi, 2015). This is a major shortcoming because external comparisons are a vital component to reconstructing the histories of language isolates and smaller families, cf. Trask (2013) for Basque and Nikolaeva (2011) for Yukaghir, among others.

Computational reconstruction. We have already started a principled reconstruction of Proto-Burushaski building on Holst's work, but utilizing more sources and laying a greater emphasis on loanword etymologizing and chronologizing. Our databases, compiled from available lexical and descriptive sources, are intended to aid this goal of comparative analysis, as well as to make data from Burushaski and neighboring languages available to other researchers.

Proto-language reconstruction is an interesting task in computational historical linguistics, and so far work has been under way in a supervised setting on known, high-quality cognate data across related languages, e.g. on Romance languages (Ciobanu and Dinu, 2018; Meloni et al., 2021).

Low-resource dependency corpora. In addition, starting with annotated texts from descriptive grammars, we plan to build a dependency treebank for Burushaski as described in §3.1. Burushaski is a low-resourced language in the sense that its domain of use is very restricted and there is no readily available internet corpus one can subject to sophisticated (computational) linguistic analyses automatically.

However, as mentioned before, there has been a steady stream of quality descriptive work on it and all published grammars come with a wealth of oral texts one can build a functional corpus with—indicating some data-scatteredness that can be leveraged.

4 Future Work

The data resources we are in the process of compiling for South Asian languages will enable a variety of research to be conducted into language history. We lay out some of the immediate potential pathways for this further research in hopes of stimulating work in this area.

4.1 Substrate studies and language history

A substrate language is one that loans words into a language of higher prestige. A perennial question in South Asian language history for at least a century has been the Indus Valley Civilisation inscriptionary corpus, and the problem of deciphering it (if it even encodes a language) and whether it belongs to a known language family of South Asia or something else entirely (Farmer et al., 2004; Fairservis, 1983). Notably, in the mid-20th century a team of Finnish and Soviet linguists and computer scientists claimed evidence that the Indus inscriptions represent a Dravidian language (Parpola, 1986).

Recent computational information-theoretic work also suggests language-like properties in the text, a subject of subsequent vociferous debate (Rao et al., 2009, 2010). A serious issue is that we do not have sufficiently diverse data from modern languages of the region against which to compare any purported decipherments of the Indus script (e.g. Proto-Dravidian reconstruction is as of now still in a preliminary stage), and thus even if the Indus language provided any substrate loans into modern families, we would be unable to comprehensively list out possible candidates. The *Jambu* database can help inform research on substrate contact in the languages of the region.

4.2 Text digitisation and OCR

One of the major bottlenecks in compiling existing linguistic data on South Asian languages is that it remains machine-unreadable. For example, many linguistics theses completed at Indian universities have recently been digitised and uploaded to Shodhganga,[11] but most are scanned images in PDF format. Optical character recognition (OCR) of such texts also requires difficult parsing of diacritics and low-resource scripts.

A recent initiative to digitise old linguistic data is the digitisation of the Linguistic Survey of India (Grierson, 1903–1928) under the project *South Asia as a linguistic area? Exploring big-data methods in areal and genetic linguistics* (Borin et al., 2020, 2018, 2014). Using OCR and subsequent information extraction from the text, Borin et al. have shown that "old" data still has much to tell for the computational study of typology and comparative linguistics.

Future work on extracting data from non-digitised South Asian language sources will have to use OCR, possibly a neural model finetuned for the purposes of our domain on a platform like Transkribus (Kahle et al., 2017).

---

4.3 Fieldwork initiatives

Hämäläinen (2021), calling for the NLP community to make a consistent distinction between "endangered" and "low-resource" languages, implores researchers to 'stop complaining about how low-resourced [a language] is, [and] get up and gather the data.'

In response to this call, we announce several currently-underway (online) fieldwork/data elicitation efforts for Indo-Aryan languages that are both endangered and data-scarce. These include Kholosi, Poguli, Kishtwari, Bhaderwahi, Torwali, and certain divergent dialects of Maldivian (e.g. Huvadhoo). By virtue of their geographical spread (Northern India/Pakistan, Iran, Maldives), linguistic data collected from these languages will further enable the consturction of typologically viable datasets for both NLP and computational historical linguistic tasks.

5 Conclusion

In this paper, we gave an overview of the state of NLP in South Asia with a special focus on historical–comparative linguistics, a research programme of which we believe will help address the issue of data scatteredness. South Asian languages are not obliged to remain low-resource (in the NLP sense), and have plenty of speakers who would like access to and would benefit from language technologies, along with a multitude of raw linguistic resources that can be used to cultivate them. Incentives have not been in place to support those demands, however, so we suggest an alternative route founded in linguistic research to gather data.

Collective efforts have had great success recently in NLP—besides institutional efforts like the Stanford Center for Research on Foundation Models (Bommasani et al., 2021) and HuggingFace's BigScience Workshop,[12] there are grassroots organisations like MaskhaneNLP for African languages (Nekoto et al., 2020) and AI4Bharat (Kakwani et al., 2020) that are working towards improving resource availability. Our proposals in this paper are the first seeds of a programme similar in spirit, motivated by a dual interest in understanding South Asian language history and remedying inequalities in technological availability.

Faithful or Extractive? On Mitigating the Faithfulness-Abstractiveness Trade-off in Abstractive Summarization

Faisal Ladhak[1*] **Esin Durmus**[2*] **He He**[3] **Claire Cardie**[4] **Kathleen McKeown**[1]
[1]Columbia University [2]Stanford University
[3]New York University [4]Cornell University

Abstract

Despite recent progress in abstractive summarization, systems still suffer from faithfulness errors. While prior work has proposed models that improve faithfulness, it is unclear whether the improvement comes from an increased level of extractiveness of the model outputs as one naive way to improve faithfulness is to make summarization models more extractive. In this work, we present a framework for evaluating the *effective faithfulness* of summarization systems, by generating a *faithfulness-abstractiveness trade-off curve* that serves as a *control* at different operating points on the abstractiveness spectrum. We then show that the baseline system as well as recently proposed methods for improving faithfulness, fail to consistently improve over the *control* at the same level of abstractiveness. Finally, we learn a selector to identify the most faithful and abstractive summary for a given document, and show that this system can attain higher faithfulness scores in human evaluations while being more abstractive than the baseline system on two datasets. Moreover, we show that our system is able to achieve a better faithfulness-abstractiveness trade-off than the *control* at the same level of abstractiveness.

1 Introduction

Generating abstractive summaries of documents has been a long-standing goal of summarization. While there has been tremendous progress towards this goal (Kryściński et al., 2018; Dong et al., 2019; Zhang et al., 2019; Lewis et al., 2020), abstractive summarization systems still suffer from faithfulness errors (Cao et al., 2018), generating information that is not present in the original text. This has led to an increased research in faithfulness evaluation of summarization systems (Falke et al., 2019; Kryscinski et al., 2020; Durmus et al., 2020) as well as methods to improve faithfulness of generated summaries (Kang and Hashimoto, 2020; Chen et al., 2021). Intuitively, one straightforward way of improving faithfulness of generated summaries is to copy a larger amount of content from the source article (i.e. more extraction). Thus, any methods that increase the level of extractiveness, whether intentionally or not, would improve faithfulness. Without reported extractiveness, it is unclear whether prior improvements mainly arise from increased extractiveness. We argue that in order to make progress in abstractive summarization, it is important to tease apart faithfulness improvements due to increased extractiveness versus improvements due to improved abstraction.

In order to tease this apart, we develop a framework for evaluating progress in faithfulness, by considering the *effective faithfulness*, i.e. the improvement in faithfulness over a baseline system (*control*) operating at the same level of extractiveness. In particular, we split the training examples into different groups by the extractiveness of the summary, and train the *control models* on each group. Each of these models corresponds to a specific tradeoff between abstractiveness and faithfulness, forming a *trade-off curve* indicating how much faithfulness can be improved solely by increasing extractiveness. Systems that improve *effective faithfulness* should lie above this curve.

Using this framework, we show that the improved faithfulness of recently proposed methods comes mainly from an increased extractiveness. We then conduct further analysis to explore whether it is possible to have a system that can be both more abstractive and more faithful than the baseline system. We train a selector on a small set of human-annotated data that, given a set of output summaries with varying levels of extractiveness, picks the most abstractive output that is faithful to the source. Our proposed system is both more abstractive and more faithful than the baseline. Moreover, we show that

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 1410 - 1421
May 22-27, 2022

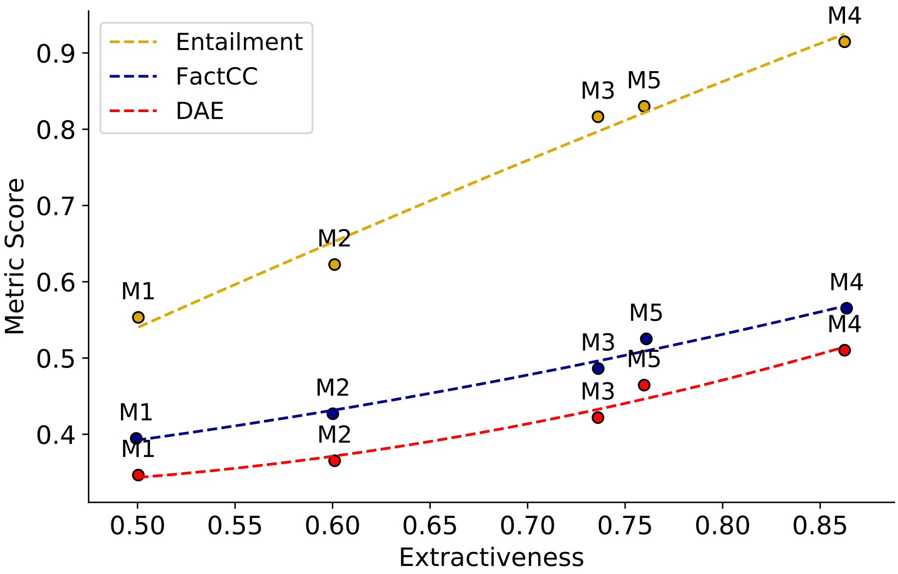

Figure 1: Extractiveness of generated outputs versus automated metric scores for Entailment, FactCC and DAE on the Gigaword dataset. We use *coverage* defined in Grusky et al. (2018) to measure extractiveness, where summaries with higher coverage are more extractive. We observe that automated metrics of faithfulness are positively correlated with extractiveness.

our system is able to improve the *effective faithfulness*, achieving a better trade-off than the *control* at the same point on the abstractiveness spectrum.

To summarize, our contributions are as follows:

1. We present a framework to evaluate the progress in improving *effective faithfulness* of models considering the *control* at the same level of extractiveness.

2. We illustrate the importance of considering *effective faithfulness* by showing that recently proposed methods for improving faithfulness are able to attain higher faithfulness scores than the baseline, but do not consistently improve over the *control curve*, indicating that most of their improvements come from generating more extractive outputs, on average.

3. We propose a selector that picks the most abstractive and faithful summary from a set of possible summaries, and show that this method gets higher effective faithfulness compared to the existing methods.

2 Dataset

We conduct our study on two English abstractive summarization datasets, one from the news domain, and one from a non-news domain. For the news domain dataset, we decided against using the popular CNN/Dailymail dataset since its reference summaries tend to be very extractive (Kedzie et al., 2018; Bommasani and Cardie, 2020), making it a poor choice for studying faithfulness in abstractive summarization. Similarly, we also decided against using XSum, another popular news summarization dataset, since almost 77% of the gold reference summaries contain hallucinations (Maynez et al., 2020). Instead, we opted for Gigaword and Wikihow, which are datasets with substantial abstraction without as much hallucination problems as XSum. Gigaword reference summaries have substantially less hallucinations than XSum (Kang and Hashimoto, 2020), and WikiHow summaries tend to be of a higher quality since they are written and curated by humans (Koupaee and Wang, 2018; Ladhak et al., 2020).

Wikihow (Koupaee and Wang, 2018) is a dataset of how-to articles covering a diverse set of topics, collected from the wikihow.com website. Each article contains several paragraphs detailing step by step instructions for a procedural task. There are about 12M such paragraphs in the dataset, paired with a one sentence summary.

Gigaword (Rush et al., 2015) is a headline generation dataset that contains around 4M examples, extracted from news articles that were collected as part of the Gigaword corpus (Graff et al., 2003). The model is tasked with generating the headline of the article given the first sentence.

2.1 Dataset Extractiveness

We follow the process detailed by Grusky et al. (2018), and use *extractive fragment coverage* and *extractive fragment density* as the measures of extractiveness of a given summary. Henceforth we will refer to these as coverage and density respectively. Coverage is the percentage of words in a summary that are from the source article. Density is the average length of the text spans copied from the document that are contained in the summary. A summary that copies larger chunks of text from the source article will have a higher density.

3 Analysis on Metrics of Faithfulness

Recent studies of faithfulness evaluation have proposed model-based automated metrics to detect whether a given summary is faithful to the source article. For example, Falke et al. (2019) **(Entailment)** have studied using pretrained entailment based methods to assess the probability of the generated output being entailed by the source article. Kryscinski et al. (2020) **(FactCC)** augment hallucinated summaries by applying rule-based transformations to the document sentences and train a BERT-based model to classify whether the generated output is faithful. Goyal and Durrett (2021) **(DAE)** have collected fine-grained annotations to study word-, dependency- and sentence-level faithfulness and use these annotations to train a factuality detection model.

Figure 1 shows the relationship between the average coverage of the generated outputs (extractiveness) vs. average metric scores (faithfulness) assigned to various abstractive summarization models trained on Gigaword.[1] We observe that there is a positive correlation between extractiveness and faithfulness scores, as models whose generated summaries have a higher average coverage tend to also get higher scores for each of the faithfulness metrics. This correlation between exractiveness and faithfulness makes it unclear whether a model gets higher factuality scores simply because it is more extractive or it is capable of generating faithful summaries at the original level of extractiveness. This highlights the need for accounting for extractiveness in order to compare faithfulness across different abstractive summarization systems.

4 Evaluating Effective Faithfulness

Given that extractiveness is confounded with faithfulness, we propose a framework for evaluating *effective faithfulness*, which takes into account the extractiveness of a system. In order to do this, we first need to determine the faithfulness of a system operating at a given level of extractiveness. We call this the *Faithfulness-Abstractiveness Tradeoff* and we describe it further in §4.1. The *effective faithfulness* of a system is then simply the relative difference between the faithfulness score assigned to the system, and the score of a system operating with the same average extractiveness according to the trade-off curve.

4.1 Faithfulness-Abstractiveness Tradeoff

In order to understand the effectiveness of a proposed system for improving faithfulness, we need to be able to account for its extractiveness. We finetune pre-trained BART models (Lewis et al., 2020) for different levels of extractiveness, without any explicit recourse for improving faithfulness. We then use these systems to create a *faithfulness-abstractiveness trade-off curve* that can serve as a control to measure the *effective faithfulness* of summarization systems. Models that improve *effective faithfulness* should lie above the *faithfulness-abstractiveness trade-off curve*.[2]

In particular, we sub-sample the training data into extractiveness quartiles by computing the coverage of the references with respect to the source articles. We then fine-tune BART on each of these quartiles to obtain **quartile models** with varying level of extractiveness. In addition, we also finetune BART on all of the data, which we call the **baseline**.

We collect faithfulness annotations for summaries generated by each of these models for a random sample of 200 articles. We collect three annotations per example on Amazon Mechanical Turk asking whether an output is faithful or unfaithful with respect to the corresponding source article. We then compute the percentage of annotators that selects "faithful", and use this as the faithfulness

---

[1] These are the baseline and quartile models that are described in §4.1.

Article	Once you decide what to outsource, look for the right contractors. Start by asking for referrals from your own professional network. Talk to other business owners and professionals about how and where they outsource. You can also check professional associations or trade groups field in which you are trying to outsource work. Use other social media platforms such as Facebook or Twitter to advertise what you are looking for. Alternately, you can connect with contractors and freelancers on sites such as eLance, Guru and oDesk. These websites allow business owners to place an ad that describes what kind of work they need to have done, and contractors respond with their qualifications and rates. [TRUNCATED] ...
Baseline	Search for contractors and freelancers to outsource the work.
Q1	Conduct an initial search for qualified contractors and freelancers.
Q2	Search for qualified contractors and freelancers to work on your project.
Q3	Search for contractors and freelancers to do the work.
Q4	Look for contractors and freelancers to bid on the work.

Table 1: Example summaries generated by the baseline and quartile models for the article "*How to Outsource Small Business Tasks*" from Wikihow dataset. The tokens that do not appear in the source article are indicated by green.

Dataset	Model	Coverage	Faithfulness
Gigaword	Baseline	76.12	83.33
	Q1	50.25	71.83
	Q2	60.57	79.50
	Q3	73.64	86.67
	Q4	86.94	89.17
Wikihow	Baseline	88.28	82.52
	Q1	81.34	67.82
	Q2	85.34	76.21
	Q3	87.59	80.35
	Q4	90.19	91.08

Table 2: Coverage and faithfulness values of the baseline and each quartile model for Gigaword and Wikihow. Quartile models with higher coverage have higher faithfulness scores.

score for each example.[3]

Table 2 shows the coverage and faithfulness scores for the baseline and the quartile models, where Q1 is the *most abstractive* and Q4 is the *most extractive* quartile.[4] We observe that the models that are fine-tuned on more extractive quartiles produce outputs with significantly higher coverage and faithfulness scores. The baseline model generates relatively extractive outputs with coverage closest to Q3 on both Gigaword and Wikihow. Furthermore, we observe that the baseline model has a higher coverage than the model fine-tuned on Q3 but it has lower faithfulness score for Gigaword.

Table 1 shows an article from the Wikihow dataset and corresponding output summaries generated by the baseline and each of the quartile models. We observe that the generated summaries are very similar in meaning; however, the output generated by the Q1 model includes a higher number of novel words (i.e. lower coverage) compared to the other models while staying faithful to the article. Conversely, Q4 model has a coverage of 1 in this example; all the words generated by this model are from the source article. On average, the Q1 model generates outputs that are more abstractive and less faithful while Q4 generates outputs that are more extractive and more faithful.

5 Mitigating the Trade-off

5.1 Oracle Experiments

We first aim to understand whether it is possible to mitigate the faithfulness-abstractiveness tradeoff by designing several oracle experiments where we have access to human judgments.

baseline + faithfulness (bf). We use the output from the baseline model if it is faithful (i.e. at least two out of three annotators agree that the output is faithful). If the baseline output is not faithful, we select the output from the quartile model that is more extractive than the baseline to see whether we can have a similar coverage as the baseline but preserve faithfulness.

baseline + faithfulness-extractiveness (bfe). This oracle system behaves similar to the one described above when the baseline output is unfaithful. However, rather than always selecting the base-

---

[3] Details of the human evaluation are included in Appendix B.

[4] Additional dataset statistics are shown in Appendix A.

Dataset		Cov.	Faithfulness
Gigaword	Baseline	76.12	83.33
	bf	77.74	89.57
	bfe	61.87	90.67
	qfe	63.55	98.00
Wikihow	Baseline	82.52	88.28
	bf	83.95	92.20
	bfe	70.52	91.32
	qfe	72.58	98.61

Table 3: Oracle coverage and faithfulness values for Gigaword and Wikihow. The oracle analysis suggests that being able to control for extractiveness can allow us to build systems that mitigate the trade-off.

line output when it is faithful, we pick the output from the quartile model that is more abstractive than the baseline whenever it is also faithful according to human judgement.

quartile + faithfulness-extractiveness (qfe). Amongst the outputs of all four quartile models, we pick the most faithful output with the highest level of abstractiveness to understand whether it is possible to generate abstractive output while remaining faithful.

Analysis. Table 3 shows the coverage and faithfulness of the baseline and each of these oracles for Gigaword and Wikihow. We observe that it is possible to be more faithful than the baseline at a similar level of abstractiveness (bf). Furthermore, we can be more abstractive than the baseline while being more faithful (bfe). Selecting the most faithful and abstractive output from the quartile models achieves a really high faithfulness score ($\approx$98%) while having significantly less coverage than the baseline. This oracle analysis suggests that it should be possible to build models that can mitigate the faithfulness-abstractiveness trade-off by controlling the level of extractiveness. Given this, we further explore whether we can learn a selector that is capable of doing this selection automatically to mitigate the faithfulness-abstractiveness trade-off.

5.2 Loss Truncation

Kang and Hashimoto (2020) have proposed a method to adaptively remove high loss examples to optimize the distinguishability of samples from the model and the reference. They have shown that the samples generated by this Loss Truncation model achieves higher factuality ratings compared to the baseline methods. We study this method to understand where it lies in terms of faithfulness-abstractiveness trade-off and whether it can achieve a improved *effective faithfulness* over the *control*.

5.3 Dependency Arc Entailment (DAE)

Goyal and Durrett (2020) have proposed a factuality evaluation metric (DAE) that evaluates whether each dependency arc in the generated output is consistent with the input. They show that their proposed metric works better than existing factuality metrics, while also being able to localize the parts of the generated output that are non-factual. Goyal and Durrett (2021) take advantage of DAE's ability to localize factuality errors, and train a summarization model only on the subset of tokens that is deemed factual according to the DAE metric. We follow their methodology to train summarization models, and assess them using our evaluation framework.

5.4 Selector Model

We aim to understand whether we can build a model that achieves a better *effective faithfulness* than Loss Truncation. We propose a selector that can identify the most abstractive but faithful output to improve this trade-off. We first generate four possible candidate summaries using the quartile models for each example in the validation set. This results in outputs with varying levels of extractiveness. For our selector, we fine-tune a FactCC model (Kryscinski et al., 2020) on the data we collected to generate the trade-off curve, using 10-fold cross validation, to assign faithfulness scores to the generated summaries (in the test folds).[5] In addition, we learn a threshold for the faithfulness score that maximizes the area under the ROC curve **(Selector-ROC)** (also using 10-fold cross validation). For each example in the test fold, we select the most abstractive candidate (amongst the four possible candidates from the quartile models) that is considered faithful according to the fintuned FactCC model (i.e. the faithfulness score is above the tuned threshold).

Instead of maximizing for the area under the ROC curve, we can also tune the faithfulness threshold to maximize F_β scores (**Selector-F_β**). Using F_β score with $\beta < 1$ allows us to assign a higher weight to the precision of our selector which would result in outputs with higher coverage and faithfulness.

---

[5] We collected annotations for 200 articles for each of the quartile models.

	Gigaword		Wikihow	
	Coverage	Faitfulness	Coverage	Faithfulness
Baseline	76.12	83.33	82.76	86.94
Loss Truncation	79.55	87.17	84.93	87.84
DAE	78.23	86.33	84.15	88.83
Selector-ROC (Ours)	64.58	84.17	78.67	87.84
Selector-F_β (Ours)				
β				
0.5	54.77	76.83	64.24	79.82
0.4	59.79	81.67	67.81	81.71
0.3	60.72	82.00	68.53	83.15
0.2	68.38	86.00	78.67	87.84
0.1	79.92	88.00	84.72	89.19

Table 4: Coverage and faithfulness scores for the baselines and our proposed methods. We show that with our method we are able to get models that are both more faithful and more abstractive than the baseline.

We find that the fine-tuning FactCC is important since the pre-trained FactCC model is trained on a different dataset and does not transfer well to our setttings. This is consistent with the findings of Goyal and Durrett (2021).

5.5 Results

Table 4 shows the coverage and faithfulness results for the baseline, Loss Truncation, DAE, and the selectors. We observe that as we use smaller values for β for Selector-F_β, we get more extractive and more faithful outputs. This allows us to have a trade-off between faithfulness and abstractiveness. Moreover, with both Selector-ROC and Selector-F_β, we produce output with less coverage but higher faithfulness scores than the baseline. For Wikihow, Selector-ROC produces outputs with lower coverage but similar faithfulness scores to Loss Truncation. We can further obtain a higher faithfulness score at a similar coverage level as DAE and Loss truncation with Selector-F_β with $\beta = 0.1$. For Gigaword, Select-ROC produces output with significantly lower coverage than Loss Truncation and DAE. Selector-F_β produces output with similar coverage to Loss Truncation with a higher faithfulness score ($\beta = 0.1$).

It is important to understand whether models improve faithfulness by simply being more extractive or if they are able to improve *effective faithfulness*. In order to understand this, we measure whether the models get improvement in faithfulness over the *control* operating at the same level of extractiveness. In Figure 2, we plot the faithfulness-abstractiveness curve with the faithfulness and abstractiveness of the quartile models. If a model lies above this curve, it improves the *effective faithfulness*. If the model is below this curve, it is not able to improve the *effective faithfulness* and it has a worse trade-off than the *control* operating at the same level of extractiveness.

For both Gigaword and Wikihow, Selector-ROC lies above the curve improving this trade-off. However, both the baseline and Loss Truncation models get worse trade-off than the *control* operating at the same level of extractiveness. Similarly, we can obtain several models that lie above the curve for both Gigaword and Wikihow using Selector-F_β. The selector approach allows us to get better *effective faithfulness* at different points in the abstractiveness-extractiveness spectrum. The DAE based model is able to improve *effective faithfulness* on the Wikihow dataset, but not on the Gigaword dataset, indicating that the improvements are not consistent across datasets. Table 5 shows example summaries generated by the baseline, Loss Truncation, DAE and the Selector-ROC models. We observe that selector model is able to generate summaries that are faithful to the original article while having more novel words and phrases in the generated summaries.

6 Related Work

There has been a lot of recent work in abstractive summarization showing that state-of-the-art systems suffer from generating inconsistent information with respect to the source article, despite their improved success in producing fluent summaries

(Falke et al., 2019; Lux et al., 2020; Wilber et al., 2021). Since word-overlap based metrics such as ROUGE have low correlation with human scores of faithfulness (Kryscinski et al., 2019; Fabbri et al., 2020), there has been significant effort to develop automated metrics that can detect such errors (Zhou et al., 2021; Gabriel et al., 2021; Pagnoni et al., 2021a). For example, Falke et al. (2019), Maynez et al. (2020) and Goyal and Durrett (2020) have proposed to assess faithfulness using entailment models, where a faithful summary should be assigned a high entailment score with respect to the original article. Kryscinski et al. (2020) presented FactCC, a weakly-supervised BERT-based entailment model, by augmenting the dataset with artificial faithfulness errors. Durmus et al. (2020) and Wang et al. (2020) proposed question-answering based evaluation frameworks by automatically generating questions from the generated summary, and comparing the corresponding answers from both the source and the generated summary in order assess information consistency. Furthermore, several benchmarks have been proposed to evaluate the strengths and weaknesses of these evaluation metric (Gabriel et al., 2021; Pagnoni et al., 2021b).

Previous studies in faithfulness evaluation, however, has not accounted for the effect of extractiveness of the output summaries. As we show in this study, the extractiveness of the output is correlated with the faithfulness scores assigned by these automated metrics. Therefore, it is not clear whether the models with higher scores are better at abstraction, or extract more from the source article. We suggest that we need to account for this confounding factor in order to assess the real progress in building models that are better at abstraction. We note that there is concurrent work that also argues for accounting for extractiveness in assessing the faithfulness of models (Dreyer et al., 2021), however, unlike our work, they do they do not propose any mitigation for the faithfulness-abstractiveness trade-off.

Improving faithfulness of summarization systems is essential for deploying these systems in real-

world scenarios, as such recent work has studied methods to improve the faithfulness of abstractive summarization systems (Matsumaru et al., 2020; Zhao et al., 2020; Dong et al., 2020; Goyal and Durrett, 2021; Xu et al., 2020; Chen et al., 2021; Zhu et al., 2021). For example, Goyal and Durrett (2021) train summarization systems by modifying the training objective to maximize the likelihood of the subset of summary tokens that are considered faithful according to their factuality detection model. Zhao et al. (2020) specifically target hallucination of quantities in generated summaries, and train a verification model that they use to re-rank summaries such that summaries containing quantities consistent with the source article are up-ranked. Although these methods have shown improvements over the compared baselines, unlike our work, they do not measure the effective faithfulness taking extractiveness of the generated outputs into account.

7 Implications and Limitations

Recent studies that propose methods to improve faithfulness evaluate progress by conducting human evaluation on generated summaries and check whether the faithfulness scores are higher for their proposed system as compared to their baselines. We show that there is a strong relationship between the extractiveness and faithfulness of generated outputs (i.e., more extractive outputs tend to be more faithful), and therefore we cannot simply disregard extractiveness in faithfulness evaluation.

We propose that we should instead be measuring *effective faithfulness* and introduce a framework that takes into account the *faithfulness-abstractiveness trade-off curve* that is generated by training *control models* at different points in the abstractiveness spectrum. We demonstrate the importance of measuring *effective faithfulness* by showing that recently proposed methods that improve faithfulness over the baseline fails to consistently improve over a simple *control* operating at the same level of abstractiveness.

We argue that measuring *effective faithfulness* is important since our goal is to build abstractive, faithful summarization systems. If the objective was to optimize for faithfulness alone, we could do so by simply building more extractive systems (such as the Q4 model we trained above).

Limitations. Note that this method relies on some diversity in the extractiveness of reference summaries, since we rely on sub-sampling to train models for the **control**. It is less likely to be effective for datasets with very little variation in the extractiveness of the generated summaries. However, in general, we see significantly more faithfulness problems for datasets with higher diversity of abstractiveness. Therefore, we suggest to account for the faithfulness-abstractiveness trade-off for such datasets in future work.

A Data Statistics

Number of examples, source article length and target summary length for each quartile are shown in Table 6. To create the quartiles, we first compute the extractiveness (e_x) of the reference summary, for each training example x, and compute the 25th (a), 50th (b), and 75th (c) percentile of the extractiveness of the training data. The quartiles are then created as follows:

$$\begin{aligned} q1 &= \{x \mid e_x \le a\} \\ q2 &= \{x \mid a < e_x \le b\} \\ q3 &= \{x \mid b < e_x \le c\} \\ q4 &= \{x \mid e_x > c\} \end{aligned}$$

Note that it is possible for there to be several points at the boundary, and therefore there are unequal number of examples in each quartile as shown in Table 6. For Gigaword, the article and summary lengths are very similar for each of the quartiles. For Wikihow, we observe that the article length is longer and summary length is shorter for more extractive quartiles.

B Human Annotation Details

We follow a similar procedure as the prior work to collect human evaluations for faithfulness of the generated summaries (Fabbri et al., 2020). Given the source articles and generated summaries, we ask annotators to judge whether the generated summary is **supported** by the article. The output is supported by the article if all the information expressed by the output can also be inferred from the article. We ask annotators to ignore minor grammatical errors and focus on the information content of the generated summaries. Figure 3 shows an example from our human evaluation.

Computing faithfulness scores. We evaluate 200 output summaries per system and each output is evaluated by 3 annotators. We restricted the study to the annotators with a high acceptance rate ($\geq 98\%$) and at least 500 HITs to ensure annotation quality.[6] We follow prior work (Durmus et al., 2020) and take the percentage of annotators who judge the summary as faithful to be the faithfulness score of a summary. To get the faithfulness score for a system, we average the summary scores across all 200 samples.

---

[6] We hired annotators from USA, UK and Australia. The data collection protocol was approved by IRB.

Dataset	Quartile	# Examples	Article Length	Summary Length
Gigaword	Q1	985,931	30.58	8.03
	Q2	961,970	32.02	8.32
	Q3	952,833	31.77	8.41
	Q4	903,223	31.05	8.17
Wikihow	Q1	328,470	50.73	7.63

Article:

The Academy Selsey suffered extensive damage and much of its contents was destroyed in the blaze on 21 August. The school's 453 pupils are currently being taught at four locations in the Selsey area. As well as classrooms, the temporary buildings will house science labs, workshops and food technology areas, the school said. The buildings, some of which have already been placed on the site by two large cranes, had previously been used to house staff and students from Bohunt School in Worthing while building work was carried out. Tom Garfield, head teacher of the academy, said: "We are absolutely delighted to see the first temporary school buildings arrive on site. It's a great milestone for us, the staff and students alike." He said once the remaining structures had arrived over the next few days the school would begin preparing the rooms for teaching.

Output 1: The first temporary school buildings have arrived at the site of a school destroyed in a fire in Selsey.

C Model details

For all summarization models, we finetune BART (406M parameters) on a single Nvidia A-100 GPU. Each model takes roughly 3 hours to train to convergence. For the selector, we finetune FactCC, on a single Nvidia A-100 GPU, using 10-Fold cross validation. Finetuning for the entire cross validation procedure takes roughly 15 minutes. We used all artifacts according to the terms indicated in their respective licenses.[7][8]

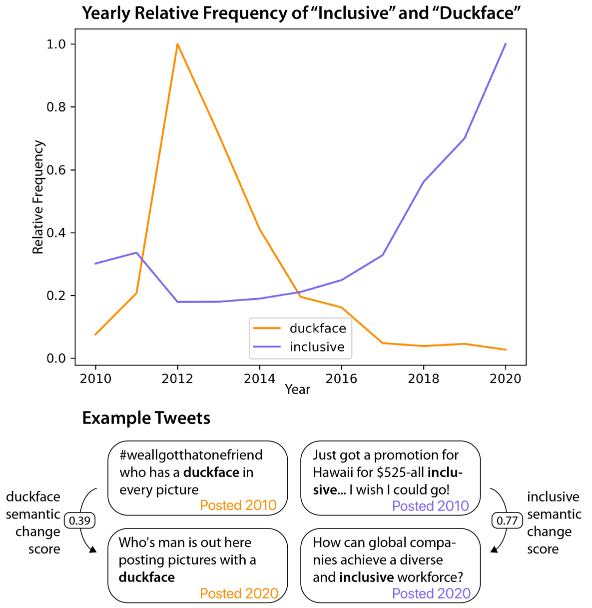
Abstract

Languages are continuously undergoing changes, and the mechanisms that underlie these changes are still a matter of debate. In this work, we approach language evolution through the lens of causality in order to model not only how various distributional factors associate with language change, but how they causally affect it. In particular, we study slang, which is an informal language that is typically restricted to a specific group or social setting. We analyze the semantic change and frequency shift of slang words and compare them to those of standard, nonslang words. With causal discovery and causal inference techniques, we measure the effect that word type (slang/nonslang) has on both semantic change and frequency shift, as well as its relationship to frequency, polysemy and part of speech. Our analysis provides some new insights in the study of language change, e.g., we show that slang words undergo less semantic change but tend to have larger frequency shifts over time.[1]

1 Introduction

Language is a continuously evolving system, constantly resculptured by its speakers. The forces that drive this evolution are many, ranging from phonetic convenience to sociocultural changes (Blank, 1999). In particular, the meanings of words and the frequencies in which they are used are not static, but rather evolve over time. Several previous works, in both historical and computational linguistics, have described diachronic mechanisms, often suggesting causal relationships. For example, semantic change, i.e. change in the meaning of a word, has both been suggested to *cause* (Wilkins, 1993; Hopper and Traugott, 2003) and *be caused by* (Hamilton et al., 2016) polysemy, while also part of speech (POS) has been implied to be a causal factor behind semantic change (Dubossarsky et al., 2016). However, none of these studies perform a causal analysis to verify these claims. Causality (Pearl, 2009) allows us to not only infer causal effects between pairs of variables, but also model their interactions with other related factors.



#weallgotthatonefriend who has a **duckface** in every picture

Who's man is out here posting pictures with a **duckface**

Just got a promotion for Hawaii for $525-all **inclusive**... I wish I could go!

How can global companies achieve a diverse and **inclusive** workforce?

Figure 1: We observe very different change dynamics for the slang word "duckface" and the nonslang word "inclusive." "Inclusive" has acquired a new meaning, reflected in a high semantic change score of 0.77 as measured by our model. "Duckface" undergoes little semantic change, scored 0.39 by our model, while its usage frequency varies greatly.

In this work, we focus on the linguistic evolution of slang, defined as colloquial and informal language commonly associated with particular groups (González, 1998; Bembe and Beukes, 2007), and use a causal framework to compare the change dynamics of slang words to those of standard language. More specifically, we compare the *semantic change* as well as the changes in frequency, i.e.,

frequency shift, over time between slang words and standard, nonslang words. We learn a *causal graphical model* (Spirtes et al., 2000) to assess how these variables interact with other factors they have been previously found to correlate with, such as *frequency*, *polysemy* and *part of speech* (Dubossarsky et al., 2016; Hamilton et al., 2016). Having discovered a graph, we proceed to use *do-calculus* (Pearl, 1995) to evaluate the causal effects of a word's *type* (slang/nonslang) on semantic change and frequency shift.

Semantic change is measured using the average pairwise distance (APD) (Sagi et al., 2009; Giulianelli et al., 2020) between time-separated contextualized representations, which were obtained from a Twitter corpus via a bi-directional language model (Liu et al., 2019). Our method builds on recent semantic change literature (Schlechtweg et al., 2020), with novel additions of dimensionality reduction and a combined distance function.

By deploying a causal analysis, we establish that there is not just an association, but a direct effect of a word's type on its semantic change and frequency shift. We find that a word being *slang* causes it to undergo slower semantic change and more rapid decreases in frequency. To illustrate, consider the slang word "duckface" and the nonslang word "inclusive" as shown in Figure 1. Duckface is a face pose commonly made for photos (Miller, 2011) in the early 2010s, and while it has largely decreased in frequency since, its meaning has not changed. In contrast, the nonslang word "inclusive" has developed a new usage in recent years (Merriam-Webster, 2019) and was given a high semantic change score by our model.

Our analysis also sheds light on a couple of previous findings in the diachronic linguistics literature. We find support for the S-curve theory (Kroch, 1989), showing a causal effect from a word's polysemy to its frequency. This relationship is evident in the increase in frequency that the word "inclusive" displays in Figure 1 after it develops a new meaning (Merriam-Webster, 2019). However, similar to Dubossarsky et al. (2017), we do not find causal links to semantic change from frequency, polysemy, or POS, which have been suggested in previous works (Hamilton et al., 2016; Dubossarsky et al., 2016).

In summary, our main contributions are threefold: (i) we formalize the analysis of change dynamics in language with a causal framework; (ii) we propose a semantic change metric that builds upon contextualized word representations; and (iii) we discover interesting insights about slang words and semantic change – e.g., showing that the change dynamics of slang words are different from those of nonslang words, with slang words exhibiting both more rapid frequency fluctuations and less semantic change.

2 Related Work

2.1 Semantic Change

A typical method for measuring semantic change is by comparing word representations across time periods (Gulordava and Baroni, 2011; Kim et al., 2014; Jatowt and Duh, 2014; Kulkarni et al., 2015; Eger and Mehler, 2016; Schlechtweg et al., 2019). With this approach, previous research has proposed laws relating semantic change to other linguistic properties (Dubossarsky et al., 2015; Xu and Kemp, 2015; Dubossarsky et al., 2016; Hamilton et al., 2016). For instance, Dubossarsky et al. (2016) find that verbs change faster than nouns, whereas Hamilton et al. (2016) discover that polysemous words change at a faster rate, while frequent words change slower. However, the validity of some of these results has been questioned via case-control matching (Dubossarsky et al., 2017), highlighting the influence of word frequency on the representations and thus on the semantic change metric (Hellrich and Hahn, 2016). Such analyses can indeed give stronger evidence for causal effects. In this work we take a methodologically different approach, considering observational data alone for our causal analysis.

The aforementioned works rely on fixed word representations, whereas more recent approaches (Hu et al., 2019; Giulianelli et al., 2020) have proposed semantic change measures based on contextualized word embeddings (Peters et al., 2018; Devlin et al., 2019), which can flexibly capture contextual nuances in word meaning. This has lead to a further stream of work on semantic change detection with contextualized embeddings (Martinc et al., 2020; Kutuzov and Giulianelli, 2020; Schlechtweg et al., 2020; Montariol et al., 2021; Kutuzov et al., 2021; Laicher et al., 2021). We build upon this line of work and extend them using principal component analysis (PCA) and a combination of distance metrics.

2.2 Characterization and Properties of Slang

Slang is an informal, unconventional part of the language, often used in connection to a certain setting or societal trend (Dumas and Lighter, 1978). It can reflect and establish a sense of belonging to a group (González, 1998; Bembe and Beukes, 2007; Carter, 2011) or to a generation (Citera et al., 2020; Earl, 1972; Barbieri, 2008).

Mattiello (2005) highlights the role slang plays in enriching the language with neologisms, and claims that it follows unique word formation processes. Inspired by this, Kulkarni and Wang (2018) propose a data-driven model for emulating the generation process of slang words that Mattiello (2005) describes. Others have described the ephemerality of slang words (González, 1998; Carter, 2011), although this property has not been previously verified by computational approaches.

3 Causal Methodology for Change Dynamics

Examining change dynamics through a causal lens helps determine the existence of direct causal effects, by modeling the interactions between variables. For example, it allows us to conclude whether word type directly influences semantic change, or rather influences polysemy, which in turn causes semantic change. In this section, we first give a short overview of relevant work on causality, before presenting how we apply these concepts to word change dynamics.

3.1 Overview of Causal Discovery and Causal Inference

A common framework for causal reasoning is through *causal directed acyclic graphs* (DAGs) (Pearl, 2009). A causal DAG consists of a pair (G, P) where $G = (V, E)$ is a DAG and P is a probability distribution over a set of variables. Each variable is represented by a node $v \in V$, and the graph's edges $e \in E$ reflect causal relationships. There are two main tasks in causality. *Causal discovery* is the task of uncovering the causal DAG that explains observed data. Assuming a causal DAG, the task of *causal inference* then concerns determining the effect that intervening on a variable, often referred to as *treatment*, will have on another variable, often referred to as *outcome*.

The causal DAG is often inferred from domain knowledge or intuition. However, in cases where we cannot safely assume a known causal structure, causal discovery methods come in useful. Constraint-based methods (Spirtes et al., 2000) form one of the main categories of causal discovery techniques. These methods use conditional independence tests between variables in order to uncover the causal structure. To do so, they rely on two main assumptions: that the graph fulfills the global Markov property and the faithfulness assumption. Together they state that we observe conditional independence relations between two variables in the distribution if and only if these two variables are d-separated (Geiger et al., 1990) in the graphical model. For more details, we refer to Appendix D.1.

Causal inference is commonly approached with do-calculus (Pearl, 1995). We denote the intervention distribution $\mathbb{P}(Y|do(X = x))$ to be the distribution of the outcome Y conditioned on an intervention $do(X = x)$ which forces the treatment variable X to take on the value x. Note that this is in general not necessarily equal to $\mathbb{P}(Y|X = x)$.[2] When they are not equal, we say that there is *confounding*. Confounding occurs when there is a third variable Z, which causes both the treatment X and the outcome Y.

We say that there is a causal effect of X on Y if there exist x and x' such that

$$\mathbb{P}(Y|do(X = x)) \neq \mathbb{P}(Y|do(X = x')). \quad (1)$$

One way to quantify the causal effect is with the *average causal effect (ACE)*:

$$\mathbb{E}[Y|do(X = x)] - \mathbb{E}[Y|do(X = x')]. \quad (2)$$

To estimate the causal effect using observational data, we need to rewrite the intervention distribution using only conditional distributions. Assuming a causal DAG, this can be done with the *truncated factorization formula* (Pearl, 2009),

$$\begin{aligned} &\mathbb{P}(X_V|do(X_W = x_W)) = \\ &= \prod_{i \in V \setminus W} \mathbb{P}(X_i|X_{pa(i)}) \mathbb{1}_{\{X_W = x_W\}}, \end{aligned} \quad (3)$$

for $W \subset V$, with X_W being the variables in P corresponding to the nodes in W.

---

[2] For instance, there is a causal effect of altitude on temperature but not vice versa. Hence, intervening on temperature will not cause a shift in the distribution of altitude, but conditioning will.

3.2 Causality for Change Dynamics

In this work, we estimate the direct causal effect of a word's type on its semantic change and frequency shift dynamics. In order to establish that such an effect exists, and to know which variables to control for, we turn to causal discovery algorithms. The variables in our causal graph additionally include frequency, polysemy and POS.

For learning the causal graph, we choose the constraint-based PC-stable algorithm (Colombo and Maathuis, 2014), an order-independent variant of the well-known PC algorithm (Spirtes et al., 2000), discussed in Appendix D.1. We are learning a mixed graphical model (Lauritzen, 1996; Lee and Hastie, 2015), consisting of both continuous (e.g., frequency) and categorical (e.g., type) variables. For this reason we opt for constraint-based algorithms, allowing us to tailor the conditional independence tests according to the various data types.

Having learned the causal graph (Section 6.2), we proceed to estimate the ACE of word type on both semantic change and frequency shift using do-calculus (Section 6.3).

4 Slang and Nonslang Word Selection

We select 100 slang words and 100 nonslang words for our study, presented in Appendix E. In the tradeoff between statistical significance and time spent on computation and data collection, we found that a set of 200 words was enough to get highly significant results. The slang words are randomly sampled from the Online Slang Dictionary,[3] which provides well-maintained and curated slang word definitions as well as a list of 4,828 featured slang words as of June 2021. We limit the scope of our study to only encompass single-word expressions, and in so doing we filter out 2,169 multi-word expressions. To further clean the data, we also delete words with only one character and acronyms. Lastly, we limit the causal analysis to words that are exclusively either slang or nonslang, excluding "hybrid" words with both slang and nonslang meanings, such as "kosher" or "tool." Including words of this type would have interfered with the causal analysis by creating a hardcoded dependency between word type and polysemy, as these words by definition are polysemous. We do however perform a separate analysis of the hybrid words in Appendix C.

For the reference set of standard, nonslang, words we sample 100 words uniformly at random from a list of all English words, supplied by the `wordfreq` library in Python (Speer et al., 2018).

5 Data Collection

We curate a Twitter dataset from the years 2010 and 2020, which we select as our periods of reference, and collect the following variables:

- **Word type:** Whether a word is slang or not
- **Word frequency:** The average number of tweets containing the word per day in 2010 and 2020 (Section 5.2)
- **Frequency Shift:** The relative difference in frequency the word has undergone between 2010 and 2020 (Section 5.3)
- **Polysemy:** The number of senses a word has (Section 5.4)
- **Part of speech:** A binary variable for each POS tag (Section 5.5)
- **Semantic change:** The semantic change score of the word from 2010 to 2020 (Section 5.6)

5.1 Twitter Dataset

As a social media platform, Twitter data is rich in both slang and nonslang words. The Twitter dataset we curated comprises 170,135 tweets from 2010 and 2020 that contain our selected words. Sampling tweets from two separate time periods allows us to examine the semantic change over a 10-year gap. For every slang and nonslang word, and each of the two time periods, we obtain 200-500 random tweets that contain the word and were posted during the corresponding year. We keep each tweet's text, tweet ID, and date it was posted. As a post-processing step, we remove all URLs and hashtags from the tweets. To protect user privacy, we further replace all user name handles with the word "user." On average, we have 346 tweets per slang word and 293 tweets per nonslang word.

5.2 Word Frequency

We approximate a word's frequency by the average number of times it is tweeted within 24 hours. This average is calculated in practice over 40 randomly sampled 24 hour time frames in a given year, in each of which we retrieve the number of tweets containing the word. The frequencies are calculated separately for 2010 and 2020. Due to the growing

---

[3] `http://onlineslangdictionary.com/`

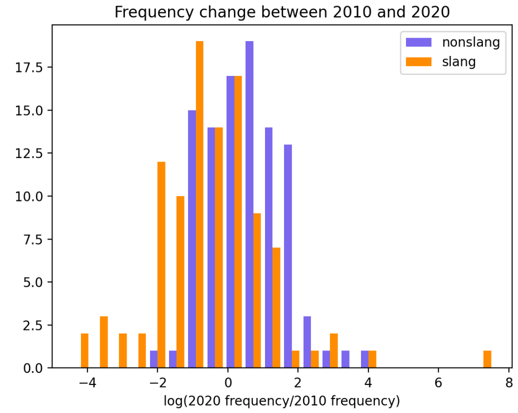

Figure 2: Relative shift in frequency from 2010 to 2020, where a positive score corresponds to an increase in frequency. We see that slang words present both the highest increases and the highest decreases in frequency. Moreover, a large frequency decrease is observed exclusively in a set of slang words, indicating these words faded from usage during the decade.

popularity of social media, the number of tweets has significantly increased over the decade. Therefore, we divide the counts from 2020 by a factor of 6.4, which is the ratio between the average word counts in both years in our dataset. The frequencies from both years are then averaged to provide the *frequency* variable for the causal analysis.

5.3 Frequency Shift

We are now interested in analyzing the dynamics of frequency shifts. To evaluate the relative change in frequency for a given word w we take

$$\text{FreqShift}(w) = \log \frac{x_{2020}(w)}{x_{2010}(w)} \tag{4}$$

where, $x_k(w)$ is the frequency of word w in year k. This has been shown to be the only metric for relative change that is symmetric, additive, and normed (Tornqvist et al., 1985). Importantly, this measure symmetrically reflects both increases and decreases in relative frequency. The mean relative changes in frequency were $-0.486(\pm 1.644)$ for slang words and $0.533(\pm 1.070)$ for nonslang words, where a positive score corresponds to an increase in frequency. As evident in Figure 2, not only did more slang words exhibit a decrease in frequency than nonslang ones, the words that showed the highest frequency increase are also slang.

We also examine the absolute value of Eq. (4) to evaluate the degree of change, may it be a decrease or an increase. We find that, as expected, slang words have significantly higher changes in frequency than nonslang words ($p < 0.05$). See Appendix C for more details.

5.4 Polysemy

We define a word's polysemy score as the number of distinct senses it has[4]. For nonslang words, we take the number of senses the word has in Merriam Webster and for slang words we take the number of definitions on the Online Slang Dictionary. We use two separate resources as we find that no dictionary encapsulates both slang and nonslang words. The mean polysemy scores are (2.074 ± 2.595) for slang words and (3.079 ± 2.780) for nonslang words with a significant difference in distribution ($p < 0.05$) according to a permutation test, implying that the latter are used with a larger variety of meanings. In addition, the slang senses of the hybrid words exhibit a distribution similar to those of the slang words (Appendix C). More polysemous words tend to have a higher word frequency in our dataset – the log transform of frequency and polysemy display a highly significant ($p < 0.001$) linear correlation coefficient of 0.350.

5.5 Part of Speech

For each word, we retrieve four binary variables, indicating whether a word can be used as noun, verb, adverb or adjective, which were the four major POS tags observed in our data. To calculate these variables we run the NLTK POS tagger (Loper and Bird, 2002) on the tweets, and collect the distribution of POS tags for each word. Note that a word may have more than one POS tag, depending on the context in which it is used. Each of the binary variables is then set to be 1 if the word had the corresponding POS tag in at least 5% of its tweets and 0 otherwise.

5.6 Semantic Change Score

In this section we explain the details of how we obtain the semantic change scores. We start by fine-tuning a bi-directional language model on a slang-dense corpus (Section 5.6.1), after which we survey the literature and propose metrics (Section 5.6.2) that we use to perform an extensive experimentation study to find the most suitable one (Section 5.6.3). Finally, we apply this metric to our

---

[4] Note that this definition also encapsulates potential cases of homonymy. We choose not to make a distinction between polysemy and homonymy in this analysis.

sets of slang and nonslang words on the Twitter data (Section 5.6.4).

5.6.1 Obtaining Contextualized Representations

We familiarize the bi-directional language model with slang words and the contexts in which they are used by fine-tuning it on the masked language modeling task. For this purpose we use a web-scraped dataset from the Urban Dictionary, previously collected by Wilson et al. (2020). After preprocessing and subsampling, the details of which can be found in Appendix A.1, we are left with a training set of $200,000$ slang-dense text sequences.

As our bi-directional language model we select RoBERTa (Liu et al., 2019). Beyond performance gains compared to the original BERT (Devlin et al., 2019), we select this model since it allows for more subword units. We reason, that this could be useful in the context of slang words since potentially some of the sub-units used in these words would not have been recognized by BERT. We choose the smaller 125M parameter base version for computational reasons. We train the model using the Adam optimizer (Kingma and Ba, 2015) with different learning rates γ. The lowest loss on the test set was found with $\gamma = 10^{-6}$, which we proceed with for scoring semantic change. For more details on training configurations, we refer to Appendix A.2.

5.6.2 Quantifying Semantic Change

In order to select a change detection metric, we evaluate our model on the SemEval-2020 Task 1 on Unsupervised Lexical Semantic Change Detection (Schlechtweg et al., 2020). This task provides the first standard evaluation framework for semantic change detection, using a large-scale labeled dataset for four different languages. We restrict ourselves to English and focus on subtask 2, which concerns ranking a set of 37 target words according to their semantic change between two time periods. The ranking is evaluated using Spearman's rank-order correlation coefficient ρ.[5] Our space of configurations includes layer representations, dimensionality reduction techniques and semantic change metrics.

Layer Representations: Previous work (Ethayarajh, 2019) has shown that embeddings retrieved from bi-directional language models are not isotropic, but are rather concentrated around a high-dimensional cone. Moreover, the level of isotropy may vary according to the layer from which the representations are retrieved (Ethayarajh, 2019; Cai et al., 2021). This leads us to experiment with representations from different layers in our fine-tuned RoBERTa model, namely, taking only the first layer, only the last layer or summing all layers.

Dimensionality Reduction: To the best of our knowledge, only one previous semantic change detection approach (Rother et al., 2020) has incorporated dimensionality reduction, more specifically UMAP (McInnes et al., 2018). As the Euclidean distances in the UMAP-reduced space are very sensitive to hyperparameters and it does not retain an interpretable notion of absolute distances, it might be unsuitable for pure distance-based metrics like APD, and we therefore also experiment with PCA.

Metrics for Semantic Change: Given representations $\mathcal{X}_t = \{\boldsymbol{x}_{1,t}, ..., \boldsymbol{x}_{n_t,t}\}$ for a particular word in time period t, we define the average pairwise distance (APD) between two periods as

$$\mathrm{APD}(\mathcal{X}_{t_1}, \mathcal{X}_{t_2}) = \frac{1}{n_{t_1} n_{t_2}} \sum_{\substack{\boldsymbol{x}_{i,t_1} \in \mathcal{X}_{t_1} \\ \boldsymbol{x}_{j,t_2} \in \mathcal{X}_{t_2}}} d(\boldsymbol{x}_{i,t_1}, \boldsymbol{x}_{j,t_2}) \,, \tag{5}$$

for some distance metric $d(\cdot,\cdot)$, where n_{t_1}, n_{t_2} are the number of words in each time period. We experiment with Euclidean distance $d_2(\boldsymbol{x}_1, \boldsymbol{x}_2)$, cosine distance $d_{\cos}(\boldsymbol{x}_1, \boldsymbol{x}_2)$ and Manhattan distance $d_1(\boldsymbol{x}_1, \boldsymbol{x}_2)$. Furthermore, we propose a novel combined metric. Note that $d_2(\cdot,\cdot) \in [0, \infty]$ and $d_{\cos}(\cdot,\cdot) \in [0, 2]$. Further note that

$$||\boldsymbol{x}_1 - \boldsymbol{x}_2||_2^2 \leq ||\boldsymbol{x}_1||_2^2 + ||\boldsymbol{x}_2||_2^2 \tag{6}$$

Normalizing both metrics for a support in $[0, 1]$, we get a combined metric with the same unit support to be the following average:

$$d_{2,\cos}(\boldsymbol{x}_1, \boldsymbol{x}_2) = \frac{0.5 \cdot d_2(\boldsymbol{x}_1, \boldsymbol{x}_2)}{\sqrt{||\boldsymbol{x}_1||^2 + ||\boldsymbol{x}_2||^2}} \tag{7}$$

$$+ \frac{d_{\cos}(\boldsymbol{x}_1, \boldsymbol{x}_2)}{4} \tag{8}$$

We argue that this provides a more complete metric, capturing both absolute distance and the angle between vectors.

In addition to the APD metrics, we experiment with distribution-based metrics (see Appendix B.1).

---

[5] We note the caveat that our model is fine-tuned on Urban Dictionary text, while the older of the two English datasets of SemEval consists of text from 1810-1860.

Reduction	h	APD	Score
PCA	100	d_2 and $d_{\cos}$	**0.489****
PCA	100	$d_{\cos}$	0.464**
PCA	100	d_2	0.298
None	768	d_2 and $d_{\cos}$	0.345*

Table 1: Spearman's rank-order correlation coefficients between our semantic change scores and the ground truth across different dimensionality reduction techniques for APD (*: $p < 0.05$, **: $p < 0.01$).

5.6.3 Evaluating the Semantic Change Scores

We first compare the results for the three types of layer representations for different APD metrics, and note that summing all layer representations yields the best results. Consequentially, we proceed with the rest of the experiments using only these representations. For both PCA and UMAP, we experiment with projecting the representations down to $h \in \{2, 5, 10, 20, 50, 100\}$ dimensions. These combinations are tested together with the APD metrics as presented in Section 5.6.2 as well as the distribution-based metrics described in Appendix B. The latter do not however in general display significant correlations.

We present a small subset of the scores resulting from the APD configurations in Table 1, highlighting our finding that both PCA dimensionality reduction and using a combined metric improve the performance. More results and comparisons to baselines are presented in Appendix B.3. We observe that the proposed combined metric consistently outperforms both d_2 and d_{cos} across values of h for PCA. We also note that UMAP projections perform poorly with the APD metrics and that projecting down to 50-100 dimensions seems to be optimal, which maintains 70-85% of the variance as we illustrate in Appendix B.2. In addition, both norm-based metrics d_1 and d_2 perform worse with dimensionality reduction. As our final metric, we choose the best performing configuration on SemEval, with PCA $h = 100$ and the combined metric, as seen in Table 1.

5.6.4 Semantic Change Scores for Slang and Nonslang Words on the Twitter Dataset

We obtain semantic change scores using the Twitter dataset described in Section 5.1. For the semantic change analysis, we exclude words that have less than 150 tweets in each time period within the dataset, which leaves us with 80 slang and 81 nonslang words. We also normalize the scores according to the sample. The resulting semantic change scores are shown in Figure 3. The mean semantic change scores are $0.564(\pm 0.114)$ for slang words and $0.648(\pm 0.084)$ for nonslang words. The difference in semantic change score distributions is significant ($p < 0.001$) via a permutation test. The word with the highest semantic change score of 1 is "anticlockwise," and the word with the lowest score of 0 is "whadja."

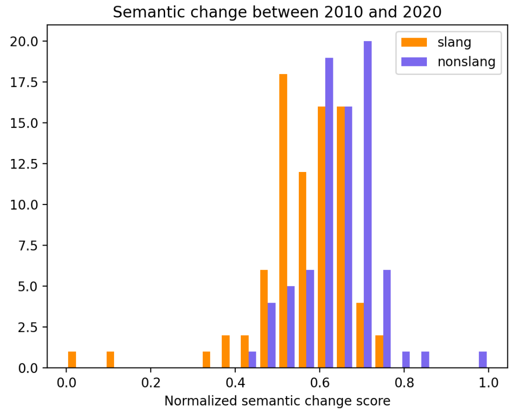

Figure 3: Semantic change scores between 2010 and 2020. We see that nonslang words typically underwent larger changes in meaning throughout the decade.

6 Causal Analysis

6.1 Preparation for Causal Discovery

PC-stable is constraint-based and thus makes use of conditional independence tests. In the case of continuous Gaussian variables, we can perform partial correlation tests to assess conditional independence, since zero partial correlation in this case is equivalent to conditional independence (Baba et al., 2004). As word frequency has been suggested to follow a lognormal distribution (Baayen, 1992), we take the log transform of it. The continuous variables *semantic change*, *frequency change* and *log-frequency* are then all assumed to be approximated well by a Gaussian distribution, which is confirmed by diagnostic density and Q-Q plots (displayed in Appendix D.2).

We categorize the discrete polysemy variable, experimenting with nine different plausible categorizations for the sake of robustness of the results. Word type and POS are categorical in nature. For the categorical variables and for mixes of categorical and continuous variables, we perform chi-squared mutual information based tests

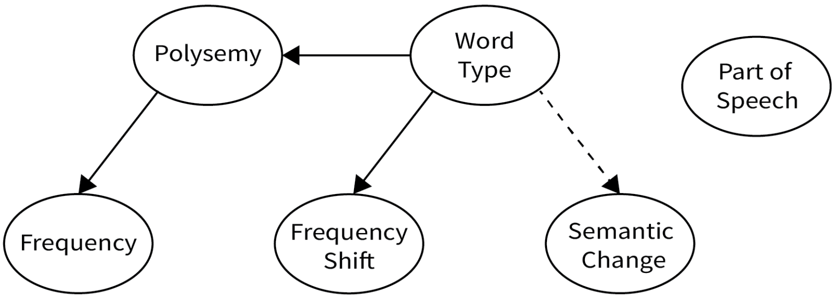

Figure 4: DAG representing the causal relationships in our dataset. We see that word type directly influences frequency shift, semantic change and polysemy, and polysemy in turn influences frequency.

(Edwards, 2000), since the approximate null distribution of the mutual information is chi-squared (Brillinger, 2004). For all conditional independence tests we experiment with significance levels $\alpha \in \{0.01, 0.03, 0.05\}$.

6.2 Resulting Causal Structure

In Figure 4 we see the result from the above approach, with dashed lines representing edges that were apparent in most but not all of the configurations. See Appendix D.3 for a sensitivity analysis.

We first observe that word type has a direct causal effect on both the semantic change score and the frequency shift, without any confounding from the other variables. We also note a direct influence of word polysemy on frequency.

Moreover, none of the four POS categories, which are all gathered in one node in Figure 4, have a causal link to any of the other variables. We additionally observe a dependency between word type and polysemy. This edge could not be oriented by the PC-stable algorithm, however we manually orient it as outgoing from type and ingoing to polysemy, since an intervention on type should have a causal effect on the number of word senses and not vice versa. It is also interesting to note that polysemy does not seem to have a causal effect on semantic change. Its association with semantic change ($p < 0.05$, rejecting the null hypothesis of independence between polysemy and semantic change) is instead confounded by word type.

6.3 Causal Effects

In our case of no confounders, evaluating the ACE of word type on semantic change is straightforward, as it reduces to the difference between the conditional expectations:

$$\mathbb{E}[S|do(T = \text{nonslang})] - \mathbb{E}[S|do(T = \text{slang})] = \\ = \mathbb{E}[S|T = \text{nonslang}] - \mathbb{E}[S|T = \text{slang}] \quad (9)$$

See Appendix D.4 for a derivation. The case of frequency shift is analogous.

We estimate the expectations by the sample means on the normalized values and get an average causal effect of 0.084, which is a highly significant value ($p < 0.001$) based on a t-test. For the observed changes in relative frequency, calculated according to Eq. (4), we get an average causal effect of 1.017 ($p < 0.001$ via a t-test).

7 Discussion

We analyze the dynamics of frequency shift and semantic change in slang words, and compare them to those of nonslang words. Our analysis shows that **slang words change slower in semantic meaning, but adhere to more rapid frequency fluctuations, and are more likely to greatly decrease in frequency**. Our study is the first computational approach to confirm this property in slang words (González, 1998; Carter, 2011).

To ensure that this is the result of a causal effect, and not mediated through another variable or subject to confounders, we model the data with a causal DAG, by also considering the potential interacting variables polysemy, frequency and POS. We discover that there is no influence of confounders, nor are there mediators between a word's type and its semantic change or its frequency shift, which **confirms a direct causal effect**. This means that if we could intervene on a word's type, i.e., by setting it to be slang instead of nonslang or vice versa, we would expect its change dynamics to differ.

Our results are consistent with those of Dubossarsky et al. (2017), which found that neither the law relating semantic change to frequency, polysemy (Hamilton et al., 2016) nor prototypicality (Dubossarsky et al., 2015) were found to be as strong as previously thought after a case-control study using a scenario without semantic change. Indeed, there is no directed path from polysemy or frequency to semantic change in our causal graph, but they are both influenced by word type. We leave for future research to explore whether other word categorizations, e.g., related to specific domains, languages or phonetic aspects, sustain this result.

In addition, our analysis does not support the claim that POS could underlie semantic change (Dubossarsky et al., 2016). We note however that as our vocabulary contains 50% slang words, the results need not be consistent with results obtained with a word sample drawn from standard language.

Moreover, in the causal structure we discover that **word polysemy has a direct effect on word frequency**, which is in line with previous linguistic studies showing that a word's frequency grows in an S-shaped curve when it acquires new meanings (Kroch, 1989; Feltgen et al., 2017), as well as a known positive correlation between polysemy and frequency (Lee, 1990; Casas et al., 2019). We emphasize that this relationship is not merely an artifact of contextualized word representations being affected by frequency (Zhou et al., 2021), since our polysemy score does not rely on word representations as in Hamilton et al. (2016). Our approach is however not without drawbacks – the polysemy variable is collected from dictionaries, which may be subjective in their assignments of word senses.

Our study, along with previous work on the dynamics of semantic change, is limited by mainly considering distributional factors. Linguists have suggested that sociocultural, psychological and political factors may drive word change dynamics (Blank, 1999; Bochkarev et al., 2014), and slang words are not an exception. Although challenging to measure, the influence of such factors on slang compared to nonslang words would be interesting to examine in future work.

In conclusion, we believe that a causal analysis as we have presented here provides a useful tool to understand the underlying mechanisms of language. Complementing the recent emergence of research combining causal inference and NLP (Feder et al., 2021), we have shown that tools from causality can also be beneficial for gaining new insights in diachronic linguistics.

8 Conclusion

In this work, we have analyzed the diachronic mechanisms of slang language with a causal methodology. This allowed us to establish that a word's type has a direct effect on its semantic change and frequency shift, without mediating effects from other distributional factors.

Acknowledgments

We would like to thank Steven R. Wilson for providing us with the Urban Dictionary data and Walter Rader for providing us with a curated set of slang words from the Online Slang Dictionary. For the Twitter data, we are thankful to have been able to get access to Twitter's Academic Research Track. Finally, we gratefully acknowledge feedback and helpful comments from Mario Giulianelli, Yifan Hou, Bernhard Schölkopf and three anonymous reviewers.

This material is based in part upon works supported by the John Templeton Foundation (grant #61156); by a Responsible AI grant by the Haslerstiftung; by an ETH Grant (ETH-19 21-1); by the German Federal Ministry of Education and Research (BMBF): Tübingen AI Center, FKZ: 01IS18039B; and by the Machine Learning Cluster of Excellence, EXC number 2064/1 – Project number 390727645.

Ethical Considerations

Our dataset is composed solely of English text. This means that our analysis applies uniquely to the English language, and results may differ in other languages. Moreover, for the purpose of this study, we curated a dataset of $170,135$ tweets. We emphasize that in order to protect the anonymity of users, we remove all author IDs from the data, and replace all usernames with the general token "user." In the Urban Dictionary dataset we received from Wilson et al. (2020), we similarly remove the author IDs and only consider the entry text.
