Message from the General Chair

Welcome to ACL 2022, the 60th Annual Meeting of the Association for Computational Linguistics! The conference will be held in Dublin, the capital of Ireland, on May 22–27, 2022.

ACL 2022 will be a hybrid conference. After two fully virtual editions, ACL 2020 and ACL 2021, due to the covid-19 pandemic, this year we are gradually coming back to normality, estimating, at the moment of writing this message, that about 50% of the registered participants will be able to attend the conference in-person, enjoying the atmosphere of the CCD congress center, the social events of the conference, and the many opportunities in Dublin. On the other side, virtual attendees will have the possibility to interact almost like they were in Dublin, thanks to a sophisticated virtual conference platform.

There are few important innovations this year. The most relevant is that ACL 2022 adopted a new reviewing process, based on "rolling review" (ARR), with the goal of coordinating and making more efficient the paper reviews of the ACL conferences. This initiative was shared with NAACL 2022, resulting in a coordinated effort. As a side effect of moving to ARR, we have been working on a new version of the software, called ACLPUB2, used to produce both the conference proceedings and the conference schedule. I would like to thank all the people who contributed to those achievements. Finally, this year we celebrate the 60th anniversary of the ACL conference. Thanks to the enthusiastic contributions of many organizations, coordinated by the Diversity and Inclusion co-chairs, we are preparing a very special initiative for our community, which, at the time of writing this message, is still secret and that will be disclosed during the opening of the conference.

I was very lucky to work together with three fantastic Program Chairs: Preslav Nakov, Smaranda Muresan and Aline Villaviciencio. I could not thank you more for the dedication and the capacity with which you have organized a very exciting scientific program and for the help in all the phases of the conference organization.

Thanks to the local organizers in Dublin, Andy Way and John Kelleher, and to the PCO, who managed the local organization in a period in which we have had very few certainties, and many more uncertainties.

We are extremely grateful to all sponsors for their continuing and generous support to help our conferences be very successful. Thank you to Chris Callison-Burch, the ACL Sponsorship Director, for managing the relations between the sponsors and ACL 2022.

I am also very grateful to the chairs of the previous years' conferences, who were always ready to help and to provide advice, contributing to the transmission, from year to year, of all the know-how and collective memory. Thanks to all the members of The ACL Executive Committee, they were always supportive, particularly when feedback on delicate issues was needed.

Many thanks to the senior area chairs, the area chairs, the reviewers, our workshop organizers, our tutorial instructors, the authors and presenters of papers, and the invited speakers.

ACL requires a long process, involving a large team of committed people. It is an honor for me to have coordinated such a team of talented people, who kindly volunteered their time to make this conference possible. I would like to thank the members of the organizing committee for their dedication and hard work, often under a tight schedule:

- Workshop Co-Chairs: Elena Cabrio, Sujian Li, Mausam;
- Tutorial Co-Chairs: Naoaki Okazaki, Yves Scherrer, Marcos Zampieri;
- Demo Co-Chairs: Valerio Basile, Zornitsa Kozareva, Sanja Štajner;
- Student Research Workshop Co-Chairs: Samuel Louvan, Brielen Madureira, Andrea Madotto;

- SRW Faculty Advisors: Cecile Paris, Siva Reddy, German Rigau;
- Publication Co-Chairs (also publication co-chairs for NAACL 2022): Danilo Croce, Ryan Cotterell, Jordan Zhang;
- Conference Handbook Chair: Marco Polignano;
- Diversity & Inclusion Co-chairs: Mona Diab, Martha Yifiru Tachbelie;
- Ethic advisor committee: Su Lin Blodgett, Christiane Fellbaum;
- Technical OpenReview Chair: Rodrigo Wilkens;
- Publicity and Social Media Co-chairs: Isabelle Augenstein, Emmanuele Chersoni, Diana Maynard, Soujanya Poria, Joel Tetreault;
- Local Arrangement Committee: Fiona McGillivray, Greg Carew, Laird Smith;
- Student Volunteer Coordinators: Filip Klubicka, Vasudevan Nedumpozhimana, Guodong Xie, Pintu Lohar;
- Internal Communications Chair: Marcely Boito Zanon.

Let me deserve a special thanks to Priscilla Rasmussen. She has been the pillar not only of this year's ACL, but of the ACL conferences for many years. She has offered her invaluable experience to the organizing committee, and her presence has always given us a pleasant sense of security.

Finally, I would like to thank all the participants, both in-person and virtual, who will be the main actors from May 22 to May 27, 2022. I am convinced that we will experience a fantastic conference, scientifically exciting and full of fond memories.

Welcome and hope you all enjoy the conference!

Bernardo Magnini (FBK, Italy)
ACL 2022 General Chair

Message from the Program Chairs

Welcome to the 60th Annual Meeting of the Association for Computational Linguistics (ACL 2022). ACL 2022 has a special historical significance, as this is the 60th Anniversary edition. It is also the first hybrid ACL conference after two years of a fully virtual format for ACL in 2020 and 2021 due to the COVID-19 pandemic. Finally, it is the first *ACL conference to fully embrace the ACL Rolling Review (ARR) as a reviewing process. Below, we discuss some of these changes and we highlight the exciting program that we have put together with the help from our community.

Using ARR for Reviewing

In coordination with the NAACL 2022 team and the ACL executive committee, we decided to fully adopt the ACL Rolling Review (ARR) as the only reviewing platform for ACL 2022. ARR is a new review system for *ACL conferences, where reviewing and acceptance of papers to publication venues is done in a two-step process: (*i*) centralized rolling review via ARR, and (*ii*) commitment to a publication venue, e.g., ACL 2022. The purpose of the ACL Rolling Review is to improve the efficiency and the turnaround of reviewing in *ACL conferences while keeping diversity (geographic and otherwise) and editorial freedom.

As ACL 2022 is the first conference to fully adopt the ARR review process, we worked very closely with ARR and we coordinated our efforts with the NAACL 2022 PC chairs. In particular, given the short distance between ACL 2022 and NAACL 2022, we allowed authors to commit their papers to ACL 2022 and simultaneously to submit a revision to ARR in January, which were eligible for NAACL 2022. We also joined ARR as Guest Editors-in-Chief (EiCs) to help with the September–November submissions to ARR, which primarily targeted ACL 2022. We worked together to integrate ARR and some of the conference workflows to ensure scaling up, and to maintain the quality and the timely processing of the submissions for November, and thus to guarantee that all papers submitted by the November 15, 2021 ARR deadline could be considered for ACL 2022 if the authors decided to commit them. This required making sure we had all reviews and meta-reviews ready in time, which we managed to achieve thanks to the combined efforts of the ARR and the ACL 2022 teams. We would also like to note that this is a community effort, and we are grateful for the support of the authors, the reviewers, the Action Editors (AEs), and the Senior Area Chairs (SACs), who have been constructively engaging and helping with ARR and ACL 2022.

Committing to ACL 2022

The commitment form for ACL 2022 asked the authors to provide a link to their paper in ARR: we asked for a link to the latest version of the paper that had reviews and a meta-review. The authors also needed to select an area (including the Special Theme area) they were submitting their paper to (this was needed as ACL 2022 had areas, while ARR did not). Finally, the authors were allowed to submit optional comments to the ACL 2022 Senior Area Chairs (SACs). Note that these comments were only visible to the SACs, and they were not sent to the reviewers or to the Action Editors: the rationale was that responding to reviewers and Action Editors should be handled in a response letter if the authors decided to do a resubmission in ARR, which is a completely different process than committing a paper to ACL 2022. These comments to the SACs were designed mainly to raise concerns about objective misunderstandings by the reviewers and/or by the Action Editor about the technical aspect of the paper that the authors believed might help the SACs in their decision-making process.

Areas While ARR did not have areas, ACL 2022 did: it had 23 areas, including the 22 areas from ACL 2021 plus our Special Theme. Our special theme was on "*Language Diversity: from Low-Resource to Endangered Languages*," to commemorate the 60th anniversary of ACL with the goal of reflecting and stimulating a discussion about how advances in computational linguistics and natural language processing can be used to promote language diversity from low-resource to endangered languages. We invited papers that discuss and reflect on the "role of the speech and language technologies in sustaining language use" (Bird, 2020) for the large variety of world languages with focus on under-resourced, indigenous, and/or endangered languages. We were interested in the challenges for developing and scaling up the current NLP technologies for the rich diversity of human languages and in the ethical, cultural, and policy implications of such technologies for local communities. We also have a best Theme paper award category.

Acceptance to ACL 2022

As ACL 2022 submissions in ARR, we count all papers from September, October, and November, which we advertised as ACL 2022 months, after removing all re-submissions and also nine papers that selected NAACL 2022 as a preferred venue (a total of 3,360 papers) + the papers from the May–August period that were actually committed to ACL 2022 and that were not resubmissions (a total of 18 papers), for a total of 3,378 papers.
This number is on par with the number of submissions to ACL 2021, which received 3,350 submissions. Subsequently, 1,918 papers were committed to ACL 2022 (i.e., 57%). After the review process, 701 papers (604 long and 97 short) were accepted into the main conference.

Acceptance Rates for the Main Conference

The quality of a conference is often perceived based on the acceptance rate of the papers submitted there, and thus it is important to have an acceptance rate that adequately represents the difficulty of publishing a paper in the conference. Given the adoption of ARR, it is also important to allow for consistency across various conferences. Thus, ACL 2022 (and NAACL 2022) adopted the following two ways of calculating the acceptance rates:

(a) *(Number of accepted papers at ACL 2022) / (Number of papers that selected ACL 2022 as the preferred venue in ARR or were committed to ACL 2022).* For ACL 2022, for the denominator we consider the 3,378 papers as explained above. Thus, the acceptance rate is 701 / 3,378 = 20.75% for the Main conference.

(b) *(Number of accepted papers at ACL 2022) / (Number of papers committed to ACL 2022).* For the denominator, we had 1,918 papers committed to ACL 2022, and thus, the acceptance rate is 701 / 1,918 = 36.54% for the Main conference.

Note that option (a) is closer to the way the acceptance rate was computed at previous *ACL conferences, where submitting and committing a paper was done in one step and papers were rarely withdrawn after the reviews, the meta-reviews, and the corresponding scores were released. However, one issue with this option for ACL 2022 was that indicating a preferred venue was only enabled starting with the October ARR submissions, and it was not available for earlier months. As mentioned above, we removed a small number of papers from our denominator that selected NAACL 2022 as a preferred venue in October and November (a total of 9 papers) and we considered the ARR submissions only for the months of September, October, and November, as these months were advertised in our CFP, plus any papers that were committed to ACL 2022 from earlier months (May–July) and which were also not resubmissions.
Option (b) yields a higher "acceptance rate", as many authors with low reviewing scores chose not to commit their paper to ACL 2022.

Best Paper Awards

From the committed ACL 2022 papers, we selected 32 papers as candidates for the following Best Paper awards, based on nominations by the Senior Area Chairs: Best Research Paper, Best Special Theme

Paper, Best Resource Paper, and Best Linguistic Insight Paper. These papers were assessed by the Best Paper Award Committee. The selected best papers will be presented in a dedicated plenary session for Best Paper Awards on May 24, 2022.

Findings of ACL 2022

Given the success of the Findings at EMNLP 2020 and 2021 and ACL-IJCNLP 2021, we also have Findings of ACL 2022 papers, which are papers that were not accepted for publication in the main conference, but nonetheless were assessed by the Program Committee as solid work with sufficient substance, quality, and novelty. A total of 361 papers were offered to be included in the Findings of ACL 2022. Given the two ways of computing acceptance rates described above, this results in a 10.68% acceptance rate in option (a), and 19.82% in option (b). Out of the 361 papers, 30 papers declined the offer, leading to 331 papers to be published in the Findings of ACL 2022. In order to increase the visibility of the Finding of ACL 2022 papers, we offered the authors of these 331 papers the possibility to present their work as a poster at ACL 2022, in addition to making a 6-minute or a 3-minute video to be included in the virtual conference site (for long and for short papers, respectively). The authors of 305 of the 331 papers accepted our invitation to present their work as a poster at ACL 2022.

TACL and Computational Linguistics

Continuing the tradition from previous years, ACL 2022 also features 43 articles that were published at the Transactions of the Association for Computational Linguistics (TACL) and 8 papers from the Computational Linguistics journal.

Keynote and Invited Speakers

Another highlight of our program are the keynotes, which we run in three different formats:

- **a keynote talk** by Angela Friederici (Max Planck Institute for Human Cognitive and Brain Sciences) on "*Language in the Human Brain*";

- **a keynote fire-side chat** on "*The Trajectory of ACL and the Next 60 years*" with Barbara Grosz (Harvard University) and Yejin Choi (University of Washington and Allen Institute for Artificial Intelligence), moderated by Rada Mihalcea (University of Michigan);

- **a keynote panel** on "How can we support linguistic diversity?" led by Steven Bird (Charles Darwin University), with panelists representing a variety of world languages, including (currently confirmed) Teresa Lynn (Irish), Robbie Jimerson (Seneca), Heather Long (Creole languages), and Manuel Mager (Wixaritari).

We further had two additional invited talk initiatives:

- **Spotlight Talks by Young Research Stars (STIRS)** by Eunsol Choi (University of Texas at Austin), Ryan Cotterell (ETH Zurich), Sebastian Ruder (Google, London), Swabha Swayamdipta (Allen Institute for AI), and Diyi Yang (Georgia Tech);

- **Next Big Ideas Talks** by Marco Baroni (Pompeu Fabra University), Eduard Hovy (The University of Melbourne and Carnegie Mellon University), Heng Ji (UIUC), Mirella Lapata (University of Edinburgh), Hang Li (Bytedance Technology), Dan Roth (University of Pennsylvania and Amazon), and Thamar Solorio (University of Houston).

Thank You

ACL 2022 is the result of a collaborative effort and a supportive community, and we want to acknowledge the efforts of so many people who have made significant efforts into the organization of ACL 2022! First of all, we would like to thank our Program Committee (the full list of names is quite long and it is included in the Program Committee pages of the Proceedings):

- Our awesome 82 Senior Area Chairs who were instrumental in every aspect of the review process, from liaising with ARR, to supporting the implementation of a two-stage reviewing system, recommending Action Editors and reviewers, working on paper acceptance, and nomination of best papers and outstanding reviewers. For all of them, this involved familiarizing themselves with a new protocol to accommodate the integration of ARR reviews and a new system, and for many of them, the scope of their responsibilities was equivalent to chairing a small conference.
- The 363 ARR Action Editors (from the June–November ARR cycles), who had the role of ACL 2022 Area Chairs interacting with reviewers, leading paper review discussions, and writing meta-reviews.
- The 2,323 ARR reviewers (from the June–November ARR cycles), who contributed for the ACL 2022 reviewing cycles, providing valuable feedback to the authors.
- The emergency ARR Action Editors and reviewers, who provided their support at the last minute to ensure a timely reviewing process.
- The amazing ARR team, who collaborated in the challenge of managing and implementing the ARR reviewing needed for the scale of ACL 2022. In particular, we acknowledge Amanda Stent and Goran Glavaš as Guest ARR Editors-in-Chief for ACL 2022, Graham Neubig as Guest ARR Chief Technical Officer for ACL 2022, and Sara Goggi as Guest ARR Editorial Manager for ACL 2022.

ACL 2022 counted on the contributions of many wonderful committees, including:

- Our Best Paper Selection Committee, who selected the best papers and the outstanding papers: Tim Baldwin, Kathleen McKeown, David Chiang, Min-Yen Kan, and Taro Watanabe.
- Our Ethics Advisory Committee, chaired by Christiane Fellbaum and Su Lin Blodgett, for their hard work to ensure that all the accepted papers addressed the ethical issues appropriately, under a very tight schedule and on a new platform.
- Our amazing Publication Chair Danilo Croce, our Handbook Chair Marco Polignano, the Technical OpenReview Chair Rodrigo Wilkens, and the Scheduler Chair Jordan Zhang, who jointly with the NAACL 2022 Publication Chair, Ryan Cotterell, made an enormous contribution to the community by implementing the integration scripts for generating the proceedings, the handbook and the schedule from the OpenReview platform.
- Our Publicity Chairs Isabelle Augenstein, Emmanuele Chersoni, Diana Maynard, Soujanya Poria, and Joel Tetreault, for their work on managing the communications on social media platforms.
- The Internal Communications Chair Marcely Boito Zanon for streamlining the processes.
- The wonderful Technical OpenReview Chair Rodrigo Wilkens, who went above and beyond to ensure that the typical ACL conference functionalities were translated to a new environment.

We would also like to thank many people who helped us with various software used for the conference:

- The ARR Tech team, in particular Sebastin Santy and Yoshitomo Matsubara, who served as Guest ARR Tech Team for ACL 2022.

- The OpenReview team, in particular Nadia L'Bahy, Celeste Martinez Gomez, and Melisa Bok, who helped to implement the integration of ARR as a reviewing platform for ACL 2022.
- The whole Underline team, in particular Sol Rosenberg, Jernej Masnec, Damira Mršić, and Mateo Antonic, who created a virtual site for the conference.

As Program chairs, we had to deal with many tasks, including handling new protocols and situations and a new conference management environment. We would not be able to complete these tasks without the advice from our colleagues, including

- Our fantastic General Chair Bernardo Magnini, who provided invaluable support and feedback throughout the whole process, including collaborating on the efforts to take on the challenge of reengineering the conference reviewing processes and pipeline.
- The Program Co-Chairs of NAACL 2022 Marine Carpuat, Marie-Catherine de Marneffe, and Ivan Vladimir Meza Ruiz, and the NAACL 2022 General Chair, Dan Roth, for collaborating in the challenge of coordinated adoption of ARR reviewing in a full scale for ACL 2022 and NAACL 2022.
- The Program Co-Chairs of previous editions of *ACL conferences, in particular the ACL-IJCNLP 2021 PC chairs Roberto Navigli, Fei Xia, and Wenjie Li, as well as the EMNLP 2021 PC chairs Lucia Specia, Scott Wen-tau Yih, and Xuanjing Huang for providing amazing guidance and support, and sharing their experience and answering our many questions, often on short notice.
- The ACL Executive Committee, especially Tim Baldwin (the ACL President), Rada Mihalcea (the ACL Past President), Shiqi Zhao (Secretary), Priscilla Rasmussen (Business Manager), and the members of the ACL executive committee for providing invaluable feedback and for helping us sort through various issues.
- The Computational Linguistics Editor-in-Chief Hwee Tou Ng, the TACL Editors-in-Chief Ani Nenkova and Brian Roark, and the TACL Editorial Assistant Cindy Robinson, for coordinating the Computational Linguistics and the TACL presentations at ACL 2022.

We would also like to thank all the authors who submitted/committed their work to ACL 2022. Although we were only able to accept a small percentage of the submissions, your hard work makes this conference exciting and our community strong. Our huge thanks goes to the *ACL communities for the kind and patient support during a year of major changes in our submission and reviewing processes.
Last, but not least, we thank our students, interns, postdocs, colleagues, and families for being so understanding and supportive during this intense year, and especially when we were swamped by countless conference deadlines and meetings. Our deepest gratitude is to all of you. We hope you will enjoy this 60th Anniversary edition of ACL.

Smaranda Muresan (Columbia University and Amazon AWS AI Labs, USA)
Preslav Nakov (Qatar Computing Research Institute, HBKU)
Aline Villavicencio (University of Sheffield, UK)

ACL 2022 Program Committee Co-Chairs

Message from the Local Chairs

Back in March 2020, just after the first COVID-19 lockdown, we submitted our bid for Dublin to host ACL 2022, conference that you are currently attending. In November 2020, we learned that our bid had been successful, which we were of course delighted to hear. Of course, at that stage – and at many points in between – we have wondered whether we would be able to meet face-to-face at all, and it is great that we are able to host you in the wonderful city of Dublin where we are privileged to live, as well as accommodating many of you online.

ACL is an opportunity to welcome not just our European friends and colleagues, but also those from farther afield. Ireland punches above its weight in the areas of NLP and Machine Learning, principally through the SFI-funded €100 million ADAPT Centre for Digital Content Technology, which comprises experts from 4 local Dublin universities as well as 4 further universities from across the country in a range of disciplines in AI. We have internationally renowned groups in machine translation, information retrieval, speech technology, parsing and grammar Induction, among others, so we believe it is appropriate that ACL is being held in our country for the first time. We are of course grateful to everyone who submitted a paper; whether your work was selected for presentation or not, if no-one had submitted, we wouldn't have had a conference. For those of you whose work was selected for presentation, many thanks for coming to Dublin, or for presenting online.

Along the way, we have been helped greatly by the General Chair Bernardo Magnini, and by Priscilla Rasmussen and others from the ACL executive team, to whom we are extremely thankful. However, by far the biggest thanks are due to Greg Carew and his team in Abbey Conference and Events for their professional support of the conference. You will have met them at registration, and they are available throughout the event to ensure your needs are met. We have been engaging with them for 2 years now on ACL, and for longer as they helped Andy host the MT Summit in 2019. We could not have made a better choice of PCO to assist us with all the requirements involved in hosting the best-regarded conference in our area. This has been a true partnership that has made this journey an enjoyable one.

We are also extremely grateful to Fáilte Ireland for their extremely generous support of this conference, and to our PostDocs Guodong Xie & Pintu Lohar (with Andy at DCU), and Vasudevan Nedumpozhimana & Filip Klubička (with John at TUD) for their huge efforts to recruit and manage the small army of student volunteers. Finally, we really hope that you all enjoy the conference, that you benefit from the excellent programme that has been assembled, and that you go away from here having made new friends. We are fortunate indeed that many of our very best friends are in the computational linguistics community, and we will try our very best to meet as many of you as possible during the event.

Andy Way (Dublin City University, Ireland)
John Kelleher (TU Dublin, Ireland)

Keynote Talk: Language in the Human Brain

Angela D. Friederici
Max Planck Institute for Human Cognitive and Brain Sciences, Leipzig, Germany

Abstract: Language is considered to be a uniquely human faculty. The different aspects of the language system, namely phonology, semantics and syntax have long been discussed with respect to their species-specificity. Syntax as the ability to process hierarchical structures appears to be specific to humans. The available neuroscientific data allow us to define the functional language network which involves Broca's area in the inferior frontal cortex and the posterior superior temporal cortex. Within this network, the posterior part of Broca's area plays a special role as it supports the processing of hierarchical syntactic structures, in particular the linguistic computation Merge which is at the root of every language. This part of Broca's area is connected to the posterior temporal cortex via a dorsally located white matter fiber tract hereby providing to structural basis for the functional interplay of these regions. It has been shown that the maturation of this white matter pathway is directly correlated with the ability to process syntactically complex sentences during human development. Moreover, this dorsal pathway appears to be weak in the prelinguistic infant and in the non-human primate. These findings suggest that the dorsal pathway plays a crucial role in the emergence of syntax in human language.

Bio: Angela D. Friederici is a cognitive neuroscientist in the domain of language. She is director at the Max Planck Institute for Human Cognitive and Brain Sciences (MPI CBS) in Leipzig, Germany and the Founding director of this institution founded in 1994.
She graduated in linguistics and psychology at the University of Bonn (Germany) and spent a postdoctoral year at MIT (USA). She was a research fellow at the Max Planck Institute in Nijmegen (NL), at the University Rene Descartes, Paris (F) and University of California, San Diego (USA). Prior to joining the Max Planck Society as a director, she was professor for Cognitive Sciences at the Free University Berlin. Friederici is honorary professor at the University of Leipzig (Psychology), the University of Potsdam (Linguistics) and the Charité Universitätsmedizin Berlin (Neurology) and she holds a Doctor honoris causa from the University of Mons, Belgium. Between 2014 and 2020 she was Vice President for the Human Sciences Section of the Max Planck Society.
Her main field of research is the neurobiology of language. She published about 500 scientific papers on this topic in major international journals. She received a number of scientific awards: 1987 Heisenberg Fellowship of the German Research Foundation, 1990 Alfried Krupp Award of the Alfried Krupp von Bohlen and Halbach-Stiftung, 1997 Gottfried Wilhelm Leibniz Prize of the German Research Foundation, and 2011 Carl Friedrich Gauss Medal of the Brunswick Scientific Society. She is member of the Berlin-Brandenburg Academy of Sciences and Humanities, member of the national German Academy of Sciences 'Leopoldina' and member of the Academia Europaea.

Keynote Fire-Side Chat with Barbara Grosz and Yejin Choi on "The Trajectory of ACL and the Next 60 Years"

For the 60th Anniversary of ACL 2022, we will feature a keynote fire-side chat on "***The Trajectory of ACL and the Next 60 years***" with two keynote talks in dialogue: Barbara Grosz and Yejin Choi followed by a moderated discussion lead by Rada Mihalcea.

Remarks on What the Past Can Tell the Future

Barbara J. Grosz
Harvard University SEAS

Abstract: Research in computational linguistics and spoken language systems has made astonishing progress in the last decade. Even so, the challenge remains of achieving human-level fluent dialogue conversational capabilities beyond narrowly defined domains and tasks. Findings of earlier ACL times research on dialogue hold some lessons for breaking the "dialogue boundary" in computational linguistics yet again, if ways can be found to integrate them into deep-learning language models. These models raise some of the most serious ethical challenges of current computing research and technologies. Expanding their powers in this direction will raise more. In discussing these topics, I will raise questions for Prof. Choi and our subsequent discussion.

Bio: Barbara J. Grosz is Higgins Research Professor of Natural Sciences in the Paulson School of Engineering and Applied Sciences at Harvard University. Her contributions to AI include fundamental advances in natural-language dialogue processing and in theories of multi-agent collaboration as well as innovative uses of models developed in this research to improve healthcare coordination and science education. She co-founded Harvard's Embedded EthiCS program, which integrates teaching of ethical reasoning into core computer science courses. A member of the National Academy of Engineering, the American Philosophical Society, and the American Academy of Arts and Sciences, she is a fellow of several scientific societies and recipient of the 2009 ACM/AAAI Allen Newell Award, the 2015 IJCAI Award for Research Excellence, and the 2017 Association for Computational Linguistics Lifetime Achievement Award.

2082: An ACL Odyssey
The Dark Matter of Intelligence and Language

Yejin Choi
Paul G. Allen School of Computer Science & Engineering at the University of Washington

Abstract: In this talk, I will wander around reflections on the past of ACL and speculations on the future of ACL. This talk will be purposefully imaginative and accidentally controversial, by emphasizing on the importance of deciphering the dark matter of intelligence, by arguing for embracing all the ambiguous aspects of language at all pipelines of language processing, by highlighting the counterintuitive continuum across language, knowledge, and reasoning, and by pitching the renewed importance of formalisms, algorithms, and structural inferences in the modern deep learning era. Looking back, at the 50'th ACL, I couldn't possibly imagine that I would be one day giving this very talk. For that reason, I will also share my personal anecdotes on the lasting inspirations from the previous lifetime achievement award speeches, how I believe talent is made, not born, and the implication of that belief for promoting diversity and equity.

Bio: Yejin Choi is Brett Helsel Professor at the Paul G. Allen School of Computer Science & Engineering at the University of Washington and a senior research manager at AI2 overseeing the project Mosaic. Her research investigates commonsense knowledge and reasoning, neuro-symbolic integration, neural language generation and degeneration, multimodal representation learning, and AI for social good. She is a co-recipient of the ACL Test of Time award in 2021, the CVPR Longuet-Higgins Prize in 2021, a NeurIPS Outstanding Paper Award in 2021, the AAAI Outstanding Paper Award in 2020, the Borg Early Career Award in 2018, the inaugural Alexa Prize Challenge in 2017, IEEE AI's 10 to Watch in 2016, and the ICCV Marr Prize in 2013.

Keynote Panel: Supporting Linguistic Diversity

Chair: **Steven Bird, Charles Darwin University**

Panelists and languages represented:

- Robert Jimerson, Rochester Institute of Technology (Seneca, USA)
- Fajri Koto, The University of Melbourne (Minangkabau, Indonesia)
- Heather Lent, University of Copenhagen (Creole languages)
- Teresa Lynn, Dublin City University (Irish)
- Manuel Mager, University of Stuttgart (Wixaritari, Mexico)
- Perez Ogayo, Carnegie Mellon University (Luo and Kiswahili, Kenya)

How do the tools and techniques of computational linguistics serve the full diversity of the world's languages? In particular, how do they serve the people who are still speaking thousands of local languages, often in highly multilingual, post-colonial situations? This 60th meeting of the ACL features a special theme track on language diversity with the goal of "reflecting and stimulating discussion about how the advances in computational linguistics and natural language processing can be used for promoting language diversity". This keynote talk-panel will showcase the special theme and identify key learnings from the conference. We hope this session will help to shape the future agenda for speech and language technologies in support of global linguistic diversity. The session will be organised around a series of questions under three headings.

Diverse Contexts. What is the situation of local languages where panel members are working? Are there multiple languages with distinct functions and ideologies? What are the local aspirations for the future of these languages. How are people advocating for language technology on the ground? How did the work begin? What does success look like?

Understanding Risks. Do the people who provide language data fully understand the ways their data might be used in future, including ways that might not be in their interest? What benefit are local participants promised in return for their participation, and do they actually receive these benefits? Are there harms that come with language standardisation? What principles of doing no harm can we adopt?

New Challenges. How can we provide benefits of text technologies without assuming language standardisation, official orthography, and monolingual usage? When working with local communities, do we always require data in exchange for technologies, or is a non-extractive NLP possible? How do we decolonise speech and language technology? At the beginning of the International Decade of Indigenous Languages 2022–2032, we ask: how do we respond as a community, and how can our field be more accessible to indigenous participation?

Abstract

Pre-trained language models have shown stellar performance in various downstream tasks. But, this usually comes at the cost of high latency and computation, hindering their usage in resource-limited settings. In this work, we propose a novel approach for reducing the computational cost of BERT with minimal loss in downstream performance. Our method dynamically eliminates less contributing tokens through layers, resulting in shorter lengths and consequently lower computational cost. To determine the importance of each token representation, we train a Contribution Predictor for each layer using a gradient-based saliency method. Our experiments on several diverse classification tasks show speedups up to 22x during inference time without much sacrifice in performance. We also validate the quality of the selected tokens in our method using human annotations in the ERASER benchmark. In comparison to other widely used strategies for selecting important tokens, such as *saliency* and *attention*, our proposed method has a significantly lower false positive rate in generating rationales. Our code is freely available at `https://github.com/amodaresi/AdapLeR`.

1 Introduction

While large-scale pre-trained language models exhibit remarkable performances on various NLP benchmarks, their excessive computational costs and high inference latency have limited their usage in resource-limited settings. In this regard, there have been various attempts at improving the efficiency of BERT-based models (Devlin et al., 2019), including knowledge distilation (Hinton et al., 2015; Sanh et al., 2019; Sun et al., 2019, 2020; Jiao et al., 2020), quantization (Gong et al., 2014; Shen et al., 2020; Tambe et al., 2021), weight pruning (Han et al., 2016; He et al., 2017; Michel et al., 2019; Sanh et al., 2020), and progressive module replacing (Xu et al., 2020). Despite providing significant reduction in model size, these techniques are generally static at inference time, i.e., they dedicate the same amount of computation to all inputs, irrespective of their difficulty.

A number of techniques have been also proposed in order to make efficiency enhancement sensitive to inputs. *Early exit* mechanism (Schwartz et al., 2020b; Liao et al., 2021; Xin et al., 2020; Liu et al., 2020; Xin et al., 2021; Sun et al., 2021; Eyzaguirre et al., 2021) is a commonly used method in which each layer in the model is coupled with an intermediate classifier to predict the target label. At inference, a halting condition is used to determine whether the model allows an example to exit without passing through all layers. Various halting conditions have been proposed, including Shannon's entropy (Xin et al., 2020; Liu et al., 2020), softmax outputs with temperature calibration (Schwartz et al., 2020b), trained confidence predictors (Xin et al., 2021), or the number of agreements between predictions of intermediate classifiers (Zhou et al., 2020).

Most of these input-adaptive techniques compress the model from the depth perspective (i.e., reducing the number of involved encoder layers). However, one can view compression from the width perspective (Goyal et al., 2020; Ye et al., 2021), i.e., reducing the length of hidden states. (Ethayarajh, 2019; Klafka and Ettinger, 2020). This is particularly promising as recent analytical studies showed that there are redundant encoded information in token representations (Klafka and Ettinger, 2020; Ethayarajh, 2019). Among these redundancies, some tokens carry more task-specific information than others (Mohebbi et al., 2021), suggesting that only these tokens could be considered through the model. Moreover, in contrast to layer-wise pruning, token-level pruning does not

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 1 - 15
May 22-27, 2022

come at the cost of reducing model's capacity in complex reasoning (Sanh et al., 2019; Sun et al., 2019). PoWER-BERT (Goyal et al., 2020) is one of the first such techniques which reduces inference time by eliminating redundant token representations through layers based on self-attention weights. Several studies have followed (Kim and Cho, 2021; Wang et al., 2021); However, they usually optimize a single token elimination configuration across the entire dataset, resulting in a static model. In addition, their token selection strategies are based on attention weights which can result in a suboptimal solution (Ye et al., 2021).

In this work, we introduce **Adap**tive **Le**ngth **R**eduction (**AdapLeR**). Instead of relying on attention weights, our method trains a set of Contribution Predictors (CP) to estimate tokens' saliency scores at inference. We show that this choice results in more reliable scores than attention weights in measuring tokens' contributions. The most related study to ours is TR-BERT (Ye et al., 2021) which leverages reinforcement learning to develop an input-adaptive token selection policy network. However, as pointed out by the authors, the problem has a large search space, making it difficult for RL to solve. To mitigate this, they resorted to extra heuristics such as imitation learning (Hussein et al., 2017) for warming up the training of the policy network, action sampling for limiting the search space, and knowledge distillation for transferring knowledge from the intact backbone fine-tuned model. All of these steps significantly increase the training cost. Hence, they only perform token selection at two layers. In contrast, we propose a simple but effective method to gradually eliminate tokens in each layer throughout the training phase using a soft-removal function which allows the model to be adaptable to various inputs in a batch-wise mode. It is also worth noting in contrast to our approach above studies are based on top-k operations for identifying the k most important tokens during training or inference, which can be expensive without a specific hardware architecture (Wang et al., 2021).

In summary, our contributions are threefold:

- We couple a simple Contribution Predictor (CP) with each layer of the model to estimate tokens' contribution scores to eliminate redundant representations.
- Instead of an instant token removal, we gradually mask out less contributing token representations by employing a novel soft-removal function.
- We also show the superiority of our token selection strategy over the other widely used strategies by using human rationales.

2 Background

2.1 Self-attention Weights

Self-attention is a core component of the Transformers (Vaswani et al., 2017) which looks for the relation between different positions of a single sequence of token representations $(x_1, ..., x_n)$ to build contextualized representations. To this end, each input vector x_i is multiplied by the corresponding trainable matrices Q, K, and V to respectively produce query (q_i), key (k_i), and value (v_i) vectors. To construct the output representation z_i, a series of weights is computed by the dot product of q_i with every k_j in all time steps. Before applying a softmax function, these values are divided by a scaling factor and then added to an *attention mask* vector $\mathbf{m}$, which is zero for positions we wish to attend and $-\infty$ (in practice, -10000) for padded tokens (Vaswani et al., 2017). Mathematically, for a single attention head, the weight attention from token x_i to token x_j in the same input sequence can be written as:

$$\alpha_{i,j} = \underset{x_j \in \mathcal{X}}{\mathrm{softmax}} \left(\frac{q_i k_j^\top}{\sqrt{d}} + m_i \right) \in \mathbb{R} \qquad (1)$$

The time complexity for this is $O(n^2)$ given the dot product $q_i k_j^\top$, where n is the input sequence length. This impedes the usage of self-attention based models in low-resource settings.

While self-attention is one of the most white-box components in transformer-based models, relying on raw attention weights as an explanation could be misleading given that they are not necessarily responsible for determining the contribution of each token in the final classifier's decision (Jain and Wallace, 2019; Serrano and Smith, 2019; Abnar and Zuidema, 2020). This is based on the fact that raw attentions are being faithful to the local mixture of information in each layer and are unable to obtain a global perspective of the information flow through the entire model (Pascual et al., 2021).

2.2 Gradient-based Saliency Scores

Gradient-based methods provide alternatives to attention weights to compute the importance of a

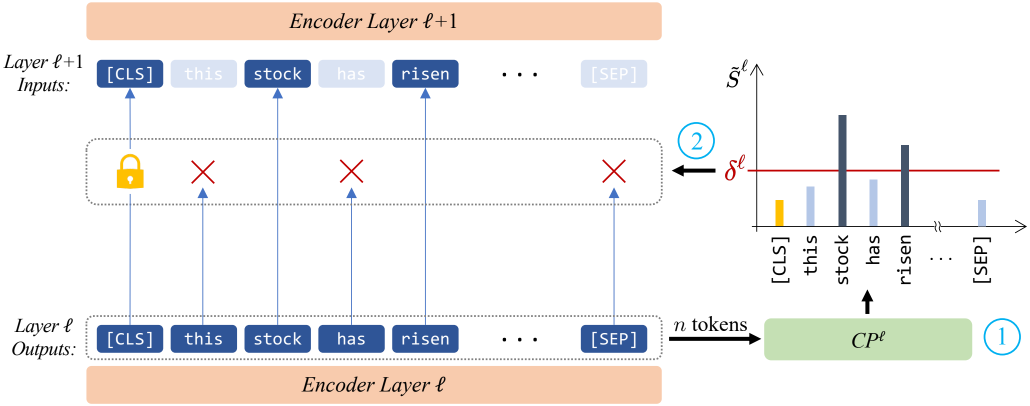

Figure 1: To reduce the inference computation, in each layer (1) the attribution score of the token representation is estimated and (2) based on a reduced uniform-level threshold ($\delta^\ell = \eta^\ell/n$) token representations with low importance score are removed. Since the final layer's classifier is connected to the [CLS] token and it could act as a pooler within each layer it is the only token that would remain regardless of its score.

specific input feature. Despite having been widely utilized in other fields earlier (Ancona et al., 2018; Simonyan et al., 2013; Sundararajan et al., 2017; Smilkov et al., 2017), they have only recently become popular in NLP studies (Bastings and Filippova, 2020; Li et al., 2016; Yuan et al., 2019). These methods are based on computing the first-order derivative of the output logit y_c w.r.t. the input embedding h_i^0 (initial hidden states), where c could be true class label to find the most important input features or the predicted class to interpret model's behavior. After taking the norm of output derivatives, we get *sensitivity* (Ancona et al., 2018), which indicates the changes in model's output with respect to the changes in specific input dimensions. Instead, by multiplying gradients with input features, we arrive at *gradient×input* (Bastings and Filippova, 2020), also known as *saliency*, which also considers the direction of input vectors to determine the most important tokens. Since these scores are computed for each dimension of embedding vectors, an aggregation method such as L2 norm or mean is needed to produce one score per input token (Atanasova et al., 2020a):

$$S_i = \parallel \frac{\partial y_c}{\partial h_i^0} \odot h_i^0 \parallel_2 \qquad (2)$$

3 Methodology

As shown in Figure 1, our approach relies on dropping low contributing tokens in each layer and passing only the more important ones to the next. Therefore, one important step is to measure the importance of each token. To this end, we opted for saliency scores which have been recently shown as a reliable criterion in measuring token's contributions (Bastings and Filippova, 2020; Pascual et al., 2021). In Section 5.1 we will show results for a series quantitative analyses that supports this choice. In what follows, we first describe how we estimate saliency scores at inference time using a set of Contribution Predictors (CPs) and then elaborate on how we leverage these predictors during inference (Section 3.2) and training (Section 3.3).

3.1 Contribution Predictor

Computing gradients during inference is problematic as backpropagation computation prolongs inference time, which is contrary to our main goal. To circumvent this, we simply add a CP after each layer ℓ in the model to estimate contribution score for each token representation, i.e., $\tilde{S}_i^\ell$. The model then decides on the tokens that should be passed to the next layer based on the values of $\tilde{S}_i^\ell$. CP computes $\tilde{S}_i^\ell$ for each token using an MLP followed by a softmax activation function. We argue that, despite being limited in learning capacity, the MLP is sufficient for estimating scores that are more generalized and relevant than vanilla saliency values. We will present a quantitative analysis on this topic in Section 5.

3.2 Model Inference

Most BERT-based models consist of L encoder layers. The input sequence of n tokens is usually passed through an embedding layer to build the initial hidden states of the model h^0. Each encoder layer then produces the next hidden states using the ones from the previous layer:

$$h^{\ell} = \text{Encoder}_{\ell}(h^{\ell-1}) \tag{3}$$

In our approach, we eliminate less contributing token representations before delivering hidden states to the next encoder. Tokens are selected based on the contribution scores $\tilde{S}^{\ell}$ obtained from the CP of the corresponding layer ℓ. As the sum of these scores is equal to one, a uniform level indicates that all tokens contribute equally to the prediction and should be retained. On the other hand, the lower-scoring tokens could be viewed as unnecessary tokens if the contribution scores are concentrated only on a subset of tokens. Given that the final classification head uses the last hidden state of the [CLS] token, we preserve this token's representation in all layers. Despite preserving this, other tokens might be removed from a layer when [CLS] has a significantly high estimated contribution score than others. Based on this intuition, we define a cutoff threshold based on the uniform level as: $\delta^{\ell} = \eta^{\ell} \cdot {}^{1}/_{n}$ with $0 < \eta^{\ell} \leq 1$ to distinguish important tokens. Tokens are considered important if their contribution score exceeds δ (which is a value equal or smaller than the uniform score). Intuitively, a larger η provides a higher δ cutoff level, thereby dropping a larger number of tokens, hence, yielding more speedup. The value of η determines the extent to which we can rely on CP's estimations. In case the estimations of CP are deemed to be inaccurate, its impact can be reduced by lowering η. We train each layer's η^{ℓ} using an auxiliary training objective, which allows the model to adjust the cutoff value to control the speedup-performance tradeoff. Also, since each input instance has a different computational path during token removal process, it is obvious that at inference time, the batch size should be equal to one (single instance usage), similarly to other dynamic approaches (Zhou et al., 2020; Liu et al., 2020; Ye et al., 2021; Eyzaguirre et al., 2021; Xin et al., 2020).

3.3 Model Training

Training consists of three phases: initial fine-tuning, saliency extraction, and adaptive length re-training. In the first phase, we simply fine-tune the backbone model (BERT) on a given target task. We then extract the saliencies of three top-perfroming checkpoints from the fine-tuning process and compute the average of them to mitigate potential inconsistencies in saliency scores (cf. Section 2.2).

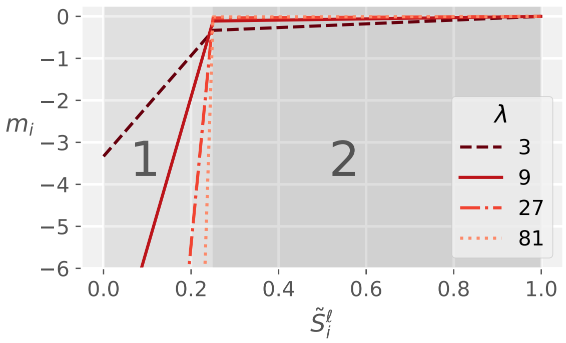

Figure 2: The soft-removal function plotted with $\lambda \in \{3, 9, 27, 81\}$ and $\delta^{\ell} = 0.25$. As λ increases, the removal region (1) gets steeper while the other zone (2), which is almost horizontal, approaches the zero level.

The final step is to train a pre-trained model using an adaptive length reduction procedure. In this phase, a non-linear function gradually fades out the representations throughout the training process. Each CP is jointly trained with the rest of the model using the saliencies extracted in the previous phase alongside with the target task labels. We also define a speedup tuning objective to determine the thresholds (via tuning η) to control the performance-speedup trade-off. In the following, we elaborate on the procedure.

Soft-removal function. During training, if tokens are immediately dropped similarly to the inference mode, the effect of dropping tokens cannot be captured using a gradient backpropagation procedure. Using batch-wise training in this scenario will also be problematic as the structure will vary with each example. Hence, inspired by the padding mechanism of self-attention models (Vaswani et al., 2017) we introduce a new procedure that gradually masks out less contributing token representations. In each layer, after predicting contribution scores, instead of instantly removing the token representations, we accumulate a negative mask to the attention mask vector M using a soft-removal function:

$$m_i^{-}(\tilde{S}_i^{\ell}) = \begin{cases} \lambda_{adj}(\tilde{S}_i^{\ell} - \delta^{\ell}) - \dfrac{\beta}{\lambda} & \tilde{S}_i^{\ell} < \delta^{\ell} \\ \dfrac{(\tilde{S}_i^{\ell} - 1)\beta}{(1 - \delta^{\ell})\lambda} & \tilde{S}_i^{\ell} \geq \delta^{\ell} \end{cases} \tag{4}$$

This function consists of two main zones (Figure 2). In the first term, the less important tokens with scores lower than the threshold (δ^{ℓ}) are assigned higher negative masking as they get more distant from δ. The slope is determined by $\lambda_{adj} = \lambda/\delta$, where λ is a hyperparameter that is increased exponentially after each epoch (e.g., $\lambda \leftarrow 10 \times \lambda$ after finishing each epoch). Increasing λ makes the soft-removal function stronger and more decisive in masking the representations. To avoid undergoing zero gradients during training, we define $0 < \beta < 0.1$ to construct a small negative slope (similar to the well known Leaky-ReLU of Maas et al. 2013) for those tokens with higher contributing scores than δ^ℓ threshold. Consider a scenario in which η^ℓ sharply drops, causing most of $\tilde{S}_i^\ell$ get over the δ^ℓ threshold. In this case, the non-zero value in the second term of Equation 4, which facilitates optimizing η^ℓ.

Training the Contribution Predictors. The CPs are trained by an additional term which is based on the KL-divergence[1] of each layer's CP output with the extracted saliencies. The main training objective is a minimization of the following loss:

$$\mathcal{L} = \mathcal{L}_{\text{CE}} + \gamma \mathcal{L}_{\text{CP}} \tag{5}$$

Where γ is a hyperparameter which that specifies the amount of emphasis on the CP training loss:

$$\begin{aligned} \mathcal{L}_{\text{CP}} &= \sum_{\ell=0}^{L-1} (L-\ell) D_{\text{KL}}(\hat{S}^\ell || \tilde{S}^\ell) \\ &= \sum_{\ell=0}^{L-1} (L-\ell) \sum_{i=1}^{N} \hat{S}_i^\ell \log(\frac{\hat{S}_i^\ell}{\tilde{S}_i^\ell}) \end{aligned} \tag{6}$$

Since S is based on the input embeddings, the [CLS] token usually shows a low amount of contribution due to not having any contextualism in the input. As we leverage the representation of the [CLS] token in the last layer for classification, this token acts as a pooler and gathers information about the context of the input. In other words, the token can potentially have more contribution as it passes through the model. To this end, we amplify the contribution score of [CLS] and renormalize the distribution ($\hat{S}^\ell$) with a trainable parameter θ^ℓ:

$$\hat{S}_i^\ell = \frac{\theta^\ell S_1^\ell \mathbf{1}[i=1] + S_i^\ell \mathbf{1}[i>1]}{\theta^\ell S_1^\ell + \sum_{i=2}^{n} S_i^\ell} \tag{7}$$

By this procedure, the next objective (discussed in the next paragraph) will have the capability of tuning the amount of pooling, consequently controlling the amount of speedup. Larger θ push the CPs to shift the contribution towards the [CLS] token to gather most of the task-specific information and avoids carrying redundant tokens through the model.

Speedup Tuning. In the speedup tuning process, we combine the cross-entropy loss of the target classification task with a length loss which is the expected number of unmasked token representations in all layers. Considering that we have a non-positive and continuous attention mask M, the length loss of a single layer would be the summation over the exponential of the mask values $\exp(m_i)$ to map the masking range $[-\infty, 0]$ to a $[0$ (fully masked/removed), 1 (fully retained)$]$ bound.

$$\begin{aligned} \mathcal{L}_{\text{SPD./PERF.}} &= \mathcal{L}_{\text{CE}} + \phi \mathcal{L}_{\text{LENGTH}} \\ \mathcal{L}_{\text{LENGTH}} &= \sum_{l=1}^{L} \sum_{i=1}^{n} \exp(m_i^\ell) \end{aligned} \tag{8}$$

Equation 8 demonstrates how the length loss is computed inside the model and how it is added to the main classification loss. During training, we assign a separate optimization process which tunes η and θ to adjust the thresholds and the amount of [CLS] pooling[2] alongside with the CP training.

The reason that this objective is treated as a separate problem instead of merging it with the previous one, is because in the latter case the CPs could be influenced by the length loss and try to manipulate the contribution scores for some tokens regardless of their real influence. So in other words, the first objective is to solve the task and make it explainable with the CPs, and the secondary objective builds the speedup using tuning the threshold levels and the amount of pooling in each layer.

4 Experiments

4.1 Datasets

To verify the effectiveness of AdapLeR on inference speedup, we selected eight various text classification datasets. In order to incorporate a variety of tasks, we utilized SST-2 (Socher et al., 2013) and IMDB (Maas et al., 2011) for sentiment, MRPC (Dolan and Brockett, 2005) for paraphrase, AG's News (Zhang et al., 2015) for topic classification, DBpedia (Lehmann et al., 2015) for knowledge extraction, MNLI (Williams et al., 2018) for NLI,

---

Table 1: Comparison of our proposed method (AdapLeR) with other baselines in eight classification tasks in terms of performance and speedup. For each dataset the corresponding metric has been reported (Accuracy: Acc., F1: F-1 Score). In the MNLI task, the speedup and performance values are the average of the evaluations on the matched and mismatched test sets.

QNLI (Rajpurkar et al., 2016) for question answering, and HateXplain (Mathew et al., 2021) for hate speech.[3] Evaluations are based on the test split of each dataset. For those datasets that are in the GLUE Benchmark (Wang et al., 2018), test results were acquired by submitting the test predictions to the evaluation server.

4.2 Experimental Setup

As our baseline, we report results for the pretrained BERT model (base-uncased) (Devlin et al., 2019) which is also the backbone of AdapLeR. We also compare against three other approaches: DistilBERT (uncased) (Sanh et al., 2019) as a static compression method, PoWER-BERT and TR-BERT as two strong length reduction methods (cf. Sec. 1). We used the provided implementations and suggested hyperparameters[4] to train these baselines. To fine-tune the backbone model, we used same hyperparameters over all tasks (see Section D for details). The backbone model and our model implementation is based on the HuggingFace's Transformers library (Wolf et al., 2020). Trainings and evaluations were conducted on a dual 2080Ti 11GB GPU machine with multiple runs.

Hyperparameter Selection. Overall, we introduced four hyperparameters ($\gamma, \phi, \lambda, \beta$)[5] which are involved in the training process. Among these, ϕ and γ are the primary terms that have considerable effects on AdapLeR's downstream performance and speedup. This makes our approach comparable to existing techniques (Goyal et al., 2020; Ye et al., 2021) which usually have two or three hyperparameters adjusted per task. We used grid search to find the optimal values for these two terms, while keeping the other hyperparameters constant over all datasets. Hyperparamter selection is further discussed in Section D.

FLOPs Computation. We followed Ye et al. (2021) and Liu et al. (2020) and measured computational complexity in terms of FLOPs, i.e., the number of floating-point operations (FLOPs) in a single inference procedure. This allows us to assess models' speedups independently of their operating environment (e.g., CPU/GPU). The total FLOPs of a given model is a summation of the measured FLOPs over all test examples. Then, a model's speedup can be defined as the total FLOPs measured on BERT (our baseline) divided by the corresponding model's total FLOPs. To have a fair comparison, we also computed FLOPs for PoWER-BERT in a single instance mode, described in Section C.

4.3 Results

Table 1 shows performance and speedup for AdapLeR and other comparison models across eight different datasets. While preserving the same level of performance, AdapLeR outperforms other techniques in terms of speedup across all tasks (ranging from +0.2x to +7.4x compared to the best model in each dataset).

It is noteworthy that the results also reveal some form of dependency on the type of the tasks. Some tasks may need less amount of contextualism during inference and could be classified by using only a fraction of input tokens. For instance, in AG's News, the topic of a sentence might be identifiable with a single token (e.g., *soccer* → Topic: Sports, see Figure 6 in the Appendix for an example). PoWER-BERT adopts attention weights in its token selection which requires at least one layer of computation to be determined, and TR-BERT ap-

---

[3] See the statistics of datasets in Table 5 in Appendix.

[4] Since some of the datasets were not used originally, we had to search the hyperparameters based on the given ranges.

[5] Note that θ and η are trainable terms that are tuned by the model during training.

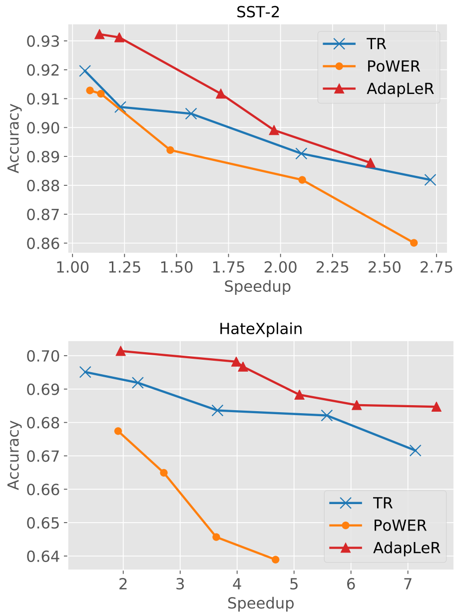

Figure 3: Accuracy-Speedup trade-off curve for AdapLeR and two other state-of-the-art reduction methods; TR: TR-BERT, PoWER: PoWER-BERT on two different tasks.

plies token elimination only in two layers to reduce the training search space. In contrast, our procedure performs token elimination for all layers of the model, enabling a more effective removal of redundant tokens. On the other hand, we observe that TR-BERT and PoWER-BERT lack any speedup gains for tasks such as QNLI, MNLI, and MRPC which need a higher degree of contextualism during inference. However, AdapLeR can offer some speedups even for these tasks.

Speedup-Performance Tradeoff. To provide a closer look at the efficiency of AdapLeR in comparison with the other state-of-the-art length reduction methods, we illustrate speedup-accuracy curves in Figure 3. We provide these curves for two tasks in which other length reduction methods show comparable speedups to AdapLeR. For each curve, the points were obtained by tuning the most influential hyperparameters of the corresponding model. As we can see, AdapLeR significantly outperforms the other two approaches in all two tasks. An interesting observation here is that the curves for TR-BERT and AdapLeR are much higher than that of PoWER-BERT. This can be attributed to the input-adaptive procedure employed by the former two methods for determining the number of reduced tokens (whereas PoWER-BERT adopts a fixed retention configuration in token elimination).

	Movie Reviews		MultiRC	
Strategy	Acc.	Speedup	Acc.	Speedup
Full input	93.3	1.0x	67.7	1.0x
Human rationale	96.7	3.7x	76.6	4.6x
Saliency	**92.3**	3.7x	**66.4**	4.4x
Attention ALL	78.5	3.7x	62.9	4.4x
Attention [CLS]	70.3	3.7x	63.7	4.4x

Table 2: Accuracy and speedup when the most important input tokens during fine-tuning are computed based on attention and saliency strategies and human rationale (the upper bound). The bold values indicate the best corresponding strategy for each task (the closest performance to the upper bound).

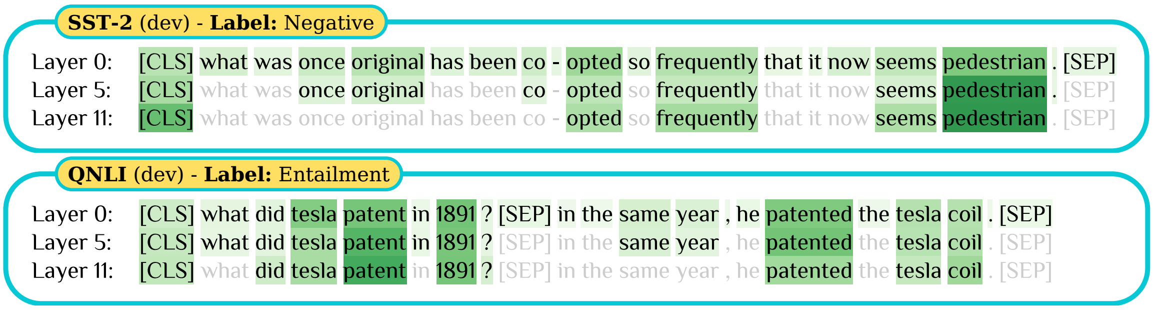
5 Analysis

In this section, we first conduct an experiment to support our choice of saliency scores as a supervision in measuring the importance of token representations. Next, we evaluate the behavior of Contribution Predictors in identifying the most important tokens in the AdapLeR.

5.1 Rationale as an Upper Bound

A natural question that arises when dealing with token pruning is that of *importance measure*: what is the most appropriate criterion for assessing the relative importance of tokens within a sentence? We resort to human rationale as a reliable upper bound for measuring token importance. To this end, we used the ERASER benchmark (DeYoung et al., 2020), which contains multiple tasks for which important spans of the input text have been highlighted as supporting evidence (aka "rationale") by human. Among the tasks in the benchmark, we opted for two diverse classification tasks: Movie reviews (Zaidan and Eisner, 2008) and MultiRC (Khashabi et al., 2018). In the former task, the model predicts the sentiment of the passage. Whereas the latter contains a passage, a question, and multiple candidate answers, which is cast as a binary classification task of passage/question/answer triplets in the ERASER benchmark.

In order to verify the reliability of human rationales, we fine-tuned BERT based on the rationales only, i.e., by excluding those tokens that are not highlighted as being important in the input. In Table 2, the first two rows show the performance of BERT on the two tasks with full input and with human rationales only. We see that fine-tuning merely



SST-2 (dev) - **Label:** Negative

Layer 11: [CLS] what was once original has been co - opted so frequently that it now seems pedestrian . [SEP]

QNLI (dev) - **Label:** Entailment

Layer 0: [CLS] what did tesla patent in 1891 ? [SEP] in the same year , he patented the tesla coil . [SEP]
Layer 5: [CLS] what did tesla patent in 1891 ? [SEP] in the same year , he patented the tesla coil . [SEP]
Layer 11: [CLS] what did tesla patent in 1891 ? [SEP] in the same year , he patented the tesla coil . [SEP]

Figure 4: The illustration of contribution scores obtained by CPs in three different layers of the model for two input examples from SST-2 (sentiment) and QNLI (Question-answering NLI) tasks. The contribution scores are shown by color intensity. Only the highlighted token representations are processed in each layer. See more full-layer plots in the appendix 6.

on rationales not only yields less computation cost, but also results in a better performance when compared with the full input setting. Obviously, human annotations are not available for a whole range of downstream NLP tasks; therefore, this criterion is infeasible in practice and can only be viewed as an upper bound for evaluating different strategies in measuring token importance.

5.2 Saliency vs. Attention

We investigated the effectiveness of saliency and self-attention weights as two commonly used strategies for measuring the importance of tokens in pre-trained language models. To compute these, we first fine-tuned BERT with all tokens in the input for a given target task. We then obtained saliency scores with respect to the tokens in the input embedding layer. This brings about two advantages. Firstly, representations in the embedding layer are non-contextualized, allowing us to measure the importance of each token independently from the others. Secondly, the backpropagation of gradients through layers to the beginning of the model provides us with aggregated values for the relative importance of each token based on the entire model. Similarly, we aggregated the self-attention weights across all layers of the model using a post-processed variant of attentions called *attention rollout* (Abnar and Zuidema, 2020), a popular technique in which the attention weight matrix in each layer is multiplied with the preceding ones to form aggregated attention values.

To assign an importance score to each token, we examined two different interpretation of attention weights. The first strategy is the one adopted by PoWER-BERT (Goyal et al., 2020) in which for each token we accumulate attention values from other tokens. Additionally, we measured how much the [CLS] token attends to each token in the sentence, a strategy which has been widely used in interpretability studies around BERT (Abnar and Zuidema, 2020; Chrysostomou and Aletras, 2021; Jain et al., 2020, *inter alia*). For a fair comparison, for each sentence in the test set, we selected the top-k salient and attended words, with k being the number of words that are annotated as rationales.

Results in Table 2 show that fine-tuning on the most salient tokens outperforms that based on the most attended tokens. This denotes that saliency is a better indicator for the importance of tokens. Nonetheless, recent length reduction techniques (Goyal et al., 2020; Kim and Cho, 2021; Wang et al., 2021) have mostly adopted attention weights as their criterion for selecting important tokens. Computing these weights is convenient as they are already computed during the forward pass, whereas computing saliency requires an additional backpropagation step. Note that in our approach, saliency scores are easily estimated within inference time by the pre-trained CPs.

5.3 Contribution Predictor Evaluation

In this section we validate our Contribution Predictors in selecting the most contributed tokens. Figure 4 illustrates two examples from the SST-2 and QNLI datasets in which CPs identify and gradually drop the irrelevant tokens through layers, finally focusing mostly on the most important token representations; *pedestrian* (adjective) in SST-2 and *tesla coil* in the passage part of QNLI (both of which are highly aligned with human rationale).

In order to quantify the extent to which AdapLeR's CPs can preserve rationales without requiring direct human annotations in an unsuper-

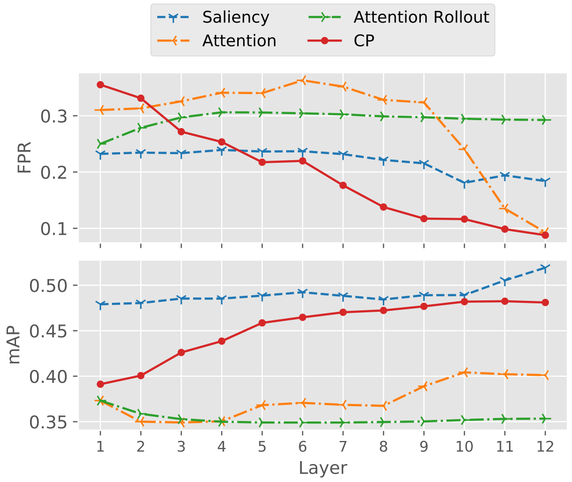

Figure 5: Agreement with human rationales in terms of mean Average Precision and False Positive Rate for Contribution Predictor (CP) and three alternative techniques.

vised manner we carried out the following experiment. To investigate the effectiveness of trained CPs in predicting human rationales we computed the output scores of CPs in AdapLeR for each token representation in each layer. We also fine-tuned a BERT model on the Movie Review dataset and computed layer-wise raw attention, attention rollout, and saliency scores for each token representation. Since human rationales are annotated at the word level, we sum the scores across tokens corresponding to each word to arrive at word-level importance scores. In addition to these soft scores, we used the uniform-level threshold (i.e., $1/n$) to reach a binary score indicating tokens selected in each layer.

As for evaluation, we used the Average Precision (AP) and False Positive Rate (FPR) metrics by comparing the remaining tokens to the human rationale annotations. The first metric measures whether the model assigns higher continuous scores to those tokens that are annotated by humans as rationales. Whereas, the intuition behind the second metric is how many irrelevant tokens are selected by the model to be passed to subsequent layers. We used soft scores for computing AP and binary scores for computing FPR.

Figure 5 shows the agreement between human rationales and the selected tokens based on the two metrics. In comparison with the other widely used strategies for selecting important tokens, such as salinecy and attention, our CPs have significantly less false positive rate in preserving rationales through layers. Despite having similar FPRs at the final layer, CP is preferable to attention in that it can better identify rationales at the earlier layers, allowing the model to combine the most relevant token representations when building the final one. This in turn results in better performance, as was also shown in the previous experiment in Section 5.2. Also, we see that the curve of mAP for saliency is consistently higher than other strategies in terms of alignment with human rationales which supports our choice of saliency as a measure for token importance.

Finally, we note that there is a line of research that attempts at guiding models to perform human-like reasoning by training rationale generation simultaneously with the target task that requires human annotation (Atanasova et al., 2020b; Zhao et al., 2020; Li et al., 2018). As a by-product of the contribution estimation process, our trained CPs are able to generate these rationales at inference without the need for human-generated annotations.

6 Conclusion

In this paper, we introduced AdapLeR, a novel method that accelerates inference by dynamically identifying and dropping less contributing token representations through layers of BERT-based models. Specifically, AdapLeR accomplishes this by training a set of Contribution Predictors based on saliencies extracted from a fine-tuned model and applying a gradual masking technique to simulate input-adaptive token removal during training. Empirical results on eight diverse text classification tasks show considerable improvements over existing methods. Furthermore, we demonstrated that contribution predictors generate rationales that are highly in line with those manually specified by humans. As future work, we aim to apply our technique to more tasks and see whether it can be adapted to those tasks that require all token representations to be present in the final layer of the model (e.g., question answering). Additionally, combining our width-based strategy with a depth-based one (e.g., early exiting) might potentially yield greater efficiency, something we plan to pursue as future work.

Broader Impact

Using our proposed method, pre-trained language models can use fewer FLOPs, reducing energy use and carbon emissions (Schwartz et al., 2020a).

A Inclusive KL Loss Consideration

We opted for an inclusive KL loss since CPs should be trained to cover all tokens considered important by saliency and not to be mode seeking (i.e., covering a subset of high contributing tokens considered by the saliency scores.). Suppose an exclusive KL is selected. Due to the limited learning capacity of the CP and miscalculation possibility from the saliency, the CP may be trained to maximize its contribution on noninformative tokens. While in an inclusive setting, it trains to extend its coverage over all high-saliency tokens.

Additionally, our initial research indicated that using a symmetric loss (e.g. Jensen-Shannon divergence) would produce similar results but with a significantly longer convergence time.

B Optimization of θ

In Section 3.3, we introduced θ^ℓ as a trainable parameter that increases the saliency score of [CLS]. We can deduce from Equations 6 and 7 that this parameter does not exist in the model's computational DAG and we need to compute the derivative of $\tilde{S}^\ell$ w.r.t. θ^ℓ to train this parameter. Hence, first we assume that $\tilde{S}^\ell$ is a close estimate of $\hat{S}^\ell$ (due to the CPs' training objective). Second, using a dummy variable θ^ℓ_d—that is involved in the computational graph and is always equal to 1—we reformulate $\tilde{S}^\ell$:

$$\hat{S}^\ell_i \approx \tilde{S}^\ell_i = \frac{\theta^\ell_d \tilde{S}^\ell_1 \mathbf{1}[i=1] + \tilde{S}^\ell_i \mathbf{1}[i>1]}{\theta^\ell_d \tilde{S}^\ell_1 + \sum_{i=2}^{n} \tilde{S}^\ell_i} \tag{9}$$

This reformulation is valid due to $\theta^\ell_d = 1$ and $\sum_{i=1}^{n} \tilde{S}^\ell_i = 1$. Now we compute the partial derivative w.r.t. θ^ℓ_d which is the gradient that is computed in the backpropagation:

$$\frac{\partial \tilde{S}^\ell_i}{\partial \theta^\ell_d} = \frac{\tilde{S}^\ell_1 (\sum_{i=2}^{n} \tilde{S}^\ell_i \mathbf{1}[i=1] - \tilde{S}^\ell_i \mathbf{1}[i>1])}{(\theta^\ell_d \tilde{S}^\ell_1 + \sum_{i=2}^{n} \tilde{S}^\ell_i)^2} \tag{10}$$

By knowing that $\theta^\ell_d = 1$:

$$\frac{\partial \tilde{S}^\ell_i}{\partial \theta^\ell_d} = \tilde{S}^\ell_1 ((1 - \tilde{S}^\ell_1)\mathbf{1}[i=1] - \tilde{S}^\ell_i \mathbf{1}[i>1]) \tag{11}$$

Now using our initial assumption ($\hat{S}^\ell_i \approx \tilde{S}^\ell_i$), we can substitute $\tilde{S}^\ell_i$ with $\hat{S}^\ell_i$ based on Equation 7:

$$\begin{aligned} \frac{\partial \tilde{S}^\ell_i}{\partial \theta^\ell_d} &= \hat{S}^\ell_1 ((1 - \hat{S}^\ell_1)\mathbf{1}[i=1] - \hat{S}^\ell_i \mathbf{1}[i>1]) \\ &= \frac{\theta^\ell S^\ell_1 (\sum_{i=2}^{n} S^\ell_i \mathbf{1}[i=1] - S^\ell_i \mathbf{1}[i>1])}{(\theta^\ell S^\ell_1 + \sum_{i=2}^{n} S^\ell_i)^2} \end{aligned} \tag{12}$$

In addition, the gradient of $\hat{S}^\ell_i$ w.r.t. θ^ℓ is as follows (cf. Equation 7):

$$\frac{\partial \hat{S}^\ell_i}{\partial \theta^\ell} = \frac{S^\ell_1 (\sum_{i=2}^{n} S^\ell_i \mathbf{1}[i=1] - S^\ell_i \mathbf{1}[i>1])}{(\theta^\ell S^\ell_1 + \sum_{i=2}^{n} S^\ell_i)^2} \tag{13}$$

By comparing Equations 12 and 13, these derivatives are related with a term of θ^ℓ:

$$\frac{\partial \hat{S}^\ell_i}{\partial \theta^\ell} \approx \frac{\partial \tilde{S}^\ell_i}{\partial \theta^\ell} = \frac{1}{\theta^\ell} \frac{\partial \tilde{S}^\ell_i}{\partial \theta^\ell_d} \tag{14}$$

Therefore, during training, we can compute the gradient w.r.t. the dummy variable θ_d^ℓ and then divide it by θ^ℓ.

C Evaluating PoWER-BERT in Single Instance Mode

Due to the static structure of PoWER-BERT, the speedup ratios reported in Goyal et al. (2020) are based on wall time acceleration with batch-wise inference procedure. This means that some inputs might need extra padding to make all inputs with the same token length. However, since our approach and other dynamic approaches are based on single instance inference, in our procedure inputs are fed without being padded. To even out this discrepancy, we apply a single instance flops computation on the PoWER-BERT, which means we compute the computational cost for all input lengths that appear in the test dataset. Some instnaces may have shorter input length than some values in the resulting retention configuration (number of tokens that are retained in each layer). To overcome this issue, we update the retention configuration by selecting the minimum between the input length and each layers' number of tokens retained, to build a new retention configuration for each input length. For instance, if the retention configuration trained model on a given task be (153, 125, 111, 105, 85, 80, 72, 48, 35, 27, 22, 5), for an input with 75 tokens length, the new configuration which is used for speedup computation will be: (75, 75, 75, 75, 75, 75, 72, 48, 35, 27, 22, 5).

D AdapLeR Training Hyperparameters

For the initial step of fine-tuning BERT, we used the hyperparameters in Table 3. For both fine-tuning and training with length reduction, we employed an AdamW optimizer (Loshchilov and Hutter, 2019) with a weight decay rate of 0.1, warmup proportion 6% of total training steps and a linear learning rate decay which reaches to zero at the end of training.

For the adaptive length reduction training step, we also used the same hyperparameters in Table 3 with two differences: Since MRPC and CoLA have small training sets, to prolong the gradual soft-removal process, we increased the training duration to 10 epochs. Moreover, we increase the learning rate to 3e-5. Other hyperparameters are stated in Table 4. To set a trend for λ, it needs to start from a small but effective value ($10 < \lambda < 100$) and grow exponentially per each epoch to reach an extremely high amount at the end of the training to mimic a hard removal function ($1e{+}5 < \lambda$). Hence, datasets with the same amount of training epochs have similar λ trends.

Abstract

This paper describes and tests a method for carrying out quantified reproducibility assessment (QRA) that is based on concepts and definitions from metrology. QRA produces a single score estimating the degree of reproducibility of a given system and evaluation measure, on the basis of the scores from, and differences between, different reproductions. We test QRA on 18 system and evaluation measure combinations (involving diverse NLP tasks and types of evaluation), for each of which we have the original results and one to seven reproduction results. The proposed QRA method produces degree-of-reproducibility scores that are comparable across multiple reproductions not only of the same, but of different original studies. We find that the proposed method facilitates insights into causes of variation between reproductions, and allows conclusions to be drawn about what changes to system and/or evaluation design might lead to improved reproducibility.

1 Introduction

Reproduction studies are becoming more common in Natural Language Processing (NLP), with the first shared tasks being organised, including REPROLANG (Branco et al., 2020) and ReproGen (Belz et al., 2021b). In NLP, reproduction studies generally address the following question: *if we create and/or evaluate this system multiple times, will we obtain the same results?*

To answer this question for a given specific system, typically (Wieling et al., 2018; Arhiliuc et al., 2020; Popović and Belz, 2021) an original study is selected and repeated more or less closely, before comparing the results obtained in the original study with those obtained in the repeat, and deciding whether the two sets of results are similar enough to support the same conclusions.

This framing, whether the same conclusions can be drawn, involves subjective judgments and different researchers can come to contradictory conclusions: e.g. the four papers (Arhiliuc et al., 2020; Bestgen, 2020; Caines and Buttery, 2020; Huber and Çöltekin, 2020) reproducing Vajjala and Rama (2018) in REPROLANG all report similarly large differences, but only Arhiliuc et al. conclude that reproduction was unsuccessful.

There is no standard way of going about a reproduction study in NLP, and different reproduction studies of the same original set of results can differ substantially in terms of their similarity in system and/or evaluation design (as is the case with the Vajjala and Rama (2018) reproductions, see Section 4 for details). Other things being equal, a more similar reproduction can be expected to produce more similar results, and such (dis)similarities should be factored into reproduction analysis and conclusions, but NLP lacks a method for doing so.

Being able to assess reproducibility of results objectively and comparably is important not only to establish that results are valid, but to provide evidence about which methods have better/worse reproducibility and what may need to be changed to improve reproducibility. To do this, assessment has to be done in a way that is also comparable across reproduction studies of different original studies, e.g. to develop common expectations of how similar original and reproduction results should be for different types of system, task and evaluation.

In this paper, we (i) describe a method for quantified reproducibility assessment (QRA) directly derived from standard concepts and definitions from metrology which addresses the above issues, and (ii) test it on diverse sets of NLP results. Following a review of related research (Section 2), we present the method (Section 3), tests and results (Section 4), discuss method and results (Section 5), and finish with some conclusions (Section 6).

2 Related Research

The situation memorably caricatured by Pedersen (2008) still happens all the time: you download

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 16 - 28

some code you read about in a paper and liked the sound of, you run it on the data provided, only to find that the results are not the same as reported in the paper, in fact they are likely to be worse (Belz et al., 2021a). When both data and code are provided, the number of potential causes of such differences is limited, and the NLP field has shared increasingly detailed information about system, dependencies and evaluation to chase down sources of differences. Sharing code and data together with detailed information about them is now expected as standard, and checklists and datasheets have been proposed to standardise information sharing (Pineau, 2020; Shimorina and Belz, 2021).

Reproducibility more generally is becoming more of a research focus. There have been several workshops and initiatives on reproducibility, including workshops at ICML 2017 and 2018, the reproducibility challenge at ICLR 2018 and 2019, and at NeurIPS 2019 and 2020, the REPROLANG (Branco et al., 2020) initiative at LREC 2020, and the ReproGen shared task on reproducibility in NLG (Belz et al., 2021b).

Despite this growing body of research, no consensus has emerged about standards, terminology and definitions. Particularly for the two most frequently used terms, *reproducibility* and *replicability*, multiple divergent definitions are in use, variously conditioned on same vs. different teams, methods, artifacts, code, and data. For example, for Rougier et al. (2017), *reproducing* a result means running the same code on the same data and obtaining the same result, while *replicating* the result is writing and running new code based on the information provided by the original publication. For Wieling et al. (2018), *reproducibility* is achieving the same results using the same data and methods.

According to the ACM's definitions (Association for Computing Machinery, 2020), results have been *reproduced* if obtained in a different study by a different team using artifacts supplied in part by the original authors, and *replicated* if obtained in a different study by a different team using artifacts *not* supplied by the original authors. The ACM originally had these definitions the other way around until asked by ISO to bring them in line with the scientific standard (ibid.).

Conversely, in Drummond's view 2009 obtaining the same result by re-running an experiment in the same way as the original is *replicability*, while *reproducibility* is obtaining it in a different way.

Whitaker (2017), followed by Schloss (2018), defines four concepts rather than two, basing definitions of *reproducibility, replicability, robustness* and *generalisability* on the different possible combinations of same vs. different data and code.

None of these definitions adopt the general scientific concepts and definitions pertaining to reproducibility, codified in the International Vocabulary of Metrology, VIM (JCGM, 2012). One issue is that they all reduce the in principle open-ended number of dimensions of variation between measurements accounted for by VIM to just two or three (code, data and/or team). Another, that unlike VIM, they don't produce comparable results.

NLP does not currently have a shared approach to deciding reproducibility, and results from reproductions as currently reported are not comparable across studies and can, as mentioned in the introduction, lead to contradictory conclusions about an original study's reproducibility. There appears to be no work at all in NLP that aims to estimate *degree* of reproducibility which would allow cross-study comparisons and conclusions.

3 Metrology-based Reproducibility Assessment

Metrology is a meta-science: its subject is the standardisation of measurements across all of science to ensure comparability. Computer science has long borrowed terms, most notably reproducibility, from metrology, albeit not adopting the same definitions (as discussed in Section 2 above).

In this section, we describe quantified reproducibility assessment (QRA), an approach that is directly derived from the concepts and definitions of metrology, adopting the latter exactly as they are, and yields assessments of the degree of similarity between numerical results and between the studies that produced them. We start below with the concepts and definitions that QRA is based on, followed by an overview of the framework (Section 3.2) and steps in applying it in practice (Section 3.3).

3.1 VIM Definitions of Repeatability and Reproducibility

The International Vocabulary of Metrology (VIM) (JCGM, 2012) defines repeatability and reproducibility as follows (defined terms in bold, see VIM for subsidiary defined terms):

2.21 **measurement repeatability** (or repeatability, for short) is **measurement precision** under a set of **repeatability conditions of measurement**.

2.20 a **repeatability condition of measurement** (repeatability condition) is a condition of **measurement**, out of a set of conditions that includes the same **measurement procedure**, same operators, same **measuring system**, same operating conditions and same location, and replicate measurements on the same or similar objects over a short period of time.

2.25 **measurement reproducibility** (reproducibility) is **measurement precision** under **reproducibility conditions of measurement**.

2.24 a **reproducibility condition of measurement** (reproducibility condition) is a condition of **measurement**, out of a set of conditions that includes different locations, operators, **measuring systems**, etc. A specification should give the conditions changed and unchanged, to the extent practical.

In other words, VIM considers repeatability and reproducibility to be properties of measurements (not objects, scores, results or conclusions), and defines them as measurement precision, i.e. both are quantified by calculating the precision of a set of measured quantity values. Both concepts are defined relative to a set of conditions of measurement: the conditions have to be known and specified for assessment of repeatability and reproducibility to be meaningful. In repeatability, conditions are the same, whereas in reproducibility, they differ.

In an NLP context, objects are systems, and measurements involve applying an evaluation method to a system usually via obtaining a sample of its outputs and applying the method to the sample (further details of how concepts map to NLP are provided in Section 3.3).

3.2 Assessment framework

The VIM definitions translate directly to the following definition of repeatability R^0 (where all conditions of measurement C are the same across measurements):

$$R^0(M_1, M_2, ...M_n) := \text{Precision}(v_1, v_2, ...v_n), \quad \text{where } M_i\colon (m, O, t_i, C) \mapsto v_i \tag{1}$$

and the M_i are repeat measurements for measurand m performed on object O at different times t_i under (the same) set of conditions C, producing measured quantity values v_i. Below, the coefficient of variation is used as the precision measure, but other measures are possible. Conditions of measurement are attribute/value pairs each consisting of a name and a value (for examples, see following section). Reproducibility R is defined in the same way as R^0 except that condition *values* (but not names) differ for one or more of the conditions of measurement C_i:

$$R(M_1, M_2, ...M_n) := \text{Precision}(v_1, v_2, ...v_n), \quad \text{where } M_i\colon (m, O, t_i, C_i) \mapsto v_i \tag{2}$$

Precision is typically reported in terms of some or all of the following: mean, standard deviation with 95% confidence intervals, coefficient of variation, and percentage of measured quantity values within n standard deviations. We opt for the coefficient of variation (CV),[1] because it is a general measure, not in the unit of the measurements (unlike mean and standard deviation), providing a quantification of precision (degree of reproducibility) that is comparable across studies (Ahmed, 1995, p. 57). This also holds for percentage within n standard deviations but the latter is a less recognised measure, and likely to be the less intuitive for many.

In reproduction studies in NLP/ML, sample sizes tend to be very small (a sample size of 8, one original study plus 7 reproductions, as in Table 6 is currently unique). We therefore need to use de-biased sample estimators: we use the unbiased sample standard deviation, denoted s^*, with confidence intervals calculated using a t-distribution, and standard error (of the unbiased sample standard deviation) approximated on the basis of the standard error of the unbiased sample variance $\text{se}(s^2)$ as $\text{se}_{s^2}(s^*) \approx \frac{1}{2\sigma}\text{se}(s^2)$ (Rao, 1973). Assuming measured quantity values are normally distributed, we calculate the standard error of the sample variance in the usual way: $\text{se}(s^2) = \sqrt{\frac{2\sigma^4}{n-1}}$. Finally, we also use a small sample correction (indicated by the star) for the coefficient of variation: $\text{CV}^* = (1 + \frac{1}{4n})\text{CV}$ (Sokal and Rohlf, 1971).[2]

Before applying CV* to values on scales that do not start at 0 (mostly in human evaluations) we shift values to start at 0 to ensure comparability.[3] This means that to calculate the CV* scores in the tables below, measurements are first shifted.

---

[1] The coefficient of variation (CV), also known as relative standard deviation (RSD) is defined as the standard deviation over the mean, often expressed as a percentage.

[2] Code and data are available here: `https://github.com/asbelz/coeff-var.`

[3] Otherwise CV* reflects differences solely due to different lower ends of scales.

3.3 Application of the framework

Using the defined VIM terms and the notations from Section 3.2, we can refine the question from the start of this paper as follows: *if we perform multiple measurements of object* O *and measurand* m *under reproducibility conditions of measurement* C_i, *what is the precision of the measured quantity values we obtain?* For NLP, this means calculating the precision of multiple evaluation scores for the same system and evaluation measure.

Focusing here on reproducibility assessment where we start from an existing set of results (rather than a set of experiments specifically designed to test reproducibility), the steps in performing QRA are as follows:

1. For a set of n measurements to be assessed, identify the shared object and measurand.
2. Identify all conditions of measurement C_i for which information is available for all measurements, and specify values for each condition, including measurement method and procedure.
3. Gather the n measured quantity values $v_1, v_2, ...v_n$.
4. Compute precision for $v_1, v_2, ...v_n$, giving reproducibility score R.
5. Report resulting R score and associated confidence statistics, alongside the C_i.

In NLP terms, the object is the ready-to-use system (binaries if available; otherwise code, dependencies, parameter values, how the system was compiled and trained) being evaluated (e.g. the NTS-default system variant in Table 1), the measurand is the quantity intended to be measured (e.g. BLEU-style modified n-gram precision), and measurement method and procedure capture how to evaluate the system (e.g. obtaining system outputs for a specified set of inputs, and applying preprocessing and a given BLEU implementation to the latter).

VIM holds that reproducibility assessment is only meaningful if the reproducibility conditions of measurement are specified for a given test. Conditions of measurement cover every aspect and detail of how a measurement was performed and how the measured quantity value was obtained. The key objective is to capture all respects in which the measurements to be assessed are *known* to be either the same or different. If QRA is performed for a set of existing results, it is often not possible to discover every aspect and detail of how a measurement was performed, so a reduced set may have to be used (unlike in experiments designed to test reproducibility where such details can be gathered as part of the experimental design).

The reproducibility and evaluation checklists mentioned in Section 2 (Pineau, 2020; Shimorina and Belz, 2021) capture properties that are in effect conditions of measurement, and in combination with code, data and other resources serve well as a way of specifying conditions of measurement, *if* they have been completed by authors. However, at the present time, completed checklists are not normally available. The following is a simple set of conditions of measurement the information required for which *is* typically available for existing work (we include object and measurand for completeness although strictly they are not conditions, as they must be the same in each measurement in a given QRA test):

1. **Object**: the system (variant) being evaluated.[4] *E.g. a given MT system.*
2. **Measurand**: the quantity intended to be evaluated.[5] *E.g. BLEU-style n-gram precision or human-assessed Fluency.*
3. Object conditions:
    - (a) **System code**: source code including any parameters. *E.g. the complete code implementing an MT system.*
    - (b) **Compile/training information**: steps from code plus parameters to fully compiled and trained system, including dependencies and environment. *E.g. complete information about how the MT system code was compiled and the system trained.*
4. Measurement method conditions:[6]
    - (a) **Method specification**: full description of method used for obtaining values quantifying the measurand. *E.g. a formal definition of BLEU.*
    - (b) **Implementation**: the method implemented in a form that can be applied to the object in order to obtain measured quantity values. *E.g. a full implementation of BLEU.*

---

[4] VIM doesn't define 'object' but refers to it as that which is being measured.

[5] For definition of 'measurand' see VIM 2.3.

[6] For definition of 'measurement method', see VIM 2.5.

    (c) **Performed by**: who performed the measurement procedure and any additional information about how they did it. *E.g. the team applying the BLEU tool, and the run-time environment they used.*

The *names* of the conditions of measurement used in this paper are boldfaced above. The *values* for each condition characterise how measurements differ in respect of the condition. In reporting results from QRA tests in the following section, we use paper identifiers as shorthand for each distinct condition value (full details in each case being available from the referenced papers).

4 QRA Tests

Table 1 provides an overview of the 18 object/ measurand pairs (corresponding to 116 individual measurements) for which we performed QRA tests in this study. For each object/measurand pair, the columns show, from left to right, information about the system evaluated (object), the evaluation measure applied (measurand), the number of scores (measured quantity values) obtained, the papers in which systems and scores were first reported, and the NLP task and type of evaluation involved.

There are three sets of related systems: (i) the (single) PASS football report generator (van der Lee et al., 2017), (ii) Vajjala and Rama (2018)'s 11 multilingual essay scoring system variants, and (iii) two variants of Nisioi et al. (2017)'s neural text simplifier (NTS). PASS is evaluated with three evaluation measures (human-assessed Clarity, Fluency and Stance Identifiability), the essay scoring systems with one (weighted F1), and the NTS systems with two (BLEU and SARI). For PASS we have one reproduction study, for the essay scorers seven, and for the NTS systems, from three to six. The PASS reproduction was carried out as part of ReproGen (Belz et al., 2021b), the reproductions of the essay-scoring systems and of one of the NTS systems as part of REPROLANG (Branco et al., 2020), and we carried out an additional reproduction study of the NTS systems for this paper.[8]

The PASS text generation system is rule-based, the essay classifiers are 'theory-guided and data-driven' hybrids, and the text simplifiers are end-to-end neural systems. This gives us a good breadth

of NLP tasks, system types, and evaluation types and measures to test QRA on.

4.1 QRA for NTS systems

The neural text simplification systems reported by Nisioi et al. (2017) were evaluated with BLEU (n-gram similarity between outputs and multiple reference texts) and SARI (based on word added/retained/deleted in outputs compared to both inputs and reference texts, summing over addition and retention F-scores and deletion Precisions).

Table 4 shows BLEU and SARI scores for the two system variants from the original paper and the two reproduction studies, alongside the four corresponding CV* values. In their reproduction, Cooper and Shardlow (2020) regenerated test outputs for NTS-w2v_def, but not for NTS_def, which explains the missing scores in Column 4. The different numbers of scores in different rows in Columns 6–9 are due to our own reproduction using Nisioi et al.'s SARI script, but two different BLEU scripts: (i) Nisioi et al.'s script albeit with the tokeniser replaced by our own because the former did not work due to changes in the NLTK library; and (ii) SacreBLEU (Xu et al., 2016).

Table 5 shows the conditions of measurement for each of the 22 individual measurements. The measured quantity values for those measurements where *Comp./trained by=Nisioi et al.* are identical for the SARI metric (scores highlighted by green/lighter shading and italics), but differ by up to 1.4 points for BLEU (scores highlighted by blue/darker shading). Because *Test set=Nisioi et al.* in all cases, the differences in these BLEU scores can only be caused by differences in BLEU scripts and how they were run. The corresponding CV* is as big as 0.838 for (just) the four NTS_def BLEU scores, and 1.314 for (just) the three NTS-w2v_def BLEU scores, reflecting known problems with non-standardised BLEU scripts (Post, 2018).

If we conversely look just at those measurements (identifiable by boldfaced measured quantity values in Table 5) where the reproducing team regenerated outputs (with the same system code) and evaluation scripts were the same, SARI CV* is 3.11 for the NTS_def variants, and 4.05 for the NTS-w2v_def variants (compared in both cases to 0 (perfect) when the same outputs are used). BLEU CV* is 2.154 for the NTS_def variants (compared to 0.838 for same outputs but different evaluation scripts, as above), and 6.598 for the NTS-w2v_def variants (compared to 1.314 for same outputs but different evaluation scripts). These differences arise simply from running the system in different environments.

The overall higher (worse) CV* values for NTS-w2v_def variants (compared to NTS_def) are likely to be partly due to the NTS models using one third party tool (openNMT), and the NTS-w2v models using two (openNMT and word2vec), i.e. the latter are more susceptible to changes in dependencies.

Table 5: Conditions of measurement for each measurement carried out for the **NTS systems**. OTE = outputs vs. targets evaluation, OITE = outputs vs. inputs and targets evaluation. Shaded cells: evaluation of the same system outputs, i.e. the reproductions did not regenerate outputs. Bold: evaluation of (potentially) different system outputs, i.e. the reproductions did regenerate outputs.

4.2 QRA for PASS system

The PASS system, developed by van der Lee et al. (2017), generates football match reports from the perspective of each of the competing teams. The original study evaluated the system for Clarity, Fluency and Stance Identifiability in an evaluation with 20 evaluators and a test set of 10 output pairs. The evaluation was repeated with a slightly different evaluation interface and a different cohort of evaluators by Mille et al. (2021). Table 2 shows the results from the original and reproduction evaluations (columns 3 and 4), where the Clarity and Fluency results are the mean scores from 7-point agreement scales, and Identifiability results are the percentage of times the evaluators correctly guessed the team whose supporters a report was written for. Columns 6–9 show the corresponding sample size (number of reproductions plus original study), mean, standard deviation (stdev), the confidence interval (CI) for the standard deviation, and CV*, all calculated on the shifted scores (see Section 3.2).

Table 3 shows the values (here, paper identifiers) for the nine conditions of measurement introduced in Section 3.3, for each of the six individual measurements (three evaluation measures times two studies). Note that both object conditions and the test set condition are the same, because Mille et al. used the system outputs shared by van der Lee et al. The values for the *Implemented by*, *Procedure* and *Performed by* conditions reflect the differences in the two evaluations in design, evaluator cohorts, and the teams that performed them.

The scores vary to different degrees for the three measurands, with CV* lowest (reproducibility best) for Stance Identifiability, and highest (worst) for Fluency. These CV* results are likely to reflect that evaluators agreed more on Clarity than Fluency. Moreover, the binary stance identification assessment has better reproducibility than the other two criteria which are assessed on 7-point rating scales.

4.3 QRA for essay scoring system variants

The 11 multilingual essay scoring system variants reported by Vajjala and Rama (2018) were evaluated by weighted F1 (wF1) score. Table 6 shows wF1 scores for the 11 multilingual system variants from each of the five papers, alongside the 11 corresponding CV* values. Table 7 in the appendix shows the corresponding conditions of measurement. The baseline classifier (mult-base) uses document length (number of words) as its only feature. For the other variants, +/- indicates that the multilingual classifier was / was not given information about which language the input was in; the mult-word variants use word n-grams only; mult-word uses POS (part of speech) tag n-grams only; mult-dep uses n-grams over dependency relation, dependent POS, and head POS triples; mult-dom uses domain-specific linguistic features including document length, lexical richness and errors; mult-emb uses word and character embeddings. The mult-base and mult-dom models are logistic regressors, the others are random forests.

A very clear picture emerges: system variant pairs that differ only in whether they do or do not use language information have very similar CV scores. For example, mult-POS$^-$ (POS n-grams without language information) and mult-POS$^+$ (POS n-grams with language information) both have a very good degree of wF1-reproducibility, their CV* being 3.818 and 3.808 respectively; mult-word$^-$ (word n-grams without language information) and mult-word$^+$ (word n-grams with language information) have notably higher CV*, around 10. This tendency holds for all such pairs, indicating that using language information makes next to no difference to reproducibility. Moreover, the mult-dom and mult-emb variants all have similar CV*.[9]

The indication is that the syntactic information is obtained/used in a way that is particularly reproducible, whereas the domain-specific information and the embeddings are obtained/used in a way that is particularly hard to reproduce. Overall, the random forest models using syntactic features have the best reproducibility; the logistic regressors using domain-specific features have the worst.

5 Discussion

Quantified reproducibility assessment (QRA) enables assessment of the degree of reproducibility of evaluation results for any given system and evaluation measure in a way that is scale-invariant[10] and comparable across different QRAs, for reproductions involving either the same or different original studies. Moreover, formally capturing (dis)similarities between systems and evaluation designs enables reproducibility to be assessed relative to such (dis)similarities. In combination, a set of results from QRA tests for the same system and evaluation measure can provide pointers to which aspects of the system and evaluation might be associated with low reproducibility. E.g. for the wF1 evaluations of the essay scoring systems above, it is clear that variations in reproducibility are associated at least in part with the different features used by systems.

It might be expected that the reproducibility of human-assessed evaluations is generally worse than metric-assessed. Our study revealed a more mixed picture. As expected, the Fluency and Clarity evaluations of the PASS system were among those with highest CV*, and the BLEU and SARI evaluation of the NTS systems and wF1 evaluation of the mult-POS and mult-dep systems were among those with lowest CV*. However, human-assessed Stance Identifiability of PASS was among the most reproducible, and metric-assessed wF1 of mult-base, mult-dom and mult-emb were among the worst.

In this paper, our focus has been QRA testing of existing research results. However, ideally, QRA would be built into new method development from the outset, where at first reporting, a detailed stan-

---

[9] The high CV* for the baseline system may be due to an issue wiith the evaluation code (macro-F1 instead of weighted-F1), as reported by Bestgen (Section 3.2, first paragraph), Caines and Buttery (Section 2.5, one before last paragraph) and Huber and Çöltekin (Section 3.2, second paragraph).

[10] If evaluation scores are multiplied by a common factor, CV* does not change.

Table 6: Precision (CV*) and component measures (mean, standard deviation, standard deviation confidence intervals) for measured quantity values obtained in multiple measurements of the **essay scoring systems**. Seed i = different approaches to random seeding and cross-validation; ei = different compile/run-time environments; ii = different test data sets and/or cross-validation folds.

dardised set of conditions of measurement is specified, and repeatability tests (where all conditions are identical except for the team conducting the tests, see Section 3.2) are performed to determine baseline reproducibility. Such repeatability QRA would provide quality assurance for new methods as well as important pointers for future reproductions regarding what degree of reproducibility to expect for given (types of) methods.

If this is not possible, post-hoc reproducibility QRA (where there are differences in conditions of measurement values) is performed instead. If this yields high (poor) CV*, one way to proceed is to minimise differences in conditions of measurement between the studies and observe the effect on CV*, changing aspects of system and evaluation design and adding further conditions of measurement if need be. For human evaluation in particular, persistently high CV* would indicate a problem with the method itself.

6 Conclusion

We have described an approach to quantified reproducibility assessment (QRA) based on concepts and definitions from metrology, and tested it on 18 system and evaluation measure combinations involving diverse NLP tasks and types of evaluation.

QRA produces a single score that quantifies the degree of reproducibility of a given system and evaluation measure, on the basis of the scores from, and differences between, multiple reproductions of the same original study. We found that the approach facilitates insights into sources of variation between reproductions, produces results that are comparable across different reproducibility assessments, and provides pointers about what needs to be changed in system and/or evaluation design to improve reproducibility.

A recent survey (Belz et al., 2021a) found that just 14% of the 513 original/reproduction score pairs analysed were exactly the same. Judging the remainder simply ‘not reproduced’ is of limited usefulness, as some are much closer to being the same than others. At the same time, assessments of whether the same conclusions can be drawn on the basis of different scores involve subjective judgments and are prone to disagreement among assessors. Quantifying the closeness of results as in QRA, and, over time, establishing expected levels of closeness, seems a better way forward.

Abstract

Recent studies have determined that the learned token embeddings of large-scale neural language models are degenerated to be anisotropic with a narrow-cone shape. This phenomenon, called the representation degeneration problem, facilitates an increase in the overall similarity between token embeddings that negatively affect the performance of the models. Although the existing methods that address the degeneration problem based on observations of the phenomenon triggered by the problem improves the performance of the text generation, the training dynamics of token embeddings behind the degeneration problem are still not explored. In this study, we analyze the training dynamics of the token embeddings focusing on rare token embedding. We demonstrate that the specific part of the gradient for rare token embeddings is the key cause of the degeneration problem for all tokens during training stage. Based on the analysis, we propose a novel method called, *adaptive gradient gating* (AGG). AGG addresses the degeneration problem by gating the specific part of the gradient for rare token embeddings. Experimental results from language modeling, word similarity, and machine translation tasks quantitatively and qualitatively verify the effectiveness of AGG.

1 Introduction

Neural language models have been developed with various architectures during recent years (Graves, 2013; Bahdanau et al., 2015; Gehring et al., 2017; Vaswani et al., 2017). Despite the improvement in model architectures, models usually share the same process for input and output. They process token embeddings as inputs to compute contextualized features and subsequently project the features into a categorical distribution of tokens at the output softmax layer whose weight is token embedding matrix (Merity et al., 2017; Yang et al., 2018; Press and Wolf, 2017). Recent studies have determined that the learned embedding distribution is biased in a common direction, thereby resulting in a narrow cone-shaped anisotropy (Mu and Viswanath, 2018; Ethayarajh, 2019; Gao et al., 2019; Biś et al., 2021). This phenomenon, named the representation degeneration problem by Gao et al. (2019), increases the overall similarity between embeddings, and leads to a problem in which the expressiveness of the token embeddings decreases. Therefore, it is difficult for the model to learn the semantic relationship between the tokens and to generate high quality texts. Existing studies addressing this problem suggest methods that apply post-processing or regularization techniques to all token embeddings based on the observed phenomena owing to the degeneration problem (Mu and Viswanath, 2018; Gao et al., 2019; Wang et al., 2019; Wang et al., 2020; Biś et al., 2021). Although these works improve the quality of token embeddings and generated texts, it is still not clear how token embeddings become degenerate during training procedure. Also, there exists the problem of over regularization for the token embeddings whose semantic relationships are trained well because the above methods are applied for all token embeddings.

In this study, we conduct empirical studies about training dynamics of token embeddings, focusing on rare token embeddings. By observing the initial training dynamics of token embeddings grouped based on appearance frequency, we hypothesize that the degeneration of the rare token embeddings triggers the degeneration of the embeddings of the remaining tokens. We show that the entire degeneration problem is mitigated by only freezing rare tokens during training, and we demonstrate that the main cause of the entire degeneration problem is the specific part of the gradient for rare token em-

beddings. This gradient part pushes away rare token embeddings from the feature vector of the non-rare targets in the current training sample. Based on the analysis, we propose a new method, *adaptive gradient gating* (AGG). With a dynamic grouping of rare tokens at each training step, AGG solves the entire degeneration problem by gating a specific part of the gradient that is solely about rare tokens. Because AGG is optimized to target the main cause of the degeneration problem, rare token embeddings, it can prevent the over regularization problem about frequent token embeddings which occurs in other methods addressing the degeneration problem. The proposed method is evaluated in three tasks: language modeling, word similarity, and machine translation. The AGG outperforms the baseline and other existing methods in all tasks. In addition, it shows compatibility with other method that addresses the neural text degeneration problem. Via qualitative studies, we identify a correlation between our method and the frequency bias problem of learned embeddings (Gong et al., 2018; Ott et al., 2018).

2 Background

2.1 Text Generation of Neural Language Models

Neural language generative models process text generation tasks as conditional language modeling, in which the model is typically trained by minimizing the negative log likelihood of the training data. With a vocabulary of tokens $V = \{v_1, ..., v_N\}$ and embedding vectors $\{\mathbf{w}_1, ..., \mathbf{w}_N\}$, where $\mathbf{w}_i$ corresponds to token v_i, at every training step, the model obtains a mini-batch input and target text corpus pair (**x**, **y**), where $x_i, y_i \in V$, and $\mathbf{y} \in V^T$. The conditional probability for the target token y_t, $P_\theta(y_t|\mathbf{h}_t)$, where $\mathbf{h}_t$ is a context feature vector of the t-th position of the generated text conditioned by ($\mathbf{x}$, $y_{<t}$), and θ denotes model parameters, which is defined as follows.

$$P_\theta(y_t|\mathbf{h}_t) = \frac{\exp{(\mathbf{h}_t \mathbf{w}^T_{I(y_t)})}}{\sum_{l=1}^{N} \exp{(\mathbf{h}_t \mathbf{w}^T_l)}}, \tag{1}$$

where **w** is the output token embedding which roles the weight of the output softmax layer, and $I(y_t)$ represents the index of token y_t. The negative log likelihood loss for an input and target pair (**x**, **y**), L_{NLL} is expressed as follows.

$$L_{NLL} = -\sum_{t=1}^{T} \log P_\theta(y_t|\mathbf{h}_t). \tag{2}$$

2.2 Embedding Problems in Neural Language Models

Recent studies on the geometric properties of contextual embedding space have observed that the distribution of embedding vectors is far from isotropic and occupies a relatively narrow cone space(Mu and Viswanath, 2018; Liu et al., 2019; Zhou et al., 2019; Ethayarajh, 2019;). Gao et al. (2019) named this phenomenon the *representation degeneration problem*. This degeneration problem results in an increase in the overall cosine similarity between token embeddings, making it difficult for the model to learn semantic relationships between tokens. Demeter et al. (2020) demonstrated that the norm information of the token embeddings is so dominant that angle information about the feature vector is ignored when calculating the logits in the output layer. Owing to this structural weakness of the embedding space, embeddings with small norms are always assigned with a low probability, which reduces the diversity of the text generated by the model. Anisotropy of the embedding space is a still problem for the pre-trained large language models, and language models with improved isotropic

embedding space performs well in downstream tasks(Biś et al., 2021; Rajaee and Pilehvar, 2021).

Although the problem has been theoretically analyzed in several studies, existing methods are based on the observed phenomena as a result of the problem. To mitigate the phenomena observed from the problem, the post-processing of the embedding vectors(Mu and Viswanath, 2018; Biś et al., 2021) or regularization terms about the phenomena(Gao et al., 2019; Wang et al., 2019; Wang et al., 2020; Zhang et al., 2020) were introduced. These methods are applied to all token embeddings, so there is the problem of over regularization for the embeddings whose semantic relationship is trained well. Also, methodologies based on the training dynamics of the token embeddings concerning the degeneration problem remain subject to study.

Frequency bias in embedding space is another problem. Ott et al. (2018) conducted a comprehensive study on the under-estimation of rare tokens in neural machine translation. Gong et al. (2018) observed that embeddings in the language model were biased towards frequency and proposed an adversarial training scheme to address this problem.

3 Empirical Study: Token Embedding Training Dynamics led by Rare Tokens

3.1 Initial Training Dynamics of Embeddings

To analyze the training procedure of token embeddings, we train a Transformer language model at the WikiText-103 dataset from scratch. Whole vocabulary tokens are divided into three groups: frequent, medium, and rare groups. Based on the appearance frequency in the training corpus, the 30%, 50%, and 20% tokens are assigned to the frequent, medium, and rare group. We visualize the initial training dynamics of these groups via the projection of the embeddings into 2D, using singular value decomposition (SVD) projection. As illustrated in Figure 1, rare groups degenerate first, as they emerge from the entire embedding distribution. Subsequently, other groups also start to degenerate, following the degeneration of the rare group. Based on this observation, we hypothesize that *the degeneration of rare token embeddings induces the degeneration of non-rare token embeddings*.

3.2 Rare Tokens Degenerate Non-Rare Tokens

Because Transformer (Vaswani et al., 2017) is representative of the current language models, we adopt the 6-layer Transformer decoder model architecture for an empirical study on the training dynamics of embedding vectors. The model is trained in language modeling task using WikiText-103 dataset (Merity et al., 2018). Experimental details regarding the model and training hyperparameter configurations can be found in the Appendix B. To verify the hypothesis of the previous subsection, we train a model while freezing the rare group token embeddings in their initial states during training, and compare it to the baseline model, where all embeddings are trained with negative log-likelihood loss. In addition, we train the models of various set-

tings relative to freezing steps and examine whether the degeneration of rare token embeddings depends on when training of rare embeddings begins.

The performance of the models is evaluated in two ways; the likelihood and isotropy of token embeddings. Perplexity (Bengio et al., 2000) is adopted to evaluate the performance of the likelihood of the model. To measure the isotropy of the token embedding distribution, we adopt the partition function $Z(\mathbf{a}) = \sum_{i=1}^{N} \exp\left(\mathbf{w}_i \mathbf{a}^T\right)$ defined in Arora et al. (2016), where $\mathbf{w}_i$ denotes the embedding vector of token v_i, and $\mathbf{a}$ represents a unit vector. Lemma 2.1. in Arora et al. (2016) demonstrate that if the embedding vectors are isotropic, $Z(\mathbf{a})$ is approximately constant. Based on this property, we measure the isotropy of an embedding matrix $\mathbf{W}$ using $I(\mathbf{W})$, which is defined as follows.

$$I(\mathbf{W}) = \frac{\min_{\mathbf{a}\in\mathbf{X}} Z(\mathbf{a})}{\max_{\mathbf{a}\in\mathbf{X}} Z(\mathbf{a})}, \tag{3}$$

where $I(\mathbf{W}) \in [0, 1]$ and $\mathbf{X}$ represents the set of eigenvectors of $\mathbf{W}^T\mathbf{W}$ (Mu and Viswanath, 2018; Wang et al., 2020; Biś et al., 2021). Furthermore, we measure the relatedness between the rare and frequent group token embeddings to verify that the degeneration of the frequent group follows the degeneration of the rare group. We calculate the average cosine similarity between the rare and frequent group embeddings to measure the relatedness.

Table 1 shows the comparison of the baseline model and the model with frozen rare tokens. We denote the baseline as "MLE" and the freezing method as "Freeze". Surprisingly, the PPL of frequent group tokens and overall $I(\mathbf{W})$ improved by simply not training the rare token embeddings. Figure 2 illustrates the change in $I(\mathbf{W})$ for the frequent and rare token embeddings, including the similarity between frequent and rare token embeddings at various freezing step settings. Whenever the rare token embeddings start to be trained, their $I(\mathbf{W})$ decreases steeply, followed by decreasing $I(\mathbf{W})$ of frequent embeddings and increasing similarities between the frequent and rare embeddings. From the analysis in this subsection, we demonstrate that the entire degeneration problem can be solved by solely handling just rare embeddings during the entire training procedure.

3.3 Finding the Primary Cause of the Degeneration Problem: From the Gradient

With T context feature vectors $\mathbf{h}_i$ ($i \in [1, T]$) from the training sample, the negative log-likelihood loss gradient for the rare token embedding $\mathbf{w}_r$ is calculated as follows.

$$\nabla_{\mathbf{w}_r} L_{NLL} = \underbrace{\sum_{y_i = v_r} (p_{r|i} - 1)\mathbf{h}_i}_{(a)} + \underbrace{\sum_{y_j \notin V_r} p_{r|j}\mathbf{h}_j}_{(b)} + \underbrace{\sum_{y_k \in V_r} p_{r|k}\mathbf{h}_k}_{(c)}, \tag{4}$$

where y_i denotes the target token for $\mathbf{h}_i$, V_r is the rare token vocabulary group, and $p_{r|i}$ represents the conditional probability of token v_r given $\mathbf{h}_i$, which is calculated as $[\text{softmax}(\mathbf{h}_i\mathbf{W}^T)]_r$. We divide the gradient for $\mathbf{w}_r$ to 3 parts in Eq. 4. Part (a) pulls $\mathbf{w}_r$ close to the feature vectors whose target tokens are v_r. Part (b) pushes away $\mathbf{w}_r$ from the feature vectors whose target tokens are not rare. Part (c) pushes away $\mathbf{w}_r$ from the feature vectors whose target tokens are rare. As an extension of the analysis in the previous subsection, we freeze these parts of the gradient with various settings during training to identify the key cause of the degeneration problem. In other words, depending on the settings, the specific gradient parts that will not be used for embedding training is detached from the computation graph during training stage. This can be easily implemented by `detach()` function of `Pytorch` (Paszke et al., 2019). All model and training configurations are the same as in the previous sections, except those to be frozen.

Table 2 presents the results of the experiments in this subsection. We freeze the parts of the gradient for the rare tokens with three settings. Because part (a) is a key component required to train the token embedding to be aligned to the target, all settings activate part (a). We notice that when part (b) is activated (solely freezing part (c)), $I(\mathbf{W})$ decreases and PPL for rare tokens increases almost 10 times compared to when part (b) is frozen. Because activating part (c) is not seen to be negative for PPL and $I(\mathbf{W})$, we conclude that part (b) of Eq. 4 is the bedrock cause for the degeneration problem. From the analysis in this section, we demonstrate that *the degeneration problem could be solved to a large extent by mainly addressing the part of the gradient for rare embeddings that pushes away rare token embeddings from non-rare feature vectors*.

4 Method

4.1 Dynamic Rare Token Grouping

To handle the specific part of the gradient for the rare token embeddings studied in the previous section, we need to properly group the rare tokens. A naive approach can be used to group rare tokens based on the appearance frequency of the training corpus, as described in the previous section. However, this static grouping method is suboptimal because the model is typically trained via mini-batch training. The group of rare tokens that appeared less frequently in recent batch samples is variable in the mini-batch training. Therefore, it is necessary to dynamically group rare tokens based on token appearances in recent batch samples.

To consider the token appearances in recent batch samples, we introduce the token counter memory that remembers the number of the appearances of each token during the previous K training steps. For K memories, $[\mathbf{m}_1, ..., \mathbf{m}_K]$, $\mathbf{m}_t \in \mathbb{R}^N$ represents the number of appearances of each token of N-size vocabulary at the t-th previous training step. Memories are set as zero vectors at the initial stage. At each training step, the token appearance, $\mathbf{a} \in \mathbb{R}^N$, is calculated as the sum of all K memories: $\mathbf{a} = \sum_{t=1}^{K} \mathbf{m}_t$. Based on $\mathbf{a}$, we determine whether token v_i is in the rare token group V_r as follows.

$$\begin{aligned} \frac{a_i}{K} &< \alpha \Rightarrow v_i \in V_r \\ \frac{a_i}{K} &\geq \alpha \Rightarrow v_i \notin V_r, \end{aligned} \tag{5}$$

where a_i is the i-th component of $\mathbf{a}$, and α is a hyper-parameter in our method that controls the proportion of rare tokens in the entire vocabulary. In this study, we set K to the number of iteration steps during one epoch of training stage.

4.2 Adaptive Gradient Gating for Rare Tokens

After dynamically grouping the rare tokens at each training step, we need to handle a specific part of the gradient for the rare token embeddings to solve the degeneration problem of all embeddings. To solely control the gradient for rare token embeddings, we introduce a *gradient gating* method for a parameter $\mathbf{x}$. We define $\tilde{\mathbf{x}}$ as a tensor whose value is the same as $\mathbf{x}$, but detached from the current training graph. This implies that $\tilde{\mathbf{x}}$ is considered a constant, hence, gradient about $\tilde{\mathbf{x}}$ does not exist. In practice, $\tilde{\mathbf{x}}$ can be easily obtained from $\mathbf{x}$ using the `detach()` function of `Pytorch` (Paszke et al., 2019). With $\tilde{\mathbf{x}}$, we can gate the gradient for $\mathbf{x}$ as follows.

$$\begin{aligned} \mathbf{x}_{gated} &= \mathbf{g} \odot \mathbf{x} + (1 - \mathbf{g}) \odot \tilde{\mathbf{x}} \\ \nabla_{\mathbf{x}} f(\mathbf{x}_{gated}) &= \mathbf{g} \odot \nabla_{\mathbf{x}} f(\mathbf{x}), \end{aligned} \tag{6}$$

where $\mathbf{x}_{gated}$ is a new parameter whose value is the same as $\mathbf{x}$, and $\mathbf{g} \in [0, 1]$ is a gate tensor. When the $\mathbf{x}_{gated}$ is fed to the function $f(\cdot)$ as input, the gradient for $\mathbf{x}$ is gated by $\mathbf{g}$.

As we described in section 3, part (b) of Eq. 4 should mainly be handled to solve the degeneration problem. To address part (b) of Eq. 4, given a context feature vector of the i-th position $\mathbf{h}_i$, we introduce a gate vector $\mathbf{g}_1 \in \mathbb{R}^N$ as follows.

$$g_{1k} = \begin{cases} a_k/K & \text{if } v_k \in V_r, v_k \neq y_i \\ 1 & \text{else }, \end{cases} \tag{7}$$

where g_{1k} denotes a k-th component of $\mathbf{g}_1$. $\mathbf{g}_1$ controls the degree to which rare token embeddings move away from non-rare feature vectors whose targets differ from each rare token embedding. Also, each component of $\mathbf{g}_1$ is calculated based on the rarity of each rare token, a_k, so gradient gating for part (b) of Eq. 4 is adaptive for each rare tokens.

Although part (c) of Eq. 4, which pushes embeddings away from the feature vectors whose targets are other rare tokens, is not to be seen as the cause of the degeneration problem in section 3, this part also induces the degeneration problem for the certain situation when rare tokens degenerate other rare tokens. To address this, we approximate the multiple levels of rarity in the rare token group to two levels in this paper: ‘less rare’ and ‘very rare’.

Human	–	–	–	–	10844	7146	300	18920	–

Table 4: Experimental results for each token group in WikiText-103 language modeling task comparing UL and UL+AGG.

We define the two rarity levels based on the average number of appearances of the entire rare tokens: if the token appearance a_k is smaller than the mean of a_r where $r \in V_r$, corresponding token is a very rare token. For the very rare token embeddings, part (c) of the gradient about embeddings pushes them away from the feature vectors whose targets are less rare tokens that are relatively frequent compared to them. This means that part (c) roles like part (b) in the above situation, which becomes the cause of the degeneration problem. Therefore, we need to handle part (c) of Eq. 4 for very rare tokens. To address part (c) of Eq. 4 for the very rare token embeddings, we introduce another gate vector $\mathbf{g}_2 \in \mathbb{R}^N$ as follows.

$$g_{2k} = \begin{cases} min(\frac{a_k}{\bar{a}_r}, 1) & \text{if } v_k \in V_r, v_k \neq y_i \\ 1 & \text{else}, \end{cases} \tag{8}$$

where g_{2k} is the k-th component of $\mathbf{g}_2$ and $\bar{a}_r$ is the mean of a_r where $r \in V_r$. $\mathbf{g}_2$ controls the degree to which very rare token embeddings move away from less rare feature vectors whose targets differ from each very rare token embedding. Also, each component of $\mathbf{g}_2$ is calculated based on the rarity of each very rare token, a_k, so gradient gating for part (c) of Eq. 4 is adaptive for each very rare tokens.

To calculate the loss of $\mathbf{h}_i$, we calculate three logits, $\mathbf{z}_i^0, \mathbf{z}_i^1,$ and $\mathbf{z}_i^2$, as follows.

$$\begin{aligned} \mathbf{z}_i^0 &= \mathbf{h}_i \tilde{\mathbf{W}}^T \\ \mathbf{z}_i^l &= \mathbf{g}_l \odot \tilde{\mathbf{h}}_i \mathbf{W}^T + (1 - \mathbf{g}_l) \odot \tilde{\mathbf{h}}_i \tilde{\mathbf{W}}^T, \end{aligned} \tag{9}$$

where $\mathbf{W}$ denotes an embedding matrix, and $l = 1, 2$. Because our method solely handles the gradient for embeddings, we calculate $\mathbf{z}_i^0$ for a gradient about $\mathbf{h}_i$, which does not need to be gated. Finally, the negative log-likelihood loss for i-th position L_i is computed as follows.

$$\begin{aligned} L_i = &- \log p^0_{I(y_i)|i} \\ &- \mathbb{1}(y_i \notin V_r) \log p^1_{I(y_i)|i} \\ &- \mathbb{1}(y_i \in V_r) \log p^2_{I(y_i)|i}, \end{aligned} \tag{10}$$

where $p^m_{I(y_i)|i}$ = [softmax$(\mathbf{z}_i^m)]_{I(y_i)}$ with m=0, 1, 2 and $\mathbb{1}(\cdot)$ denotes the Indicator function. Derivation of the gradient for rare token embeddings, $\nabla_{\mathbf{w}_r} L_i$, is provided in Appendix A.

5 Experiments

We evaluate our method on various tasks including language modeling, word similarity, and machine translation. In the language modeling task, we focus on verifying the diversity of the generated texts. We test the learning of the semantic relationships between tokens on the word similarity task. Finally, we evaluate the quality of generated texts on the machine translation task. For all the experimental results below, we adopt the state-of-the-art model architecture as a baseline to properly demonstrate the effectiveness of our method. Every detail on the experiment, such as model hyper-parameters and training configurations, regard the reproducibility are provided in Appendix B.

5.1 Language Modeling

Setting We conduct experiments using WikiText-103 dataset, which is a significantly large dataset for language modeling task with approximately 103M words and 260K vocabulary size (Merity et al., 2018). Texts in the dataset are preprocessed based on the byte-pair encoding(Sennrich et al., 2016). We adopt the GPT-2 medium architecture(Radford et al., 2019), which comprises 24 Transformer decoder layers as a baseline model. Because our method is about learning token embeddings, we train the models from scratch for a maximum of 50k iterations and evaluate them based on the perplexity of the validation set. For hyper-parameter searching, we select $\alpha \in \{0.01, 0.02, 0.03, 0.04, 0.05\}$ for AGG method on the language modeling task. The hyper-parameter sensitivity for the AGG are given in Appendix D.

We use three quantitative metrics to evaluate our method: Perplexity, Uniq, and $I(\mathbf{W})$. Related to the likelihood of generated texts, Perplexity quantifies the prediction difficulty over the next token. Uniq (Welleck et al., 2020) quantify the number of unique next-token predictions, measuring the token diversity. As described in section 3, $I(\mathbf{W})$ measures the isotropy of the token embedding space.

Results We present our results for the testset in Table 3. We denote the baseline method as 'MLE' and our method as 'AGG'. We measure Perplexity and Uniq for each token group defined in Section 3. As presented in Table 3, AGG improves the overall metrics for the medium and rare groups while maintaining performance for the frequent token group. This shows that our method not only improves the quality of rare token embeddings, but also the quality of non-rare token embeddings. In particular, for the rare group, the Perplexity score decrease significantly and the number of unique predictions surpasses the human distribution. The $I(\mathbf{W})$ for all token embeddings increased over 2 times the baseline. Experimental results of $I(\mathbf{W})$ for the embeddings of each frequency groups can be found in Appendix C. Table 5 shows examples of generated texts from MLE baseline and AGG. We also show additional examples of generated texts in Appendix F.

Compatibility Neural text degeneration problem is another problem in neural text generative models, where the model generates texts that are less likely to match human word distributions. Existing methods for this problem focus on the diversity of the generated texts by adding an auxiliary loss to the original negative log-likelihood loss (Welleck et al., 2020). Although Welleck et al. (2020) and AGG attempts to address the same problem about diversity, AGG can be compatible with the existing method in the text degeneration problem because AGG does not alter the form of the loss function in MLE training. Table 4 presents the results of the experiments about fusion of unlikelihood training(Welleck et al., 2020) and AGG. We denote the unlikelihood training as UL. From Table 4, we notice that when UL and AGG are fused, it produces a synergistic effect that exceeds the gain of each for the baseline. This indicates that AGG is compatible with methods that address other problems in text generation.

5.2 Word Similarity

Setting We evaluate the semantic relationship between tokens for AGG and the baseline with four word similarity datasets: MEN, WS353, RG65, and RW(Bruni et al., 2014; Agirre et al., 2009; Rubenstein and Goodenough, 1965; Luong et al., 2013). Methods are tested whether the similarity between the given two words in the embedding space is consistent with the ground truth, in terms of Spear-

Datasets	MLE	AGG

man's rank correlation. We adopt cosine distance to compute the similarity between embeddings. We use the same models trained on language modeling tasks with the WikiText-103 dataset for the word similarity task.

Results Table 6 presents the result obtained from the evaluation of the word similarity task. From this table, it can be observed that our method outperforms the baseline on overall datasets. Although AGG handles only training of rare tokens, the semantic relationships between all tokens are also well learned. Qualitative studies on semantic alignment between tokens are provided in Appendix E.

5.3 Machine Translation

Setting We utilize a dataset from standard WMT 2014 containing 4.5M English→German sentence pairs. The source and target sentences are encoded by 37K shared tokens based on byte-pair encoding(Sennrich et al., 2016). We adopt the two version of Transformer(Vaswani et al., 2017) as the baseline model for applying our method: `base` and `big`. The model configuration is the same as that proposed in Vaswani et al. (2017). To evaluate the quality of the generated texts, we measure BLEU score (Papineni et al., 2002), which is standard metric for machine translation task.

Results Table 7 presents a comparison of our method and other methods in terms of the BLEU score. Our method achieves 1.4 and 1.41 BLEU score improvements on the machine translation task for the `base` and `big` baseline models. In addition, our method is better than all other previous works in handling the representation degeneration problem that reported BLEU scores in the same tasks. These results demonstrate the effectiveness of AGG in the quality of the generated texts. While other methods addressing the degeneration problem targets all token embeddings, target of AGG, rare token embeddings, are optimized based on the analysis about the training dynamics of token embeddings. Due to this difference, our method can prevent the over regularization problem for frequent token embeddings, which is the main advantage of AGG compared to other works. Qualitative study about cross-lingual semantic alignment between tokens of the source and target languages is provided in Appendix E.

6 Analysis of AGG

6.1 Ablation Study

In our method, AGG, we introduce two gate vectors, $\mathbf{g}_1$, and $\mathbf{g}_2$, to handle the gradient for rare and very rare token embeddings. We conduct experiments on these gate vectors. Table 8 presents the results of the ablation studies compared with the MLE and AGG. When $\mathbf{g}_1$ is excluded from AGG (denoted as 'no $\mathbf{g}_1$'), Uniq and $I(\mathbf{W})$ decreased significantly, because $\mathbf{g}_1$ is the key component for the gradient gating. When $\mathbf{g}_2$ is excluded from AGG (denoted as 'no $\mathbf{g}_2$'), Uniq and $I(\mathbf{W})$ slightly decrease. Accordingly, we notice that $\mathbf{g}_2$ is important for the gating of gradients fort the very rare token embeddings.

Also, we present the analysis about rare token grouping method of AGG. Figure 4 presents the

Figure 3: (a), (b) Token embedding visualization for the baseline model and AGG on the language modeling task with WikiText-103. Red, green, and blue points represent rare, medium, and frequent groups respecively; (c) Normalized singular value for MLE and AGG.

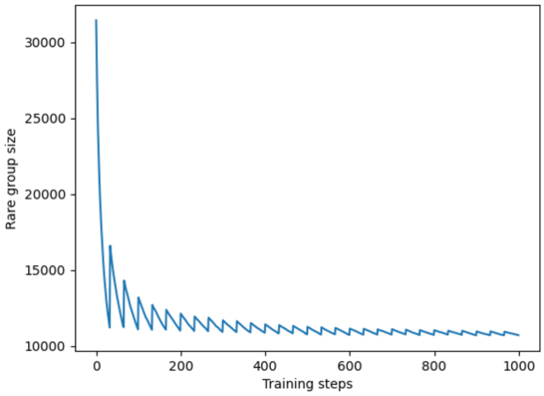

Figure 4: Size of the rare token group during initial 1k steps of training with WikiText-103 dataset.

size of the rare token group during initial 1k training steps when the model is trained with WikiText-103 dataset. As presented in the figure, rare group size fluctuate wildly at the initial training stage. We expect for this grouping method to determine an optimal rare token group for the current training step. Table 9 presents the results of ablation study about dynamic grouping. To except dynamic grouping from AGG, we fixed the rare token group after 1 epoch. For this static grouping AGG method, Next-token diversity(Uniq) and the isotropy of the token embedding space($I(\mathbf{W})$) perform worse than dynamic grouping AGG.

6.2 Visualization

Figure 3 (a) and (b) present the visualizations of the embedding space of baseline MLE and our method. In the figure, applying the AGG method restores the isotropy of the token embedding space. In addition, we observe that the regions occupied by each token group are not disjoint when applying AGG. For baseline, the regions occupied by rare group and the frequent group are disjoint, which is refered as the frequency bias problem of embeddings (Gong et al., 2018). From the analysis of the visualization of the embedding space, we notice that the manipulating the training of the rare token embeddings can alleviate the frequency bias problem. Figure 3 (c) presents the plot of the normalized singular value of embedding matrix for MLE and AGG. Slowly decaying singular values of AGG demonstrate an isotropic distribution of the embedding space.

7 Conclusion

In this study, we analyzed the training dynamics of the token embeddings concerning the representation degeneration problem of the learned embeddings, focusing on the rare tokens. Based on the analysis, we propose an adaptive gradient gating method that solves the problem by solely handling the training for rare token embeddings. Experiments and qualitative studies in various tasks of text generation demonstrate the effectiveness of our method. Beyond the two-level approximation of rarity of rare tokens which is applied to our study, addressing multiple levels of rarity can be an interesting region to study for the future work.

A Derivation of the gradient of AGG loss *w.r.t.* rare token embedding

We follow the same notation as in the main paper. Before we write the derivation of the gradient about rare token embedding $\mathbf{w}_r$, we write the gradient of $f(\tilde{\mathbf{w}}_j)$ and $(z_i^l)_j$ about $\mathbf{w}_r$, where $f(\tilde{\mathbf{w}}_j)$ is the function of $\tilde{\mathbf{w}}_j$ with $j = 1, ..., N$ and $(z_i^l)_j$ is a j-th component of $\mathbf{z}_i^l$ with $l = 0, 1, 2$ as follows.

$$\begin{aligned} \nabla_{\mathbf{w}_r} f(\tilde{\mathbf{w}}_j) &= \nabla_{\tilde{\mathbf{w}}_j} f(\tilde{\mathbf{w}}_j) \odot \nabla_{\mathbf{w}_r} \tilde{\mathbf{w}}_j \\ &= \nabla_{\tilde{\mathbf{w}}_j} f(\tilde{\mathbf{w}}_j) \odot 0 \\ &= 0 \text{ for all } j \\ &(\because \tilde{\mathbf{w}}_j \text{ is treated as a constant.}) \end{aligned} \tag{11}$$

$$\begin{aligned} \nabla_{\mathbf{w}_r} (z_i^l)_j &= \nabla_{\mathbf{w}_r} [g_{lj} \cdot \tilde{\mathbf{h}}_i \mathbf{w}_j^T + (1 - g_{lj} \cdot \tilde{\mathbf{h}}_i \mathbf{w}_j^{\tilde{T}})] \\ &= g_{lj} \nabla_{\mathbf{w}_r} \tilde{\mathbf{h}}_i \mathbf{w}_j^T + 0 \\ &= \begin{cases} g_{lj} \tilde{\mathbf{h}}_i & \text{if } j = r \\ 0 & \text{else} \end{cases} \\ &= \begin{cases} g_{lj} \mathbf{h}_i & \text{if } j = r \\ 0 & \text{else} \end{cases} \\ &(\because \mathbf{h}_i = \tilde{\mathbf{h}}_i \text{ in terms of value.}) \end{aligned} \tag{12}$$

Considering the case of $y_i \notin V_r$, AGG negative log-likelihood loss for the i-th position of token generation, L_i^{AGG} is written as follows.

$$L_i^{AGG} = -\log p^0_{I(y_i)|i} - \log p^1_{I(y_i)|i} \tag{13}$$

Then gradient of L_i^{AGG} about $\mathbf{w}_r$ is written as follows.

$$\begin{aligned} &\nabla_{\mathbf{w}_r} L_i^{AGG} \\ &= -\nabla_{\mathbf{w}_r} \log p^0_{I(y_i)|i} - \nabla_{\mathbf{w}_r} \log p^1_{I(y_i)|i} \\ &= -\nabla_{\mathbf{w}_r} \log p^1_{I(y_i)|i} - 0 \\ &(\because \log p^0_{I(y_i)|i} \text{ is a function of } \tilde{\mathbf{w}}_r.) \\ &= -\frac{1}{p^1_{I(y_i)|i}} \nabla_{\mathbf{w}_r} p^1_{I(y_i)|i} \\ &= -\frac{1}{p^1_{I(y_i)|i}} \sum_{j=1}^{N} \nabla_{(z_i^1)_j} p^1_{I(y_i)|i} \cdot \nabla_{\mathbf{w}_r} (z_i^1)_j \\ &(\because p^1_{I(y_i)|i} \text{ is a function of } (z_i^1)_j, j = 1, ..., N.) \\ &= -\frac{1}{p^1_{I(y_i)|i}} \nabla_{(z_i^1)_r} p^1_{I(y_i)|i} \cdot \nabla_{\mathbf{w}_r} (z_i^1)_r \\ &(\text{By Eq. 12.}) \end{aligned} \tag{14}$$

As $p^1_{I(y_i)|i} = [\text{softmax}(\mathbf{z}_i^1)]_{I(y_i)|i}$,

$$\nabla_{(z_i^1)_r} p^1_{I(y_i)|i} = -p^1_{I(y_i)|i} p^1_{r|i}. \tag{15}$$

Thus, $\nabla_{\mathbf{w}_r} L_i^{AGG}$ is computed as follows.

$$\begin{aligned} &\nabla_{\mathbf{w}_r} L_i^{AGG} \\ &= -\frac{1}{p^1_{I(y_i)|i}} \nabla_{(z_i^1)_r} p^1_{I(y_i)|i} \cdot \nabla_{\mathbf{w}_r} (z_i^1)_r \\ &(\text{By Eq. 14.}) \\ &= p^1_{r|i} \cdot \nabla_{\mathbf{w}_r} (z_i^1)_r \\ &= g_{1r} p^1_{r|i} \mathbf{h}_i \\ &(\text{By Eq. 12.}) \end{aligned} \tag{16}$$

Considering the case of $y_i \in V_r$ but $y_i \neq v_r$, L_i^{AGG} is written as follows.

$$L_i^{AGG} = -\log p^0_{I(y_i)|i} - \log p^2_{I(y_i)|i} \tag{17}$$

Then $\nabla_{\mathbf{w}_r} L_i^{AGG}$ is written as follows.

$$\begin{aligned} &\nabla_{\mathbf{w}_r} L_i^{AGG} \\ &= -\nabla_{\mathbf{w}_r} \log p^0_{I(y_i)|i} - \nabla_{\mathbf{w}_r} \log p^2_{I(y_i)|i} \\ &= -\nabla_{\mathbf{w}_r} \log p^2_{I(y_i)|i} - 0 \\ &(\because \log p^0_{I(y_i)|i} \text{ is a function of } \tilde{\mathbf{w}}_r.) \\ &= -\frac{1}{p^2_{I(y_i)|i}} \nabla_{\mathbf{w}_r} p^2_{I(y_i)|i} \\ &= -\frac{1}{p^2_{I(y_i)|i}} \sum_{j=1}^{N} \nabla_{(z_i^2)_j} p^2_{I(y_i)|i} \cdot \nabla_{\mathbf{w}_r} (z_i^2)_j \\ &(\because p^2_{I(y_i)|i} \text{ is a function of } (z_i^2)_j, j = 1, ..., N.) \\ &= -\frac{1}{p^2_{I(y_i)|i}} \nabla_{(z_i^2)_r} p^2_{I(y_i)|i} \cdot \nabla_{\mathbf{w}_r} (z_i^2)_r \\ &(\because \text{Eq. 12.}) \end{aligned} \tag{18}$$

As $p^2_{I(y_i)|i} = [\text{softmax}(\mathbf{z}_i^2)]_{I(y_i)|i}$,

$$\nabla_{(z_i^2)_r} p^2_{I(y_i)|i} = -p^2_{I(y_i)|i} p^2_{r|i}. \tag{19}$$

Thus, $\nabla_{\mathbf{w}_r} L_i^{AGG}$ is computed as follows.

$$\begin{aligned} &\nabla_{\mathbf{w}_r} L_i^{AGG} \\ &= -\frac{1}{p^2_{I(y_i)|i}} \nabla_{(z_i^2)_r} p^2_{I(y_i)|i} \cdot \nabla_{\mathbf{w}_r} (z_i^2)_r \\ &(\text{By Eq. 18.}) \\ &= p^2_{r|i} \cdot \nabla_{\mathbf{w}_r} (z_i^2)_r \\ &= g_{2r} p^2_{r|i} \mathbf{h}_i \\ &(\text{By Eq. 12.}) \end{aligned} \tag{20}$$

Considering the remained case of $y_i = v_r$, since $y_i \in V_r$, L_i^{AGG} is same as the second case, and derivation process of $\nabla_{\mathbf{w}_r} L_i^{AGG}$ shares the same process with Eq. 18. As $I(y_i) = r$,

$$\nabla_{(z_i^2)_r} p^2_{I(y_i)|i} = p^2_{I(y_i)|i}(1 - p^2_{I(y_i)|i}) \tag{21}$$

Thus, $\nabla_{\mathbf{w}_r} L_i^{AGG}$ is computed as follows.

$$\begin{aligned}
&\nabla_{\mathbf{w}_r} L_i^{AGG} \\
&= -\frac{1}{p^2_{I(y_i)|i}} \nabla_{(z_i^2)_r} p^2_{I(y_i)|i} \cdot \nabla_{\mathbf{w}_r} (z_i^2)_r \\
&\text{(By Eq. 21.)} \\
&= -(1 - p^2_{I(y_i)|i}) \cdot \nabla_{\mathbf{w}_r} (z_i^2)_r \\
&= -g_{2r}(1 - p^2_{I(y_i)|i})\mathbf{h}_i \\
&\text{(By Eq. 12.)} \\
&= (p^2_{r|i} - 1)\mathbf{h}_i \\
&(\because I(y_i) = r \text{ and } g_{2r} = 1 \text{ if } I(y_i) = r.)
\end{aligned} \tag{22}$$

As $p_{r|i} = p^m_{r|i}$ with $m = 0, 1, 2$ in terms of value, we finally write $\nabla_{\mathbf{w}_r} L_i^{AGG}$ as follows.

$$\nabla_{\mathbf{w}_r} L_i = \begin{cases} (p_{r|i} - 1)\mathbf{h}_i & \text{if } y_i = v_r \\ g_{1r} p_{r|i} \mathbf{h}_i & \text{if } y_i \notin V_r \\ g_{2r} p_{r|i} \mathbf{h}_i & \text{else,} \end{cases} \tag{23}$$

B Experimental Details

In this section, we present the details of the experiments in main page. All the experiments were conducted with a single GPU on our machine (GPU: NVIDIA A40) and from single run. For each task in the experiments, we use the same model architecture and train it with different objectives(*i.e.,* MLE, AGG, UL). The hyper-parameters used for different training methods in the same task are exactly same. The detailed hyper-parameters are described in Table 12.

C Experimental Results of I(W) for each frequency groups

In this section, we present the experimental results about $I(\mathbf{W})$ for the embeddings of each frequency groups. Table 10 shows the $I(\mathbf{W})$ comparing MLE baseline and AGG. Table 11 shows the $I(\mathbf{W})$ comparing UL baseline and the fusion of UL and AGG. As presented in Table 10 and 11, AGG improves isotropy of the embedding space for all frequency groups, indicating that our method solves the whole degeneration problem.

Methods	**I(W)↑**		
	Freq	Med	Rare
MLE	0.51	0.33	0.278
AGG	**0.702**	**0.714**	**0.813**

Table 10: Experimental results about $\mathbf{I}(\mathbf{W})$ for each token group in WikiText-103 language modeling task comparing MLE baseline and AGG.

Methods	**I(W)↑**		
	Freq	Med	Rare
UL	0.533	0.351	0.293
UL + AGG	**0.731**	**0.626**	**0.696**

Table 11: Experimental results about $\mathbf{I}(\mathbf{W})$ for each token group in WikiText-103 language modeling task comparing UL baseline and UL + AGG.

D Hyperparameter Sensitivity

In this sections we show how the metrics used on language modeling task change with the hyperparameter α in Figure 5. We observed an interesting phenomenon about the non-rare token group when rare token group size increases over a specific threshold. For the rare token group, Uniq and I(W) metrics have a positive correlation. They increase together up to a certain alpha value and decrease together as alpha increases over that value. However, for the non-rare token group, Uniq increases as alpha increases over that certain value while there are negative effects where I(W) decreases and Ppl increases. Because non-rare tokens are a major group, Figure 5 (b) and (c) present the above phenomenon about the non-rare token group although they present metrics for overall tokens. We consider this phenomenon to be another degeneration problem, as the increase of Uniq with negative impacts on isotropy and likelihood does not imply improvement of text quality, implying just generation of unproper tokens. This problem which occurs when rare token group size increases over a certain threshold can be handled in future work.

E Qualitative Study about Semantic Alignments between Tokens

In this section, we present qualitative studies about semantic alignments between tokens for language modeling and machine translation tasks. We select three rare token from each datasets: "homepage", "Werewolf", and "policymakers" for WikiText-103 dataset, and "optimum", "criminal", and "happiness" for WMT14 En→De dataset. For each rare token, we extract the top-5 nearest neighbor token predicted by the cosine distance between token embeddings. Compared with baseline MLE method, AGG shows significant improvement to train semantic alignments for rare tokens. From Table 13, we notice that the rare tokens trained with AGG are semantically well aligned and not biased about token frequency. Table 14 demonstrates that token embeddings trained with AGG also learn the cross-lingual semantic alignments between target language tokens.

F Examples

We present additional generated text samples from the model trained on language modeling task in Table 15. From the table, we notice that the model trained with AGG generates more diverse and high quality text than the baseline.

Hyperparameter	**Empirical Study**	**Language Modeling**	**Machine Translation**	
			`Base`	`Big`

Abstract

Large Pre-trained Language Models (PLMs) have become ubiquitous in the development of language understanding technology and lie at the heart of many artificial intelligence advances. While advances reported for English using PLMs are unprecedented, reported advances using PLMs for Hebrew are few and far between. The problem is twofold. First, so far, Hebrew resources for training large language models are not of the same magnitude as their English counterparts. Second, most benchmarks available to evaluate progress in Hebrew NLP require morphological boundaries which are not available in the output of PLMs. In this work we remedy both aspects. We present *AlephBERT*, a large PLM for Modern Hebrew, trained on larger vocabulary and a larger dataset than any Hebrew PLM before. Moreover, we introduce a novel neural architecture that recovers the morphological segments encoded in contextualized embedding vectors. Based on this new morphological component we offer an evaluation suite consisting of multiple tasks and benchmarks that cover *sentence-level, word-level* and *sub-word level* analyses. On all tasks, *AlephBERT* obtains state-of-the-art results beyond contemporary Hebrew state-of-the-art models. We make our *AlephBERT* model, the morphological extraction component, and the Hebrew evaluation suite publicly available, for future investigations and evaluations of Hebrew PLMs.

1 Introduction

Contextualized word representations provided by models such as BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), GPT3 (Brown et al., 2020), T5 (Raffel et al., 2020) and more, were shown in recent years to be a critical component for obtaining state-of-the-art performance on a wide range of Natural Language Processing (NLP) tasks, from surface syntactic tasks as tagging and parsing, to downstream semantic tasks as question answering, information extraction and text summarization.

While advances reported for English using such models are unprecedented, previously reported results using PLMs in Modern Hebrew are far from satisfactory. Specifically, the BERT-based Hebrew section of multilingual-BERT (Devlin et al., 2019) (henceforth, mBERT), did not provide a similar boost in performance as observed by the English section of mBERT. In fact, for several reported tasks, the results of the mBERT model are on a par with pre-neural models or neural models based on non-contextual embeddings (Tsarfaty et al., 2020; Klein and Tsarfaty, 2020). An additional Hebrew BERT-based model, HeBERT (Chriqui and Yahav, 2021), has been recently released, yet without empirical evidence of performance improvements on key components of the Hebrew NLP pipeline.

The challenge of developing PLMs for *morphologically-rich* and *medium-resourced* languages such as Modern Hebrew is twofold. First, contextualized word representations are obtained by pre-training a large language model on massive quantities of unlabeled texts. In Hebrew, the size of published texts *available* for training is relatively small. To wit, Hebrew Wikipedia (300K articles) used for training mBERT is orders of magnitude smaller compared to English Wikipedia (6M articles). Second, commonly accepted benchmarks for evaluating Hebrew models, via Morpho-Syntactic Tagging and Parsing (Sadde et al., 2018), or Named Entity Recognition (Bareket and Tsarfaty, 2020) require decomposition of words into *morphemes*,[1] which are distinct of the sub-words (a.k.a. word-pieces) provided by standard PLMs. Such *morphemes* are as of yet not readily available in the PLMs' output embeddings.

Evaluating BERT-based models on morpheme-level tasks is thus non-trivial due to the mismatch between the sub-word tokens used as sub-word

---

[1] These morphemes are affixes and clitics bearing their own POS. They are termed *syntactic words* in UD (Zeman et al., 2018), or *segments* in previous literature on Hebrew NLP.

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 46 - 56
May 22-27, 2022

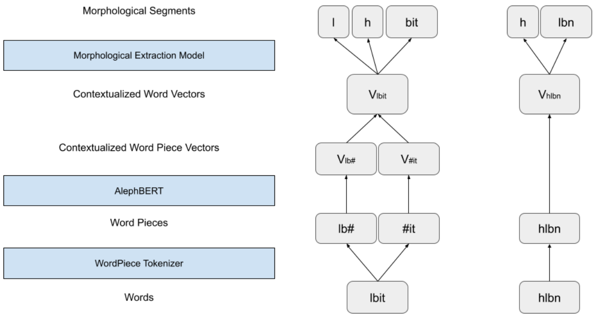

Figure 1: PLM Morphological Extraction Pipeline. The two-word phrase "לבית הלבן", transliterated as "lbit hlbn", mapped to word-pieces which are consumed by a PLM to generate contextualized vectors and extract the sub-word morphological units. In this example the WordPiece Tokenizer splits the first word, "lbit", into two pieces while leaving the second word, "hlbn", intact. Consequently, AlephBERT generates 3 embedded vectors - the vectors associated with the split word pieces are averaged to form a single contextualized vector. Finally, the resulting two word vectors are used by the Morphological Extraction Model that generates the disambiguated morphological segments.

input units used by the PLMs and the sub-word morphological units needed for evaluation. PLMs employ sub-word tokenization mechanisms such as WordPiece or Byte-Pair Encoding (BPE) for the purposes of minimizing Out-Of-Vocabulary words (Sennrich et al., 2016). These sub-word tokens are generated in a pre-processing step, without utilization of any linguistic information, and passed as input to the PLM. Crucially, such word-pieces *do not reflect morphological units*. Extracting morphological units from contextualized vectors provided by PLMs is challenging yet necessary in order to enable morphological-level evaluation of Hebrew PLMs on standard benchmarks.

In this paper we introduce *AlephBERT*, a Hebrew PLM trained on more data and a larger vocabulary than any Hebrew PLM before.[2] Moreover, we propose a novel architecture that extracts the *morphological* sub-word units *implicitly* encoded in the contextualized vectors outputted by PLMs. Using AlephBERT and the proposed morphological extraction model we enable evaluation on *all* existing Hebrew benchmarks. We thus present a processing and evaluation pipeline tailored to fit Morphologically Rich Languages (MRLs), i.e., covering sentence-level, word-level and most importantly sub-word morphological-level tasks (*Segmentation, Part-of-Speech Tagging, full Morphological Tagging, Dependency Parsing, Named Entity Recognition (NER)* and *Sentiment Analysis*), and present new and improved SOTA for Modern Hebrew on all of these tasks.

2 Previous Work

Contextualized word embedding vectors are a major driver for improved performance of deep learning models on many Natural Language Understanding (NLU) tasks. Initially, ELMo (Peters et al., 2018) and ULMFit (Howard and Ruder, 2018) introduced contextualized word embedding frameworks by training LSTM-based models on massive amounts of texts. The linguistic quality encoded in these models was demonstrated over 6 tasks: Question Answering, Textual Entailment, Semantic Role labeling, Coreference Resolution, Name Entity Extraction, and Sentiment Analysis. The next big leap was obtained with the introduction of the GPT-1 framework by Radford and Sutskever (2018). Instead of using LSTM layers, GPT is based on 12 layers of Transformer decoders with each decoder layer composed of a 768-dimensional feed-forward layer and 12 self-attention heads. Devlin et al. (2019) followed along the same lines and implemented Bidirectional Encoder Representations from Transformers, or BERT in short. BERT attends to the input tokens in both forward and backward directions while optimizing a *Masked Language Model* and a *Next Sentence Prediction* objective objectives.

BERT Benchmarks An integral part involved in developing various PLMs is providing NLU multi-task benchmarks used to demonstrate the linguistic abilities of new models and approaches. English BERT models are evaluated on 3 standard major benchmarks. The Stanford Question Answering Dataset (SQuAD) (Rajpurkar et al., 2016) is used for testing paragraph-level reading comprehension abilities. Wang et al. (2018) selected a diverse and relatively hard set of sentence and sentence-pair tasks which comprise the General Language Understanding Evaluation (GLUE) benchmark. The SWAG (Situations With Adversarial Generations) dataset (Zellers et al., 2018) presents models with partial description of grounded situations to see if they can consistently predict subsequent scenarios, thus indicating abilities of commonsense reasoning.

---

[2] We make our PLM `https://huggingface.co/onlplab/alephbert-base` and demo `https://nlp.biu.ac.il/~amitse/alephbert/` publicly available, to qualitatively assess present and future Hebrew PLMs.

When evaluating Hebrew PLMs, one of the key pitfalls is that there are no Hebrew versions for these benchmarks. Furthermore, none of the suggested benchmarks account for examining the capacity of PLMs for encoding the word-internal morphological structures which are inherent in MRLs. In this work we enable a generic morphological-level evaluation pipeline that is suited for PLMs of MRLs.

Multilingual vs. Monolingual BERT Devlin et al. (2019) produced 2 BERT models, for English and Chinese. To support other languages, they trained a multilingual BERT (mBERT) model combining texts covering over 100 languages, in the hoped to benefit low-resource languages with the linguistic information obtained from languages with larger datasets. In reality, however, mBERT performance on specific languages has not been as successful as English. Consequently, several research efforts focused on building monolingual BERT models as well as providing language-specific evaluation benchmarks. Liu et al. (2019) trained CamemBERT, a French BERT model evaluated on syntactic and semantic tasks in addition to natural language inference tasks. Rybak et al. (2020) trained HerBERT, a BERT PLM for Polish. They evaluated it on a diverse set of existing NLU benchmarks as well as a new dataset for sentiment analysis for the e-commerce domain. Polignano et al. (2019) created Alberto, a BERT model for Italian, using a massive tweet collection. They tested it on several NLU tasks — subjectivity, polarity (sentiment) and irony detection in tweets. In order to obtain a large enough training corpus in low-resources languages, such as Finnish (Virtanen et al., 2019) and Persian (Farahani et al., 2020), a great deal of effort went into filtering and cleaning text samples obtained from web crawls.

BERT for MRLs Languages with rich morphology introduce another challenge involving the identification and extraction of sub-word morphological information. In many MRLs words are composed of sub-word morphological units, with each unit acting as a single syntactic unit bearing as single POS tag (mimicking 'words' in English). Antoun et al. (2020) addressed this for Arabic, a Semitic MRLs, by pre-processing the training data using a morphological segmenter, producing morphological segments to be used for training AraBERT instead of the actual words. By doing so, they were able to produce output vectors that correspond to morphological segments rather than the original space-delimited word-tokens. However, this approach requires the application of the same segmenter at inference time as well, and like any pipeline approach, this setup is susceptible to error propagation. This risk is magnified as words in MRLs may be morphologically ambiguous, and the predicted segments might not represent the correct interpretation of the words. As a result, the quality of the PLM depends on the accuracy achieved by the segmenting component. A particular novelty of this work is *not* making any changes to the input, letting the PLM encode morphological information associated with *complete* Hebrew tokens. Instead, transforming the resulting contextualized word vectors into morphological-level segments via a novel neural architecture which we discuss shortly.

Language	Oscar (duped) Size	Wikipedia Articles
English	2.3T	6,282,774
Russian	1.2T	1,713,164
Chinese	508G	1,188,715
French	282G	2,316,002
Arabic	82G	1,109,879
Hebrew	**20G**	**292,201**

Table 1: Corpora Size Comparison: Resource-savvy languages vs. Hebrew.

Evaluating PLMs for MRLs Across all of the above-mentioned language-specific PLMs, evaluation was performed on the word-,sentence- or paragraph-level. Non examined the capacity of PLMs to encode sub-word morphological-level information which we focus on in this work. Şahin et al. (2019) probed various information types encoded in embedded word vectors. Similarly to us, they focused on languages with rich morphology where linguistic signals are encoded at the morphological, subword level. Their work is more about explainability — showing high positive correlation of probing tasks to the downstream tasks, especially for morphologically rich languages. Unlike us, they assume a single POS tag and set of features per word in their probing tasks. In Hebrew, Arabic and other MRLs, tokens may carry multiple POS per word, and are required to be segmented for further processing. We provide a framework that extracts subword morphological units given contextualized word vectors, that enables to evaluate PLMs on morphologically-aware datasets where words can have multiple POS tags and feature-bundles.

Corpus	File Size	Sentences	Words
Oscar (deduped)	9.8GB	20.9M	1,043M
Twitter	6.9GB	71.5M	774M
Wikipedia	1.1GB	6.3M	127M
Total	**17.9GB**	**98.7M**	**1.9B**

Table 2: AlephBERT's Training Data.

3 AlephBERT Pre-Training

Data The PLM termed *AlephBERT* that we provide herein is trained on a larger dataset and a larger vocabulary than any Hebrew BERT instantiation before. The data we train on is listed in Table 2. Concretely, we employ the following datasets for pre-training: **(i) Oscar:** Deduplicated Hebrew portion extracted from Common Crawl via language classification, filtering and cleaning (Ortiz Suárez et al., 2020). **(ii) Wikipedia:** Texts from all of Hebrew Wikipedia, extracted using Attardi (2015). **(iii) Twitter:** Hebrew tweets collected between 2014-09-28 and 2018-03-07. We removed markers ("*RT:*", "@" user mentions and URLs), and eliminated duplicates. For data statistics, see Table 2.

The Hebrew portions of **Oscar** and **Wikipedia** provide us with a training-set size orders-of-magnitude smaller compared with resource-savvy languages, as shown in Table 1. In order to build a strong PLM we need a considerable boost in the amount of sentences the PLM can learn from, which in our case comes form massive amounts of **tweets** added to the training set. We acknowledge the potential inherent concerns associated with this data source (population bias, behavior patterns, bot masquerading as humans etc.) and note that we have not made any explicit attempt to identify these cases. Honoring ethical and legal constraints we have not manually analyzed nor published this data source. While the free form language expressed in tweets might differ significantly from the text found in Oscar and Wikipedia, the sheer volume of tweets helps us close the resource gap substantially with minimal effort.[3]

Model We used the Transformers training framework of Huggingface (Wolf et al., 2020) and trained two different models — a *small* model with 6 hidden layers learned from the Oscar portion of our dataset, and a *base* model with 12 hidden layers which was trained on the entire dataset. The processing units used are wordpieces generated by training BERT tokenizers over the respective datasets with a vocabulary size of 52K in both cases. Following the work on RoBERTa (Liu et al., 2019) we optimize AlephBERT with a masked-token prediction loss. We deploy the default masking configuration where 15% of word piece tokens are masked. In 80% of the cases, they are replaced by [MASK], in 10% of the cases, they are replaced by a random token and in the remaining cases, the masked tokens are left as is.

Operation To optimize GPU utilization and decrease training time we split the dataset into 4 chunks based on the number of tokens in a sentence and consequently we are able to increase batch sizes and dramatically shorten training time.

	chunk1	chunk2	chunk3	chunk4
max tokens	0>32	32>64	64>128	128>512
num sentences	70M	20M	5M	2M

We trained for 5 epochs with learning rate 1e-4 followed by an additional 5 epochs with learning rate at 5e-5 for a total of 10 epochs. We trained AlephBERT$_{\text{base}}$ over the entire dataset on an NVidia DGX server with 8 V100 GPUs which took 8 days. AlephBERT$_{\text{small}}$ was trained over the Oscar portion only, using 4 GTX 2080ti GPUs taking 5 days in total.

4 The Morphological Extraction Model

Modern Hebrew is a Semitic language with rich morphology and complex orthography. As a result, the basic processing units in the language are typically smaller than raw space-delimited tokens. Subsequently, most standard evaluation tasks require knowledge of the internal morphological boundaries within the raw tokens. To accommodate this granularity requirement we developed a neural model designed to produce the *disambiguated* morphological segments for each token in context. These linguistic segmentations are distinct of the word-pieces employed by the PLM.

In the morphological extraction neural model, each input token is represented by (one or more) contextualized word-vectors produced by the PLM. Each word-piece token is associated with a vector, and for each space-delimited token, we average the word-piece vectors. We feed the resulting vector into a seq2seq model and encode the surface token as a sequence of characters using a BiLSTM, followed by a decoder that generates an output sequence of characters, using *space* as a special symbol signaling morphological boundaries.

---

[3] For more details and an ethical discussion, see Section 8.

Raw input	לבית הלבן (lbit hlbn)				
Space-delimited words	הלבן (hlbn)		לבית (lbit)		
Index	5	4	3	2	1
Segmentation	לבן (lbn) white	ה (h) the	בית (bit) house	ה (h) the	ל (l) to
POS	ADJ	DET	NOUN	DET	ADP
Morphology	Gender=Masc|Number=Sing	PronType=Art	Gender=Masc|Number=Sing	PronType=Art	-
Dependencies	3/amod	5/det	1/obj	3/def	0/ROOT
Word-level NER	E-ORG		B-ORG		
Morpheme-level NER	E-ORG	I-ORG	I-ORG	B-ORG	O

Table 3: Illustration of Evaluated Word-Based and Morpheme-Based Downstream Tasks. The two-word input phrase “לבית הלבן”, transliterated as “lbit hlbn” (*to the White House*), decompose into five morphological segments (‘to-the-house the-white’). The Hebrew text goes from right to left.

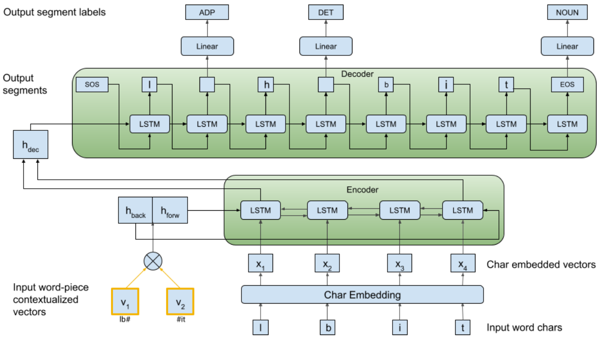

Figure 2: Illustration of the Morphological Extraction Model. The embedded vectors associated with the word-pieces (v1 and v2 representing word-piece vectors generated in Figure 1) are combined (averaged) to produce a single word context vector. This context vector initializes the hidden (forward and backward) state of a BiLSTM that encodes the characters of the origin word. The decoder LSTM outputs a sequence of characters, where a special empty symbol indicates a morphological segment boundary. In multi-task setup, a fully connected linear layer is used to predict a label whenever a segment boundary is detected.

For tasks involving both segments and labels (Part-of-Speech Tagging, Morphological-Features Tagging, Named-Entity Recognition) we expand this network in a multi-task learning setup; when generating an end-of-segment (space) symbol, the model also predicts task label, and we combine the segment-label losses. The complete morphological extraction architecture is illustrated in Figure 2.

5 Experimental Setup

Goal In order to empirically gauge the effect of model size and data quantity on the quality of the language model, we compare the performance of AlephBERT (both *small* and *base*) with all existing Hebrew BERT instantiations. In this Section, we detail the tasks and evaluation metrics. In the next Section, we present and analyze the results.

5.1 Sentence-Based Modeling

Sentiment Analysis We first report on a sentence classification task, assigning a sentence with one of three sentiment values: negative, positive, neutral. Sentence-level predictions are achieved by directly fine-tuning the PLM using an additional sentence-classification head The sentence-level embedding vector representation is the one associated with the special [CLS] BERT token.

We used a version of the Hebrew Facebook Sentiment dataset (henceforth FB) of Amram et al. (2018) which we corrected by removing leaked samples.[4] We fine-tuned all models for 15 epochs with 5 different seeds, and report mean accuracy.

5.2 Word-Based Modeling

Named Entity Recognition In this setup we assume a sequence labeling task based on space-delimited word-tokens. The input comprises of the sequence of words in the sentence, and the output contains BIOES tags indicating entity spans. Word-level NER predictions are achieved by directly fine-tuning the PLMs using an additional token-classification head In cases where a word is split into multiple word pieces by the PLM tokenizer, we employ common practice and use the first word-piece vector.

We evaluate this model on two corpora. (i) The Ben-Mordecai (BMC) corpus (Ben Mordecai and Elhadad, 2005), which contains 3294 sentences with 4600 entities and seven different entity categories (Date, Location, Money, Organization, Person, Percent, Time). To remain compatible with the original work we train and test the models on 3

---

[4] This version has a total of 8,465 samples and is publicly available here: `https://github.com/OnlpLab/Hebrew-Sentiment-Data`

different splits as in Bareket and Tsarfaty (2020). (ii) The Named Entities and MOrphology (NEMO) corpus[5] (Bareket and Tsarfaty, 2020) which is an extension of the SPMRL dataset with Named Entities. The NEMO corpus contains 6220 sentences with 7713 entities of nine entity types (Language, Product, Event, Facility, Geo-Political Entity, Location, Organization, Person, Work-Of-Art). We trained both models for 15 epochs with 5 different seeds and report mean F1 scores on entity spans.

5.3 Morpheme-Based Modeling

Finally, to probe the PLM capacity to accurately predict word-internal structure, we test all models on five tasks that require knowledge of the internal morphology of raw words. The input to all these tasks is a Hebrew sentence represented as a raw sequence of space-delimited words:

> **(i) Segmentation**: Generating a sequence of morphological segments representing the basic processing units. These units comply with the 2-level representation of tokens defined by UD, each unit with a single POS tag.[6]
> **(ii) Part-of-Speech (POS) Tagging**: Tagging each segment with a single POS.
> **(iii) Morphological Tagging**: Tagging each segment with a single POS and a set of features. Equivalent to the AllTags evaluation defined in the CoNLL18 shared task.[7]
> **(iv) Morpheme-Based NER**: Tagging each segment with a BIOES and its entity-type.
> **(v) Dependency Parsing**: Use each segment as a node in the predicted dependency tree.

We train and test all morphologically-aware models using two available morphologically-aware Hebrew resources:

- The Hebrew Section of the SPMRL Task (Seddah et al., 2013).
- The Hebrew Section of the UD treebanks collection (Sadde et al., 2018)

All models were trained for 15 epochs with 5 different seeds and we report two variants of mean F1 scores as described next.

For tasks (i)–(iv) we use the morphological extraction model (Section 4) to extract the morphological segments of each word in context and also predict the labels via Multitask training.

For task (iv) the NER task, we use the morphologically-annotated data files of the aforementioned SPMRL-based NEMO corpus (Bareket and Tsarfaty, 2020). In addition to the multi-task setup described earlier, we design another setup in which we first *only* segment the text, and then perform fine-tuning with a token classification attention head directly applied to the PLM output for the segmented tokens (similar to the way we fine-tune the PLM for the word-based NER task described in the previous section). We acknowledge that we are fine-tuning the PLM on morphological segments the model was not originally pre-trained on, however, as we shall see shortly, this seemingly unintuitive strategy performs surprisingly well.

For task (v) we set up a dependency parsing evaluation pipeline using the standalone Hebrew parser offered by More et al. (2019) (a.k.a YAP) which was trained to produce SPMRL dependency labels. The morphological information for each word (namely the segments and POS tags) is recovered by our morphological extraction model, and is used as input features for the YAP standalone dependency parser.

5.4 Morpheme-Based Evaluation Metrics

Aligned Segment The CoNLL18 Shared Task evaluation campaign[8] reports scores for segmentation and POS tagging[9] for all participating languages. For multi-segment words, the gold and predicted segments are aligned by their Longest Common Sub-sequence, and only matching segments are counted as true positives. We use the script to compare aligned segment and tagging scores between oracle (gold) segmentation and realistic (predicted) segmentation.

Aligned Multi-Set In addition to the CoNLL18 metrics, we compute F1 scores, with a slight but important difference from the shared task, as defined by More et al. (2019) and Seker and Tsarfaty (2020). For each word, counts are based on multiset intersections of the gold and predicted labels ignoring the order of the segments while account-

ing for the number of each segment. *Aligned mset* is based on set difference which acknowledges the possible undercover of covert morphemes which is an appropriate measure of morphological accuracy.

Discussion To illustrate the difference between *aligned segment* and *aligned mset*, let us take for example the gold segmented tag sequence: *b/IN, h/DET, bit/NOUN* and the predicted segmented tag sequence *b/IN, bit/NOUN*. According to *aligned segment*, the first segment (*b/IN*) is aligned and counted as a true positive, the second segment however is considered as a false positive (*bit/NOUN*) and false negative (*h/DET*) while the third gold segment is also counted as a false negative (*bit/NOUN*). On the other hand with aligned multi-set both *b/IN* and *bit/NOUN* exist in the gold and predicted sets and counted as true positives, while *h/DET* is mismatched and counted as a false negative. In both cased the total counts across words in the entire datasets are incremented accordingly and finally used for computing Precision, Recall and F1.

6 Results

Sentence-Level Task Sentiment analysis accuracy results are provided in Table 4. All BERT-based models substantially outperform the original CNN Baseline reported by Amram et al. (2018). AlephBERT$_{\text{base}}$ is setting a new SOTA.

Word-Based Task On our two NER benchmarks, we report F1 scores on the word-based fine-tuned model in Table 4. While we see noticeable improvements for the mBERT and HeBert variants over the current SOTA, the most significant increase is achieved by AlephBERT$_{\text{base}}$, setting a new and improved SOTA on this task.

Morpheme-Level Tasks As a particular novelty of this work, we report BERT-based results on sub-word (segment-level) information. Specifically, we evaluate word segmentation, POS, Morphological Features, NER and dependencies compared against morphologically-labeled test sets.

Task	Segment	POS	Features	UAS	LAS
Prev. SOTA	NA	90.49	85.98	75.73	69.41
mBERT	97.36	93.37	89.36	80.17	74.9
HeBERT	97.97	94.61	90.93	81.86	76.54
AlephBERT$_{\text{small}}$	97.71	94.11	90.56	81.5	76.07
AlephBERT$_{\text{base}}$	**98.10**	**94.90**	**91.41**	**82.07**	**76.9**

Table 5: Morpheme-Based results on the SPMRL corpus. Aligned MultiSet (mset) F1 for Segmentation, POS tags and Morphological Features - previous SOTA reported by Seker and Tsarfaty (2020) (POS) and More et al. (2019) (features). Labeled and Unlabeled Accuracy Scores for morphological-level Dependency Parsing - previous SOTA reported by More et al. (2019) (uninfused/realistic scenario)

Task	Segment	POS	Features
Prev. SOTA	NA	94.02	NA
mBERT	97.70	94.76	90.98
HeBERT	98.05	96.07	92.53

AlephBERT$_{\text{base}}$	**98.20**	**96.20**	**93.05**

Table 6: Morpheme-Based Aligned MultiSet (mset) F1 results on the UD corpus. Previous SOTA reported by Seker and Tsarfaty (2020) (POS)

In all cases, we use raw space-delimited tokens as input and produce morphological segments with our morphological extraction model.

Table 5 presents evaluation results for the SPRML dataset, compared against the previous SOTA of More et al. (2019). For segmentation, POS tagging, and morphological tagging we report aligned multiset F1 scores. BERT-based segmentations are similar, all scoring in the high range of 97-98 F1, which are hard to improve further.[10]

For POS tagging and morphological features, all BERT-based models considerably outperform the previous SOTA. For syntactic dependencies we report labeled and unlabeled accuracy scores of the trees generated by YAP (More et al., 2019) on our predicted segmentation. Here we see impressive improvement compared to the previous SOTA of a joint morpho-syntactic framework. It confirms that morphological errors early in the pipeline negatively impact downstream tasks, and highlight the importance of morphologically-driven benchmarks

---

[10] According to error analysis, most of these errors are annotation errors or truly ambiguous cases.

as an integral part of PLM evaluation for MRLs.

All in all we see a repeating trend placing AlephBERT$_{\text{base}}$ first on all morphological tasks, indicating the depth of the model and a larger pre-training dataset improve the ability of the PLM to capture word-internal structure. These trends are replicated on the UD Hebrew corpus, for two different evaluation metrics — the Aligned MultiSet F1 Scores as in previous work on Hebrew (More et al., 2019), (Seker and Tsarfaty, 2020), and the Aligned Segment F1 scores metrics as described in the UD shared task (Zeman et al., 2018) — reported in Tables 6 and 7 respectively.

Morpheme-Level NER results Earlier in this section we considered NER a word-level task that simply requires fine-tuning on the word level. However, this setup is not accurate enough and less useful for downstream tasks, since the exact entity boundaries are often word internal (Bareket and Tsarfaty, 2020). We hence report morpheme-based NER evaluation, respecting the exact boundaries of entity mentions.

To obtain morpheme-based labeled-span of Named Entities, we could either employ a pipeline, first predicting segmentation and then applying a fine-tuned labeling model *directly on the segments*, or employ a multi-task model and predict NER labels *while* performing segmentation.

Table 8 presents segmentation and NER results for 3 different scenarios: (i) a pipeline assuming gold segmentation (ii) a pipeline assuming predicted segmentation (iii) segmentation and NER labels obtained jointly in a multi-task setup. AlephBERT$_{\text{base}}$ consistently scores highest in all 3.

Looking at the Pipeline-Predicted scores, there is a clear correlation between a higher segmentation quality of a PLM and its ability to produce better NER results. Moreover, the differences in NER scores are considerable (unlike the subtle differences in segmentation, POS and morphological features scores) and draw our attention to the relationship between the size of the PLM, the size of the pre-training data and the quality of the final NER models. Specifically, HeBERT and AlephBERT$_{\text{small}}$ were both pre-trained on similar datasets and comparable vocabulary sizes (heBERT with 30K and AlephBERT-small with 52K) but HeBERT, with its 12 hidden layers, performs better compared to AlephBERT$_{\text{small}}$ which is composed of only 6 hidden layers. It thus appears that semantic information is learned in those deeper layers, helping in both discriminating entities and improving the morphological segmentation capacity.

In addition, comparing AlephBERT$_{\text{base}}$ and HeBERT we note that they are both modeled with the same 12 hidden layer architecture — the only differences between them are in the size of their vocabularies (30K vs 52K respectively) and the size of the training data (Oscar-Wikipedia vs Oscar-Wikipedia-Tweets). The improvements exhibited by AlephBERT$_{\text{base}}$, compared to HeBERT, suggest large amounts of training data and larger vocabulary are invaluable. By exposing AlephBERT$_{\text{base}}$ to a substantially larger amount of text we increased the ability of the PLM to encode syntactic and semantic signals associated with Named Entities.

Our NER experiments further suggest that a pipeline composed of our accurate morphological segmentation model followed by AlephBERT$_{\text{base}}$ with a token classification head is the best strategy for generating morphologically-aware NER labels. Finally, we observe that while AlephBERT excels at morphosyntactic tasks, on tasks with a more semantic flavor there is room for improvement.

7 Conclusion

Modern Hebrew, a morphologically-rich and medium-resourced language, has for long suffered from a gap in the resources available for NLP applications, and lower level of empirical results than observed in other, resource-rich languages. This work provides the first step in remedying the situation, by making available a large Hebrew PLM, named AlephBERT, with larger vocabulary and larger training set than any Hebrew PLM before, and with clear evidence as to its empirical advantages. Crucially, we augment the PLM with a morphological disambiguation component that matches the input granularity of the downstream tasks. Our system does not presuppose Hebrew-specific linguistic-rules, and can be transparently applied to any language for which 2-level segmentation data (i.e., the standard UD benchmarks) exists. AlephBERT$_{\text{base}}$ obtains state-of-the-art results on morphological segmentation, POS tagging, morphological feature extraction, dependency parsing, named-entity recognition, and sentiment analysis, outperforming all existing Hebrew PLMs. Our proposed morphologically-driven pipeline[11] serves as a solid foundation for future evaluation of Hebrew PLMs and of MRLs in general.

8 Ethical Statement

We follow Bender and Friedman (2018) regarding professional practice for NLP technology and address ethical issues that result from the use of data in the development of the models in our work.

Pre-Training Data. The two initial data sources we used to pre-train the language models are Oscar and Wikipedia. In using the Wikipedia and Oscar we followed standard language model training efforts, such as BERT and RoBERTa (Devlin et al., 2019; Liu et al., 2019). We use the language-specific Oscar data according to the terms specified in Ortiz Suárez et al. (2020) and we extract texts from language-specific Wikipedia dumps. On top of that, a big portion of the data used to train AlephBERT originates from the Twitter sample stream.[12] As shown in Table 2, this data set includes 70M Hebrew tweets which were collected over a period of 4 years (2014 to 2018). We acknowledge the potential concerns inherently associated with Twitter data (population bias, behavior patterns, bot masquerading as humans etc.) and note that we have not made any explicit attempt to identify these cases. We only used the text field of the tweets and *completely discard* any other information included in the stream (such as identities, followers, structure of threads, date of publication, etc). We have not made any effort to identify or filter out any samples based on user properties such as age, gender and location nor have we made any effort to identify content characteristics such as genre or topic. To reduce exposure of private information we cleaned up all user mentions and URLs from the text. Honoring ethical and legal constraints we have not manually analyzed nor published this data source. While the free-form language expressed in tweets might differ significantly from the text found in Oscar/Wikipedia, the sheer volume of tweets helps us close the substantial resource gap.

Training and Evaluation Benchmarks. The SPMRL (Seddah et al., 2013) and UD (Sadde et al., 2018) datasets we used for evaluating segmentation, tagging and parsing, were used to both train our morphological extraction model as well as provide us with the test data to evaluate on morphological level tasks. Both datasets are publicly available and widely used in research and industry.

The NEMO corpus (Bareket and Tsarfaty, 2020) used to train and evaluate word and morpheme level NER is an extension of the SPMRL dataset augmented with entities and follows the same license terms. The BMC dataset used for training and evaluating word-level NER was created and published by Ben Mordecai and Elhadad (2005) and it is publicly available for NER evaluation.

We used the sentiment analysis dataset of Amram et al. (2018) for training and evaluating AlephBERT on a sentence level task, and we follow their terms of use. As mentioned, this dataset had some flows, and we describe carefully the steps we've taken to fix them before using this corpus in our experiments for internal evaluation purposes. We make our in-house cleaning scripts and split information publicly available.

Abstract

Neural discrete reasoning (NDR) has shown remarkable progress in combining deep models with discrete reasoning. However, we find that existing NDR solution suffers from large performance drop on hypothetical questions, *e.g.,* "*what the annualized rate of return would be if the revenue in 2020 was doubled*". The key to hypothetical question answering (HQA) is counterfactual thinking, which is a natural ability of human reasoning but difficult for deep models. In this work, we devise a Learning to Imagine (L2I) module, which can be seamlessly incorporated into NDR models to perform the imagination of unseen counterfactual. In particular, we formulate counterfactual thinking into two steps: 1) identifying the fact to intervene, and 2) deriving the counterfactual from the fact and assumption, which are designed as neural networks. Based on TAT-QA, we construct a very challenging HQA dataset with 8,283 hypothetical questions. We apply the proposed L2I to TAGOP, the state-of-the-art solution on TAT-QA, validating the rationality and effectiveness of our approach.

1 Introduction

Neural discrete reasoning (Dua et al., 2019) is an emerging technique for machine reading comprehension (Rajpurkar et al., 2016) which aims at answering numerical questions from textual (Dua et al., 2019) or hybrid (Zhu et al., 2021) context[1]. NDR combines deep neural network with discrete and symbolic reasoning (*e.g.,* addition, sorting, or counting) (Dua et al., 2019) and enables the comprehension of complex contexts and compositional questions, which is critical for many practical applications such as automatic diagnosis (Wei et al., 2018) and robo-advisor (Fisch et al., 2019). Existing state-of-the-art NDR models implement the numerical reasoning process as neural network modules (Ran et al., 2019; Herzig et al., 2020; Zhu et al., 2021), *e.g.,* a graph neural network for sorting (Ran et al., 2019; Chen et al., 2020a).

In this work, we extend NDR to *hypothetical question answering* (HQA), where the question consists of an assumption beyond the context (Figure 1). The ability of HQA will undoubtedly enhance the practical use of NDR due to the universality of hypothetical questions. However, current NDR models face severe generalization failure on hypothetical questions. An empirical evidence on such vulnerability is that the state-of-the-art model (Zhu et al., 2021) encounters a sharp performance drop (F1 score drops from 68.6% to 3.8%) on the TAT-QA dataset when changing the questions to be hypothetical by adding a related assumption (see details in Section 2, Table 3). We postulate that the failure is due to unable of imagining the counterfactual context according to the assumption (Figure 1). To pursue such reasoning ability, we resort to the concept of counterfactual thinking (Pearl, 2019) from the theory of causality, which is the ability to imagine and reason over unseen cases based on the seen facts and counterfactual assumptions.

In this light, we consider modeling counterfactual thinking as neural network modules that can be seamlessly incorporated into existing NDR models. One straightforward solution is to model counterfactual thinking as a generation procedure with the fact and assumption as inputs by using a generation model such as GPT (Brown et al., 2020). However, such uncontrollable model (Zou et al., 2021) can hardly generate high-quality context for two reasons: 1) the context is more complex than plain text, which can include a table (Figure 1); and 2) NDR requires a precise context with the correct numbers (Figure 1, *\$132,935* for the *finished goods* in *2019*). Therefore, we resort to an alternative approach: constructing the counterfactual

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 57 - 69

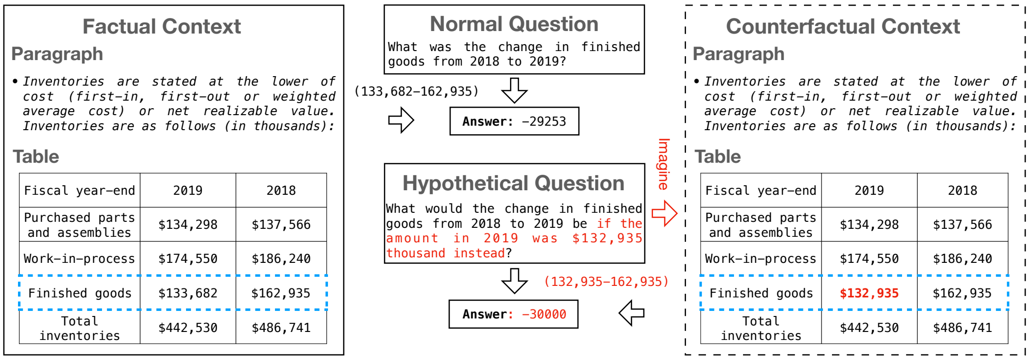

Figure 1: Illustration of hypothetical question and the corresponding counterfactual context to be imagined.

by intervening on the factual context. As shown in Figure 1, the assumption changes one entry in the table, *e.g., $133,682* to *$132,935*. This is coherent with the causal inference theory (Pearl, 2009) where the target variable is intervened according to the hypothetical condition to infer a counterfactual.

We propose Learning to Imagine, where the counterfactual thinking is implemented with two intervening steps: 1) identifying the facts to intervene, and 2) deriving the result of intervention. To pursue accurate context, we derive the intervention with a set of discrete operators such as *SWAP* and *ADD* for imagination. To evaluate the counterfactual thinking ability, we recruit volunteers with domain expertise to construct an HQA dataset based on TAT-QA (Zhu et al., 2021) by posting an assumption for each original question, named TAT-HQA. We apply L2I to TAGOP (Zhu et al., 2021), and obtain a promising solution for HQA. In summary, the main contributions are as follows:

- We highlight the importance of counterfactual thinking in NDR and formulate counterfactual thinking as an intervening procedure to achieve precise imagination.
- We devise the L2I module, which is designed as neural network operations and can be seamlessly incorporated into the NDR model for answering hypothetical questions.
- We construct a challenging HQA dataset and conduct extensive experiments on the dataset, where the performance validates the rationality and effectiveness of the proposed L2I.

2 Hypothetical Question Answering

In the general setting of machine reading comprehension, the task is to answer a question according to the facts in a given context. Formally, it is to learn a function $\boldsymbol{y} = f(\boldsymbol{q}, \boldsymbol{c})$, where $\boldsymbol{y}$, $\boldsymbol{q}$, and $\boldsymbol{c}$ are the word list representing the answer, the question, and the context[2] respectively. This work studies a new and more challenging task that focuses on hypothetical question. As shown in Figure 1, a hypothetical question includes an assumption, *e.g.,* "*if the amount in 2019 was $132,935 thousand instead*". The target of HQA is to learn $\boldsymbol{y} = f(\boldsymbol{q}, \boldsymbol{c}, \boldsymbol{a})$ where $\boldsymbol{a}$ denotes the assumption. The existence of an assumption calls for the imagination of a counterfactual context before inferring the answer, pushing the NDR model to grasp both semantic understanding and counterfactual thinking.

To facilitate the evaluation of HQA and diagnose counterfactual thinking, we construct an HQA dataset based on TAT-QA (Zhu et al., 2021), which is a QA dataset with a mix of tabular and textual context extracted from financial reports. Inspired by previous work on constructing counterfactual samples (Kaushik et al., 2019), we recruit college students with finance-related majors to imagine an intervention based on the factual question and context from TAT-QA which involves numerical thinking, *e.g.,* a change of number. Then they phrase the intervention into an assumption, forming a "*what if*" type of question, and calculate the answer (see an example in Figure 1). To ensure the diversity of the phrasing, annotators are free to generate various phrasing of the assumption, and there is no restriction on the position of the assumption. Usually, the assumption appears either before of after the factual question. Each hypothetical question is related to one factual question from TAT-QA, but each factual question in TAT-QA is not guaranteed to have one hypothetical question. We follow the quality control approaches of annotator training and two-round validation in TAT-QA to guarantee the quality of the hypothetical questions.

---

[2] Note that recent NDR methods flatten the tabular context (if available) and concatenate it with the textual context. We thus denote the context as a word list for brief notation.

Table 1: Statistics of TAT-HQA dataset by answer type and answer location.

	Tab	Text	Tab-Text	Total
Span	565	16	175	756
Multi-Span	133	1	57	191
Counting	101	5	271	377
Arithmetic	4,423	140	2,396	6,959
Total	5,222	162	2,899	8,283

Table 2: Statistics of TAT-HQA dataset by data split.

Statistics	**Train**	**Val.**	**Test**
# of hybrid contexts	2207	274	277
# of hypothetical questions	6229	823	831
Avg. length of question [words]	23.9	23.6	24.1
Avg. length of assumption [words]	10.58	10.31	10.66

Following TAT-QA, the hypothetical questions are also labeled with four answer types: *arithmetic*, *span*, *count*, and *multi-span*, three types of answer sources: table, text and table-text, and a derivation on how the answer is derived from the context. In total, we obtain 8,283 hypothetical questions, naming it as TAT-HQA. The statistics of TAT-HQA are shown in Table 1. We follow the split of training, testing and validation set of TAT-QA as shown in Table 2.

We conduct a pilot study on the generalization ability of existing NDR models on hypothetical questions. In particular, we evaluate TAGOP (Zhu et al., 2021), which is the state-of-the-art model on TAT-QA (see detailed settings in Section 4.1) by training on TAT-QA and testing on TAT-HQA. In Table 3, the huge performance drop shows that even the state-of-the-art NDR model lacks counterfactual thinking ability.

3 Methodology

We aim to empower NDR models with counterfactual thinking ability. Firstly, we decide to choose the approach of explicitly modeling discrete operations, since existing NDR solutions have demonstrated its superiority (Dua et al., 2019; Ran et al., 2019; Herzig et al., 2020; Zhu et al., 2021). We devise a Learning to Imagine module to model counterfactual thinking (Section 3.1), and then incorporate the L2I module (Section 3.2) into existing NRD methods, followed by a discussion about potential extensions (Section 3.3).

3.1 Learning to Imagine

Functionally speaking, the L2I module aims to construct a counterfactual context based on the factual context and the assumption. We formulate it as: $\boldsymbol{c}' = g(\boldsymbol{c}, \boldsymbol{a})$, where the counterfactual context $\boldsymbol{c}'$ is the status of the context $\boldsymbol{c}$ after the assumption $\boldsymbol{a}$ is executed. Resorting to the language of causality, it can be expressed as the do-operation that intervenes a variable to execute the assumption and the *action* to derive the outcome of the intervention[3] (Pearl, 2009). The key to achieving counterfactual thinking in NDR lies in: 1) parsing the assumption to identify the target fact to intervene; and 2) deriving the assumed value to construct the counterfactual context. Taking the hypothetical question in Figure 1 as an example, an ideal L2I should recognize the target variable (*finished goods in 2019*), identify the corresponding fact (*$133,682*), and replace the fact with the assumed value (*$132,935*).

Table 3: Performance of NDR model on TAT-QA and TAT-HQA.

Testing	TAT-QA		TAT-HQA	
	EM	F1	EM	F1
TAGOP	61.3	68.6	2.8	3.8

Two-step Formulation. To this end, we propose a two-step formulation of counterfactual thinking for HQA to perform the identification and derivation. Formally,

$$\textbf{Step 1: } i = r(\boldsymbol{c}, \boldsymbol{a}, \boldsymbol{q}) \qquad (1)$$

$$\textbf{Step 2: } c'_i = d\left(c_i, \boldsymbol{c}, \boldsymbol{a}\right), \; c'_j = \begin{cases} c'_j, j = i, \\ c_j, \text{ otherwise.} \end{cases}$$

- **Step 1: Identifying the target fact.** $r(\cdot)$ denotes the tagging function which scans the factual context $\boldsymbol{c}$ to recognize the fact related to the assumption $\boldsymbol{a}$ and the question $\boldsymbol{q}$. i is the word position of the identified fact c_i.
- **Step 2: Deriving intervention result.** $d(\cdot)$ denotes the deriving function that parses the assumption $\boldsymbol{a}$ to infer the discrete operation and the premise to derive the assumed value c'_i. As to the assumption in Figure 1, the derivation requires a *SWAP* operation and a premise *$132,935*. This step then calls for an editing operation to construct the counterfactual context $\boldsymbol{c}'$.

Module Design. Based on the two-step formulation, we then design the L2I module as neural network operations. We have two considerations for the module design: 1) the module should recognize the semantic connection between the assumption and the context, and 2) the module should uniformly support various discrete operations to

---

[3] Note that we adopt the do-expression (Pearl, 2009) of counterfactual.

enable accurate derivation. To this end, we devise four key building blocks for the L2I module:

- *Encoder*. It projects the raw content into latent representation. Inspired by the recent research on NDR, we employ a pre-trained language model (PLM), *i.e.,* RoBERTa (Liu et al., 2019), as the encoder to learn an overall representation of the context, question, and assumption;

$$\boldsymbol{H} = \text{PLM}\left([\text{CLS}, \boldsymbol{c}, \text{SEP}, \{\boldsymbol{q}, \boldsymbol{a}\}, \text{SEP}]\right) \tag{2}$$

  where L and M are the length of the tokenized inputs. CLS and SEP denote the beginning and the separation token of the input. $\{\boldsymbol{q}, \boldsymbol{a}\}$ represents that the relevant position of $\boldsymbol{a}$ to $\boldsymbol{p}$ can vary. We do not assume $\boldsymbol{q}$ to always precede $\boldsymbol{a}$ due to the various location of $\boldsymbol{a}$ in the annotation.

- *Matching block*. It distills the semantic connection between the factual question, the factual context and the hypothetical assumption (Figure 1, "*amount in 2019*" and "*$132,935*"). After applying the token-level self-attention of PLM, we aim to further distill the sequence-level semantic connection between the factual part (the question and the context) and the hypothetical part (the assumption). We obtain the factual and assumption representations by masking $\boldsymbol{H}$ according to the position of the question, the context and the assumption, which splits $\boldsymbol{H}$ into 2 non-overlapping parts. Inspired by the success of cross-attention (Kim et al., 2018) in associating different sources, *e.g.,* image-image (Hou et al., 2019) and image-text (Lu et al., 2019), we adopt cross-attention between the factual representation and the assumption representation, followed by self-attention respectively. Formally, the calculation of the k-th layer is,

$$\begin{aligned}
\boldsymbol{H}_f &= \text{mask}\left(\boldsymbol{H}, \text{pos}(\{c, q\})\right)\\
\boldsymbol{H}_a &= \text{mask}\left(\boldsymbol{H}, \text{pos}(a)\right)\\
\hat{\boldsymbol{H}}_f^k &= \text{MHA}\left(\boldsymbol{H}_f^{k-1}, \boldsymbol{H}_a^{k-1}, \boldsymbol{H}_a^{k-1}\right)\\
\hat{\boldsymbol{H}}_a^k &= \text{MHA}\left(\boldsymbol{H}_a^{k-1}, \boldsymbol{H}_f^{k-1}, \boldsymbol{H}_f^{k-1}\right)\\
\boldsymbol{H}_f^k &= \text{MHA}\left(\hat{\boldsymbol{H}}_f^k, \hat{\boldsymbol{H}}_f^k, \hat{\boldsymbol{H}}_f^k\right)\\
\boldsymbol{H}_a^k &= \text{MHA}\left(\hat{\boldsymbol{H}}_a^k, \hat{\boldsymbol{H}}_a^k, \hat{\boldsymbol{H}}_a^k\right)
\end{aligned}$$

  where MHA$(\cdot)$ denotes the multi-head attention (Vaswani et al., 2017) with a triple of query, key, and value as the input. The residual connection and batch normalization are applied as the default choice. mask$(\cdot)$ denotes the masking operation, and pos(x) is a binary vector with the same length of $\boldsymbol{H}$ denoting the positions of x in the input of PLM.

- *Tagging head*. It models the identification of target fact as a token-wise tagging. Formally,

$$\begin{aligned}
t_i &= \begin{cases} 1, \exists(j), argmax(\boldsymbol{p_j}) = 1 \wedge \boldsymbol{h}_j^K \mapsto c_i, \\ 0, \text{ otherwise.} \end{cases}\\
\boldsymbol{p_j} &= softmax(\text{MLP}\left(\boldsymbol{h}_j^K\right))
\end{aligned} \tag{3}$$

  where t_i is a binary tag for the fact c_i. c_i will be a target as at least one of its tokens is tagged. We use $\boldsymbol{h}_j^K \mapsto c_i$ to represent the mapping between token and fact, which is true if token j belongs to fact c_i. For each token, we employ a 2-way classifier MLP $\left(\boldsymbol{h}_j^K\right)$ to predict its probability of being tagged as $\boldsymbol{p_j}$ where $argmax(\boldsymbol{p_j}) = 1$ means positive (see Appendix A for more details).

- *Deriving head*. It derives the intervention result for the target fact. To calculate the intervention result, we select a set of commonly used discrete operators such as *SWAP*, *ADD*, and *MINUS* (*cf.* Appendix B). Then, we model the derivation as making a choice across the operators and tagging the premise for executing the operator. In particular, we adopt a tagging head to identify the premise and a multi-way classifier for choosing operators, which is formulated as: $\boldsymbol{o} = softmax(\text{MLP}(\boldsymbol{h}_{CLS}))$. $\boldsymbol{o} \in \mathbb{R}^O$ is a distribution over the operators where O denotes the number of operators. $\boldsymbol{h}_{CLS}$ corresponds to the CLS token in $\boldsymbol{H}$.

3.2 NDR with L2I

Most recent NDR models (Ran et al., 2019; Andor et al., 2019; Chen et al., 2020a; Herzig et al., 2020; Zhu et al., 2021) consist of two main modules: 1) a PLM to encode the context and the question into latent representations, and 2) a reasoning module that chooses the discrete operator and identifies the operands according to the latent representations. As shown in Figure 2, we can seamlessly incorporate the proposed L2I into such NDR model as an intermediate module, which performs imagination before discrete reasoning. In particular, we simply let the reasoning module conduct operand look-up within the counterfactual context constructed by L2I. Besides, we let L2I reuse the PLM in the NDR model to reduce the model complexity and training time.

Model training. Existing NDR methods typically follow the supervised learning paradigm to optimize the model parameters (Dua et al., 2019).

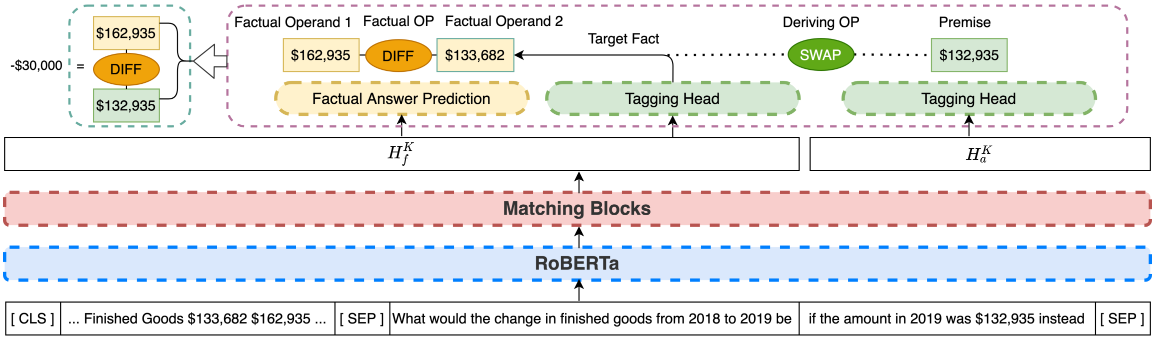

Figure 2: Illustration of NDR equipped with the proposed L2I module for answering hypothetical questions.

Suppose we have a set of labeled questions $\mathcal{D} = \{< \bar{\boldsymbol{y}}, (\boldsymbol{q}, \boldsymbol{c}, \boldsymbol{a}) >\}$, the training objective can be abstracted as $\min_{\boldsymbol{\theta}} \sum_{\mathcal{D}} QA\left(\bar{\boldsymbol{y}}, f(\boldsymbol{q}, \boldsymbol{c}, \boldsymbol{a})\right)$ where $\boldsymbol{\theta}$ denotes model parameters. Note that $QA(\cdot)$ measures the discrepancy between the ground-truth and the predicted answers which can have different formats. For instance, it can be a combination of the cross-entropy (CE) loss over the operand look-up and the CE loss over the choice of discrete operation (Herzig et al., 2020; Yin et al., 2020; Zhu et al., 2021). When applying L2I to an existing NDR method, we keep its question-answering objective unchanged. To optimize the L2I module, we incorporate supervision on the classifiers in the tagging head and deriving head. Formally,

$$\min_{\boldsymbol{\theta}} \sum_{\mathcal{D}} \Big(QA(\bar{\boldsymbol{y}}, f(\boldsymbol{q}, \boldsymbol{c}, \boldsymbol{a})) + \frac{1}{L} \sum_{j<L} \mathrm{CE}\big(\bar{p}_j, \mathrm{MLP}(\boldsymbol{h}_j^K)\big) + \mathrm{CE}\big(\bar{\boldsymbol{o}}, \mathrm{MLP}(\boldsymbol{h}_{CLS})\big) \Big), \tag{4}$$

where $\bar{p}_j \in \{0, 1\}$ denotes the label of the target fact (token j in context) or the premise (token j in assumption); and $\bar{\boldsymbol{o}} \in \mathbb{R}^O$ is the label of the deriving operator (see Appendix C for the details of label construction).

3.3 Discussion

Readers might have raised the following two concerns for L2I: 1) the operators defined are limited, and 2) the operators are tailored to one step of derivation on one target fact. Actually, it is a common approach for current state-of-the-art NDR models to apply a set of defined operators (Ran et al., 2019; Chen et al., 2020a; Zhu et al., 2021). For the first concern, by doing more fine-grained classification on the numerical reasoning process in the dataset, we can derive new operators and simply plug them into L2I. Note that the annotation of numerical intervention of TAT-HQA does not follow the defined operators in Appendix C, but the operators are summarized from the data. Our defined operators can cover over 90% of the training data. For the second concern, we discuss two potential solutions by our L2I framework, and we leave the implementation as future work.

Multi-fact intervention. The assumption $\boldsymbol{a}$ can include intervening multiple facts, *e.g.*, "*if the Finished goods in 2018 and 2019 were both doubled*". Apparently, if the target facts are independent, we can easily handle such an assumption by executing L2I in multiple iterations. In other cases, L2I needs to recognize the relationship among the target facts. If such relationship is available, L2I should be able to handle such cases as the corresponding multi-variable operator is added to the deriving head.

Multi-iteration derivation. In causal inference, a rigorous derivation of an intervention considers the successors of the target variable, *e.g.*, *finished goods in 2019* affects *total inventories in 2019*. Currently, we omit the following iterations in Step 2 of L2I (*cf.* Eq 1). This is because not all successors are necessary for answering the question. For instance, answering the question in Figure 1 does not require the post-intervention value of *total inventories in 2019*. In conventional causal inference, such successors will also be omitted according to the *local surgery* principle (Pearl, 2009). Moreover, we believe that the following iterations can be achieved by the current L2I module in an iterative manner. Assume that NDR model equipped with L2I can answer the hypothetical questions requiring one-iteration derivation (*i.e.*, $c_i \rightarrow c_i'$). We can thus derive the value of successors (*e.g.*, $c_i' \rightarrow c_j'$) by forming a simple hypothetical question: "*What c_j would be if c_i is c_i'?*" and answering it with the NDR model.

4 Experiments

We conduct experiments on TAT-HQA dataset to answer the following questions: **RQ1:** How does L2I perform on HQA? **RQ2:** What factors influ-

Table 4: Performance of compared methods on the TAT-HQA dataset. The best and the second-best performance *w.r.t.* each metric are highlighted with bold font and underline, respectively. RI means the relative improvement achieved by TAGOP-L2I over the best baseline.

	BERT-RC	NumNet+ V2	TAPAS-WTQ	Hybrider	TAGOP	TAGOP-CLO	TAGOP-L2I	*RI*
EM	4.7±0.4	9.7±0.4	4.7±0.3	4.6±0.2	41.1±0.7	45.4±1.1	**54.4±1.0**	*19.8%*
F_1	10.4±0.5	11.7±0.4	5.9±0.2	4.9±0.1	41.4±0.8	45.7±1.2	**54.7±1.0**	*19.7%*

ence the effectiveness of L2I?

4.1 Experiment Settings

Following Dua et al. (2019) and Zhu et al. (2021), we evaluate the performance with two commonly used metrics: Exact Match (EM) and numerically-focused F_1 score, where higher value (in [0, 100]) means better performance. We tune the hyper-parameters on the validation set, and report the average test performance of five different runs.

Compared methods. To validate the effectiveness of our proposed L2I module, we apply it to TAGOP, obtaining an NDR model for HQA, named TAGOP-L2I. In addition to the vanilla TAGOP, we compare our method against representative methods of traditional QA, numerical QA, tabular QA, and hybrid QA. Besides, we want to select baselines that are effective for learning counterfactual samples. The baselines are: **BERT-RC** (Devlin et al., 2019), a traditional QA method that selects answer spans from the context. **NumNet+ V2** (Ran et al., 2019), a numerical QA method with numerically-aware graph neural network. **TAPAS-WTQ** (Herzig et al., 2020), a tabular QA method that focuses on parsing and understanding tables, pre-trained over tables collected from Wikipedia before training on TAT-HQA. **HyBrider** (Chen et al., 2020c), a hybrid QA method that considers the connection between the table and text. **TAGOP**, a hybrid QA method that performs discrete reasoning over both the tabular and textual contexts. It is the state-of-the-art method on TAT-QA dataset. **TAGOP-CLO**, incorporating the Contrastive Learning Objective (CLO) into the training objective of TAGOP, which is shown to be effective in learning the relationship between factual and counterfactual samples (Liang et al., 2020).

Parameter settings. We implement TAGOP-L2I based on TAGOP[4]. We set the number of cross-attention layers to 3, and fine tune from TAGOP trained on TAT-QA with a learning rate of 5e-5, batch size of 32, and gradient accumulation step of 4. All compared methods are initialized with the model trained on TAT-QA and then fine-tuned on TAT-HQA. For TAGOP-CLO, we conduct max pooling for $\boldsymbol{H}$ and adopt cosine similarity as the distance metric. We select the corresponding factual question as the positive sample and a randomly selected factual question as the negative sample. The weight for the contrastive loss is 0.1.

4.2 Performance Comparison (RQ1)

Overall performance. Table 4 shows the performance of the compared methods on the TAT-HQA dataset. We can observe that: **1)** TAGOP-L2I achieves the best performance among all the compared methods. In particular, it outperforms the best baselines by 19.8% and 19.7% on EM and F_1, respectively. Such significant performance gain validates the effectiveness of the L2I module and reveal the rationality of modeling counterfactual thinking as a neural network module. **2)** TAGOP-CLO outperforms TAGOP by 10.5% and 10.4% on EM and F_1. The only difference between these two methods is that TAGOP-CLO incorporates an extra CLO. The improvement indicates that learning the relationship between the factual and counterfactual samples with CLO provides some clue for counterfactual imagination, yet it is still worse than directly learning to imagine with neural network modules. **3)** As to the remaining methods, their performance has a clear gap between TAGOP, which is consistent with the result on the TAT-QA dataset (Zhu et al., 2021). This is because both datasets have textual and tabular texts, where the ability of TAGOP to perform discrete reasoning across hybrid contexts brings significant advantages. **4)** The performance achieved is still low *w.r.t.* the two metrics (*e.g.,* 54.4→100), showing a large space for future exploration on the challenging TAT-HQA dataset.

Detailed performance. To further investigate the effectiveness of the proposed L2I module, we perform a detailed comparison between TAGOP-L2I and TAGOP *w.r.t.* the discrete operation required in answering the question or counterfactual thinking. We group the questions according to 1) the answer type and 2) the operator to derive the intervention. Table 5 shows the group-wise

---

[4] `https://github.com/NExTplusplus/TAT-QA`.

Table 5: Detailed performance of TAGOP-L2I and TAGOP *w.r.t.* answer type and deriving operator type.

Answer Type	TAGOP-L2I		TAGOP	
	EM	F_1	EM	F_1
Span	52.1±3.0	53.4±2.8	46.7±1.7	47.5±1.6
Multi-Span	57.1±3.8	62.0±1.7	51.9±0.0	60.3±0.0
Counting	66.1±4.5	66.1±4.5	52.7±5.6	52.7±5.6
Arithmetic	54.0±1.4	54.0±1.4	39.4±0.8	39.4±0.8

Operator Type	TAGOP-L2I	TAGOP
SWAP	60.5±1.5	47.4±0.9
ADD, MINUS	29.6±1.5	2.0±0.0
MULT, DIV	40.0±14.0	0.0±0.0
PERCENT INC, DEC	56.0±6.8	0.0±0.0
SWAP MIN NUM	5.0±4.1	6.7±8.2

performance. As to answer type (the left half), we have the following observations: **1)** TAGOP-L2I outperforms TAGOP on all groups, showing the superior ability of learning to imagine to all types of questions. **2)** Particularly, on the *arithmetic* group, which is also the largest group (*cf.* Table 1), TAGOP-L2I largely outperforms TAGOP. For this group, the key difference between TAGOP-L2I and TAGOP is whether the derivation of intervention and calculation of the answer are achieved by separate modules. The superior performance of TAGOP-L2I validates the rationality of modeling counterfactual thinking as a separate module. It should be noted that the separation also facilitates the generalization to new operations since the modules can be separately updated. **3)** The performance of TAGOP on *arithmetic* has a large gap with other types, showing that *arithmetic* questions are more difficult to conduct imagination and reasoning even though *arithmetic* makes up the majority of TAT-HQA data. As to TAGOP-L2I, the gap between *arithmetic* question and other types of question largely reduces, validating the effectiveness of learning intervention with discrete operators and neural network modules.

As to operator types (the right half), we observe that: **1)** TAGOP-L2I achieves imagination on the majority of operator types with better performance than TAGOP, yet TAGOP can only achieve imagination on a few operator types. The better performance of TAGOP-L2I is attributed to modeling the deriving operations as specific operators. We thus believe that TAGOP-L2I can generalize well to more deriving operations by simply incorporating the operators, as long as the corresponding training questions are not rare. This result thus reflects the advantage of the unified operator framework adopted by the L2I module, which is consistent with previous work (Andor et al., 2019). **2)** Across the groups, TAGOP achieves relatively good performance on the *SWAP* group, which replaces the target fact with a number in the assumption. It corresponds to the simplest imagination since the assumed value (*i.e.,* c_i') is explicitly mentioned in the assumption. Therefore, the result shows that the NDR model can achieve simple counterfactual thinking by learning to answer hypothetical questions. However, such indirect guidance on imagination fails on the groups requiring more complex imagination, *e.g.,* requiring add or minus. **3)** TAGOP-L2I achieves the worst performance on *SWAP MIN NUM*, which is merely comparable to TAGOP. We suspect the reason is that the operation of *SWAP MIN NUM* is very close to *SWAP*, which may confuse the deriving head when making classification over the operators. To address this issue, it is worth considering the operator relation in the deriving head in the future.

4.3 In-depth Analysis (RQ2)

Study on L2I module design. We then explore the influence of network architecture on the effectiveness of the L2I module from three perspectives: 1) module depth; 2) configuration of the matching block; and 3) the setting of PLM.

Figure 3(a) shows the validation result of TAGOP-L2I as increasing the matching block from 1 to 4 layers. We can observe that: **1)** Stacking more layers does not always bring performance gain. **2)** In particular, three layers of matching block achieve the best performance on TAGOP-L2I. The result indicates that three layers should be sufficient to capture the semantic connection across the context, question and assumption. This is reasonable since the average length of both assumption and question are only around 10 words (*cf.* Table 2).

As to the architecture of the matching block, we evaluate three variants from the default choice *p-s, self-a* which enables parameter sharing across layers (*i.e., ps*) and applies both cross-MHA on the factual and assumption representations and self-MHA for each of them (*i.e., self-a*). The three variants are: 1) *p-s, w/o self-a*, which removes self-MHA; 2) *w/o p-s, self-a*, which disables parameter sharing; and 3) *w/o p-s, w/o self-a*, which adopts both changes. Figure 3(b) shows the performance of the four versions of TAGOP-L2I with

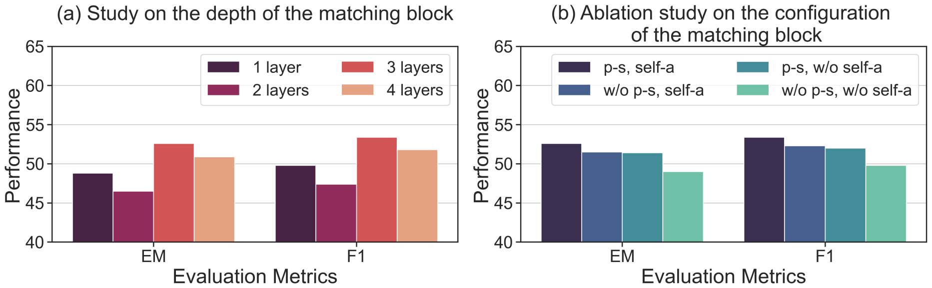

Figure 3: Performance of TAGOP-L2I under difference module configurations.

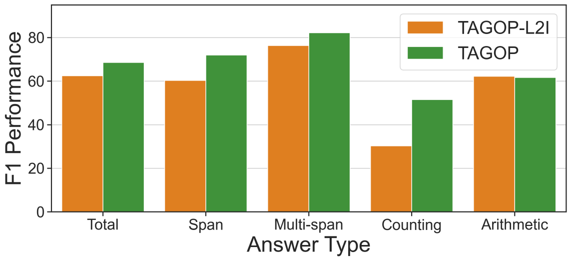

Figure 4: Performance of TAGOP-L2I and the original TAGOP trained on TAT-QA on the test set of TAT-QA.

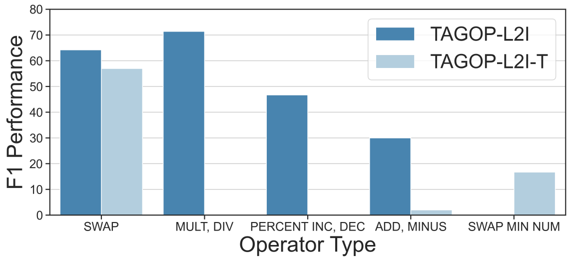

Figure 5: Group-wise performance of TAGOP-L2I and TAGOP-L2I-T *w.r.t.* operator type.

three layers of the matching block. From the figure, we can observe that: **1)** The default choice largely outperforms the variants, validating the rationality of our module design. **2)** Disabling parameter sharing hinders the counterfactual thinking, which indicates that keeping the same parameters through the process of matching factual and assumption representations is beneficial for extracting the semantic correlation. **3)** Removing self-MHA also leads to sharp performance drop, which justifies the contribution of self-MHA in the L2I module. It is thus essential to also separately process the semantic information of the factual and the assumption representations in the matching block.

We also conduct experiments on fixing the parameter of PLM during training on TAT-HQA as initialized by TAT-QA. The performance drops to EM 48.5 and F_1 49.0. Fixing the parameter of PLM largely impedes the performance of TAGOP-L2I on TAT-HQA, showing that encoding factual and hypothetical questions requires different mechanisms. To further investigate the difference in answering factual and hypothetical questions, we test TAGOP-L2I on TAT-QA. The result in Figure 4 shows that training on TAT-HQA causes a performance drop in *counting*, *span* and *multi-span* groups of TAT-QA, and performs similar on the in *arithmetic* group. We conjecture the performance drop in the first three groups is because the question-answering label in TAT-HQA under the same $\boldsymbol{c}$ and $\boldsymbol{q}$ is different from TAT-QA. However, for *arithmetic* questions, the question-answering label for one pair of $\boldsymbol{c}$ and $\boldsymbol{q}$ remains the same between TAT-HQA and TAT-QA, and the intervention is achieved explicitly by deriving operators and tagging head.

Study on L2I training objective. We then investigate the influence of imagination-oriented training objectives on the effectiveness of L2I. In particular, we evaluate a variant TAGOP-L2I-T trained only with the question-answering objective (*i.e.,* $\text{QA}(\cdot)$). That is, TAGOP-L2I-T learns to implicitly imagine the final answer. Figure 5 shows the group-wise performance of TAGOP-L2I and TAGOP-L2I-T *w.r.t.* the type of operator for deriving the intervention. We can observe the followings. **1)** On most groups, TAGOP-L2I largely outperforms TAGOP-L2I-T, demonstrating the rationality of learning to imagine explicitly. **2)** On *SWAP* group TAGOP-L2I-T achieves comparable result to TAGOP-L2I. As *SWAP* is the simplest deriving operator, the result shows that the implicit guidance can achieve simple imagination, yet is still less effective than the explicit manner. **3)** TAGOP-L2I-T achieves better performance on *SWAP MIN NUM* group. As *SWAP MIN NUM* is a rare operator (*cf.* Table 6) and involves the most complex imagination process (*cf.* Appendix B), we conjecture that learning complex operators is more difficult than implicitly learning. This may shed light on the rules of deriving new operators that simple operators with ample training data is preferred over complex operators with less training data.

5 Related Work

Counterfactual thinking. Existing research incorporates counterfactual thinking into deep models from two main perspectives: *counterfactual training* and *counterfactual inference*.

Counterfactual sample has become an emerging data augmentation technique in computer vision (Chen et al., 2020b) and natural language processing (Kaushik et al., 2019) to enhance model robustness. For instance, the technique is applied in visual QA (Chen et al., 2020b; Agrawal et al., 2018; Agarwal et al., 2020; Gokhale et al., 2020), vision-language navigation (Fu et al., 2020; Parvaneh et al., 2020), table entailment (Eisenschlos et al., 2020), sentiment analysis (Kaushik et al., 2019; Yang et al., 2020), natural language inference (Kaushik et al., 2019), named entity recognition (Zeng et al., 2020), and dialogue system (Zhu et al., 2020). Along this line, a series of studies explore how to maximize the effect of counterfactual samples by combining with different learning paradigms, such as adversarial training (Zhu et al., 2020; Fu et al., 2020; Teney et al., 2020), contrastive learning (Liang et al., 2020), causal graph (Gokhale et al., 2020), posterior regularization (Ramakrishnan et al., 2018), and designing new learning paradigms (Gokhale et al., 2020). A few studies along this line also generate counterfactual samples with neural networks (Sauer and Geiger, 2021; Yue et al., 2021). They are inherently different from our work due to their reliance on causal graph and the causal expression of the hypothetical condition for improving robustness. Moreover, they supervise the generation with other related tasks such as image classification. In contrast, we formulate imagination as an explicit learning objective, *i.e.,* learning to imagine. Additionally, in commonsense reasoning, counterfactual samples are also utilized through hyperbole generation (Tian et al., 2021), story generation (Qin et al., 2019) and commonsense QA(Huang et al., 2019), which is also a related yet different strand of research.

Another line of research performs *counterfactual inference* over the predictions of deep model to incorporate counterfactual thinking (Yue et al., 2021; Wang et al., 2021; Niu et al., 2021; Tang et al., 2020). However, they perform counterfactual inference according to causal graph which is not available in NDR tasks.

Neural discrete reasoning. Recent research on NDR focuses on enhancing the discrete reasoning ability of deep models in two main directions: *reasoning with more discrete operations* (Dua et al., 2019; Ran et al., 2019; Chen et al., 2020a) and *reasoning over more complex context*. For instance, NumNet (Ran et al., 2019) and QDGAT (Chen et al., 2020a) leverage graph neural network to enhance comparison oriented operations. GenBERT (Geva et al., 2020) uses pre-trained language models to generate the numerical answer, which breaks the limitation of fixed operators. NMN (Gupta et al., 2019) and FinQA (Chen et al., 2021) model the discrete reasoning process as executing programs. As to extending the context, several studies try to enable the NDR model to operate on context with semi-structured tabular data and hybrid data (Chen et al., 2020c; Herzig et al., 2020; Chen et al., 2021). Our paper studies the hybrid data, yet extends the scope of NDR to hypothetical questions. Moreover, beyond the ability of discrete operations, the main idea is to endow NDR models with the ability to think counterfactually.

6 Conclusion

In this work, we pointed out a key issue of existing NDR models: lacking counterfactual thinking. We proposed an L2I module, which can imagine the counterfactual according to a textual assumption. By applying the proposed module in the NDR model, we enable the model to answer hypothetical questions. We constructed a HQA dataset and conducted extensive experiments on the dataset, which validates the effectiveness of our method.

This work opens up a new research direction about modeling counterfactual thinking through neural network. In the future, we will further extend the L2I from the following perspectives: 1) handling of multiple interventions; 2) rigorous derivation of intervention with consideration of successors; 3) incorporation of the relations across the deriving operators; and 4) construction of complex operators by dynamically combining basic operators. Moreover, we will explore the translation between assumptions in natural language and causal expression to further connect the L2I framework with conventional causal theory, and facilitate automatic causal inference with neural network.

A Working Process of the Tagging Head

The *tagging head* (*cf.* Section 3.1) in L2I identifies the target fact from the factual context, which is formulated as the Inside-Outside (IO) Tagging (Ramshaw and Marcus, 1999). A 2-way classifier, which is a 2-layer MLP followed by softmax, computes the probability of being tagged as negative and positive for each token in the sequence. Then, the positive score for each fact is aggregated by the maximum probability of its tokens. For instance, the fact "$133,682" has four tokens "$", "133", ",", "682" where each token obtains a latent representation from the PLM. The 2-layer MLP takes the latent representation as input to predict the score for each token. The maximum score represents the score of fact "$133,682".

B Deriving Operators

The *deriving head* consists of two steps: 1) selecting the deriving operators; and 2) identifying the premises for the selected operator. The deriving operator is defined as a function $f(T, P)$ over the target fact T and premise P. The value of $f(T, P)$ replaces T in the factual context to form the counterfactual context. In particular, we define eight operators as follows:

- **SWAP**: $f(T, P) = P$.
- **ADD**: $f(T, P) = T + P$.
- **MINUS**: $f(T, P) = T - P$.
- **MULTIPLY**: $f(T, P) = T * P$.
- **DIVISION**: $f(T, P) = T/P$.
- **PERCENT INC**: $f(T, P) = T*(100+P)/100$, where P is a percentage.
- **PERCENT DEC**: $f(T, P) = T * (100 - P)/100$, where P is a percentage.
- **SWAP MIN NUM**: This is a multivariable operator, which intervenes two facts: the target fact T and the sum including the target fact op_2. Apart from swapping T with P, this operator also replaces op_2 with $op_2 - T + P$.

As to the identification of the premise, we simply use the outputs of the tagging head where every fact has a score. We select the fact with the highest score in the context as the target fact and the one in the assumption as the premise.

C Labels for Tagging Head and Deriving Head

Note that each hypothetical question in TAT-HQA corresponds to a question in TAT-QA. Both datasets provide the derivation to answer the question (*e.g., 133,682 - 162,935*), which can be used to construct the ground-truth for training the *tagging head* and *deriving head* of L2I (Equation 4). In particular, we compare the counterfactual derivation with the original derivation. Under the assumption of one-step intervention, we postulate that the counterfactual derivation differs from the original derivation by involving in one more number or substituting one number, where we name the new number in the counterfactual derivation as the premise. By identifying the premise, we construct the label for the tagging head. According to the operator around the premise, we construct the label of the deriving operator. The statistics of the deriving operator are shown in Table 6.

D Accuracy of Deriving Operator Selection and Target Fact Picking

We calculate the accuracy of operator selection and target fact picking of L2I. The average testing result for 5 runs is 96.4% for operator selection, and 82.9% for target fact picking, showing that L2I can select the correct operator and target fact quite precisely. The good performance on selection operators and target facts owes to the superior ability of PLM to understand questions and contexts. We also try a naive lexical match to select operators and target facts. For operator selection, we define a set of keywords(*e.g.,* increase to, decrease by) for the question as a sign of the operator type. For target fact selection, we utilize the word overlap between the assumption and the context to locate the target fact. The accuracy for selecting operators is 89.4%, and for picking up target facts is 52.5%. The gap between L2I and lexical match demonstrates that the generalization ability of PLM plays an important part in operator selection and target fact picking in L2I.

E Computation Resources

We train TAGOP-L2I on a NVIDIA Tesla V100 GPU with 32GB RAM.

	SWAP	ADD	MINUS	MULT	DIV	PERCENT INC	PERCENT DEC	SWAP MIN NUM

Abstract

Complex word identification (CWI) is a cornerstone process towards proper text simplification. CWI is highly dependent on context, whereas its difficulty is augmented by the scarcity of available datasets which vary greatly in terms of domains and languages. As such, it becomes increasingly more difficult to develop a robust model that generalizes across a wide array of input examples. In this paper, we propose a novel training technique for the CWI task based on domain adaptation to improve the target character and context representations. This technique addresses the problem of working with multiple domains, inasmuch as it creates a way of smoothing the differences between the explored datasets. Moreover, we also propose a similar auxiliary task, namely text simplification, that can be used to complement lexical complexity prediction. Our model obtains a boost of up to 2.42% in terms of Pearson Correlation Coefficients in contrast to vanilla training techniques, when considering the CompLex from the Lexical Complexity Prediction 2021 dataset. At the same time, we obtain an increase of 3% in Pearson scores, while considering a cross-lingual setup relying on the Complex Word Identification 2018 dataset. In addition, our model yields state-of-the-art results in terms of Mean Absolute Error.

1 Introduction

The overarching goal of the complex word identification (CWI) task is to find words that can be simplified in a given text (Paetzold and Specia, 2016b). Evaluating word difficulty represents one step towards achieving simplified, which in return facilitates access to knowledge to a wider audience texts (Maddela and Xu, 2018). However, complex word identification is a highly contextualized task, far from being trivial. The datasets are scarce and, most of the time, the input entries are limited or cover different domains/areas of expertise. Therefore, developing a robust and reliable model that can be used to properly evaluate the complexity of tokens is a challenging task. Table 1 showcases examples of complex words annotations from the CompLex LCP (Shardlow et al., 2020, 2021b) and English CWI (Yimam et al., 2018) datasets employed in this work.

	Domain	**Text**
CompLex LCP Dataset	Bible	But let each man test his own work, and then he will take pride in himself and not in his neighbor.
	Biomedical	A genome database search revealed orthologs of ADAM11, ADAM22 and ADAM23 genes to exist in vertebrates such as mammals, fish, and amphibians, but not in invertebrates.
	Europarl	They also allow for easy compensation for the thousands of accidents involving vehicles from more than one Member State.
English CWI Dataset	Wikipedia	Normally, the land will be passed down to future generations in a way that recognizes the community's traditional connection to that country.
	WikiNews	The JAS 39C Gripen crashed onto a runway at around 9:30 am local time (02:30 UTC) and exploded, closing the airport to commercial flights.
	News	The car has been removed from the scene for forensic technical examination.

Table 1: Examples of complex words annotated for each of the domains from CompLex LCP and CWI datasets. The shades indicate the complexity; the darker the shade, the more complex the sequence of words. Best viewed in color.

Nevertheless, certain training techniques and auxiliary tasks help the model improve its generalization abilities, forcing it to focus only on the most relevant, general features (Schrom et al., 2021). Techniques like domain adaptation (Ganin et al., 2016) can be used for various tasks, with the purpose of selecting relevant features for follow-up processes. At the same time, the cross-domain scenario can be transposed to a cross-lingual setup, where the input entries are part of multiple available languages. Performance can be improved by

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 70 - 80
May 22-27, 2022

also employing the power of domain adaptation, where the domain is the language; as such, the task of identifying complex tokens can be approached even for low resource languages.

We propose several solutions to improve the performance of a model for CWI in a cross-domain or a cross-lingual setting, by adding auxiliary components (i.e., Transformer (Vaswani et al., 2017) decoders, Variational Auto Encoders - VAEs (Kingma and Welling, 2014)), as well as a domain adaptation training technique (Farahani et al., 2021). Moreover, we use the domain adaptation intuition and we apply it in a multi-task adversarial training scenario, where the main task is trained alongside an auxiliary one, and a task discriminator has the purpose of generalizing task-specific features.

We summarize our main contributions as follows:

- Applying the concept of domain adaptation in a monolingual, cross-domain scenario for complex word identification;
- Introducing the domain adaptation technique in a cross-lingual setup, where the discriminator has the purpose to support the model extract only the most relevant features across all languages;
- Proposing additional components (i.e., Transformer decoders and Variational Auto Encoders) trained alongside the main CWI task to provide more meaningful representations of the inputs and to ensure robustness, while generating new representations or by tuning the existing ones;
- Experimenting with an additional text simplification task alongside domain/language adaptation, with the purpose of extracting cross-task features and improving performance.

2 Related Work

Domain Adaptation. Several works employed domain adaptation to improve performance. For example, Du et al. (2020) approached the sentiment analysis task by using a BERT-based (Devlin et al., 2019) feature extractor alongside domain adaptation. Furthermore, McHardy et al. (2019) used domain adaptation for satire detection, with the publication source representing the domain. At the same time, Dayanik and Padó (2020) used a technique similar to domain adaptation, this time for political claims detection. The previous approaches consisted of actor masking, as well as adversarial debiasing and sample weighting. Other studies considering domain adaptation included suggestion mining (Klimaszewski and Andruszkiewicz, 2019), mixup synthesis training (Tang et al., 2020), and effective regularization (Vernikos et al., 2020).

Cross-Lingual Domain Adaptation. Chen et al. (2018) proposed ADAN, an architecture based on a feed-forward neural network with three main components, namely: a feature extractor, a sentiment classifier, and a language discriminator. The latter had the purpose of supporting the adversarial training setup, thus covering the scenario where the model was unable to detect whether the input language was from the source dataset or the target one. A similar cross-lingual approach was adopted by Zhang et al. (2020), who developed a system to classify entries from the target language, while only labels from the source language were provided.

Keung et al. (2019) employed the usage of multilingual BERT (Pires et al., 2019) and argued that a language-adversarial task can improve the performance of zero-resource cross-lingual transfers. Moreover, training under an adversarial technique helps the Transformer model align the representations of the English inputs.

Under a Named Entity Recognition training scenario, Kim et al. (2017) used features on two levels (i.e., word and characters), together with Recurrent Neural Networks and a language discriminator used for the domain-adversarial setup. Similarly, Huang et al. (2019) used target language discriminators during the process of training models for low-resource name tagging.

Word Complexity Prediction. Gooding and Kochmar (2019) based their implementation for CWI as a sequence labeling task on Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) networks, inasmuch as the context helps towards proper identification of complex tokens. The authors used 300-dimensional pre-trained word embeddings as inputs for the LSTMs. Also adopting a sequence labeling approach, Finnimore et al. (2019) considered handcrafted features, including punctuation or syllables, that can properly identify complex structures.

The same sequence labeling approach can be applied under a plurality voting technique (Polikar, 2006), or even using an Oracle (Kuncheva et al., 2001). The Oracle functions best when applied to multiple solutions, by jointly using them to obtain a final prediction. At the same time, Zaharia et al. (2020) explored the power of Transformer-based models (Vaswani et al., 2017) in cross-lingual environments by using different training scenarios, depending on the scarcity of the resources: zero-shot, one-shot, as well as few-shot learning. Moreover, CWI can be also approached as a probabilistic task. For example, De Hertog and Tack (2018) introduced a series of architectures that combine deep learning features, as well as handcrafted features to address CWI as a regression problem.

3 Method

3.1 Datasets

We experimented with two datasets, one monolingual - CompLex LCP 2021 (Shardlow et al., 2020, 2021b) - and one cross-lingual - the CWI Shared Dataset (Yimam et al., 2018). The entries of *CompLex* consist of a sentence in English and a target token, alongside the complexity of the token, given its context. The complexities are continuous values between 0 and 1, annotated by various individuals on an initial 5-point Likert scale; the annotations were then normalized.

The *CompLex* dataset contains two types of entries, each with its corresponding subset of entries: a) single, where the target token is represented by a single word, and b) multiple, where the target token is represented by a group of words. While the single-word dataset contains 7,662 training entries, 421 trial entries, and 917 test entries, the multi-word dataset has lower counts, with 1,517 training entries, 99 trial entries, and 184 for testing. At the same time, the entries correspond to three different domains (i.e., biblical, biomedical, and political), therefore displaying different characteristics and challenging the models towards generalization.

The *CWI dataset* was introduced in the CWI Shared Task 2018 (Yimam et al., 2018). It is a multilingual dataset, containing entries in English, German, Spanish, and French. Moreover, the English entries are split into three categories, depending on their proficiency levels: professional (News), non-professional (WikiNews), and Wikipedia articles. Most entries are for the English language (27,299 training and 3,328 validation), while the fewest training entries are for German (6,151 training and 795 validation). The French language does not contain training or validation entries.

3.2 The Domain Adaption Model

The overarching architecture of our method is introduced in Figure 1. All underlying components are presented in detail in the following subsections. Our model combines character-level BiLSTM features (i.e., $\mathcal{F}_t$) with Transformer-based features for the context sentence (i.e., $\mathcal{F}_c$). The concatenated features ($\mathcal{F}_c$+$\mathcal{F}_t$) are then passed through three linear layers, with a dropout separating the first and second. The output is a value representing the complexity of the target word.

Three configurations were experimented. Within **Basic Domain Adaptation**, the previous features are passed through an additional component, the domain discriminator, composed of a linear layer followed by a softmax activation function. A *gradient reversal* layer (Ganin and Lempitsky, 2015) is added between the feature concatenation and the discriminator to reverse the gradients through the backpropagation phase and support extracting general features. The loss function is determined by Equation 1 as:

$$L = L_r - \beta\lambda L_d \tag{1}$$

where L_r is the regression loss, L_d is the general domain loss, β is a hyperparameter used for controlling the importance of $\mathrm{L_d}$, and λ is another hyperparameter that varies as the training process progresses.

The following setups also include the Basic Domain Adaptation training setting.

VAE and Domain Adaptation considers the previous configuration, plus the VAE encoder, that yields the $\mathcal{F}_v$ features, and the VAE decoder, which aims to reconstruct the input. The concatenation layer now contains the BiLSTM and Transformer features, along with the VAE encoder features ($\mathcal{F}_v$), namely $\mathcal{F}_t$+$\mathcal{F}_c$+$\mathcal{F}_v$. The loss function is depicted by Equation 2 as:

$$L = L_r - \beta\lambda L_d + \alpha L_v \tag{2}$$

where, additionally, L_v represents the VAE loss described in Equation 6.

Transformer Decoder and Domain Adaptation adds a Transformer Decoder with the purpose of reconstructing the original input, for a more robust context feature extraction. The loss is denoted by Equation 3 as:

$$L = L_r - \beta\lambda L_d + \alpha L_{dec} \tag{3}$$

where L_{dec} represents the decoder loss described in Equation 9.

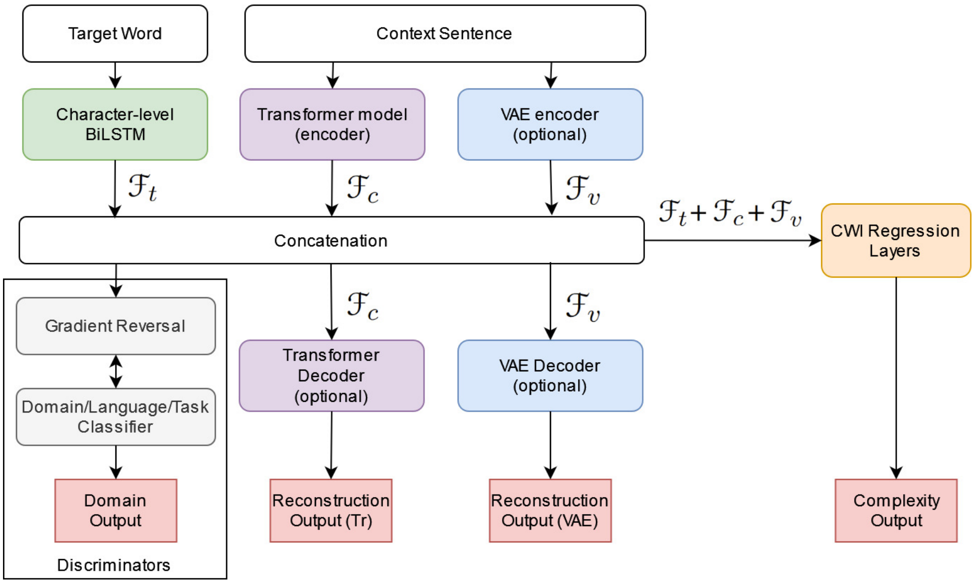

Figure 1: The overarching architecture for the domain adaptation model.

3.2.1 Character-level BiLSTM for Target Word Representation

The purpose of this component is to determine the complexity of the target token, given only its constituent characters. A character-level Bidirectional Long Short-Term Memory (BiLSTM) network receives as input an array of characters corresponding to the target word (or group of words), and yields a representation that is afterwards concatenated to the previously mentioned Transformer-based representations. Each character c is mapped to a certain value obtained from the character vocabulary V, containing all the characters present in the input dataset.

The character sequence is represented as $C^i = [c_1, c_2, \ldots, c_n]$, where n is the maximum length of a target token. C^i is then passed through a character embedding layer, thus yielding the output Emb_{target}. Emb_{target} is then fed to the BiLSTM, followed by a dropout layer, thus obtaining the final target word representation, $\mathcal{F}_t$.

3.2.2 Transformer-based Context Representation

We rely on a Transformer-based model as the main feature extractor for the context of the target word (i.e., the full sentence), considering their superior performance on most natural language processing tasks. The selected model for the first dataset is RoBERTa (Liu et al., 2019), as it yields better results when compared to its counterpart, BERT. RoBERTa is trained with higher learning rates and larger mini-batches, and it modifies the key hyperparameters of BERT. We employed the usage of XLM-RoBERTa (Conneau et al., 2020), the multilingual counterpart of RoBERTa, now trained on a very large corpus of multilingual texts, for the second cross-lingual task. The features used for our task are represented by the pooled output of the Transformer model. The feature vector $\mathcal{F}_c$ of 768 elements captures information about the context of the target word.

3.2.3 Variational AutoEncoders

We aim to further improve performance by adding extra features via Variational AutoEncoders (VAEs) (Kingma and Welling, 2014) to the context representation for a target word. More specifically for the CWI task, we use the latent vector z, alongside the Transformer and the Char BiLSTM features. Moreover, we also need to ensure that the Encoder representation is accurate; therefore, we consider the VAE encoding and decoding as an additional task having the purpose of minimizing the reconstruction loss.

The VAE consists of two parts, namely the encoder and the decoder. The encoder $g(x)$ produces the approximation $q(z|x)$ of the posterior distribution $p(z|x)$, thus mapping the input x to the latent space z. The process is presented in Equation 4. We use as features the representation z, denoted as $\mathcal{F}_v$.

$$p(z|x) \approx q(z|x) = \mathcal{N}(\mu(x), \sigma(x)) \qquad (4)$$

The decoder $f(z)$ maps the latent space to the input space (i.e., $p(z)$ to $p(x)$), by using Equation 5.

$$\begin{aligned} p(x) &= \int p(x|z)p(z)dz \\ &= \int \mathcal{N}(f(z), I)p(z)dz \end{aligned} \tag{5}$$

Equation 6 introduces the loss function, where D_{KL} represents the Kullback Leibler divergence. Furthermore, $\mathbb{E}_{\mathrm{q}}$ represents the expectation with relation to the distribution q.

$$\begin{aligned} L(f,g) = \sum_i \{ &-D_{KL}[q(z|x_i)||p(z)] \\ &+ \mathbb{E}_{q(z|x_i)}[\ln p(x_i|z)]\} \end{aligned} \tag{6}$$

3.2.4 Discriminators

The features extracted by our architecture can vary greatly as the input entries can originate from different domains or languages. Consequently, we introduced a generalization technique to extract only cross-domain features that do not present a bias towards a certain domain. We thus employ an adversarial training technique based on domain adaptation, forcing the model to only extract relevant cross-domain features.

A discriminator acts as a classifier, containing three linear layers with corresponding activation functions. The discriminator classifies the input sentence into one of the available domains. Unlike traditional classification approaches, our purpose is not to minimize the loss, but to maximize it. We want our model to become incapable of distinguishing between different categories of input entries, therefore extracting the most relevant, cross-domain features.

Our architecture is encouraged to generalize in terms of extracted features by the *gradient reversal* layer that reverses the gradients during the backpropagation phase; as such, the parameters are updated towards the direction that maximizes the loss instead of minimizing it.

Three scenarios were considered, each one targeting a different approach towards domain adaptation.

Domain Discriminator. The first scenario is applied on the first dataset, CompLex, with entries only in English, but covering multiple domains. The discriminator has the purpose of identifying the domain of the entry, namely biblical, biomedical or political. The intuition is that, by grasping only cross-domain features, the performance of the model increases on all three domains, instead of performing well only on one, while poorer on the others.

Language Discriminator. The intuition is similar to the previous scenario, except that we experimented with the second multilingual dataset. Therefore, our interest was that our model extracts cross-lingual features, such that the performance is equal on all the target languages.

Task Discriminator. In this scenario, we trained a similar, auxiliary task, represented by text simplification. A task discriminator is implemented to detect the origin of the input entry: either the main task or the auxiliary task (i.e., simplified version). The dataset used for text simplification is represented by BenchLS (Paetzold and Specia, 2016a)[1]. The employed simplification process consists of masking the word considered to be complex and then using a Transformer for Masked Language Modeling to predict the best candidate. The corresponding flow is described in Algorithm 1, while the loss function is presented in Equation 7:

$$L = L_r - \beta\lambda L_{task\_id} + L_{ML} \tag{7}$$

where L_{ML} is the Sparse Categorical Cross Entropy loss.

All previous discriminators use the same loss, namely Categorical Cross Entropy (Zhang and Sabuncu, 2018).

The overall loss consists of the difference between the task loss and the domain/language loss. Moreover, the importance of the latter can be controlled by multiplication with a λ hyperparameter, that changes over time, and a fixed β hyperparameter. The network parameters, θ_p are updated according to Equation 8, where η is the learning rate, L_d is the domain loss, L_r is the task loss and β is the weight for the domain loss. A similar equation for language loss (L_l) is in place for the second dataset, where instead of the domain loss L_d we used the language identification loss L_l, having the same formula.

$$\theta_p = \theta_p - \eta(\frac{\partial L_r}{\partial \theta_p} - \beta\lambda\frac{\partial L_d}{\partial \theta_p}) \tag{8}$$

3.2.5 Transformer Decoder

Our model also considers a decoder to reconstruct the original input, starting from the Transformer representation. The intuition behind introducing

---

[1] `http://ghpaetzold.github.io/data/BenchLS.zip`

Algorithm 1: The Multi-Task Adversarial algorithm (Task 1 - lexical complexity prediction; Task 2 - text simplification).

```
Inputs: Preprocessed dataset, split into batches ($x_i$, $y_i$), $i=1,n$ (where $n$ is the number of batches, $x_i$ are the input features for the target word and the context, and $y_i$ is the complexity);
Outputs: Updated parameters $\theta_p$;
Initialization: Initialize $\theta_p$ with random weights;
for every batch do
    Select entries E1 from Task 1;
    Select entries E2 from Task 2;
    out1 = Apply initial architecture on E1;
    out2 = Apply Masked Language Modeling Transformer on E2;
    F = Combine the features from applying architecture on E1 and E2;
    out_task = Pass F through task discriminator;
    loss1 = $L_r$(out1, ref1);
    loss2 = $L_{ML}$(out, ref2);
    task_loss = $L_{task\_id}$(out_task, ref_task);
    loss = loss1+loss2-$\beta\lambda$task_loss;
    Backpropagate loss;
    Update $\theta_p$;
end
```

this decoder is to increase the robustness of the context feature extraction.

The decoder receives as input the outputs of the hidden Transformer layer alongside an embedding of the original input, which are passed through a Gated Recurrent Unit (GRU) (Chung et al., 2014) layer for obtaining the final representation of the initial input. Additionally, two linear layers separated by a dropout are introduced before obtaining the final representation, $y = \mathcal{F}_d$. The loss is computed by using the Negative Log Likelihood loss between the outputs of the decoder and the original Transformer input id representation of the entries (see Equations 9 and 10).

$$L(x, y) = \sum_{n=1}^{N} l_n \tag{9}$$

$$\begin{gathered} l_n = -w_{y_n} x_{n,y_n}, \\ w_c = weight[c] \cdot \mathbb{1}\{c \neq ignore\_index\} \end{gathered} \tag{10}$$

3.3 Experimental Setup

The optimizer used for our models is represented by AdamW (Kingma and Ba, 2014). The learning rate is set to *2e-5*, while the loss functions used for the complexity task are the L1 loss (Janocha and Czarnecki, 2016) for the CompLex LCP dataset and the Mean Squared Error (MSE) loss (Kline and Berardi, 2005) for the CWI dataset. The auxiliary losses are summed to the main loss (i.e., complexity prediction) and are scaled according to their priority, with a factor of α, where α is set to 0.1 for the VAE loss, and 0.01 for the Transformer decoder and task discriminator losses. The λ parameter used for domain adaptation was updated according to Equation 11:

$$\lambda = \frac{2}{1 + e^{-\gamma\epsilon}} - 1 \tag{11}$$

where ϵ is the number of epochs the model was trained; γ was set to 0.1, while β was set to 0.2. Moreover, each model was trained for 8 epochs, except for the one including the VAE features, which was trained for 12 epochs.

4 Results

4.1 LCP 2021 CompLex Dataset

We consider as baselines two models used for the LCP 2021 competition (Shardlow et al., 2021a), as well as the best-registered score. Almeida et al. (2021) employed the usage of neural network solutions; more specifically, they used chunks of the sentences obtained with Sent2Vec as input features. Zaharia et al. (2021) created models that are based on target and context feature extractors, alongside features resulted from Graph Convolutional Networks, Capsule Networks, and pre-trained word embeddings.

Table 2 depicts the results obtained for the English dataset using domain adaptation and various configurations. "Base" denotes the initial model (RoBERTa + Char BiLSTM) on which we apply domain adaptation, as well as the auxiliary tasks. The domain adaptation technique offers improved performance when applied on top of an architecture, considering that the model learns cross-domain features. The only exception is represented by a slightly lower Pearson score on the model that uses domain adaptation alongside the Transformer decoding auxiliary task (Base + Decoder + DA), with a value of .7969 on the trial dataset, when compared

Table 2: Results on the LCP 2021 English dataset.

* LA = Language Adaptation; VAE = Variational AutoEncoder; Decoder = Transformer Decoder; EN-N = English-News; EN-WN = English-WikiNews; EN-W = English-Wikipedia; DE = German; ES = Spanish; FR = French; P = Pearson Correlation Coefficient; MAE = Mean Absolute Error.

to the initial .7987 (Base). However, the remaining models improve upon the starting architecture, with the largest improvements being observed for domain adaptation and the text simplification auxiliary task (Base + Text simplification + DA), with a Pearson correlation coefficient on the test dataset of .7744, 2.42% better than the base model. The improved performance can be also seen for the Mean Absolute Error score (MAE = .0652).

While the Transformer decoder auxiliary task does not offer the best performance for the single word dataset, the same architecture offers the second-best performance for the multi-word dataset, with a Pearson score of .8252 compared to the best one, .8285. The domain adaptation and VAE configuration provide improvements upon the base model (.7554 versus .7502 Pearson), but the VAE does not have an important contribution, considering that the Base + domain adaptation model has a slightly higher Pearson score of .7569.

4.2 CWI 2018 Dataset

We also experimented with a multilingual dataset, where the discriminant is considered to be the language. The baseline consists of three models used from the CWI 2018 competition. The performance is evaluated in terms of MAE; however, we also report the Pearson Correlation Coefficient. First, Kajiwara and Komachi (2018) based their models on regressors, alongside features represented by the number of characters or words and the frequency of the target word in certain corpora. Second, the approach of Bingel and Bjerva (2018) is based on Random Forest Regressors, as well as feed-forward neural networks alongside specific features, such as log-probability, inflectional complexity, or target-sentence similarity; the authors focused on non-English entries. Third, Gooding and Kochmar (2018) approach the English section of the dataset by employing linear regressions. The authors used several types of handcrafted features, including word n-grams, POS tags, dependency parse relations, and psycholinguistic features.

Table 3 presents the results obtained on the multilingual validation dataset and compares the performance of different configurations. The best overall performance in terms of Pearson correlation coefficient is yielded by the Base model (XLM-RoBERTa + Char BiLSTM) alongside the text simplification auxiliary task and the domain adaptation technique (Base + Text simplification + LA), with values of .8602 on English News, .8555 on English WikiNews, as well as .7842 on English Wikipedia and .7147 on German. The best Pearson score for the Spanish language is obtained by the base model, with .6944. The Base + VAE + LA architecture offers improvements over the Base model, but falls behind when compared to the Base + Text simplification + LA model, with Pearson correlation ranging from .8557 on the English News dataset to .6805 on the Spanish dataset.

However, when switching to MAE, the metric used for evaluation in the CWI 2018 competition, the best performance is split between the first three models, namely Base, Base + LA, and Base + VAE + LA. The Base + LA approach yields the best, lowest MAE score on the German and Spanish datasets, while the Base architecture performs the best on English WikiNews and English Wikipedia. The English News achieves the best MAE results from the Base + VAE + LA model.

Nevertheless, the best overall performance is obtained by the Base + VAE + LA model on the test dataset (see Table 4), with dominating Pearson and MAE scores on the Spanish and French languages: 0.6912 Pearson, 0.595 MAE for Spanish, as well as .5559 Pearson, and .0752 MAE for French, respectively. The Base + Text simplification + LA model performs the best in terms of Pearson Correlation Coefficient on the English WikiNews and Wikipedia datasets, with Pearson scores of .8338 and .7420. However, the best MAE scores for the same datasets are generated by the Base + LA model (.0513 English WikiNews) and Base + VAE + LA (.0671 English Wikipedia).

5 Discussions

The domain adaptation technique supports our model to learn general cross-domain or cross-language features, while achieving higher performance. Moreover, jointly training on two different tasks (i.e., lexical complexity prediction and text simplification), coupled with domain adaptation to generalize the features from the two tasks, can lead to improved results.

However, there are entries for which our models were unable to properly predict the complexity score, namely: a) entries with a different level of complexity (i.e. biomedical), and b) entries part of a language that was not present in the training dataset (i.e., French). For the former, scientific terms (e.g., "sitosterolemia"), abbreviations (e.g., "ES"), or complex elements (e.g., "H3-2meK9") impose a series of difficulties for our feature extractors, considering the absence of these tokens from the Transformer vocabulary. The latter category of problematic entries creates new challenges in the sense that it represents a completely new language on which the architecture is tested. However, as seen in the results section, the cross-lingual domain adaptation technique offers good improvements, helping the model achieve better performance on French, even though the initial architecture was not exposed to any French example.

6 Conclusions and Future Work

This work proposes a series of training techniques, including domain adaptation, as well as multi-task adversarial learning, that can be used for improving the overall performance of the models for CWI. Domain adaptation improves results by encouraging the models to extract more general features, that can be further used for the lexical complexity prediction task. Moreover, by jointly training the model on the CWI tasks and an auxiliary similar task (i.e., text simplification), the overall performance is improved. The task discriminator also ensures the extraction of general features, thus making the model more robust on the CWI dataset.

For future work, we intend to experiment with meta-learning (Finn et al., 2017) alongside domain adaptation (Wang et al., 2019), considering the scope of the previously applied training techniques. This would enable us to initialize the model's weights in the best manner, thus ensuring optimal results during the training phase.

Abstract

Zero-shot stance detection (ZSSD) aims to detect the stance for an unseen target during the inference stage. In this paper, we propose a joint contrastive learning (JointCL) framework, which consists of stance contrastive learning and target-aware prototypical graph contrastive learning. Specifically, a stance contrastive learning strategy is employed to better generalize stance features for unseen targets. Further, we build a prototypical graph for each instance to learn the target-based representation, in which the prototypes are deployed as a bridge to share the graph structures between the known targets and the unseen ones. Then a novel target-aware prototypical graph contrastive learning strategy is devised to generalize the reasoning ability of target-based stance representations to the unseen targets. Extensive experiments on three benchmark datasets show that the proposed approach achieves state-of-the-art performance in the ZSSD task[1].

1 Introduction

Stance detection aims to automatically identify one's opinionated standpoint/attitude (e.g. *Pro*, *Con*, or *Neutral*, etc.) expressed in text towards a specific proposition, topic, or target (Somasundaran and Wiebe, 2010; Augenstein et al., 2016; Mohammad et al., 2016; Sobhani et al., 2017). For example, a text "*Everyone is able to believe in whatever they want.*" expresses a stance of "*Pro*" towards the target "*Atheism*".

Existing methods achieved promising performance in in-target stance detection when trained and tested on the datasets towards the same set of targets (Mohtarami et al., 2018; Graells-Garrido et al., 2020), and in cross-target stance detection that identifies the stance of a destination target using models trained on a related source target in a one-to-one way (Xu et al., 2018; Zhang et al., 2020; Liang et al., 2021a). In practice, however, it is infeasible to enumerate all possible (in-target) or related (cross-target) targets beforehand for training stance detection models. Hence, zero-shot stance detection (ZSSD) (Allaway and McKeown, 2020), which aims to detect the stance for unseen targets during the inference stage is a promising scenario forward.

To deal with ZSSD, intuitively, we can either reason the target-based stance features from the learned stance information based on the context (i.e., from the *context-aware* perspective), or identify stance information that is potentially relevant with unseen targets from the learned target-related stance expressions (i.e., from the *target-aware* perspective). Existing research attempted to explore attention mechanism (Allaway and McKeown, 2020), adversarial learning (Allaway et al., 2021), or graph architecture based on external commonsense knowledge (Liu et al., 2021) to learn the stance representations from the context regarding the known targets, aiming to generalize the learned stance features to the unseen targets for ZSSD. But they tend to ignore that the stance information of an unseen target can be represented in the light of the known targets from the *target-aware* perspective.

In this paper, to generalize the stance features to the unseen targets, we propose a joint contrastive learning (`JointCL`) framework to leverage the stance features of known targets from both the *context-aware* and the *target-aware* perspectives. On the one hand, from the *context-aware* perspective, we explore a **Stance Contrastive Learning**

strategy, which effectively improves the quality of stance features by leveraging the similarity of training instances in a stance class while pushing away instances from other stance classes. This essentially allows the exploitation of target-based contextual stance features to better generalize to the unseen targets. On the other hand, from the *target-aware* perspective, we propose a feasible solution to capture the relationships between the known targets and the unseen ones. Specifically, inspired by (Li et al., 2021), we explore a clustering method to generate prototypes from all training instances. We then build prototypical graphs linking the prototypes with the target-based representations, in which each prototype is regarded as a bridge that allows the sharing of the graph structures between known targets and unseen ones. Based on the prototypical graphs, we devise a novel **Target-Aware Prototypical Graph Contrastive Learning** strategy to learn the correlation and difference among the target-based representations. Specifically, a novel edge-oriented graph contrastive loss is deployed to make the graph structures similar for similar target-based representations, and different for dissimilar ones. This essentially generalizes the graph structures learned from the known targets to the unseen ones, so as to better derive target-aware stance information for the unseen targets by the graph representations.

The main contributions of our work are summarized as follows:

- The ZSSD task is approached from a new perspective for detecting stance of an unseen target via reasoning the target-based stance features from the learned stance information based on the context or devising the target-aware stance information that is potentially relevant with the unseen target from the learned ones.

- We propose a novel joint contrastive learning (`JointCL`) framework, which consists of stance contrastive learning and target-aware prototypical graph contrastive learning, to generalize the target-based stance features to the unseen targets.

- Extensive experiments on three benchmark datasets show that the proposed `JointCL` framework outperforms state-of-the-art baselines in the ZSSD task. Further, the proposed `JointCL` framework can be easily extended to the few-shot and cross-target stance detection and achieves outstanding performance.

2 Related Work

2.1 Zero-Shot Stance Detection

Zero-shot stance detection (ZSSD) aims to detect stance for destination unseen targets by learning stance features from known targets (Allaway and McKeown, 2020). To deal with zero-shot stance detection, Allaway and McKeown (2020) created a new dataset consisting of a large range of topics covering broad themes, called Varied Stance Topics (VAST). Based on it, they proposed a topic-grouped attention model to implicitly capture relationships between targets by using generalized topic representations. Allaway et al. (2021) adopted a target-specific stance detection dataset (Mohammad et al., 2016) and deployed adversarial learning to extract target-invariant transformation features in ZSSD. More recently, to exploit both the structural-level and semantic-level information of the relational knowledge, Liu et al. (2021) proposed a commonsense knowledge enhanced graph model based on BERT (Devlin et al., 2019) to tackle ZSSD.

2.2 Contrastive Learning

Contrastive learning in the latent space has recently shown great promise, which aims to make the representation of a given anchor data to be similar to its positive pairs and dissimilar to its negative pairs (Hadsell et al., 2006; Wu et al., 2018; Tian et al., 2020; Chen et al., 2020a; Khosla et al., 2020; Chen et al., 2020b; Zhang et al., 2021; Wang et al., 2021; Gunel et al., 2021). Various contrastive learning approaches have been developed to deal with natural language processing tasks (Kachuee et al., 2021; Qin et al., 2021; Yang et al., 2021; Liu and Liu, 2021; Liang et al., 2021b), including unsupervised text representation learning (Giorgi et al., 2021), text classification (Qiu et al., 2021), and text clustering (Zhang et al., 2021).

More recently, Li et al. (2021) presented prototypical contrastive learning and a ProtoNCE loss to encourage representations to be closer to their assigned prototypes. However, this method only models the relationship between an anchor instance and its nearest prototype. On the other hand, You et al. (2020) proposed a graph contrastive learning framework based on graph data augmentation, which improves the graph representations for better generalizability and robustness. However, their ap-

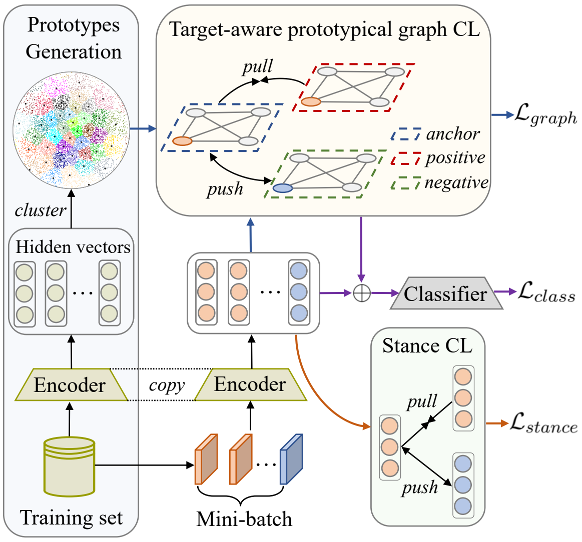

Figure 1: The architecture of our `JointCL` framework. $\oplus$ is vector concatenation. In the graphs, the gray ellipses denote prototypes, others denote hidden vectors. Vectors with the same color hold the same stance.

proach ignores the relationships of edges regarding the graph structures. In our (`JointCL`) framework, we devise a novel edge-oriented graph contrastive loss to learn the contrastive information of the relationships between prototypes and the targets, thus generalizing the graph structures to the unseen targets for learning target-aware stance information.

3 Methodology

In this section, we describe the proposed Joint Contrastive Learning (`JointCL`) framework for zero-shot stance detection in detail. As demonstrated in Figure 1, the architecture of the `JointCL` framework contains four main components: 1) *stance contrastive learning*, which performs contrastive learning based on the supervised signal of stance labels for better generalization of stance features; 2) *prototypes generation*, which derives the prototypes of the training data by a clustering method; 3) *target-aware prototypical graph contrastive learning*, which performs the edge-oriented graph contrastive learning strategy based on the target-aware prototypical graphs for sharing the graph structures between known targets and unseen ones; 4) *classifier*, which detects the stances of targets based on the hidden vectors and graph representations.

3.1 Task Description

Formally, let $\mathcal{D}_s = \{(r_s^i, t_s^i, y_s^i)\}_{i=1}^{N_s}$ be the training set for the source targets, where t_s^i and y_s^i are the training target and the stance label towards the context r_s^i respectively. N_s is the number of the training instances. Further, let $\mathcal{D}_d = \{(r_d^i, t_d^i)\}_{i=1}^{N_d}$ be the testing set for the targets which are unseen in the training set. Here, t_d^i is the testing target in the context r_d^i. The goal of ZSSD is to predict a stance label (e.g. "*Pro*", "*Con*", or "*Neutral*") of each testing instance by training a model on the training set.

3.2 Encoder Module

Given a sequence of words $r = \{w_i\}_{i=1}^{n}$ and the corresponding target t, where n is the length of the sentence r, we adopt a pre-trained BERT (Devlin et al., 2019) as the Encoder Module and feed "$[CLS]r[SEP]t[SEP]$" as input into the encoder module to obtain a d_m-dimensional hidden representation $\boldsymbol{h} \in \mathbb{R}^{d_m}$ of each input instance:

$$\boldsymbol{h} = \text{BERT}([CLS]r[SEP]t[SEP])_{[CLS]} \quad (1)$$

Here, we use the vector of the $[CLS]$ token to represent the input instance. For the training set $\mathcal{D}_s$, the hidden representations of the training instances can be represented as $\mathcal{H} = \{\boldsymbol{h}_i\}_{i=1}^{N_s}$.

3.3 Stance Contrastive Learning

As previously discussed in Gunel et al. (2021), good generalization requires capturing the similarity between examples in one class and contrasting them with examples in other classes. To improve the generalization ability of stance learning, we define a stance contrastive loss on the hidden vectors of instances with the supervised stance label information. Given the hidden vectors $\{\boldsymbol{h}_i\}_{i=1}^{N_b}$ in a mini-batch $\mathcal{B}$ (here, N_b is the size of mini-batch), and an *anchor* of hidden vector $\boldsymbol{h}_i$, $\boldsymbol{h}_i, \boldsymbol{h}_j \in \mathcal{B}$ with the same stance label is considered as a *positive* pair, i.e. $y^i = y^j$, where y^i and y^j are the stance labels of $\boldsymbol{h}_i$ and $\boldsymbol{h}_j$, respectively, while the samples $\{\boldsymbol{h}_k \in \mathcal{B}, k \neq i\}$ are treated as *negative* representations with respect to the *anchor*. Then the contrastive loss is computed across all *positive* pairs, both $(\boldsymbol{h}_i, \boldsymbol{h}_j)$ and $(\boldsymbol{h}_j, \boldsymbol{h}_i)$ in a mini-batch:

$$\mathcal{L}_{stance} = \frac{-1}{N_b} \sum_{\boldsymbol{h}_i \in \mathcal{B}} \ell^s(\boldsymbol{h}_i) \quad (2)$$

$$\ell^s(\boldsymbol{h}_i) = \log \frac{\sum_{j \in \mathcal{B} \setminus i} \mathbb{1}_{[y^i = y^j]} \exp(f(\boldsymbol{h}_i, \boldsymbol{h}_j)/\tau_s)}{\sum_{j \in \mathcal{B} \setminus i} \exp(f(\boldsymbol{h}_i, \boldsymbol{h}_j)/\tau_s)} \quad (3)$$

where $\mathbb{1}_{[i=j]} \in \{0,1\}$ is an indicator function evaluating to 1 iff $i = j$. $f(\boldsymbol{u},\boldsymbol{v}) = sim(\boldsymbol{u},\boldsymbol{v}) = \boldsymbol{u}^\top \boldsymbol{v}/\|\boldsymbol{u}\|\|\boldsymbol{v}\|$ denotes the cosine similarity between vectors $\boldsymbol{u}$ and $\boldsymbol{v}$.

3.4 Prototypes Generation

In the Prototypical Networks for few-shot learning, Snell et al. (2017) derived the prototype of each class by computing the mean vector of the embedded support points belonging to the class. However, in the ZSSD data, the distribution of targets is usually imbalanced. Therefore, inspired by (Li et al., 2021), we perform k-means clustering on the hidden vectors of the training instances $\mathcal{H} = \{\boldsymbol{h}_i\}_{i=1}^{N_s}$ to generate k clusters as the prototypes $\mathcal{C} = \{\boldsymbol{c}_i\}_{i=1}^{k}$ with respect to the target-based representations of training set. Here, a prototype is defined as *a representative embedding for a group of semantically similar instances* (Li et al., 2021). Clustering is performed at each training epoch to update the prototypes.

3.5 Prototypical Graph

Once the prototypes are generated, a prototypical graph is constructed to capture the relationships between the prototypes and the known targets. This enables the learning of the representation of a target-based instance by modeling the different weights of edges between its corresponding target and various prototypes, so as to generalize the learned graph information to the unseen targets. Here, the prototypes and the target-based representations are updated in an alternative manner. For a hidden vector $\boldsymbol{h}_i$ of a training instance i, we first treat the prototypes $\mathcal{C}$ and the hidden vector $\boldsymbol{h}_i$ as nodes of the prototypical graph: $\boldsymbol{X} = [\boldsymbol{c}_1, \boldsymbol{c}_2, \cdots, \boldsymbol{c}_k, \boldsymbol{h}_i]$, and then construct the adjacency matrix $\mathcal{G} \in \mathbb{R}^{(k+1)\times(k+1)}$ of the fully-connected graph, $\mathcal{G}_{i,j} = \mathcal{G}_{j,i} = 1$.

Next, we feed the nodes $\boldsymbol{X}$ and the corresponding adjacency matrix $\mathcal{G}$ into a graph attention network (GAT) (Velickovic et al., 2018) to derive the attention scores $\boldsymbol{\alpha}_i$ and the graph representation $\boldsymbol{z}_i$ for the target-based instance i:

$$\boldsymbol{\alpha}_i = a(\mathrm{GAT}(\boldsymbol{X};\mathcal{G})) \tag{4}$$

$$\boldsymbol{z}_i = f(\mathrm{GAT}(\boldsymbol{X};\mathcal{G})) \tag{5}$$

where $\mathrm{GAT}(\cdot)$ represents GAT operation. $a(\cdot)$ denotes retrieving the attention score matrix from the GAT operation, $f(\cdot)$ denotes retrieving the graph representation for $\boldsymbol{h}_i$.

3.6 Target-Aware Prototypical Graph Contrastive Learning

From the target-aware perspective, we further explore a Target-Aware Prototypical Graph Contrastive Learning strategy, aiming at generalizing the graph structures learned from the known targets to the unseen ones. Specifically, for the attention matrices $\{\boldsymbol{\alpha}_i\}_{i=1}^{N_b}$ in each mini-batch $\mathcal{B}$, we devise a novel edge-oriented prototypical graph contrastive loss, making the graph structure of similar target-based representations to be similar. This essentially allows the model to learn the representations of (unseen) targets through the prototypes, thus generalizing the target-aware stance information to the unseen targets.

For an *anchor* instance i with edge weights (i.e., the attention score matrix) $\boldsymbol{\alpha}_i$, we construct a *positive* pair $(\boldsymbol{\alpha}_i, \boldsymbol{\alpha}_j)$ by retrieving the attention score matrix of instance j which is either about the same target or has been assigned to the same prototype, and expresses the same stance as i. We also construct negative pairs, $(\boldsymbol{\alpha}_i, \boldsymbol{\alpha}_k), \boldsymbol{\alpha}_k \in \mathcal{B}, k \neq i$. Then, the edge-oriented graph contrastive loss is defined as[2]:

$$\mathcal{L}_{graph} = \frac{-1}{N_b} \sum_{\boldsymbol{\alpha}_i \in \mathcal{B}} \ell^g(\boldsymbol{\alpha}_i) \tag{6}$$

$$\ell^g(\boldsymbol{\alpha}_i) = \log \frac{\sum_{j \in \mathcal{B}\backslash i} \Phi(i,j) \exp(f(\boldsymbol{\alpha}_i, \boldsymbol{\alpha}_j)/\tau_g)}{\sum_{j \in \mathcal{B}\backslash i} \exp(f(\boldsymbol{\alpha}_i, \boldsymbol{\alpha}_j)/\tau_g)} \tag{7}$$

$$\Phi(i,j) = \begin{cases} 1 & \text{if } y^i = y^j \text{ and } p^i = p^j \\ 0 & \text{otherwise} \end{cases} \tag{8}$$

where $p^i = p^j$ represents the instances i and j correspond to the same target or belong to the same prototype, and express the same stance.

The calculation of the stance and edge-oriented prototypical graph contrastive losses for each mini-batch $\mathcal{B}$ is illustrated in Algorithm 1.

3.7 Stance Detection

For each instance i, we first concatenate the hidden vector $\boldsymbol{h}_i$ and the graph representation $\boldsymbol{z}_i$ to get the output representation $\boldsymbol{v}_i$ towards the instance i:

$$\boldsymbol{v}_i = \boldsymbol{h}_i \oplus \boldsymbol{z}_i \tag{9}$$

Then the output representation $\boldsymbol{v}_i$ is fed into a classifier with a softmax function to produce the pre-

---

[2] Here, to compute the cosine similarity, we flatten each matrix $\boldsymbol{\alpha}_i$ into a one-dimensional array.

Algorithm 1: Calculation of the stance and edge-oriented prototypical graph contrastive losses for each mini-batch $\mathcal{B}$.

```
Input: $\mathcal{B} = \{\boldsymbol{h}_i, \boldsymbol{\alpha}_i\}_{i=1}^{N_b}$, $\ell^s, \ell^g \leftarrow 0, 0$

    ▷ Computing edge-oriented prototypical graph
      contrastive loss for each $\boldsymbol{\alpha}_i$
    $\ell^g += \ell^g(\boldsymbol{\alpha}_i)_{pos}/\ell^g(\boldsymbol{\alpha}_i)_{neg}$
▷ Stance contrastive loss for a mini-batch $\mathcal{B}$
$\mathcal{L}_{stance} = -\ell^s/N_b$
▷ Edge-oriented prototypical graph contrastive loss
  for a mini-batch $\mathcal{B}$
$\mathcal{L}_{graph} = -\ell^g/N_b$
```

dicted stance distribution $\hat{\boldsymbol{y}}_i \in \mathbb{R}^{d_y}$:

$$\hat{\boldsymbol{y}}_i = \mathrm{softmax}(\boldsymbol{W}\boldsymbol{v}_i + \boldsymbol{b}) \tag{10}$$

where d_y is the dimensionality of stance labels. $\boldsymbol{W} \in \mathbb{R}^{d_y \times d_m}$ and $\boldsymbol{b} \in \mathbb{R}^{d_y}$ are trainable parameters. We adopt a cross-entropy loss between predicted distribution $\hat{\boldsymbol{y}}_i$ and ground-truth distribution $\boldsymbol{y}_i$ of instance i to train the classifier:

$$\mathcal{L}_{class} = -\sum_{i=1}^{N_b}\sum_{j=1}^{d_y} y_i^j \log \hat{y}_i^j \tag{11}$$

3.8 Learning Objective

The learning objective of our proposed model is to train the model by jointly minimizing the three losses generated by stance detection, stance contrastive learning, and target-aware prototypical graph contrastive learning. The overall loss $\mathcal{L}$ is formulated by summing up three losses:

$$\mathcal{L} = \gamma_c \mathcal{L}_{class} + \gamma_s \mathcal{L}_{stance} + \gamma_g \mathcal{L}_{graph} + \lambda ||\Theta||^2 \tag{12}$$

where γ_c, γ_s and γ_g are tuned hyper-parameters. Θ denotes all trainable parameters of the model, λ represents the coefficient of L_2-regularization.

4 Experimental Setup

4.1 Datasets

We conduct experiments on three datasets to evaluate the proposed `JointCL` framework. 1) **Vast** (Allaway and McKeown, 2020), which contains a large variety of targets. Each instance consists of a sentence r, a target t, and a stance label y ("*Pro*", "*Con*", or "*Neutral*") towards t. To show the generalizability of coping with few-shot stance detection, following (Allaway and McKeown, 2020), we also conduct experiments on few-shot condition. The statistics of Vast dataset are shown in Table 1. 2) **Sem16**, which contains 6 pre-defined targets, including *Donald Trump* (DT), *Hillary Clinton* (HC), *Feminist Movement* (FM), *Legalization of Abortion* (LA), *Atheism* (A), and *Climate Change* (CC). Each instance can be classified as *Favor*, *Against* or *Neutral*. 3) **Wt-wt**, which contains 5 pre-defined company pairs (target), including *CVS_AET* (CA), *CI_ESRX* (CE), *ANTM_CI* (AC), and *AET_HUM* (AH). Each instance refers to a stance label from *Support* (corresponding to *Favor*), *Refute* (corresponding to *Against*), *Comment* (corresponding to *Neutral*), or *Unrelated*. The statistics of Wt-wt and Sem16 datasets are shown in Table 2. Following (Allaway et al., 2021) and (Conforti et al., 2020), for **Sem16** and **Wt-wt** datasets, we use the leave-one-target-out evaluation setup.

4.2 Implementation Detail

Training Settings The pre-trained uncased BERT-base (Devlin et al., 2019) is used as the embedding module in which each word token is mapped to a 768-dimensional embedding. The learning rate is set to 3e-5. Following (Xu et al., 2018), the coefficient λ is set to 1e-5. Adam is utilized as the optimizer. The mini-batch size is set to 16, considering the trade-off between computational resource and evaluation performance. For contrastive losses, both the temperature parameters τ_s and τ_g are set to 0.07. For clustering, the number of clusters are set to $k = 100$ for the VAST dataset and $k = 10$ for the WT-WT and SEM16 datasets respectively. Corresponding to the number of k, we set $\gamma_c = 0.8$, $\gamma_s = 1$, and $\gamma_g = 0.1$ for VAST dataset and $\gamma_g = 0.5$ for WT-WT and SEM16 datasets, respectively. They are the optimal hyper-parameters in the pilot studies. We apply early stopping in training process and the patience is 5. We report averaged scores of 10 runs to obtain statistically stable results.

Evaluation Metric For the VAST dataset, following (Allaway and McKeown, 2020), we calculate Macro-averaged F1 of each label to measure the testing performance of the models. For the SEM16 dataset, following (Allaway et al., 2021), we report F_{avg}, the average of F1 on *Favor* and *Against*. For the WT-WT dataset, following (Conforti et al., 2020), we report the Macro F1 score of each target.

4.3 Comparison Models

We compare the proposed `JointCL` with a series of strong stance detection baselines, including neural network-based method: `BiCond` (Augenstein et al., 2016), attention-based models: `CrossNet` (Xu et al., 2018) and `SiamNet` (Santosh et al., 2019), knowledge-based method: `SEKT` (Zhang et al., 2020), graph network method: `TPDG` (Liang et al., 2021a), adversarial learning method: `TOAD` (Allaway et al., 2021), and BERT-based methods: `BERT` (Devlin et al., 2019), `TGA Net` (Allaway and McKeown, 2020), `BERT-GCN` (Liu et al., 2021), and `CKE-Net` (Liu et al., 2021).

In addition, we provide variants of our proposed `JointCL` in the ablation study:

(1) "**w/o** $\mathcal{L}_{stance}$" denotes without stance contrastive learning.

(2) "**w/o** $\mathcal{L}_{graph}$" denotes without prototypical graph contrastive learning.

(3) "**w/o** $graph$" denotes that this model performs the target-aware contrastive learning on the hidden representations of the instances with the supervised information from target labels. That is, the contrastive loss functions of Eq. 6 and Eq. 7 are replaced by:

$$\mathcal{L}_{graph} = \frac{-1}{N_b} \sum_{\boldsymbol{h}_i \in \mathcal{B}} \ell^g(\boldsymbol{h}_i) \tag{13}$$

$$\ell^g(\boldsymbol{h}_i) = \log \frac{\sum_{j \in \mathcal{B} \setminus i} \mathbb{1}_{[t^i = t^j]} \exp(f(\boldsymbol{h}_i, \boldsymbol{h}_j)/\tau)}{\sum_{j \in \mathcal{B} \setminus i} \exp(f(\boldsymbol{h}_i, \boldsymbol{h}_j)/\tau)} \tag{14}$$

(4) "**w/o** $cluster$" denotes without using clustering to generate prototypes. That is, this model simply takes the mean of target-based hidden representations as a prototype.

(5) "**w/o** $edge$" denotes without considering edge information, i.e., it performs the prototypical graph contrastive learning on the graph representations of the instance nodes. The contrastive loss functions of Eq. 6 and Eq. 7 are replaced by:

$$\mathcal{L}_{graph} = \frac{-1}{N_b} \sum_{\boldsymbol{z}_i \in \mathcal{B}} \ell^g(\boldsymbol{z}_i) \tag{15}$$

$$\ell^g(\boldsymbol{z}_i) = \log \frac{\sum_{j \in \mathcal{B} \setminus i} \mathbb{1}_{[p^i = p^j]} \exp(f(\boldsymbol{z}_i, \boldsymbol{z}_j)/\tau)}{\sum_{j \in \mathcal{B} \setminus i} \exp(f(\boldsymbol{z}_i, \boldsymbol{z}_j)/\tau)} \tag{16}$$

5 Experimental Results

5.1 Main Results

The main comparison results of ZSSD on three benchmark datasets are reported in Table 3. It can be observed from the experimental results, our proposed `JointCL` framework performs consistently better than the non-BERT and the BERT-based comparison models on both the VAST and WT-WT datasets, and achieves overall better performance than the comparison baselines on the SEM16 dataset. This verifies the effectiveness of our `JointCL` framework in the ZSSD task. Furthermore, the significance tests of `JointCL` over the baseline models show that our `JointCL` significantly outperforms the baseline models (the results of $p-$value on most of the evaluation metrics are less than 0.05). More concretely, in comparison with the adversarial learning-based model (`TOAD`), our `JointCL` achieves significant improvement across all datasets. This indicates that exploring graph contrastive learning to model the relationships among targets can better generalize the target-based stance features to the unseen targets. In addition, the comparison results between our `JointCL`

Table 4: Experimental results of ablation study.

and the previous BERT-based models demonstrate that the stance representations learned from known targets can be better generalized to the unseen targets with our proposed novel contrastive learning strategy.

5.2 Ablation Study

To analyze the impact of different components in our proposed `JointCL` on the performance, we conduct an ablation study and report the results in Table 4. We can observe that the removal of stance contrastive learning ("**w/o** $\mathcal{L}_{stance}$") sharply reduces the performance in all evaluation metrics and across all datasets. This indicates that performing contrastive learning based on stance information can improve the quality of stance representations for better generalizing the learned stance features to the unseen targets, and thus improve the performance of ZSSD. The removal of edge-oriented prototypical graph contrastive learning ("**w/o** $\mathcal{L}_{graph}$") leads to considerable performance degradation. This implies that performing target-based contrastive learning for prototypical graph can generalize the graph relations between known targets and prototypes to the unseen targets, which enables the model to derive better representation for the examples of unseen targets, and thus leads to improved ZSSD performance.

In addition, from the results of "**w/o** $graph$" we can see that purely performing the target-based contrastive learning on the hidden representations slashes the learning ability of stance contrastive learning, and thus leads to poorer performance. This verifies the effectiveness of exploring prototypical graph contrastive learning in our `JointCL`. We also observe that the performance of "**w/o** $cluster$" drops consistently across datasets, which indicates that exploring clustering method can effectively relieve the problem of the imbalanced distribution of targets in the dataset. The removal of edge-oriented graph contrastive strategy ("**w/o** $\mathcal{L}_{edge}$") leads to noticeable performance degradation. This implies that, to represent the (unseen) targets with prototypes, we should pay more attention to the relationships between targets and prototypes, rather than simply drawing closer similar target-based representations in the graph.

5.3 Impact of the Values of k

To analyze the impact of using different values of k in k-means clustering on the performance, we conduct experiments on the three datasets, and show the results in Figure 2. Here, for VAST, we show the results of all labels. For the SEM16 and WT-

Figure 2: Experimental results of different values of k.

Model	Pro	Con	Neu	All
`BiCond`	45.4	46.3	25.9	39.2
`Cross-Net`	50.8	50.5	41.0	47.4
`SEKT`	51.0	47.9	21.5	47.4
`BERT`	54.4	59.7	79.6	64.6
`TGA Net`	58.9	59.5	80.5	66.3
`BERT-GCN`	62.8	63.4	83.0	69.7
`CKE-Net`	**64.4**	62.2	83.5	70.1
`JointCL` (ours)	63.2	**66.7**	**84.6**	**71.5**

Table 5: Experimental results of few-shot condition. Results of baselines are retrieved from (Liu et al., 2021).

WT, we show the average performance of all targets. We observe that for VAST that contains a large number of targets (more than 5,000 in the training set), the performance increases with the increasing value of k and peaks at $k = 100$. Further increasing the values of k results in worse performance. Similarly, for SEM16 and WT-WT, better performance is obtained in the region of $k \in [10, 20]$ and peaks when $k = 10$. This implies that we can set an appropriate region for the value of k according to the number of targets in the dataset.

5.4 Generalizability Analysis

Analysis of Few-Shot Condition To evaluate the generalizability of our `JointCL` framework in few-shot stance detection, following (Allaway and McKeown, 2020; Liu et al., 2021), we also evaluate `JointCL` in the few-shot condition on the VAST dataset. From the experimental results shown in Table 5, we can see that `JointCL` performs overall better than all the comparison methods under the few-shot condition. This verifies the effectiveness and generalizability of `JointCL` in dealing with both zero-shot and few-shot stance detection.

Analysis of Cross-Target Scenario We further conduct comparison experiments in the cross-target scenario on the SEM16 dataset. Cross-target stance detection trains on a source target and tests on an unseen but related one, which is a task related to ZSSD. We report the results in Table 6. It can be observed that `JointCL` achieves consistently better performance on all cross-target scenarios, which verifies that our `JointCL` can generalize the learning ability to deal with cross-target scenarios. In addition, when compared with the results of Table 3, we see that the results of cross-target stance detection are generally better than ZSSD. This shows that recognizing the relationships among targets in advance can potentially improve the stance detection performance for the unseen targets, which illustrates the challenge of the ZSSD task from another angle.

Model	HC→DT	DT→HC	FM→LA	LA→FM
`BiCond`	29.7	35.8	45.0	41.6
`CrossNet`	43.1	36.2	45.4	43.3
`BERT`	43.6	36.5	47.9	33.9
`SEKT`	47.7	42.0	53.6	51.3
`TPDG`	50.4	52.9	58.3	54.1
`JointCL` (ours)	**52.8**	**54.3**	**58.8**	**54.5**

(a) BERT-GCN (b) JointCL

Figure 3: Visualization of intermediate embeddings. Red dots denote Pro examples, green dots denote Con examples, and blue dots denote $Neutral$ examples.

5.5 Visualization

To qualitatively demonstrate how the proposed `JointCL` captures good generalization of stance features for unseen targets in ZSSD, we randomly select 200 test instances for each label from VAST dataset and show the t-SNE (van der Maaten and Hinton, 2008) visualization of intermediate embeddings learned by `BERT-GCN` and our proposed `JointCL` on VAST in Figure 3. It can be seen that the distributions of representations derived from `BERT-GCN` largely overlap especially for the *Pro* and *Con* stances. But there are clear separations between different stances (including the *Pro* and *Con* stances) produced by our proposed `JointCL`. This verifies that the novel joint contrastive learning strategy in `JointCL` can better separate representations from different stances, so as to improve the performance of ZSSD.

6 Conclusion

In this paper, we propose a novel joint contrastive learning (`JointCL`) framework to deal with the zero-shot stance detection (ZSSD) task. On the one hand, we deploy a stance contrastive learning strategy to improve the quality of stance representations, so as to capture good generalization of stance features for the unseen targets. This is based on our observation that for some cases we can determine the stance towards a specific target from its associated context. On the other hand, we devise a target-aware prototypical graph contrastive learning strategy to generalize the learned graph information to the unseen targets by leveraging the prototypes as a bridge to model the relationships between known and unseen targets. This is for other cases when it is difficult to infer the stance for an unseen target from the context, but instead, could be relatively easier by exploiting the target-aware stance information from the learned associated targets. Experimental results on three benchmark datasets show that our `JointCL` achieves state-of-the-art performance in ZSSD. Further, the generalizability analysis shows that our `JointCL` can also perform outstandingly on few-shot and cross-target stance detection.

`hassy@logos.t.u-tokyo.ac.jp`
`cxiong@salesforce.com`

Abstract

The recent success of reinforcement learning (RL) in solving complex tasks is often attributed to its capacity to explore and exploit an environment. Sample efficiency is usually not an issue for tasks with cheap simulators to sample data online. On the other hand, Task-oriented Dialogues (ToD) are usually learnt from offline data collected using human demonstrations. Collecting diverse demonstrations and annotating them is expensive. Unfortunately, RL policy trained on off-policy data are prone to issues of bias and generalization, which are further exacerbated by stochasticity in human response and non-markovian nature of annotated belief state of a dialogue management system. To this end, we propose a batch-RL framework for ToD policy learning: Causal-aware Safe Policy Improvement (CASPI). CASPI includes a mechanism to learn fine-grained reward that captures intention behind human response and also offers guarantee on dialogue policy's performance against a baseline. We demonstrate the effectiveness of this framework on end-to-end dialogue task of the Multiwoz2.0 dataset. The proposed method outperforms the current state of the art. Further more we demonstrate sample efficiency, where our method trained only on 20% of the data, are comparable to current state of the art method trained on 100% data on two out of there evaluation metrics.

1 Introduction

Offline task-oriented dialogue (ToD) systems involves solving disparate tasks of belief states tracking, dialogue policy management, and response generation. Of these tasks, in this work we focus on dialogue policy management to improve the end-to-end performance of ToD. The need for sample efficiency is key for learning offline task-oriented dialogue system, as access to data are finite and expensive. Recent advancements in off-policy reinforcement learning methods that uses offline data as against a simulator has proven to be sample efficient (Thomas and Brunskill, 2016). The effective use of these techniques are hindered by the nature of ToD. For instance, bias correction in off-policy based methods usually requires estimation of behaviour policy for a given state of Markov Decision Process (MDP). In ToD, per-turn annotated belief-state does not capture the true state of the MDP. Example of such annotated belief-state are shown in Fig:1. Latent state information such as prosody, richness of natural language and among others induces stochasticity in the agents response. In addition to these short comings, the direct use of automatic evaluation metric as reward for policy learning is not desirable, since these automatic evaluation metrics are often for the entire dialogue and not per turn. Hence such rewards are sparse and under-specified (Wang et al., 2020). Use of under-specified reward will often lead to policy that suffers from high variance (Agarwal et al., 2019). Alternatively use of imitation learning based methods falls short of reasoning on the outcome. This is demonstrated in Fig:1. Turns#3 and #2 are rich in semantic information and Turn#3 is key to success of the booking process. While Turn#4 contributes least to successful outcome. Though the turns have varying levels of importance, each of the turns are treated equally in imitation learning. In worst case, turns like Turn#4 will appear more often than turns Turn#2 and #3 in a ToD dataset, there by taking greater share of the gradient budget.

We address aforementioned shortcomings with following key contributions:

1.We introduce pairwise causal reward learning to learn fine grained per turn reward that reason the intention of human utterance.

2.We propose a safe policy improvement method

Figure 1: A typical Task oriented dialogue conversation in MultiWoz2.0 dataset

for task oriented dialogue setting that guarantees performance against a baseline.

By use of these two methods, we demonstrate performance and sample efficiency.

2 Related Works

With the release of multi-domain, multi-turn MultiWoz2.0 dataset (Budzianowski et al., 2018a), there has been flurry of recent works, of which Zhang et al. (2019) uses data augmentation. Rastogi et al. (2019) and Hosseini-Asl et al. (2020) frame dialogue policy learning as language modeling task. Among the works that uses reinforcement learning. Mehri et al. (2019) uses supervised learning to bootstrap followed by RL fine tuning, whereas Zhao et al. (2019) uses policy gradient on latent action space as against handcrafted ones. Jaques et al. (2019) and Wang et al. (2020) uses Batch-RL for dialogue policy learning. (Wang et al., 2020) is first to argue the use of automated evaluation metrics directly as reward is under-specified for ToD policy learning. Recently there's has been proliferation in use of large pretrained language model based systems like Hosseini-Asl et al. (2020), Lin et al. (2020), Chen et al. (2019) etc. More details on contrasting the merits and limitations of these methods can be found in Sec:A.1

The line of inverse RL used in this work can be traced back to Ziebart et al. (2008), which proposes roll-outs from expert demonstration should have rewards exponentially higher than any other arbitrary roll-outs. This method requires a normalizing constant that integrates across rollouts, which is challenging. Christiano et al. (2017) and Thananjeyan et al. (2020) propose to do relative comparison of two roll-outs there by eliminating the need for normalization constant and they demonstrate in online setting.

3 Method

3.1 Preliminaries

We model task-oriented dialogue as a Markov decision process (MDP) (Sutton and Barto, 2018) with set of states S and actions A. The agent at time step t with state s_t performs a composite action a_t as per a target policy $\pi_e(a_t|s_t)$ on the environment. The environment is defined by transition probabilities $P(s_{t+1}|s_t, a_t)$, a latent reward function, $R(s_t, a_t, g)$, discount factor $\gamma \in [0, 1]$ and goal of dialogue g. Then the objective of the target policy π_e, is to maximizes the discounted sum of future reward on the MDP, given by the state-action value function $Q^{\pi_e}(a_t, s_t) = \mathbb{E}_{a_t\sim\pi_e, s_t\sim P}[\sum_{t'=t}^{T} \gamma^{t-t'} R(s_{t'}, a_{t'}, g)]$.

In offline Batch-RL. The agent does not get to interact with the environment, instead we are provided with offline data D logged by human agents performing actions based on a latent stochastic behaviour policy π_b. Rollout of a dialogue $\tau^i \in D$ is composed of $\tau^i = ((o_0^i, a_0^i), ..., (o_{T-1}^i, a_{T-1}^i))$. Here o_t is the observation at turn t, composing of $o_t = (b_t, u_t^u, u_{t-1}^a)$, where b_t is the belief state of the agent at turn t, u_t^u and u_{t-1}^a are the user and agent utterance at time t and $t-1$ respectively.

3.2 Safe policy improvement

Batch-RL entails training target policy π_e on rollout generated by a latent behaviour policy π_b. Directly optimizing on the rollouts generated by policy other than the target policy, will lead to large bias in the value function estimation, poor generalization characteristic, and sample inefficiency (Thomas and Brunskill, 2016). Safe policy improvement ensures the new policy performance is bounded by performance against a baseline policy. This is expressed as:

$$Pr(V^{\pi_e} \geq V^{\pi_b} - \zeta) \geq 1 - \delta,$$

where V^{π_e} and V^{π_b} are value functions of the target and behaviour policy respectively. Here $1 - \delta$ and ζ are the high probability and approximation meta-parameters respectively. Schulman et al. (2015)

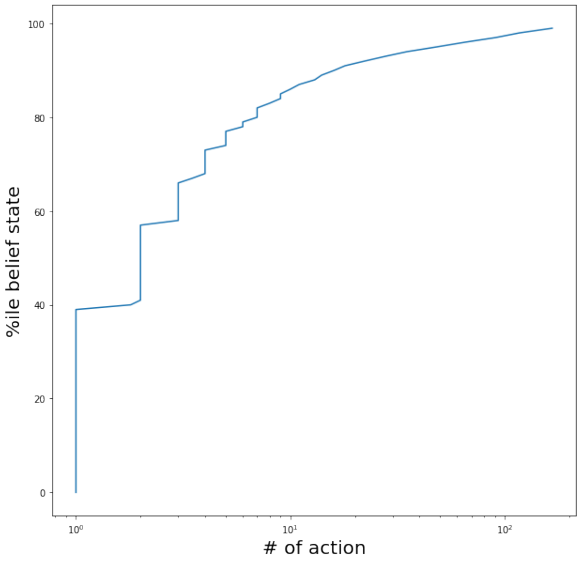

Figure 2: Shows stochacity i.e number of different dialogue act against each delexicalized belief state in MultiWoz2.0 dataset

provide such update mechanism, (1), whose errors are bounded as long as the constraints of (1) are met, where $D_{KL}(.||.)$ is the KL divergence and η is a hyper-parameter.

$$L_{sto}(\theta) = \min_{\substack{s_t \sim P^{\pi_{bs}} \\ a_t \sim \pi_{bs}}} -\mathbb{E}\left[\frac{\pi_e(a_t|s_t;\theta)}{\pi_{bs}(a_t|s_t)} Q^{\pi_{bs}}(s_t, a_t)\right]$$
$$s.t. \underset{s_t \sim P^{\pi_{bs}}}{\mathbb{E}}\left[D_{KL}(\pi_{bs}(.|s_t)||\pi_e(.|s_t))\right] \leq \eta \tag{1}$$

(Schulman et al., 2015) originally formulated (1) for online learning as trust region for policy updates and uses policy before gradient update as the baseline policy, $\pi_{bs}(a_t|b_t;\theta_{old})$. In this work we adapt it to offline setting and use behaviour policy π_b as the baseline policy. Use of this update rule requires access to the behavior policy $\pi_b(a_t|s_t)$ which is intractable to estimate and the learnt ones might have bias. Use of such behavior policy to perform bias correction by Important Sampling (Precup, 2000) might lead to worse policy. Instead we estimate the behaviour policy conditioned only the annotated belief-state b_t as against true state s_t in (1), which result in a stochastic behavior policy. This stochasticity of dialogue act vis-à-vis annotated belief state can observed in Fig:2. We also estimate the Q-function of the behavior policy, $Q^{\pi_b}(b_t, a_t)$ using learnt reward $R(s_t, a_t, g)$. More on learnt reward in Sec: 3.3.

The belief state b_t is part of the observation o_t, hence we purport that, on availability of more evidence of the observation o_t, (beside b_t) the mode of the policy collapse to a near deterministic action. To factor this into the policy learning, we have an additional loss:

$$L_{det}(\theta) = \min - \underset{(o_t,a_t)\sim D}{\mathbb{E}}[G(\tau, t)\log \pi_e(a_t|o_t;\theta)] \tag{2}$$

where return $G(\tau, t) = \sum_{t'=t}^{T} \gamma^{t'-t} R(s_{t'}, a_{t'}, g)$ is the discounted sum of future reward for rollout τ with goal g. Hence policy optimization loss function is given by:

$$L(\theta) = \alpha L_{sto}(\theta) + (1-\alpha)L_{det}(\theta) \tag{3}$$

We achieve this by doing two forward passes of the policy network $\pi_e(a_t|o_t;\theta)$, first with only the belief state, b_t as the input and second pass with entire observation i,e $o_t := (b_t, u_t^u, u_t^a)$ as input to the policy network. We then use the corresponding action distribution $\pi_e(a_t|b_t;\theta)$ and $\pi_e(a_t|o_t;\theta)$ in loss functions (1) and (2) respectively.

3.3 Pairwise causal reward learning

Algorithm 1 CASPI

```
Input: Dialogue dataset $D$ and evaluation metric $M(.)$
Sub-sample K-folds of train and val set $\{(D_T, D_V)_1, ..., (D_T, D_V)_k | (D_T, D_V) \sim D\}$

for $\forall (D_T, D_V)$ do
  Learn ToD in supervised setting by optimizing for objective:
  $-\min \mathbb{E}_{a_t, s_t \sim D_T} \log(\pi_m(a_t|s_t))$
  for $\forall$ epoch do
    Using $\pi_m(a_t|s_t)$ predict actions on the valset $D_V$ and add it to the dataset, $D_P$ along with corresponding metric score $M(\tau)$ for pairwise causal reward learning
    $D_P = D_P \cup (\tau, M(\tau)) | \tau \sim \pi_m$
  end for
end for
repeat
  Sample pair of rollouts $(\tau^1, \tau^2) \sim D_P$
  Learn for $R(.)$ by optimizing for objective (4)
until Convergence using data $D_P$
repeat
  Optimize for policy $\pi_e$ using objective (3)
until Convergence using data $D$
```

The policy optimization objective introduced in the previous section requires access to per time-step reward $R(s_t, a_t, g)$. To this end, we provide a

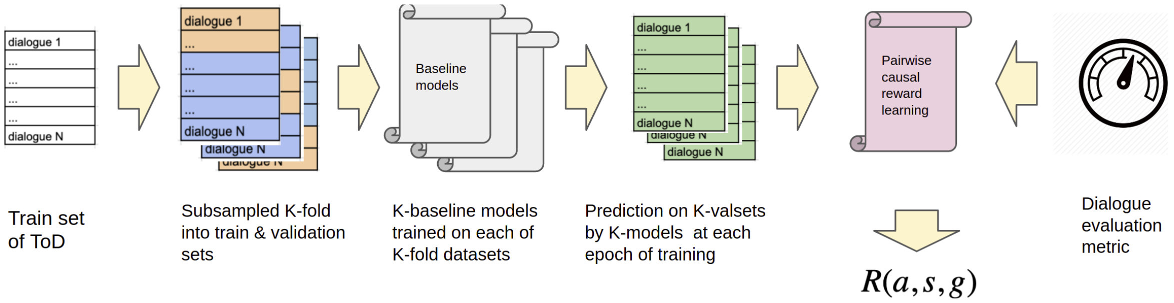

Figure 3: Process flow of pairwise causal reward learning

mechanism to learn a reward that is causally reasoned on the intention of the human demonstrator. Usually ToD are evaluated using dialogue level automatic evaluation metrics $M(.)$. Given the large state-action space of the dialogue management system, these dialogue level feedback are under-specified for for effective policy learning (Wang et al., 2020). Details about the the choice of evaluation metric $M(.)$ are covered in Sec:4.4.2.

To address this under-specified feedback, we adapt preference learning introduced by (Christiano et al., 2017) from an online to an offline setting, to learn fine grained per dialogue turn (ie. per timestep t) reward, $R(s_t, a_t, g)$. Given a pair of rollouts $\tau^1, \tau^2 \in D$ with actions for each state in the rollout is sampled from a pair of different policies π^1_m and π^2_m respectively. Let $\tau^1 \succ \tau^2$ represent preference of rollout τ^1 over rollout τ^2. This preference is true when sum of rewards of each dialogue turn of the two rollouts satisfies: $\sum_{t=0}^{T} R(s_t, a_t, g|(s_t, a_t) \in \tau^1) > \sum_{t=0}^{T} R(s_t, a_t, g|(s_t, a_t) \in \tau^2)$. For brevity, henceforth we refer $\sum_{t=0}^{T} R(s_t, a_t, g|(s_T, a_t) \in \tau)$ as $R(\tau)$. Then preferential probability of one rollout over an another, can be represented by:

$$P[\tau^1 \succ \tau^2] = \frac{\phi(R(\tau^1))}{\phi(R(\tau^1)) + \phi(R(\tau^2))}$$

Here $\phi(.)$ could either be $exp(.)$ or identity $\mathbb{1}(.)$. In our experiments, the later works best. We optimize for reward, $R(s_t, a_t, g)$ by minimizing binary cross-entropy loss between the preference probability and the normalized metrics score, $\mu(\tau)$ between a pair of rollout.

$$\begin{aligned} L(\theta) = \min - \mathop{\mathbb{E}}_{\tau^1 \sim \pi^1_m, \tau^2 \sim \pi^2_m} & [\mu(\tau^1) \log P[\tau^1 \succ \tau^2] \\ & + \mu(\tau^2) \log P[\tau^2 \succ \tau^1]] \end{aligned} \tag{4}$$

where,

$$\mu(\tau^1) = \frac{M(\tau^1)}{M(\tau^1) + M(\tau^2)} \tag{5}$$

We observe that the dialogue roll-outs are generated by expert latent policy. The data (dialogue rollouts) are distributed as per the optimal latent policy and transition probability. We propose that predictions made by a policy while in the process of learning to maximize the likelihood of the data is a good curriculum for exploring the state-action space for pairwise reward learning. This is a key insight of this work.

We formalize this insight into a method depicted in Fig:3 and Algo:1. The (train) dataset is subsampled into K-fold train & val sets. K-baseline policies are trained to fit the data distribution generated by experts using cross entropy loss, i.e supervised learning. During the process of fitting the data distribution, the still learning K-policies are used to predict on their corresponding K-fold valset at every epoch of the training. Each of these predictions are the scored by a chosen dialogue level metric, $M(.)$. On convergence of this supervised learning process, pairs of dialogue predictions generated by the above process, along with their corresponding metric score are used to train for fine grained reward $R(a_t, s_t, g)$ using objective (4).

The use of K-fold subsampling, K-baseline policies, π_m and actions sampled from these K-policies that are still in the process of learning help generate counter factual examples in the action space. These counter factual actions close to optimal policy, along with the goal of the dialogue helps us to learn subtle nuance of fine grained reward function $R(a_t, s_t, g)$ in the region of action space that matters the most.

4 Experimental Settings

4.1 Model

4.1.1 CASPI(.)

The learnt reward using CASPI $R(s_t, a_t, g)$ is akin to sample weights for each dialogue turn, that helps to redistribute the gradient budget among dialogue turns based of their contribution to the overall success of the ToD.

$$\theta := \theta - R(s_t, a_t, g)\nabla\pi_{blackbox}(a_t|s_t;\theta) \quad (6)$$

Hence we believe our pairwise casual reward learning and associated improvement in sample efficiency are independent of model architecture. To this end we choose two ToD methods that are at the extremes of model architecture spectrum 1) One uses a light weight custom model and 2) Other uses a large standard pre-trained out-of-the box universal language model.

4.1.2 CASPI(DAMD)

In this setting , we use the neural model proposed by Zhang et al. (2019). DAMD is composed of three $seq2seq$ generative model using GRUs. The three $seq2seq$ models are one each for belief state, dialogue act and response generation modules. An attention layers is used to attend the outputs of the $seq2seq$ models with the context vector of previous turn for copy over mechanism. The outputs of these attention layer are used as representation for predicting series of tokens for their respective modules. For more details on the model architecture and parameter setting refer Zhang et al. (2019). In this setting we use both stochastic, L_{sto} and deterministic, L_{det} loss functions on dialogue act. For DST and response generation, we retain the cross entropy loss as is from DAMD (Zhang et al., 2019).

4.1.3 CASPI(MinTL)

On the other extreme of model complexity, we use the Task oriented Dialogue model, MinTL(Lin et al., 2020). MinTL uses a large pretrained language model BART (Lewis et al., 2019). BART use as a standard encoder decoder transformer architecture with a bidirectional encoder and an autoregressive decoder. It is pre-trained on the task of denoising corrupt documents. BART is trained using cross-entropy loss between the decoder output and the original document. For more details of the model architecture and parameter setting, we suggest referring to (Lin et al., 2020) (Lewis et al., 2019).

MinTL doesn't explicitly predict dialogue act. Hence we only use the deterministic loss, L_{det} directly on the generated response and for DST we retain the loss as is from MintTL (Lin et al., 2020).

4.1.4 Pairwise Causal Learning Network

For k-model training of pairwise casual reward learning illustrated in Fig:3, we chose DAMD (Zhang et al., 2019) model for it's light weight model architecture. In all our experiments, we use $K = 10$.

For the pairwise casual reward learning network, we use three single bi-LSTM layers, one each to encode goal, belief state and either dialogue act or response sequences at each dialogue turn on each of the sampled roll-outs pairs, τ^1 and τ^2. The three encoded representations are concatenate and are fed through a couple of feed-forward layers before making a bounded reward prediction $R(s_t, a_t, g) \in [0, 1]$ for each turn using a sigmoid function. The per turn rewards are summed to form a global reward $R(\tau)$ for the roll-out τ. Using a pair of dialogue rewards $R(\tau^1)$ and $R(\tau^2)$, we compute the probabilistic preference between the roll-outs $P[\tau^1 \succ \tau^2]$ either by standard normalization or a softmax function. The output of this optimized using binary crossentopy loss described in Eqn:4. The above described architecture is illustrated in Fig:10 .

4.2 Dataset

To evaluate our proposed method on Multi-domain Wizard-of-Oz (MultiWoz) (Budzianowski et al., 2018a) dataset. It is a large scale multidomain, task oriented dataset generated by human-to-human conversation , where one participant plays the role of a user while the other plays the agent.The conversations are between a tourist and a clerk at an information center. The conversations span across 7 domains including attraction, hospital, hotel, police, restaurant, taxi and train. Each dialogue is generated by users with a defined goal which may cover 1-5 domains with a maximum of 13 turns in a conversation. The dataset has 10438 dialogues split into 8438 dialogues for training set and 1000 dialogues each for validation and test set.

4.3 Prepossessing

We represent DB results as one-hot vectors as proposed by Budzianowski et al. (2018b). To reduce surface-level variability in the responses, we use domain-adaptive delexicalization preprocessing proposed in Wen et al. (2016). As proposed in Zhang et al. (2019), We generate delexicalized responses with placeholders for specific values which can be filled with information in DST and database.

4.4 Metrics

4.4.1 Evaluation

We evaluate performance of our method on end-to-end dialogue modeling task of Multiwoz2.0 (Budzianowski et al., 2018a). We uses three evaluations metrics proposed by (Budzianowski et al., 2018a). These include: 1) inform rate - measures the fraction of dialogue, the system has provided the correct entity, 2) success rate - fraction of dialogues, the system has answered all the requested information and 3) BLEU (Papineni et al., 2002) - measures the fluency of the generated response. We also report the combined score $(Inform + Success) \times 0.5 + BLEU$ proposed by Mehri et al. (2019). All the numbers of CASPI reported in this work are median of 5 runs with different seeds.

4.4.2 Training

For the metric M used in pairwise causal reward learning , we use the following:

$$M := Inform + Success + \lambda \times BLEU \quad (7)$$

This is very similar to combined score used in evaluation and both are equivalent when $\lambda = 2$. We introduced hyperparamter λ to normalize the achievable scale of $BLEU$. We observe that success rate, if used as is, will result in non-markovian and stochastic per turn reward function. This is because the reward of current state will depend on the performance of future states. Hence, we also use a soft version of the metric M_{soft}, where the success rate measures a fraction of requested information provided in a dialogue. We refer the original metric that uses the discrete variant of success rate as M_{hard}. The choice of action in reward function $R(s_t, a_t, g)$ can either be dialogue act or generate response, we refer corresponding variants of metrics as $M(act)$ and $M(resp)$. To demonstrate the versatility of our method to adapt to different metrics, we use all the discussed variants of the metric.

5 Result

We compare both adaptation of our methods CASPI(DAMD) and CASPI(MinTL) on the end-to-end dialogue tasks defined by MultiWoz2.0 (Budzianowski et al., 2018a). The results are tabulated at Table:1. CASPI(DAMD) with its light weight model architecture and no pretraining on any external corpus, except for (Lubis et al., 2020), out perform all other previous methods, these includes methods that use large pretrained language models such as Hosseini-Asl et al. (2020), Peng et al. (2020) and Lin et al. (2020). This show using CASPI to shepard the gradient update process as sample weights for each dialogue turn leads to a model that's well aligned with true objective of the task. CASPI(MinTL) with its robust pretrained model out performs CASPI(DAMD) and LAVA (Lubis et al., 2020) by a large margin. This demonstrates the ease of adaptation of existing methods with CASPI.

5.1 Sample Efficiency

Inverse reinforcement learning, coupled with off-policy policy learning and evaluation are proven to be sample efficient (Thomas and Brunskill, 2016) . We argue CASPI is competitive with other sample efficiency techniques, such as data augmentation and transfer learning as performed by Zhang et al. (2019) and Lin et al. (2020) respectively. To demonstrate the hypothesis, we test our method against baseline in a low sample complexity regime. For experimental setup, we adopt the low resource testing strategy from Lin et al. (2020). We train our model on 5%, 10%, and 20% of the training data and compared with other baselines on end-to-end dialogue task, Table 2 list the results. CASPI(MinTL) trained only on 20% of data was able to out perform previous state of the art method, LAVA (Lubis et al., 2020) and MINTL (Lin et al., 2020) trained on 100% data on two of the three performance metrics. This goes to show that having the right reward function to guide the budget of the gradient update process to reach the true objective is important in extremely low resource setting.

5.2 Human Evaluation

Automatic evaluation metrics have their own biases. True objective of ToD is human experience while interacting with the dialogue systems, which automatic evaluation metrics might fall short to capture. To this end we conduct human evaluation on the quality of the generated response. We define quality by the following criterias:

1) Appropriateness: Are the generated responses appropriate for the given context in the dialogue turn?

Model	**Pre-trained model**	**Inform %**	**Success %**	**BLEU**	**Combined Score**
DAMD	No	72.79	60.45	16.93	83.55
DAMD + multi-action	No	76.33	64.35	17.96	88.30
SimpleTOD	Yes	84.4	70.10	15.01	92.26
SOLOIST	Yes	85.5	72.90	16.54	95.74
MinTL-BART	Yes	84.88	74.91	17.89	97.79
LAVA	Yes	91.80	81.80	12.03	98.47
CASPI(DAMD), $M_{soft}(act)$	No	89.1	76.1	**18.08**	100.68
CASPI(MinTL), $M_{soft}(act)$	Yes	**94.59**	**85.59**	17.96	**108.05**
CASPI(MinTL), $M_{hard}(act)$	Yes	93.79	84.88	17.47	106.81

Table 1: Comparison of results for end-to-end task of Multiwoz2.0.

Model	**5%**			**10%**			**20%**		
	Inform	Success	BLEU	Inform	Success	BLEU	Inform	Success	BLEU
MD-Sequicity	49.40	19.70	10.30	58.10	34.70	11.40	64.40	42.10	13.00
DAMD	56.60	24.50	10.60	62.00	39.40	14.50	68.30	42.90	11.80
MinTL	75.48	60.96	**13.98**	78.08	66.87	**15.46**	82.48	68.57	13.00
CASPI(MinTL), $M_{soft}(resp)$	87.69	**71.17**	13.51	82.08	72.27	14.10	89.39	78.58	**15.16**
CASPI(MinTL), $M_{hard}(resp)$	**89.69**	69.47	13.33	**92.59**	**78.58**	14.48	**94.19**	**83.28**	13.65

Table 2: Comparison of results for end-to-end of Multiwoz2.0. in low resource setting

2) Fluency: Are the generated responses coherent and comprehensible?

A dialogue turn in the test set is randomly picked. The human evaluators were shown context leading up to the turn. The predictions for the turn by different methods were anonymized and displayed to the evaluators. This is illustrated in Fig:4. The human evaluators were asked to give a score between 1 and 5 for appropriateness and fluency, with score of 5 being best and 1 being the worst. 100 randomly selected dialogue turns were presented to 10 participants .We report the mean and variance of the score. We compare our model performance against MinTL (Lin et al., 2020), SimpleTOD (Hosseini-Asl et al., 2020), LAVA (Lubis et al., 2020) and DAMD (Zhang et al., 2019). Fig:5 shows the results of the evaluation. CASPI(MinTL) outperforms all other models in appropriateness score. While fluency score of CASPI(MinTL), MinTL and SimpleTOD are comparable to each other. It is worth noting that though LAVA (Lubis et al., 2020) performs well on automatic evaluation metrics, it performs poorly on human evaluation. We suspect the policy learnt by (Lubis et al., 2020) exploits gaps in the reward function. In case of LAVA (Lubis et al., 2020), success rate is used as the reward function. In our analysis, low BLEU score is good indicator if the learnt policy indulges in reward hacking, which LAVA (Lubis et al., 2020) exhibits. More on reward hacking in Sec:5.4.2.

5.3 Human in the loop training

In the previous section we argued that automatic dialogue evaluation metrics are biased and doesn't truly reflect the human objective, but in our method we use these very same dialogue evaluation metrics to learn reward $R(s_t, a_t, g)$. To bridge this gap, we performed the following human-in-the-loop (HITL) experiment. We first trained a pair CASPI(MINTL) models with different seeds, on 5% of Multiwoz2.0 dataset. We then used these pair of models to predict on 0.5% of Multiwoz2.0 train data (40 dialogues) and had a human score these pairs of generated response relative to each other. We then trained for reward $R(s_t, a_t, g)$ using pairwise causal reward learning as described in Sec:3.3, where examples of the mini batch are randomly sampled either from human scored examples or the ones scored by the automatic evaluation metric as show in Fig:6. We then trained a fresh CASPI(MINTL) model on the original 5% of data and the learnt $R(s_t, a_t, g)$. We perform human evaluation on 24 dialogues using 3 participants. Fig:7

user	i need to find a [value_type] that has free parking .
agent	sure i can help with that . what area will you be staying in ?
user	in the [value_area] , i more specifically am looking for a [value_type] with a [value_stars] star rating in that area .
agent-gt	[value_name] is a [value_stars] star [value_type] located in the [value_area] has both free parking and wifi . what days are you interested in staying there ? can i book for you ?

CASPI(MinTL)	i have [value_choice] [value_type] in the [value_area] . [value_name] is [value_price] and [value_stars] stars . would you like me to book it ?
DAMD	i have [value_choice] options for you . is there a certain area you are looking for ?
SimpleTOD	there are no guesthouses with a [value_count] star rating in the [value_area], but there are [value_count] star guesthouses with free parking in the [value_pricerange] to [value_pricerange] price range
LAVA	the [hotel_name] is located at [hotel_address] , postcode [hotel_postcode] . the phone number is [hotel_phone] .

Figure 4: Example of generated responses by different ToD models

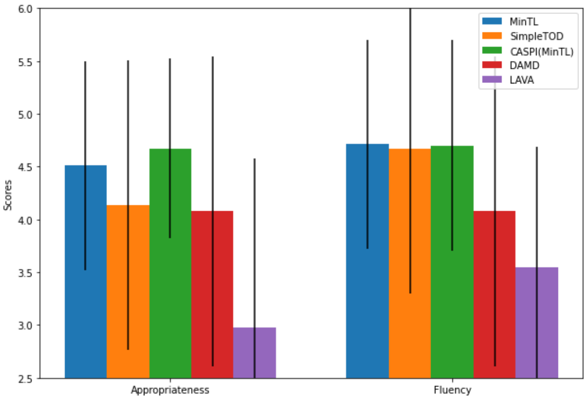

Figure 5: Human evaluation on criterias:Appropriateness and Fluency

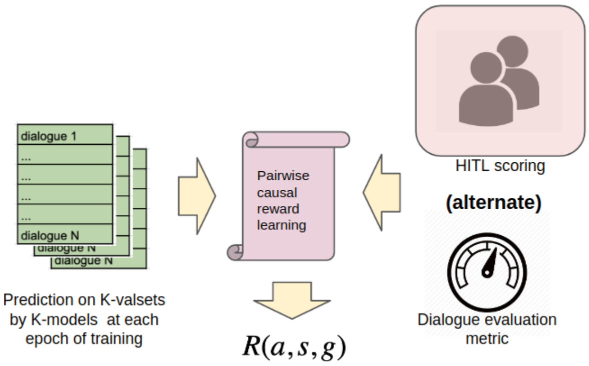

Figure 6: Mixed Human-in-the-loop and automatic evaluation metric scores for pairwise causal reward learning

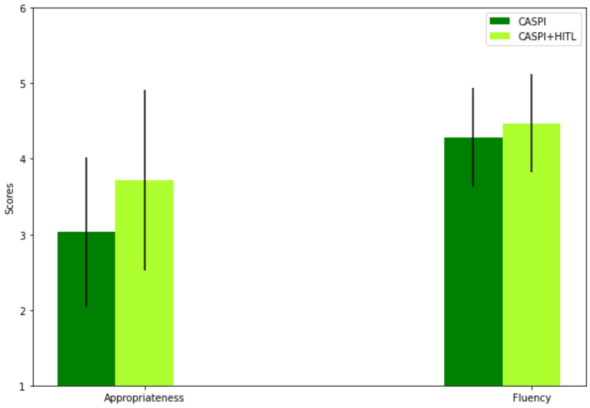

Figure 7: Human evaluation of Human in the loop training of CASPI(MinTL) on 5% of Multiwoz2.0 dataset

shows the performance.

Though CASPI(MINTL) using just 5% of the data outperforms DAMD trained on 100% of data in 2 out of the 3 automatic evaluation metrics shown in Table:1 and 2, performs poorly in human appropriateness score. With the HITL score in the reward learning, we see a boost in performance in both the human evaluation criteria: appropriateness and fluency. The 5% data CASPI(MINTL)'s human appropriateness score is now comparable to 100% data DAMD. This goes to show the versatility of the pairwise causal reward learning. With enough expressiveness of the neural network used, the pairwise causal reward learning can generalize to unknown dialogue evaluation criteria.

5.4 Analysis

5.4.1 Rewards

In this section we qualitatively analyze the results of pairwise causal reward learning. Fig:8 is the same conversation between a tourist and information center agents that we introduced earlier, now we have learnt reward $R(s_t, a_t, g)$, against each turn. We observe that Turn#3 has received the highest reward, retrospectively we realize the transaction happens in this turn, which is crucial and has to be risk averse for the success of the dialogue. Turn#2 gets the next best reward which captures crucial information needed for transaction to happen in Turn#3. Turn#4 gets reward an order lower than Turn#3 & 2 because other than nicety, it doesn't contribute much to the success of the conversation. It should be noted that responses like Turn#4 will appear in almost all conversations and in supervised learning, these turns will be receiving the highest share of the gradient budget. The learnt reward redistributes the gradient budget based on the turns contribution to the success of the dialogue objective.

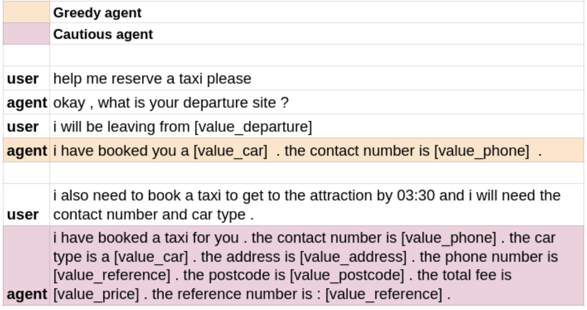
5.4.2 Type of agents

In this section we analyze the type of behaviour CASPI agents sometime exhibit, especially when trained in low sample regime.

Greedy agent: In certain domains, the agents has a tendency to book a service before it has gathered all the required information or before the user requested or agreed for booking a service. The first example in Fig:9 demonstrate this behaviour. Here the user has requested for a taxi, before enough information such as destination or time of departure

			R(a,s,g)
	Goal	{"train": {"info": { "leaveat": "09:00","destination": "broxbourne","day": "sunday","departure": "cambridge"},"fail_info": {},"book": {"invalid": true,"people": "8"},"fail_book": {}}}	
Turn-1	User	i am looking for a train . the train should leave after [value_leave] and should go to [value_destination] .	
	Agent	[train] [request] day	0.0614
		what day will this be on ?	
Turn-2	User	on [value_day] .	
	Agent	[train] [offerbook] leave id	0.1298
		[value_id] leaves at [value_leave] would you like me to book it ?	
Turn-3	User	yes please . i need that booked for [value_people] people .	
	Agent	[train] [offerbooked] reference people [general] [reqmore]	0.2295
		i was able to get you [value_people] tickets . your reference number is [value_reference] . can i help you with anything else ?	
Turn-4	User	no , thank you , that is all for now . have a great day .	
	Agent	[general] [welcome] [bye]	0.0249
		you are welcome . have a great trip !	

Figure 8: Example of learnt reward



🟧	**Greedy agent**
🟪	**Cautious agent**
user	help me reserve a taxi please
agent	okay , what is your departure site ?
user	i will be leaving from [value_departure]
agent	i have booked you a [value_car] . the contact number is [value_phone] .
user	i also need to book a taxi to get to the attraction by 03:30 and i will need the contact number and car type .
agent	i have booked a taxi for you . the contact number is [value_phone] . the car type is a [value_car] . the address is [value_address] . the phone number is [value_reference] . the postcode is [value_postcode] . the total fee is [value_price] . the reference number is : [value_reference] .

Figure 9: Example of agent behaviour in low sample regime.

are gathered, the agent books the taxi. This happens because there are gaps in automatic evaluation metrics. A low BLEU score and relatively high inform and success rate might indicate greedy agent behaviour. Other reasons for low BLEU score includes: lack of diversity in the responses or malformation of response.

Cautious agent: The agent tends to be cautious by providing long winded replies packed with more information than needed. Agent tend to do this to prevent the risk of loosing rewards by missing out any requested information. This behaviour is demonstrated in the second example in Fig:9

These subtle behaviour demonstrates gap in automatic evaluation metrics, which could be weeded out using Human in the loop learning described in Sec:5.3.

6 Conclusion

In this work we introduced a fine grained reward learning process using an under-specified metrics and expert demonstrations for efficiently learn task oriented dialogue. We demonstrated the efficacy of our method on MultiWoz2.0 dataset with results comparable to the existing state of the art method with only 20% of data. We believe the methods is generic and can be extend to other NLP tasks.

A Appendix

A.1 Baselines

DAMD: Introduced by (Zhang et al., 2019)is a domain-aware multi-decoder network. The method also exploits stochastic nature of the dialogue act by using a data-augmentation technique called the multi-action data augmentation. DAMD with data augmentation is denoted here as DAMD + multiaction.

HDSA by (Chen et al., 2019) proposes to use hierarchical graph representation for dialogue act. It uses a pre-trained 12-layer BERT model (Devlin et al., 2019) to represent dialogue act. The predicted dialogue act is transformed to the hierarchical graph structure using disentangled self-attention model, a 3-layer self-attention model (Vaswani et al., 2017)

SOLOIST (Peng et al., 2020) and SimpleTOD (Hosseini-Asl et al., 2020) uses pretrained GPT-2-based methods. These method are trained on turn-level data without generated belief state and system act in dialog history.

MinTL-BART (Lin et al., 2020), introduced Levenshtein belief spans framework that predicts only the incremental change in dialogue state per turn. It leverages the pretrained T5 and BART (Lewis et al., 2019) as backbone for model architecture.

LAVA (Lubis et al., 2020), reduces the action space of policy in end-to-end ToD, by using the latent space of a variational model with an informed prior. The work use variable distribution: via pretraining, to obtain an informed prior, and uses autoencoding as the auxiliary task, to capture generative factors of dialogue responses.

HDNO proposed by (Wang et al., 2020) is a dialogue policy learning method to solve context-to-response generation task of Multiwoz2.0 (Budzianowski et al., 2018a). It exploits the hierarchical nature of dialogue act and response generation task by proposing an option based framework of Hierarchical RL and variational model to learn a latent dialogue act that corresponds to natural language response. Unlike our method, HDNO though highlights the risk of sparsity of metric function such as success rate as reward function, resorts to shaping a proxy reward function. It uses markov language model as a proxy reward function. The language model is learnt independent of the metric function. Our method refrains from reward shaping and is independent of the nature of any underspecified metric function. Since we learn fine grained turn specific credit assignment, our solution can adapt to other metric function as long as the pairwise reward network is rich enough to factorize them.

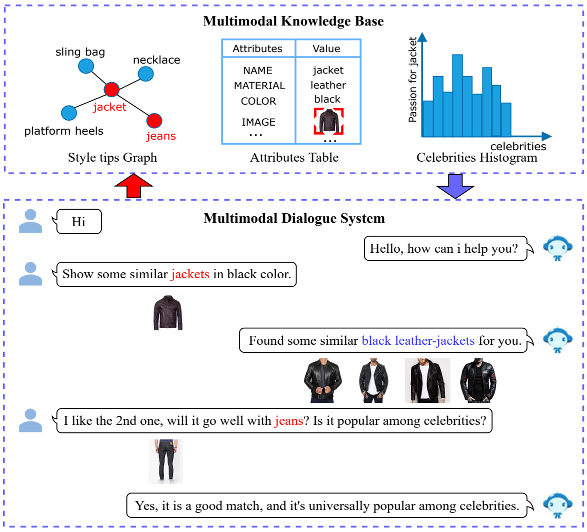
Abstract

As a more natural and intelligent interaction manner, multimodal task-oriented dialog system recently has received great attention and many remarkable progresses have been achieved. Nevertheless, almost all existing studies follow the pipeline to first learn intra-modal features separately and then conduct simple feature concatenation or attention-based feature fusion to generate responses, which hampers them from learning inter-modal interactions and conducting cross-modal feature alignment for generating more intention-aware responses. To address these issues, we propose UniTranSeR, a Unified Transformer Semantic Representation framework with feature alignment and intention reasoning for multimodal dialog systems. Specifically, we first embed the multimodal features into a unified Transformer semantic space to prompt inter-modal interactions, and then devise a feature alignment and intention reasoning (FAIR) layer to perform cross-modal entity alignment and fine-grained key-value reasoning, so as to effectively identify user's intention for generating more accurate responses. Experimental results verify the effectiveness of UniTranSeR, showing that it significantly outperforms state-of-the-art approaches on the representative MMD dataset.



Hi

Hello, how can i help you?

Show some similar jackets in black color.

Found some similar black leather-jackets for you.

I like the 2nd one, will it go well with jeans? Is it popular among celebrities?

Yes, it is a good match, and it's universally popular among celebrities.

Figure 1: Example of multimodal task-oriented dialog including multimodal entity alignment and knowledge query from the MMD dataset (Saha et al., 2018). Note that red marks the entities to be queried in the multimodal knowledge base and blue marks the acquired knowledge information.

1 Introduction

The multimodal task-oriented dialog systems are designed to help users achieve specific goals such as clothing recommendation or restaurant reservation, which is in growing demand in the current business environment. As a leading study, Saha et al. (2018) released a multimodal dialog dataset (MMD) in the online retail domain. Based on such a benchmark dataset, many multimodal dialog models incorporating domain knowledge have recently been proposed (Chauhan et al., 2019; Zhang et al., 2019, 2021), which basically exploit taxonomy-based method (Liao et al., 2018; Cui et al., 2019) or attention-based method (Nie et al., 2019; He et al., 2020) to incorporate knowledge base (KB) information for better performance.

Though achieving remarkable progress, existing multimodal task-oriented dialog systems still suffer from the following three limitations. **Firstly**, prior models only learn the intra-modal features (including textual features, visual features and domain knowledge) separately before fusing them. Since these multimodal cues in general can enhance and complement each other, projecting them into a unified semantic space to learn the inter-modal features, with no doubt, can help improve the abilities of natural language understanding, which in turn will benefit the response generation. **Secondly**, prior models only conduct simple feature concatenation (Saha et al., 2018; Nie et al., 2019) or attention-based feature fusion (Cui et al., 2019) af-

ter acquiring intra-modal representations, but without learning fine-grained alignment between different modalities before fusion, which is not favorable to query knowledge for accurate multimodal response generation. Take the dialog in Figure 1 as an example, when answering the user's query on similar style of jackets, the model is expected to align the word *"jackets"* with the corresponding visual features for proper semantic complement and entity enhancement. **Thirdly**, prior models basically lack the capability of entity-level reasoning, which prevents them from performing reasoning over crucial entities to guide intention-aware response generation. For example, in Figure 1, when the user asks *"show some similar jackets in black color"*, the chatbot is expected to properly explore the pivot attribute *"black"* that connects the start query cue *"jackets"* with the target recommended product images. Specifically, the model needs to perform a 2-hop reasoning over triples *(jacket_q, attribute, black_v)* and *(black_q, image, jacket_v)* and obtain the intended 4 images.

To address the aforementioned limitations, we propose a Unified Transformer Semantic Representation framework with feature alignment and intention reasoning, UniTranSeR for short. Specifically, to address the first limitation, we stand on the shoulder of Vision-and-Language Pre-training (VLP) methods (Lu et al., 2019; Li et al., 2019; Chen et al., 2020; Li et al., 2021) to propose a unified-modal Transformer encoder, which is used to project all the multimodal features into a unified semantic space to prompt inter-modality interactions, with the objective of learning better representations. Based on the unified encoder, we further address the second limitation by designing a feature alignment module to perform cross-modal feature alignment. Finally, to address the third limitation, we devise a fine-grained intention reasoning module for capturing users' real intentions, by leveraging a key-value attention based memory mechanism to perform multi-hop knowledge query for generating text or image responses.

We conduct experiments on MMD, one of the most influential benchmark datasets for multimodal dialog generation. We follow the mainstream evaluation script of dialog generation and demonstrate that UniTranSeR significantly outperforms the current state-of-the-art baselines. Ablation study also shows the efficacy of each component in improving the performance of dialog generation, and a further case study reveals that our model can effectively perform fine-grained token-level feature alignment for multimodal dialog generation.

2 Related Work

2.1 Unimodal Dialog Systems

Recent years has witnessed the remarkable success in textual dialog systems, which can be roughly divided into two categories: open-domain conversations with casual chi-chat (Song et al., 2020; Gangal et al., 2021; Chan et al., 2021; Yang et al., 2021) and task-oriented dialog systems (Pei et al., 2021; Santra et al., 2021; Wang et al., 2021; Mi et al., 2021; Madotto et al., 2021; Gou et al., 2021; Raghu et al., 2021), which are designed to help users achieve specific goals. Early efforts mainly adopt a sequence-to-sequence (Seq2Seq) architecture, but cannot work well in KB retrieval and reasoning. To alleviate this problem, copy mechanism (Eric and Manning, 2017) have been adopted and many memory augmented Seq2Seq models have been proposed (Bordes et al., 2017; Wen et al., 2018; Madotto et al., 2018; Wu et al., 2019; Reddy et al., 2019; Qin et al., 2019; Wang et al., 2020; Qin et al., 2020), which achieve promising results.

2.2 Multimodal Dialog Systems

With the flourishing of social media platforms, massive amounts of multimedia data are generated daily, which poses great demand for multimodal dialog systems. However, due to the lack of large-scale multimodal dialog datasets, researches in this domain have been limited. To this end, Saha et al. (2018) provided a vertical retail domain dataset MMD to promote the research and proposed a multimodal hierarchical encoder-decoder model (MHRED) as a baseline. Based on MHRED, Liao et al. (2018) incorporated the style tips into a knowledge-aware multimodal dialog model (KMD). Cui et al. (2019) designed a user attention-guided multimodal dialog system (UMD) by additionally considering the hierarchical product taxonomy and user's attention to products. Chauhan et al. (2019) introduced an ordinal and attribute aware multimodal dialog system (OAM) by employing a novel position and attribute aware attention mechanism. Later, Nie et al. (2019) proposed a multimodal dialog system with adaptive decoders (MAGIC), which can incorporate different forms of domain knowledge to generate different kinds of responses. Recently, combining with

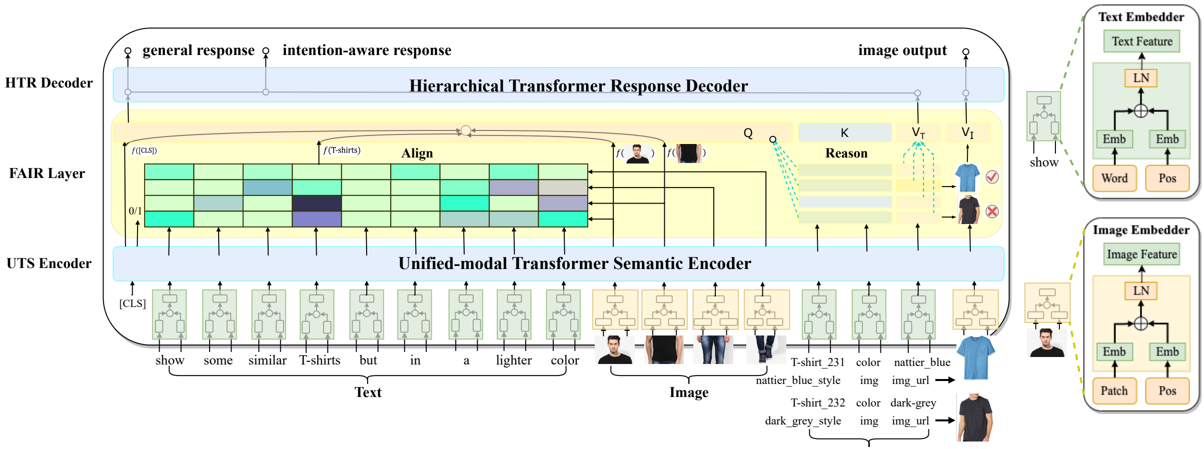

Figure 2: The Proposed Framework.

Transformer (Vaswani et al., 2017), He et al. (2020) advanced a multimodal dialog system via capturing context-aware dependencies of semantic elements (MATE) for textual response generation.

Most existing multimodal dialog systems learn intra-modal features separately for later feature concatenation or fusion. Different from them, our proposed UniTranSeR can project all the multimodal features into a unified semantic space to perform fine-grained feature alignment and intention reasoning, which can lead to more accurate responses. Vision-and-Language Pre-training (VLP) (Lu et al., 2019; Li et al., 2021) is another line of research relevant to our work, but different from ours in that it focuses more on boosting the performance of representation learning, while the multimodal dialog systems focus more on multi-turn multimodal interaction between users and agents.

3 Methodology

The proposed UniTranSeR mainly comprises three parts: Unified-modal Transformer Semantic (UTS) encoder (Sec. 3.1), Feature Alignment and Intention Reasoning (FAIR) layer (Sec. 3.2), and Hierarchical Transformer Response (HTR) decoder (Sec. 3.3), as shown in Figure 2. We define the multimodal dialog generation task as generating the most likely response sequence $Y = \{y_1, y_2, \cdots, y_n\}$ and selecting top-**k** most matched images, giving multimodal context utterances $U = \{u_1, u_2, \ldots, u_{|U|}\}$ and multimodal knowledge base B as inputs. The probability of a textual response can be formally defined as,

$$P(Y|U,B) = \prod_{t=1}^{n} P\left(y_t|y_1, \ldots, y_{t-1}, U, B\right) \quad (1)$$

where y_t represents the current token decoded by the HTR decoder.

The UTS encoder is used to project all the multimodal features into a unified vector space for inter-modal interactions, while the FAIR layer is designed to align cross-modal hidden features, with textual features and visual features from previous UTS encoder as inputs. Similar to MAGIC (Nie et al., 2019), our HTR decoder is designed to decode three types of responses: general responses that refer to the highly frequent responses (e.g., courtesy greetings) in the conversation, such as *"How can I help you?"*; intention-aware responses that refer to the task-oriented utterances, such as *"Found some similar black leather-jackets for you"*; and multimodal responses that refer to the intention-aware responses with image output. The response type is determined by a query vector $\mathbf{Q}$ from the FAIR layer, in which an intention classifier is trained to decide which kind of response should be given out.

3.1 UTS Encoder

We first use a text embedder and an image embedder to extract textual features and visual features, respectively, and extract informative features from external knowledge by utilizing both text and image embedders. Afterwards, we feed these three kinds of features into a unified Transformer encoder for unified-modal semantic representation learning.

Text Embedder. To learn textual intra-modal features, we use a BERT tokenizer to split the input sentence into words and exploit a single transformer layer to obtain these words' initial embeddings. Note the self-attention mechanism in Transformer is order-less. So, it is necessary to encode the words' position as additional inputs. The final representation for each word is derived via summing up its word embedding and position embedding, followed by a layer normalization (LN) layer.

Image Embedder. To learn visual intra-modal features, we use a contour slicer to cut the input images into patches and exploit ResNet-50 (He et al., 2016) to extract these patches' visual features. We notice that people usually focus on four parts of a clothing image: head, upper body, lower body, and feet, so we intuitively use an equal-height mode to slice an image into four patches, which efficiently solves the problem of region feature extraction, without using complex target detection networks such as Faster R-CNN (Ren et al., 2015). Then, we feed the patches into ResNet-50 to get the patches' initial embeddings. Similarly, we also encode the position features for each patch via a 4-dimensional vector $[image\_index, patch\_index, width, height]$. Both visual and position features are then fed through a fully-connected (FC) layer, to be projected into the same embedding space. The final visual embedding for each patch is obtained by first summing up the two FC outputs, and then passing them through an LN layer.

Knowledge Embedder. To integrate informative features from external knowledge[1] into the task-oriented dialog, we equip the product knowledge base for each utterance through searching a fashion item table provided by MMD. We then treat these searched knowledge entries into the same triplet format, i.e., *(product, match, product)*, *(product, attribute, value)*, *(product, celebrity, passion_score)*. Next, for the text and image elements of these triples, we use the text and image embedders to obtain their respective representations.

Unified Transformer Encoder. After obtaining the multimodal initial embeddings, denoted as $\mathbf{h}_t$, $\mathbf{h}_v$ and $\mathbf{h}_k$ respectively, we project them into a unified semantic space to obtain interactive representations by using a unified Transformer encoder. Specifically, in each utterance, the textual features, visual features and informative features correspond to l tokens with "[TXT]", 4 tokens[2] with "[IMG]" and 4 tokens[3] with "[KNG]". In order to integrate dialog history of previous rounds, we initialize the current $[\text{CLS}]^p$ by using the representation of the previous round $[\text{CLS}]^{p-1}$. The output hidden state representations can then be phrased as:

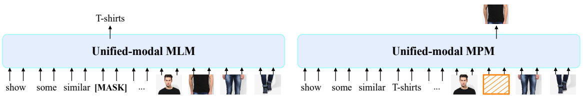

Figure 3: Illustration of MLM and MPM.

$$\mathbf{H}^p = f\left([\text{CLS}]^{p-1}\mathbf{h}_t^p[\text{TXT}]\mathbf{h}_v^p[\text{IMG}]\mathbf{h}_k^p[\text{KNG}]\right) \tag{2}$$

where $f(\cdot)$ denotes the Transformer encoder, $\mathbf{H}_0^p$ denotes the hidden state representation of the current round $[\text{CLS}]^p$, which is regarded as the contextual semantic vector of the entire utterance in this round, $\mathbf{H}_{1:l}^p$ denotes the representations for the text sequence, $\mathbf{H}_{l+1:l+4}^p$ denotes the representations for the patch sequence, and $\mathbf{H}_{l+5:l+8}^p$ denotes the representations for knowledge entries. Note the superscript p is omitted for simplicity if no confusion occurs in the following discussion.

To obtain better representations, we introduce the Masked Language Modeling (MLM) loss and Masked Patch Modeling (MPM) loss to train them. We denote the input words as $w = \{w_1, \ldots, w_l\}$, the image patches as $v = \{v_1, \ldots, v_4\}$, the knowledge elements as $k = \{k_1, \ldots, k_4\}$, and the mask indices as $m \in \mathbb{N}^L$, where $\mathbb{N}$ is the natural numbers and L is the length of masked tokens. In MLM, we randomly mask out the input words with a probability of 15%, and replace the masked ones w_m with a special token "[MASK]", as illustrated in Figure 3. The goal is to predict these masked words by attentively integrating the information of their surrounding words $w_{\backslash m}$, image patches v and knowledge elements k, by minimizing the following loss:

$$\mathcal{L}_{\text{MLM}}(\theta) = -\mathbb{E}_{(w,v,k)\sim U} \log P_\theta\left(w_m | w_{\backslash m}, v, k\right) \tag{3}$$

Similar to MLM, in MPM, we also randomly mask out the image patches and use zeros tensor to replace them, as shown in Figure 3. Unlike textual words that can be categorized as discrete labels, visual features are high-dimensional and continuous tensors, thus cannot be supervised via a negative log-likelihood loss. Following UNITER (Chen et al., 2020), we built the MPM loss as:

$$\mathcal{L}_{\text{MPM}}(\theta) = \mathbb{E}_{(w,v,k)\sim U} g_\theta\left(v_m | v_{\backslash m}, w, k\right) \tag{4}$$

where v_m are masked image patches and $v_{\backslash m}$ are remaining patches. Note here g_θ is defined as an

---

[1] External knowledge of MMD includes: style tips graph, attributes table and celebrities histogram, as shown in Figure 1.

[2] Note when an utterance contains multiple images, it can be unrolled into a sequence of utterances, each containing a single image, the same as previous work.

[3] Including 3 textual features and 1 visual features.

L2 regression function, where

$$g_\theta\left(v_m|v_{\backslash m}, w, k\right) = \sum_{i=1}^{L} \left\| f_\theta\left(v_m^{(i)}\right) - \mathbf{h}_{v_m^{(i)}} \right\|_2^2 \tag{5}$$

3.2 The FAIR Layer

To align the cross-modal features for accurate intention classification and knowledge query, we devise a feature alignment and intention reasoning (FAIR) layer. In feature alignment, we use Image-Text Matching (ITM) and Word-Patch Alignment[4] (WPA) to conduct a two-level alignment. That is, ITM is used to align text and image in sentence-level, while WPA is used to align each split word and each sliced patch in token-level. In intention reasoning, we fuse $f([\text{CLS}])$ and aligned entities' hidden state representations to obtain a query vector $\mathbf{Q}$, which is then used for intention classification and knowledge query.

3.2.1 Feature Alignment

Image-Text Matching (ITM). In ITM, we use the output $f([\text{CLS}])$ of the unified Transformer encoder to compute the match probability of the sampled pair. Specifically, we feed $f([\text{CLS}])$ into an FC layer and a sigmoid function to predict a probability score $P_\theta(w, v)$, which is between 0 and 1. During training, we sample a positive or negative pair (w, v) from the dataset D at each step. The negative pair is created by randomly replacing the image or text in the same batch. We employ a binary cross-entropy loss for optimization:

$$\begin{aligned}\mathcal{L}_{\text{ITM}}(\theta) = -\,\mathbb{E}_{(w,v)\sim D}[y \log P_\theta(w, v) + \\ (1-y)\log\left(1 - P_\theta(w, v)\right)]\end{aligned} \tag{6}$$

where y is a binary truth label. Note here we only use ITM to train image-text pairs but without considering the knowledge vector, because it has already matched the textual sequence when being searched out.

Word-Patch Alignment (WPA). For more fine-grained alignment between each word and image patch, we introduce a WPA technology, which is used to train the consistency and exclusiveness between these cross-modal features to prompt alignment. We use a WPA loss to supervise the process, which is defined as:

$$\mathcal{L}_{\text{WPA}}(\theta) = -\sum\nolimits_{i=1}^{l} \sum\nolimits_{j=1}^{4} \mathbf{T}_{ij} \cdot \phi\left(w_i, v_j\right) \tag{7}$$

where ϕ denotes the $\cos(\cdot)$ similarity function, $\mathbf{T} \in \mathbb{R}^{l\times 4}$ is a ground truth table and each $\mathbf{T}_{ij} \in \mathbf{T}$ is a binary label 0 or 1. During training, we sample positive or negative pairs (w_i, v_j) from each multimodal utterance to construct a probability table, as shown in Figure 2. The above loss function $\mathcal{L}_{\text{WPA}}$ is then used to update the parameters θ. During inference, we continue to fuse aligned entities' hidden state representation and $f([\text{CLS}])$ to obtain a unified query vector $\mathbf{Q}$, which contains multimodal query information with entity enhancement, and will be used for subsequent intention reasoning.

3.2.2 Intention Reasoning

Intention Classify (IC). Given the query vector $\mathbf{Q}$, this component aims to understand the users' intention and thereafter determine which type of response should be generated. To be clear, there are a total of 17 types labeled in the MMD dataset, and each user's utterance is labeled with a specific intention type. Following MAGIC, we customize the type of response specifically for each intention, as shown in Table 1. Subsequently, we leverage an MLP layer to predict $\mathbf{Q}$'s probability distribution and select the highest probability to generate a response. Besides, a cross-entropy loss is applied to optimizing the intention classifier:

$$\mathcal{L}_{\text{IC}}(\theta) = \sum\nolimits_{i=1}^{|U|} \sum\nolimits_{j=1}^{17} I_{ij}^{*} \log P_\theta\left(I_{ij} \mid \mathbf{Q}\right) \tag{8}$$

where $P_\theta\left(I_{ij} \mid \mathbf{Q}\right)$ denotes the probability of being predicted as intention I_{ij}, and I_{ij}^{*} is a ground truth label. The intention classifier is trained by the loss function $\mathcal{L}_{\text{IC}}(\theta)$ to update parameter θ, and finally outputs a reliable intention prediction result I in the inference phase.

Knowledge Query (KQ). Given the predicted intention result I, this component first determines whether knowledge query is required based on Table 1. If required, we adopt a key-value memory mechanism to query all embedded knowledge triples[5]. Specifically, these embedded knowledge triples are divided into key parts and value parts, which are respectively denoted as vector $\mathbf{K}$ and vector $\mathbf{V}$. Note here $\mathbf{K}$ is obtained through a linear

fusion of the embedded head-entities and relations. The knowledge query process is as follows:

$$\alpha_i = \text{Softmax}\left(\mathbf{Q}^{\text{T}} \cdot \mathbf{K}_i\right) \tag{9}$$

$$\mathbf{V}_T = \sum\nolimits_{i=1}^{|M|} \alpha_i \mathbf{V}_i \tag{10}$$

where α_i denotes the attentive probability score for $\mathbf{K}_i$, $|M|$ is the number of knowledge triples, and $\mathbf{V}_T$ is a weighted sum of $\mathbf{V}_i$, which will be used for textual decoding in an intention-aware response.

Multi-hop Recommend (MR). Given the predicted intention result I and one-hop query result $\mathbf{V}_T$, this component first needs to determine whether an image recommendation is required based on Table 1. If required, we continue to use $\mathbf{V}_T$ as a query vector to perform another hop query over the entire knowledge base, which implies that the product images will be recommended, if the key parts of their corresponding triples have high similarity to $\mathbf{V}_T$. Specifically,

$$\beta_i = \text{Softmax}\left(\mathbf{V}_T^{\text{T}} \cdot \mathbf{K}_i\right) \tag{11}$$

After deriving β_i, we use $\mathbf{V}_I = \{q_i\}$, an image pointer vector, to select images with top β_i for recommendation, where

$$q_i = \begin{cases} 1, & \text{if } \mathbf{V}_i = \mathbf{1}_{1\times 512} \\ 0, & \text{otherwise} \end{cases} \tag{12}$$

and $\mathbf{1}_{1\times 512}$ is a column vector with each element equal to 1, which denotes for the special token [URL] of the image's link. Note here 512 is the embedding size in our unified Transformer encoder. It is not difficult to see that UniTranSeR can extend the above one-hop knowledge query to multi-hop by iteratively performing attention-based key-value reasoning and ultimately achieve multi-hop image recommendation.

3.3 HTR Decoder

As mentioned earlier, we used a hierarchy mechanism to decode different types of response sequences, including general responses, intention-aware responses and multimodal responses. They share the same uni-directional Transformer layer, but the semantic representations fed to this decoder are different. Specifically, for general responses, we just take the sentence-level representations f([CLS]) as input. For intention-aware responses, we take the concatenation of f([CLS]) and attentive vector $\mathbf{V}_T$ followed by an FC layer as input. For multimodal responses, we take the input for the intention-aware responses, as well as $\mathbf{V}_I$, the image pointer vector, as input.

Dataset Statistics	Train	Valid	Test

Proportion	70%	15%	15%

Table 2: Statistics of the MMD dataset.

4 Experimental Setup

4.1 Datasets and Metrics

To evaluate the performance of UniTranSeR, we conduct experiments on the widely-used benchmark dataset MMD contributed by Saha et al. (2018). The MMD dataset consists of over 150k conversations between users and chatbots in the retail domain, and each conversation describes a complete online shopping process. During the conversations, the user proposes his/her requirements in multimodal utterances and the chatbot introduces different products step by step until they make a deal. In our experiments, we follow Nie et al. (2019) to partition MMD. The statistics the dataset after partition are presented in Table 2, and more detailed statistics can be found in Appendix A.4.

Following several previous work (Nie et al., 2019; He et al., 2020; Zhang et al., 2021), we use Bleu-$\mathbf{n}$, Nist and Recall@$\mathbf{k}$ to evaluate our model over two basic tasks separately, i.e., text task and image task. For the text task, we employ the proposed HTR decoder to produce all general responses and intention-aware responses. As the length of 20.07% target responses in MMD is less than 4, such as *"Hello!"* and *"Thanks a lot!"*, we follow Nie et al. (2019) to calculate Bleu-$\mathbf{n}$ by

Methods		Text Task					Image Task		
		Bleu-1	**Bleu-2**	**Bleu-3**	**Bleu-4**	**Nist**	**Recall@1**	**Recall@2**	**Recall@3**
Previous Methods	**MHRED** (Saha et al., 2018)	32.60	25.14	23.21	20.52	3.0901	0.7980	0.8859	0.9345
	KMD (Liao et al., 2018)	-	-	-	-	-	0.9198	0.9552	0.9755
	UMD (Cui et al., 2019)	42.78	33.69	28.06	23.73	-	0.9796	0.9980	0.9990
	OAM (Chauhan et al., 2019)	48.30	38.24	32.03	27.42	4.3236	-	-	-
	MAGIC (Nie et al., 2019)	50.71	39.57	33.15	28.57	4.2135	0.9813	0.9927	0.9965
	MATE (He et al., 2020)	56.55	47.89	42.48	38.06	-	-	-	-
Ours	**UniTranSeR**	**63.27**	**55.93**	**51.31**	**48.07**	**4.9774**	**0.9983**	**0.9995**	**0.9998**

Table 3: Main results. Relevance (higher better) between generated responses and golden responses. Note all our results are statistically significant with $p < 0.05$ under t-test.

varying $\mathbf{n}$ from 1 to 4. Note higher Bleu and Nist scores indicate that more $\mathbf{n}$-gram overlaps exist between the predicted and target responses, and hence are more favorable. For the image task, we adopt Recall@$\mathbf{k}$ to evaluate the efficacy of image response, where $\mathbf{k}$ is varied from 1 to 3. Note the image response is correct only if the positive image is recommended in the top-$\mathbf{k}$ product images.

4.2 Baselines

We compare our model with the following state-of-the-art baselines.

- **MHRED** (Saha et al., 2018)[6] is the first baseline work to integrate the visual features into a hierarchical encoder-decoder model for their constructed MMD dataset.
- **KMD** (Liao et al., 2018) incorporates the style tips into the memory augmented neural model and adopts deep reinforcement learning to boost the performance.
- **UMD** (Cui et al., 2019)[7] proposes a user attention-guided multimodal dialog system by considerring the hierarchical product taxonomy and the user's attention to products.
- **OAM** (Chauhan et al., 2019) proposes a novel ordinal and attribute aware attention mechanism for multimodal dialog generation.
- **MAGIC** (Nie et al., 2019)[8] adopts the adaptive decoders with intention understanding to explicitly generate three types of responses.
- **MATE** (He et al., 2020)[9] utilizes a multimodal element-level encoder to integrate dialog context and leverages a knowledge-aware two-stage decoder for response generation, and achieves state-of-the-art performance.

4.3 Implementation Details

Following Saha et al. (2018) and Nie et al. (2019), we utilize two-turn utterances prior to the target response as the context, and set the vocabulary size to $26,422$. In our trainings, the batch size is set to 64, learning rate is set to $1e^{-4}$ and the max number of training epoches is set to $1e^{4}$. Adam optimizer is used to optimize all models. All experiments are conducted with PyTorch. More details about hyper-parameter settings can be found in Appendix A.1.

5 Evaluation Results

5.1 Response Quality Evaluation

Automatic Evaluation Following KMD, UMD and MAGIC, we evaluate model performance automatically from two aspects: text response and image response. From the results in Table 3, we can observe that our model UniTranSeR achieves the state-of-the-art performance on both tasks. Specifically, in text task, UniTranSeR exhibits the highest Bleu-$\mathbf{n}$ with varying $\mathbf{n}$ from 1 to 4 compared with other baselines, indicating that our model can generate responses closer to the golden ones. Moreover, our model outperforms MATE, a recent model that can capture context-aware dependencies of semantic elements, by 26.3% in Bleu-4 score, which verifies the effectiveness of our model in learning cross-modal feature alignment and conduct intention reasoning to generate more accurate and informative responses. In image task, an extremely difficult performance improvement can be observed, which further verifies the superiority of our model.

Human Evaluation The human evaluation mainly focuses on four aspects: fluency, relevance, correctness, and informativeness, which are all important for task-oriented dialogue systems (Cui et al., 2019; Nie et al., 2019; He et al., 2020). We first randomly selected 200 dialogs from the MMD datasets, and used different models to generate responses, including UMD, OAM, MAGIC, MATE

and UniTranSeR. Then, we hired human experts to score the responses and golden responses in blind review on a scale from 1 to 5, which simulated a real-life multimodal task-oriented conversation scenario. By calculating the average score of the above metrics, we obtained the final manual evaluation results, as shown in Table 4. It can be observed that UniTranSeR consistently outperforms the other four models on all metrics, which is in line with the results of automatic evaluation.

5.2 Ablation Study

In this part, we perform ablation experiments to evaluate the effectiveness of each component. We focus on five crucial components and set them accordingly: 1) w/o UTS Encoder denotes that we use a BiGRU to replace the unified-modal Transformer encoder for multimodal encoding; 2) w/o HTR Decoder denotes that we use a Uni-directional GRU to replace the hierarchical Transformer decoder for response generation; 3) w/o ITM denotes that we remove the $\mathcal{L}_{\text{ITM}}$ loss to make the parameters not updated; 4) w/o WPA denotes that we remove the $\mathcal{L}_{\text{WPA}}$ loss and just regard the sentence-level representation $f([\text{CLS}])$ as query vector $\mathbf{Q}$ to query knowledge; 5) w/o IR Module denotes that we remove the IC and KQ components and just adopt the context vector $f([\text{CLS}])$ to generate responses[10]; From Table 5, we can observe that removing each component will result in a performance degradation. Specifically, w/o IR Module causes 54.96% drops in Bleu-4 score and 54.18% drops in Nist score, which verifies the great efficacy of intention classify and knowledge query components. Moreover, w/o WPA, w/o ITM and w/o UTS Encoder respectively cause 28.54%, 20.48% and 14.37% drops in Nist score, which further demonstrates the effectiveness of cross-modal feature alignment and unified-modal semantic encoding.

5.3 Case Study and Visualization

To better illustrate the advantage of our model and understand what the feature alignment module has learned, we visualize several examples of text-to-image attention, as shown in Figure 4. It can be observed that our model is able to capture fine-grained entity alignment between different modalities. The reason may be that: 1) We adopt a unified-modal Transformer semantic encoder, which enables to map different modalities of semantic cues into a same vector space to prompt inter-modality interactions for better representations; 2) Based on the obtained representations, the WPA technology can help supervise fine-grained word-patch alignment, which is beneficial to identifying user's real intention and generate more intention-aware responses.

6 Conclusion

In this paper, we propose a Unified Transformer Semantic Representation framework with feature alignment and intention reasoning, referred to UniTranSeR. Specifically, we project the multimodal features into a unified semantic space by utilizing a Transformer encoder to prompt inter-modal interactions. We further design a feature alignment and intention reasoning layer to conduct cross-modal feature alignment and fine-grained intention rea-

---

[10] Equivalent to generating general responses, since there is no knowledge query.

soning, with the objective of generating more accurate and intention-aware responses. Experiments on the representative MMD dataset demonstrate the effectiveness and superior performance of our UniTranSeR model in both automatic and human evaluation.

A Appendices

A.1 Hyperparameters Setting

The hyperparameters used for MMD dataset are shown in Table 6.

Hyperparameter Name	MMD
Batch Size	64
Epoches	10,000
Text Embedding Size	512
Image Embedding Size	512
Transformer Embedding Size	512
Learning Rate	0.0001
Dropout Ratio	0.15
Teacher Forcing Ratio	0.9
Mask Length	6
Mask Probability	0.15
Replace Probability	0.15
Vocabulary Size	26,422

Table 6: Hyperparameters we used for MMD.

A.2 Description of Special Tokens

The special tokens used in our experiments are shown in Table 7.

Token	Description
[CLS]	Utterances classfication token
[TXT]	Text token
[IMG]	Image token
[KNG]	Knowledge token
[MASK]	Mask token
[URL]	Image link token
[PAD]	Padding token
[UNK]	Unknown token

Table 7: Description of special tokens in our experiments.

A.3 Loss Function

Our total loss function $\mathcal{L}_{Total}$ comprises three parts: UTS encoder loss $\mathcal{L}_E$, FAIR layer loss $\mathcal{L}_F$ and HTR decoder loss $\mathcal{L}_D$, which can be calculated as follows:

$$\mathcal{L}_{Total} = \gamma_E \mathcal{L}_E + \gamma_F \mathcal{L}_F + \gamma_D \mathcal{L}_D \tag{13}$$

where γ_E, γ_F and γ_D are hyperparameters, and are initialized equally, i.e., 0.33, 0.33 and 0.33. Then, we tune them on the verification set to obtain a better weight setting of 0.30, 0.35 and 0.35.

The UTS encoder loss $\mathcal{L}_E$ contains two parts: $\mathcal{L}_{\text{MLM}}$ and $\mathcal{L}_{\text{MPM}}$,

$$\mathcal{L}_E = \mathcal{L}_{\text{MLM}} + \mathcal{L}_{\text{MPM}} \tag{14}$$

the FAIR layer loss contains three parts: $\mathcal{L}_{\text{ITM}}$, $\mathcal{L}_{\text{WPA}}$ and $\mathcal{L}_{\text{IC}}$:

$$\mathcal{L}_F = \mathcal{L}_{\text{ITM}} + \mathcal{L}_{\text{WPA}} + \mathcal{L}_{\text{IC}} \tag{15}$$

and the HTR decoder loss is divided into two types: the textual decoding loss $\mathcal{L}_{\text{TXT}}$ for text task and image recommend loss $\mathcal{L}_{\text{IMG}}$ for image task, which is consistent with previous work (Nie et al., 2019).

$$\mathcal{L}_D = \mathcal{L}_{\text{TXT}} + \mathcal{L}_{\text{IMG}} \tag{16}$$

A.4 Dateset Statistics

A detailed statistics of the MMD dataset is presented in Table 8.

A.5 Error Analysis

To better understand the limitations of our model, we conduct an error analysis on UniTranSeR. We randomly select 100 responses generated by UniTranSeR that achieve low human evaluation scores in the test set of MMD. We report several reasons for the low scores, which can roughly be classified into four categories. (1) KB information in the generated responses is incorrect (38%), especially when the corresponding equipped knowledge base is large and complex. (2) The sentence structure of the generated responses is incorrect and there are serious grammatical and semantic errors (24%). (3) The model makes incomplete response when there are multiple intentions contained in users' utterances (21%). (4) The model selects incorrect product images since different products have similar attributes (17%).

Dynamic Schema Graph Fusion Network for Multi-Domain Dialogue State Tracking

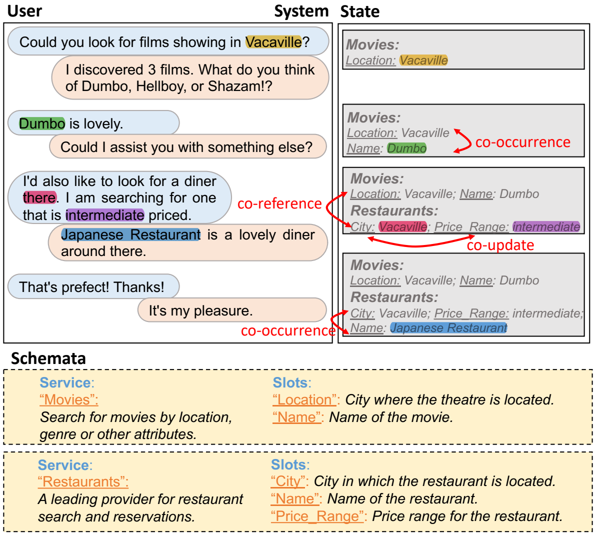
Abstract

Dialogue State Tracking (DST) aims to keep track of users' intentions during the course of a conversation. In DST, modelling the relations among domains and slots is still an under-studied problem. Existing approaches that have considered such relations generally fall short in: (1) fusing prior slot-domain membership relations and dialogue-aware dynamic slot relations explicitly, and (2) generalizing to unseen domains. To address these issues, we propose a novel **D**ynamic **S**chema **G**raph **F**usion **Net**work (**DSGFNet**), which generates a dynamic schema graph to explicitly fuse the prior slot-domain membership relations and dialogue-aware dynamic slot relations. It also uses the schemata to facilitate knowledge transfer to new domains. DSGFNet consists of a dialogue utterance encoder, a schema graph encoder, a dialogue-aware schema graph evolving network, and a schema graph enhanced dialogue state decoder. Empirical results on benchmark datasets (i.e., SGD, MultiWOZ2.1, and MultiWOZ2.2), show that DSGFNet outperforms existing methods.

1 Introduction

Task-oriented dialogue systems can help users accomplish different tasks (Huang et al., 2020), such as flight reservation, food ordering, and appointment scheduling. Conventionally, task-oriented dialogue systems consist of four modules (Zhang et al., 2020c): natural language understanding (NLU), dialogue state tracking (DST), dialogue manager (DM), and natural language generation (NLG). In this paper, we will focus on the DST module. The goal of DST is to extract users' goals or intentions as dialogue states and keep these states updated over the whole dialogue. In order to track users' goals, we need to have a predefined domain knowledge referred to as a schema, which consists of slot names and their descriptions. Figure 1 gives an example of DST in a sample dialogue.



Could you look for films showing in Vacaville?

I discovered 3 films. What do you think of Dumbo, Hellboy, or Shazam!?

Dumbo is lovely.

Could I assist you with something else?

I'd also like to look for a diner there. I am searching for one that is intermediate priced.

Japanese Restaurant is a lovely diner around there.

That's prefect! Thanks!

It's my pleasure.

Figure 1: An example of DST. Given the schemata for all domains, the slot values are extracted from the user and system utterances (e.g., spans highlighted with the same color in the figure). The dialogue state of each turn is represented as a set of slot-value pairs. Among the domains and slots, there are prior slot-domain membership relations which are expressed in the predefined schemata, and also dialogue-aware dynamic slot relations which depend on the dialogue context (e.g., co-reference, co-update, and co-occurrence).

Many models have been developed for DST due to its importance in task-oriented dialogue systems. Traditional approaches use deep neural networks or pre-trained language models to encode the dialogue context and infer slot values from it (Zhong et al., 2018; Ramadan et al., 2018; Wu et al., 2019; Ren et al., 2019; Zhang et al., 2020a; Hu et al., 2020; Gao et al., 2020; Zhang et al., 2020a,b). These models predict slot values without considering the relations among domains and slots. However, domains and slots in a dialogue are unlikely to be entirely independent, and ignoring the relations among domains and slots may lead to sub-optimal perfor-

Volume 1: Long Papers, pages 115 - 126

mance. To address this issue, several recent works have been proposed to model the relations among domains and slots in DST. Some of them introduce predefined schema graphs to incorporate prior slot-domain membership relations, which are defined based on human experience in advance (Chen et al., 2020; Zhu et al., 2020). The others use an attention mechanism to capture dialogue-aware dynamic slot relations (Feng et al., 2021; Heck et al., 2020). The dialogue-aware dynamic relations are the logical relations of slots across domains, which are highly related to specific dialogue contexts.

However, existing DST models that involve the relations among domains and slots suffer from two major issues: (1) They fail to fuse the prior slot-domain membership relations and dialogue-aware dynamic slot relations explicitly; and (2) They fail to consider their generalizability to new domains. In practical scenarios, task-oriented dialogue systems need to support a large and constantly increasing number of new domains.

To tackle these issues, we propose a novel approach named DSGFNet (Dynamic Schema Graph Fusion Network). For the first issue, DSGFNet dynamically updates the schema graph consisting of the predefined slot-domain membership relations with the dialogue-aware dynamic slot relations. To incorporate the dialogue-aware dynamic slot relations explicitly, DSGFNet adds three new edge types to the schema graph: *co-reference relations*, *co-update relations*, and *co-occurrence relations*. For the second issue, to improve its generalizability, DSGFNet employs a unified model containing schema-agnostic parameters to make predictions.

Specifically, our proposed DSGFNet comprises of four components: a *BERT-based dialogue utterance encoder* to contextualize the current turn dialogue context and history, a *BERT-based schema graph encoder* to generalize to unseen domains and model the prior slot-domain membership relations on the schema graph, a *dialogue-aware schema graph evolving network* to augment the dialogue-aware dynamic slot relations on the schema graph, and a *schema graph enhanced dialogue state decoder* to extract value spans from the candidate elements considering the evolved schema graph.

The contributions of this paper can be summarized as follows:

- We improve DST by proposing a dynamic, explainable, and general schema graph which explicitly models the relations among domains and slots based on both prior knowledge and the dialogue context, no matter whether the domains and slots are seen or not.
- We develop a fusion network, DSGFNet, which effectively enhances DST generating a schema graph out of the combination of prior slot-domain membership relations and dialogue-aware dynamic slot relations.
- We conduct extensive experiments on three benchmark datasets (i.e., SGD, MultiWOZ2.1, and MultiWOZ2.2) to demonstrate the superiority of DSGFNet[1] and the importance of the relations among domains and slots in DST.

2 Related Work

Recent DST approaches mainly focus on encoding the dialogue contexts with deep neural networks (e.g., convolutional and recurrent networks) and inferring the values of slots independently (Zhong et al., 2018; Ramadan et al., 2018; Wu et al., 2019; Ren et al., 2019; Zhang et al., 2020a; Hu et al., 2020; Gao et al., 2020). With the prevalence of pre-trained language models, such as BERT (Devlin et al., 2019) and GPT-2 (Radford et al., 2019), a great variety of DST approaches have been developed on top of these pre-trained models (Zhang et al., 2020a,b; Lin et al., 2020). The relations among domains and slots are not considered in the above approaches. However, the prior slot-domain membership relations can facilitate the sharing of domain knowledge and the dialogue-aware dynamic slot relations can conduce dialogue history understanding. Ignoring these relations may lead to sub-optimal performance.

To fill in this gap, several new DST approaches, which involve the relations among domains and slots, have been proposed. Some of them leverage a graph structure to capture the slot-domain membership relations (Lin et al., 2021; Chen et al., 2020; Zhu et al., 2020; Zeng and Nie, 2020; Ouyang et al., 2020). Specifically, a predefined schema graph is employed to represent the slot-domain membership relations. However, they fail to incorporate the dialogue-aware dynamic slot relations into the schema graph. The other approaches utilize the attention mechanism to learn dialogue-aware dynamic slot relation features in order to facilitate information flow among slots (Zhou and Small, 2019;

---

[1] The code is available at `https://github.com/sweetalyssum/DSGFNet`.

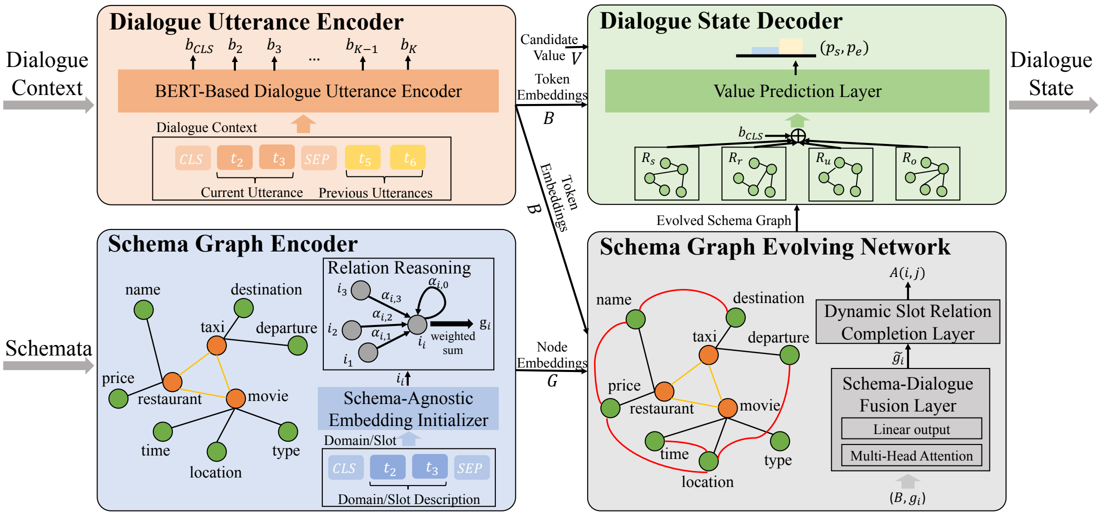

Figure 2: The architecture of DSGFNet, which contains a dialogue utterance encoder, a schema graph encoder, a schema graph evolving network, and a dialogue state decoder.

Feng et al., 2021; Heck et al., 2020; Hu et al., 2020; Ye et al., 2021). However, these approaches ignore the slot-domain membership relations defined by prior knowledge. Since both the prior slot-domain membership relations and dialogue-aware dynamic slot relations can enhance DST performance, our approach is developed to combine them in an effective way.

Given that a deployed dialogue system may encounter an ever-increasing number of new domains that have limited training data available, the DST module should be capable of generalizing to unseen domains. Recent DST approaches have focused on using zero-shot learning to achieve this goal (Rastogi et al., 2020; Noroozi et al., 2020). These approaches exploit the natural language descriptions of schemata to transfer knowledge across domains. However, they ignore the relations among domains and slots. In this work, we propose a unified framework to fuse the prior slot-domain membership relations and dialogue-aware dynamic slot relations, no matter whether the domains are seen or not.

3 Dynamic Schema Graph Fusion Network

The proposed DSGFNet consists of four components: (1) a *BERT-based dialogue utterance encoder* that aims to contextualize the tokens of the current turn and the dialogue history; (2) a *schema graph encoder* that is able to generalize to unseen domains and shares information among predefined slot-domain membership relations; (3) a *dialogue-aware schema graph evolving network* that adds the dialogue-aware dynamic slot relations into the schema graph; and (4) a *schema graph enhanced dialogue state decoder* that extracts the value span from the candidate elements based on the evolved schema graph. Figure 2 illustrates the architecture.

3.1 Dialogue Utterance Encoder

This encoder takes as input the current and previous dialogue utterances. Specifically, the input is a sequence of tokens with length K, i.e., $[t_1, ..., t_K]$. Here, we set the first token t_1 to `[CLS]`; subsequent are the tokens in the current dialogue utterance and the ones in the previous dialogue utterances, which are separated by `[SEP]`. We employ BERT (Devlin et al., 2019) to obtain contextual token embeddings. The output is a tensor of all the token embeddings $\boldsymbol{B} = [\boldsymbol{b}_1, ..., \boldsymbol{b}_K]$, with one embedding for each token.

3.2 Schema Graph Encoder

To make use of the slot-domain membership relations defined by prior domain knowledge, we construct a schema graph based on the predefined ontology. An example is shown in Figure 2. In this schema graph, each node represents either a domain or a slot, and all the slot nodes are connected to their corresponding domain nodes. In order to allow information propagation across domains, all the domain nodes are connected with each other.

Schema-Agnostic Embedding Initializer. To generalize to unseen domains, DSGFNet initializes the schema graph node embeddings via a schema-agnostic projection. Inspired by zero-shot learning (Romera-Paredes and Torr, 2015), we propose a schema-agnostic embedding initializer to project schemata across domains into a unified semantic distribution. Specifically, we feed a natural language description of one slot/domain into BERT, using the output of `[CLS]` as the semantic embeddings for this slot/domain. The semantic embeddings for the set of slot and domain is $\boldsymbol{I} = [\boldsymbol{i}_1, ..., \boldsymbol{i}_{N+M}]$, where N and M are the number of slots and domains, respectively. We constrain the schema embedding initializer not to have any domain-specific parameters so that it can generalize to unseen domains.

Slot-Domain Membership Relation Reasoning Network. To involve the prior slot-domain membership relations into the schema graph node embeddings, DSGFNet propagates information among slots and domains over the schema graph. We add a self-loop to each node because the nodes need to propagate information to themselves. Inspired by the GAT model (Veličković et al., 2018), we propose a slot-domain membership relation reasoning network to propagate information over the schema graph. For each node, we first compute attention scores $\boldsymbol{\alpha}$ for its neighbours. These attention scores are used to weigh the importance of each neighboring node. Formally, the attention scores are calculated as follows:

$$h_{i,j} = \text{ReLU}(\mathbf{W}^\top \cdot [\boldsymbol{i}_i, \boldsymbol{i}_j]), \tag{1}$$

$$\alpha_{i,j} = \frac{\exp(h_{i,j})}{\sum_{k \in \mathcal{N}_i} \exp(h_{i,k})}, \tag{2}$$

where $\mathbf{W}$ is a matrix of parameters and $\mathcal{N}_i$ is the neighborhood of the i-th node. The normalized attention coefficients and the activation function are used to compute a non-linear weighted combination of the neighbours. This is used to compute the tensor of the schema graph node embeddings $\boldsymbol{G} = (\boldsymbol{g}_1, ..., \boldsymbol{g}_{N+M})$:

$$\boldsymbol{g}_i = \text{ReLU}\left(\sum_{j \in \mathcal{N}_i} \alpha_{i,j} \cdot \boldsymbol{i}_j\right), \tag{3}$$

where $i \in \{1, \ldots, N+M\}$. To explore the higher-order connectivity information of slots across domains, we stack l layers of the reasoning network. Each layer takes the node embeddings from the previous layer as input, and outputs the updated node embeddings to the next layer.

3.3 Schema Graph Evolving Network

We propose a schema graph evolving network to incorporate the dialogue-aware dynamic slot relations into the schema graph, which is composed of two layers, a schema-dialogue fusion layer and a dynamic slot relation completion layer.

Schema-Dialogue Fusion Layer. Since the dynamic slot relations are related to the dialogue context, we need to fuse the dialogue context information into the schema graph. We adopt the multi-head attention (Vaswani et al., 2017) to achieve this goal. The mathematical formulation is:

$$\boldsymbol{H} = \text{MultiHead}(\text{Q} = \boldsymbol{g_i}, \text{K} = \boldsymbol{B}, \text{V} = \boldsymbol{B}), \tag{4}$$

$$\tilde{\boldsymbol{g}}_i = \boldsymbol{H} \cdot \boldsymbol{W}_a, \tag{5}$$

where $\boldsymbol{W}_a$ is learnable parameters of a linear projection after the multi-head attention, and $\tilde{\boldsymbol{g}}_i$ is the dialogue-aware schema graph node embeddings.

Dynamic Slot Relation Completion Layer. This layer aims to augment the dynamic slot relations on the schema graph based on the dialogue-aware node embeddings. To involve the dialogue-aware dynamic slot relations into DST explicitly, DSGFNet defines three types of dynamic slot relations: (1) Co-reference relations occur when a slot value has been mentioned earlier in the dialogue and has been assigned to another slot; (2) Co-update relations occur when slot values are updated together at the same dialogue turn, and; (3) Co-occurrence relations occur when slots with a high co-occurrence probability in a large dialogue corpus appear together in the current dialogue. Specifically, we feed the dialogue-aware slot node representations into a multi-layer perceptron followed by a 4-way softmax function to identify the relations between slot pairs, which include the *none* relation and the three dynamic relations mentioned above. Formally, given the i-th and j-th dialogue-aware slot node embeddings $\tilde{\boldsymbol{g}}_i$ and $\tilde{\boldsymbol{g}}_j$, we obtain an adjacent matrix of the dynamic slot relations for all slot pairs as follows:

$$\boldsymbol{A}(i,j) = \arg\max\left(\text{softmax}(\text{MLP}(\tilde{\boldsymbol{g}}_i \oplus \tilde{\boldsymbol{g}}_j))\right). \tag{6}$$

With $\boldsymbol{A}$, we add dynamic slot relation edges to the schema graph.

3.4 Dialogue State Decoder

To decode the slot values by means of incorporating the slot-domain membership relations and dialogue-aware dynamic slot relations which are captured by the evolved schema graph, we propose a schema graph enhanced dialogue state decoder.

To learn a more comprehensive slot node embedding, we need to fuse multiple relations on the evolved schema graph. DSGFNet divides different relations on the schema graph into sub-graphs R_s, R_r, R_u, R_o, which represent slot-domain membership relation, co-reference relation, co-update relation, and co-occurrence relation, respectively. For each sub-graph R_i, its node embeddings $\boldsymbol{s}_i$ are obtained by attending over the neighbors, which is the same as the method used in Section 3.2. Considering that different relation types have different contributions to the node interactions for different dialogue contexts (Wang et al., 2019), we aggregate these different sub-graphs via an attention mechanism as follows:

$$\boldsymbol{S} = [\boldsymbol{s}_s; \boldsymbol{s}_r; \boldsymbol{s}_u; \boldsymbol{s}_o], \tag{7}$$

$$\boldsymbol{\beta} = \text{softmax}(\boldsymbol{S}^\top \cdot \tanh(\boldsymbol{W}_s \cdot \boldsymbol{b}_{[CLS]} + \boldsymbol{b}_s)), \tag{8}$$

$$\boldsymbol{s} = \boldsymbol{S} \cdot \boldsymbol{\beta}, \tag{9}$$

where $\boldsymbol{W}_s$, $\boldsymbol{b}_s$ are learnable weights, $\boldsymbol{b}_{[CLS]}$ is the output of BERT-based dialogue utterance encoder.

Each slot value is extracted by a value predictor based on the corresponding fused slot node embeddings $\boldsymbol{s}$. The value predictor is a trainable nonlinear classifier followed by two parallel softmax layers to predict start and end positions in candidate elements $\boldsymbol{C}$, which are composed by the dialogue context $\boldsymbol{B}$ and slots' candidate value vocabulary $\boldsymbol{V}$:

$$\boldsymbol{C} = [\boldsymbol{B}; \boldsymbol{V}] \tag{10}$$

$$[\boldsymbol{l}_s, \boldsymbol{l}_e] = \boldsymbol{r}_d \cdot \tanh(\boldsymbol{s}^\top \cdot \boldsymbol{W}_d \cdot \boldsymbol{C} + \boldsymbol{b}_d), \tag{11}$$

$$p_s = \text{softmax}(\boldsymbol{l}_s), \tag{12}$$

$$p_e = \text{softmax}(\boldsymbol{l}_e), \tag{13}$$

where $\boldsymbol{r}_d$, $\boldsymbol{W}_d$, and $\boldsymbol{b}_d$ are trainable parameters. Note that if the end position is before the start position, the resulting span will simply be "None". If the start position is in the slots' candidate value vocabulary, the resulting span will only pick the candidate value in this position.

3.5 Training and Inference

During training, we use ground truth dynamic slot relation graph to optimize the dialogue state decoder. Cross-entropy between predicted value span $[p_s, p_e]$ and ground truth value span is utilized to measure the loss of the value span prediction $\mathcal{L}_s$. The dynamic slot relation identifier is optimized by the cross-entropy loss $\mathcal{L}_r$ between predicted dynamic relation $\boldsymbol{A}$ and the ground truth dynamic slot relation. We train dialogue state decoder and dynamic slot relation identifier together, the joint loss $\mathcal{L}$ is computed as follows:

$$\mathcal{L} = \lambda \cdot \mathcal{L}_r + (1 - \lambda) \cdot \mathcal{L}_s, \tag{14}$$

where $\lambda \in [0, 1]$ is a balance coefficient. During inference, the predicted dynamic slot relation $\boldsymbol{A}$ is used to predict value span as dialogue state.

4 Experiments

4.1 Datasets

We conduct experiments on three task-oriented dialogue benchmark datasets: SGD (Rastogi et al., 2020), MultiWOZ2.2 (Zang et al., 2020), and MultiWOZ2.1 (Eric et al., 2020). Among them, SGD is by far the most challenging dataset which contains over 16,000 conversations between a human-user and a virtual assistant across 16 domains. Unlike the other two datasets, it also includes unseen domains in the test set. MultiWOZ2.2 and MultiWOZ2.1 are smaller human-human conversations benchmark datasets, which contain over 8,000 multi-turn dialogues across 8 and 7 domains, respectively. MultiWOZ2.2 is a revised version of MultiWOZ2.1, which is re-annotated with a different set of annotators and also canonicalized entity names. Details of datasets are provided in Table 1.

Table 1: Characteristics of the datasets in experiments. The numbers provided are for the training sets of the corresponding datasets.

Characteristics	**SGD**	**MultiWOZ2.2**	**MultiWOZ2.1**
No. of domains	16	8	7
No. of dialogues	16,142	8,438	8,438
Total no. of turns	329,964	113,556	113,556
Avg. turns per dialogue	20.44	13.46	13.46
Avg. tokens per turn	9.75	13.13	13.38
No. of slots	215	61	37
Unseen domains in test set	Yes	No	No

4.2 Baselines

We compare with the following existing models, which are divided into two categories. (1) Models that can predict dialogue state on unseen domains: *SGD-baseline* (Rastogi et al., 2020), a schema-guided paradigm that predicts states for unseen domains; *FastSGT* (Noroozi et al., 2020), a BERT-based model that uses multi-head attention projections to analyze dialogue; *Seq2Seq-DU* (Feng et al., 2021), a sequence-to-sequence framework which decodes dialogue states in a flatten format. (2) Models that cannot predict dialogue state on unseen domains: *TRADE* (Wu et al., 2019), a generation model which generates dialogue states from utterances using a copy mechanism; *DS-DST* (Zhang et al., 2020a), a dual strategy that classifies over a picklist or finding values from a slot span; *TripPy* (Heck et al., 2020), an open-vocabulary model which copies values from dialogue context, or slot values in previous dialogue state; *SOM-DST* (Kim et al., 2020), a selectively overwriting mechanism which first predicts state operation on each of the slots and then overwrites with new values; *MinTL-BART* (Lin et al., 2020), a plug-and-play pre-trained model which jointly learns dialogue state tracking and dialogue response generation; *SST* (Chen et al., 2020), a graph model which fuses information from utterances and static schema graph; *PPTOD* (Su et al., 2021), a multi-task pre-training strategy that allows the model to learn the primary TOD task completion skills from heterogeneous dialog corpora.

4.3 Evaluation Measures

Our evaluation metrics are consistent with prior works on these datasets. We compute the Joint Goal Accuracy (Joint GA) on all test sets for straightforward comparison with the state-of-the-art methods. Joint GA is defined as the ratio of dialogue turns for which all slots have been filled with the correct values according to the ground truth.

4.4 Training

We use BERT model (i.e., BERT-base and uncased) to encode utterances and schema descriptions. The BERT models are fine-tuned in the training process. The maximum length of an input sequence is set to 512. The hidden size of the schema graph encoder and the schema graph evolving network is set to 256. The dropout probability is 0.3. The balance coefficient λ is 0.5. Adam (Kingma and Ba, 2014) is used for optimization with an initial learning rate (LR) of 2e-5. We conduct training with a warm-up proportion of 10% and let the LR decay linearly after the warm-up phase.

5 Results and Discussion

Tables 2, 3, 4 show the performance of DSGFNet as well as the baselines on three datasets respectively. It is shown that DSGFNet achieves state-of-the-art performance in unseen domains on SGD, all domains on SGD, and MultiWOZ2.2. All improvements observed compared to the baselines are statistically significant according to two sided paired t-test (p ¡ 0.05). And the performance on MultiWOZ2.1 are comparable with the state-of-the-art[2]. Most notably, DSGFNet improves the performance on SGD most significantly, which has unseen domains and more complex schemata domains, compared to the runner-up. It indicates that DSGFNet can facilitate knowledge transfer to new domains and improve relation construction among complex schemata domains. We conjecture that it is due to DSGFNet containing the schema-agnostic encoder and dynamic schema graph. The following analysis provides a better understanding of our model's strengths.

Table 2: Joint GA of DSGFNet and baselines in unseen domains and all domains on SGD dataset. DSGFNet significantly improves over the best baseline (two-sided paired t-test, $p < 0.05$).

Models	**SGD Unseen Domains**	**SGD All Domains**
SGD-baseline (Rastogi et al., 2020)	20.0%	25.4%
FastSGT (Noroozi et al., 2020)	20.8%	29.2%
Seq2Seq-DU (Feng et al., 2021)	23.5%	30.1%
DSGFNet	**24.4%**	**32.1%**

Table 3: Joint GA of DSGFNet and baselines on MultiWOZ2.2. DSGFNet significantly improves over the best baseline (two-sided paired t-test, $p < 0.05$).

Model	**MultiWOZ2.2**
SGD-baseline (Rastogi et al., 2020)	42.0%
TRADE (Wu et al., 2019)	45.4%
DS-DST (Zhang et al., 2020a)	51.7%
TripPy (Heck et al., 2020)	53.5%
Seq2Seq-DU (Feng et al., 2021)	54.4%
DSGFNet	**55.8%**

Table 4: Joint GA of DSGFNet and baselines on MultiWOZ2.1. DSGFNet achieves comparable performance of the best baseline.

Model	**MultiWOZ2.1**
SGD-baseline (Rastogi et al., 2020)	43.4%
TRADE (Wu et al., 2019)	46.0%
DS-DST (Zhang et al., 2020a)	51.2%
SOM-DST (Kim et al., 2020)	53.0%
MinTL-BART (Lin et al., 2020)	53.6%
SST (Chen et al., 2020)	55.2%
TripPy (Heck et al., 2020)	55.3%
PPTOD (Su et al., 2021)	**57.1%**
DSGFNet	56.7%

---

[2] TRADE, SST use the original MultiWOZ datasets. The other models use the data preprocessed by TripPy.

Table 5: Ablation study on unseen domains of SGD, all domains of SGD, MultiWOZ2.2 and MultiWOZ2.1.

Model	Joint GA Unseen Domains SGD	Joint GA All Domains SGD	Joint GA MultiWOZ 2.2	Joint GA MultiWOZ 2.1
DSGFNet	24.4%	32.1%	55.8%	56.7%
-w/o Slot-Domain Membership Relations	21.9%	29.8%	53.4%	54.1%
-w/o Dynamic Slot Relations	20.6%	28.6%	52.2%	53.2%
-w/o Relation Aggregation	23.8%	31.5%	55.2%	55.9%

5.1 Ablation Study

We conduct an ablation study on DSGFNet to quantify the contributions of various factors: the usage of slot-domain membership relations, dynamic slot relations, and multiple relation aggregation. The results indicate that the dynamic schema graph of DSGFNet is indispensable for DST.

Effect of Slot-Domain Membership Relations

To check the effectiveness of the slot-domain membership relations, we remove the schema graph by replacing the prior slot-domain relation adjacency matrix with an identity matrix $\boldsymbol{I}$. Results in Table 5 show that the joint goal accuracy of DSGFNet without the slot-domain membership relations decreases markedly on unseen domains of SGD, all domains of SGD, MultiWOZ2.2, and MultiWOZ2.1. It indicates the schema graph, which contains slot-domain membership relations, can facilitate knowledge sharing among domain and slot no matter whether the domain is seen or not.

Effect of Dynamic Slot Relations

To investigate the effectiveness of the dialogue-aware dynamic slot relations in the schema graph, we eliminate the evolving network of DSGFNet. Table 5 shows the results on unseen domains of SGD, all domains of SGD, MultiWOZ2.2, and MultiWOZ2.1 in terms of joint goal accuracy. One can observe that without the dynamic slot relations the performance deteriorates considerably. In addition, there is a more markedly performance degradation compared with the results of the slot-domain membership relations. It indicates that the dynamic slot relations are more essential for DST, which can facilitate the understanding of the dialogue context.

Effect of Multiple Relation Aggregation

To validate the effectiveness of the schema graph relation aggregation mechanism in the dialogue state decoder, we directly concatenate all sub-graph representations instead of calculating a weighted sum via the sub-graph attention. As shown in Table 5, the performance of the models without the relation aggregation layer in terms of joint goal accuracy decreases markedly compared to DSGFNet. It indicates that the attentions to different types of relations affect the dialogue understanding ability.

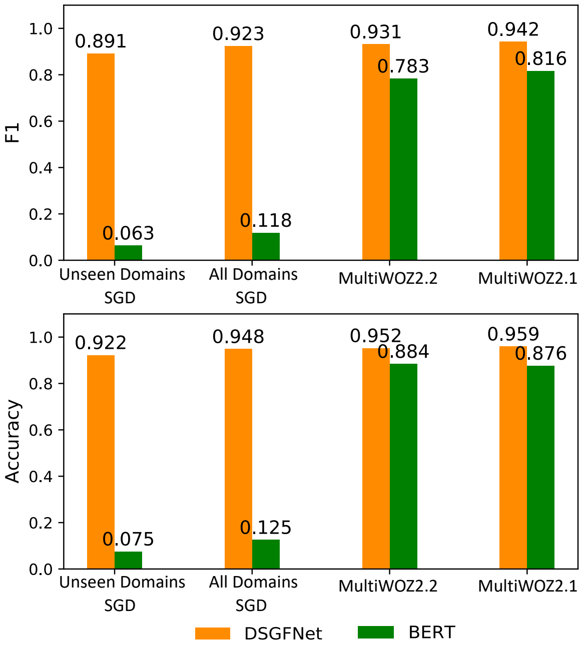

Figure 3: F1 and Accuracy of DSGFNet and BERT for dynamic relation prediction on unseen domains SGD, all domains of SGD, MultiWOZ2.2 and MultiWOZ2.1.

5.2 Further Analysis

Prediction of Dynamic Slot Relations

In order to test the discriminative capability of DSGFNet for dynamic slot relations, we evaluate the performance of the schema graph evolving network. Since baselines cannot predict the dynamic slot relations explicitly, we compare DSGFNet with the BERT-based classification approach. Following the classification task in BERT, the input sequence starts with [CLS], followed by the tokens of the dialogue context and slot pairs, separated by [SEP], and the [CLS] representation is fed into an output layer for classification. Figure 3 shows the results on unseen domains of SGD, all domains of SGD, MultiWOZ2.2, and MultiWOZ2.1 in terms of F1 and Accuracy. From the results, we observe that DSGFNet outperforms BERT significantly. We conjecture that it is due to the exploitation of schema graph with slot-domain membership relations in DSGFNet. In addition, since BERT without schema encoder cannot solve unseen domains, there is a significant performance degradation on SGD which contains a large number of unseen domains in the test set.

Table 6: Case study of DSGFNet and Seq2Seq-DU on SGD. Slot values are extracted from the dialogue context with the same color. The relation of yellow high-light slot pair is predicted as co-reference. The relation of red underline slot pair is predicted as co-update. The relation of bold font slot pair is predicted as co-occurrence. Slot values in red high-light are incorrectly predicted ones.

Dialogue Utterance	[*User*]: What's the weather going to be like in vancouver on March 10th? [*Sys*]: The forecast average is 68 degrees with a 25 per cent chance of rain. [*User*]: Any good attractions in town? [*Sys*]: I have 10 good options including Bloedel Conservatory, a city park. [*User*]: Lovely! Can you book me a ride there? [*Sys*]: Do you want a luxury or pool ride? How many people? [*User*]: Just a regular ride please, book for 1. [*Sys*]: Confirming you want to book a regular cab to Bloedel Conservatory for 1 person.

Table 7: Performance comparison with different dynamic slot relations and fully-connected relations on unseen domains of SGD, all domains of SGD, MultiWOZ2.2 and MultiWOZ2.1.

Model	Joint GA Unseen Domains SGD	Joint GA All Domains SGD	Joint GA MultiWOZ 2.2	Joint GA MultiWOZ 2.1
-w All Dynamic Relations	24.4%	32.1%	55.8%	56.7%
-w Co-reference Relation	21.5%	29.8%	53.9%	54.7%
-w Co-occurrence Relation	23.8%	31.7%	55.3%	55.9%
-w Co-update Relation	22.3%	30.1%	53.5%	54.5%
-w/o Dynamic Relations	20.6%	28.6%	52.2%	53.2%
-w Fully-connected Relations	21.3%	29.9%	54.2%	54.9%

Effects of Each Type of Dynamic Slot Relation

To better illustrate the effectiveness of augmenting slot relations on the schema graph, we study how different dynamic slot relations affect the DST performance. Table 7 presents the joint goal accuracy of DSGFNet with different dynamic relations on unseen domains of SGD, alll domains of SGD, MultiWOZ2.2, and MultiWOZ2.1. One can see that the performance of DSGFNet with each type of dynamic slot relation surpasses that without any dynamic slot relations considerably. Thus, all types of dynamic slot relations in the schema graph are helpful for dialogue understanding. Furthermore, the performance of DSGFNet with co-occurrence relation is superior to the performance with the other two dynamic slot relations. We conjecture that it is due to the fact that a large percentage of dynamic relations is the co-occurrence relation, which has an incredible effect on DST.

Effect of Automatic Relation Completion

To demonstrate the effectiveness of automatically completing each type of slot relations on the schema graphs, we replace four automatically-completed sub-graphs in DSGFNet with four fully-connected graphs. As shown in Table 7, the performance of the model with the fully-connected graphs in terms of joint goal accuracy decreases significantly compared to DSGFNet (two-sided paired t-test, $p < 0.05$). We believe that this is caused by the noise introduced by the redundancy captured by the relations between all pairs of slots. In addition, sampling the relations using our strategy can also reduce the memory requirements when the number of slots and domains are large.

Case Study

We make qualitative analysis on the results of DSGFNet and Seq2seq-DU on SGD. We find that DSGFNet can make a more accurate inference of dialogue states by using the dynamic schema graph. For example, as shown in Table 6, "city"-"location" is predicted as co-reference relation, "city"-"date" and "number of seats"-"ride type" are predicted as co-update relation, "city"-"date" is predicted as co-occurrence relation. Based on the dynamic schema graph, DSGFNet propagates information involving slot-domain membership relations and dynamic slot relations. Thus, it infers slot values more correctly. In contrast, since Seq2seq-DU ignores the dynamic slot relations, it cannot properly infer the values of "location" and "ride type", which have dynamic slot relations with other slots.

6 Conclusion

We have proposed a new approach to DST, referred to as DSGFNet, which effectively fuses prior slot-domain membership relations and dialogue-aware dynamic slot relations on the schema graph. To incorporate the dialogue-aware dynamic slot relations into DST explicitly, DSGFNet identifies co-reference, co-update, and co-occurrence relations. To improve the generalization ability, DSGFNet employs a schema-agnostic graph attention network to share information. Experimental results show that DSGFNet outperforms the existing methods in DST on three benchmark datasets, including unseen domains of SGD, all domains of SGD, MultiWOZ2.1, and MultiWOZ2.2. For future work, we intend to further enhance our approach by utilizing more complex schemata and data augmentation techniques.

A Dynamic Slot Relations Label Collection

Dynamic schema graph in DSGFNet has three types of dynamic slot relations, which includes co-reference relations, co-update relations and co-occurrence relations. The labels of these relations are used to train the schema graph evolving network. We first collected all possible slot pairs from ground truth dialogue state for each dialogue turn. And then we labeled these slot pairs by the rules as follows: (1) If one slot value has been assigned to another slot in earlier turn of the dialogue, we label the relation between these two slots as co-reference. (2) If values of two slot in the same dialogue turn are updated together, we label the relation between these two slots as co-update. (3) If the co-occurrence probability of two slots in the training set of SGD, MultiWOZ2.1, and MultiWOZ2.2 is higher than 5%, we label the relation between these two slots as co-occurrence. Table 8 shows the the proportion of different types of dynamic slot relations on these datasets.

Table 8: The proportion of different types of dynamic slot relations on SGD, MultiWOZ2.2, and MultiWOZ2.1 in training sets.

Relation	**SGD**	**MultiWOZ2.2**	**MultiWOZ2.1**
Co-reference	5.11%	4.21%	4.29%
Co-update	9.31%	4.01%	4.13%
Co-occurrence	31.13%	37.53%	36.53%

Table 9: Accuracy of DSGFNet in each domain on SGD test set. Domains marked with '*' are those for which the schemata in the test set are not present in the training set. Domains marked with '**' have both the unseen and seen schemata. For other domains, the schemata in the test set are also seen in the training set.

Domain	**Joint GA**	**Domain**	**Joint GA**
*RentalCars**	5.11%	*Homes*	22.46%
*Messaging**	5.48%	*Events**	32.02%
*Payment**	7.31%	*Hotels***	33.13%
*Music**	11.87%	*Movies***	42.13%
*Buses**	12.72%	*Services***	45.39%
*Trains**	16.39%	*Travel*	48.30%
*Flights**	16.64%	*Alarm**	53.27%
*Restaurants**	17.01%	*RideSharing*	56.42%
*Media**	20.83%	*Weather*	68.49%

B Performance on Different Domains

We further investigate the performance of DSGFNet on different domains. Table 9 shows the joint goal accuracy of DSGFNet in different domains on SGD. We observe that the presence of schemata in the training data is the major factor affecting the performance. We see that the best performance can be obtained in the domains with all seen schemata. The domains which have partially unseen schemata achieve higher accuracy, such as "Hotels", "Movies", and "Services" domains. The accuracy declines in the domains with only unseen schemata, such as "RentalCars" and "Messaging". However, among the domains with only unseen schemata, those have similar schemata to training data resulting in superior performance, such as "Alarm" and "Events" domains. We conclude that DSGFNet is able to perform zero-shot learning and share knowledge across domains. However, more sharing of information should be utilized to enhance the generalization ability.

C Analysis of Parameters in DSGFNet

We further investigate the impacts of parameter settings on the performance of DSGFNet on SGD, MultiWOZ2.2, and MultiWOZ2.1. We validate the effects of four factors: the layer of propagation on the schema graph, the number of selected dialogue turns used in the schema-dialogue fusion layer, the layer of MLP in the dynamic slot relation completion layer, and the balance coefficient λ in the loss function. Figures 4, 5, 6, 7 show the results of DSGFNet with varying parameters on SGD, MultiWOZ2.2, and MultiWOZ2.1 in terms of joint goal accuracy. We observe that the optimal layer of propagation is not consistent across datasets. It seems that 3 is desired in more datasets. In addition, DSGFNet demonstrates the best performance when leveraging full dialogue history. We conjecture that it is due to that the incomplete dialogue history leads to confusing information. Moreover, 8 layers MLP for relation completion obtains the optimal performance over three datasets. Furthermore, the optimal performance is consistently achieved when the balance coefficient λ is around 0.5.

Attention Temperature Matters in Abstractive Summarization Distillation

Abstract

Recent progress of abstractive text summarization largely relies on large pre-trained sequence-to-sequence Transformer models, which are computationally expensive. This paper aims to distill these large models into smaller ones for faster inference and with minimal performance loss. Pseudo-labeling based methods are popular in sequence-to-sequence model distillation. In this paper, we find simply manipulating attention temperatures in Transformers can make pseudo labels easier to learn for student models. Our experiments on three summarization datasets show our proposed method consistently improves vanilla pseudo-labeling based methods. Further empirical analysis shows that both pseudo labels and summaries produced by our students are shorter and more abstractive. Our code is available at `https://github.com/Shengqiang-Zhang/plate`.

1 Introduction

Automatic document summarization is the task of rewriting a long document into its shorter form while still retaining its most important content. In the literature, there are mainly two kinds of methods for summarization: *extractive summarization* and *abstractive summarization* (Nenkova and McKeown, 2011). In this work, we focus on abstractive summarization, which is viewed as a sequence-to-sequence (Seq2Seq) learning problem, since recent abstractive models outperform their extractive counterparts and can produce more concise summaries (Raffel et al., 2020; Lewis et al., 2020; Zhang et al., 2020; Liu and Lapata, 2019). Recent progress of abstractive summarization largely relies on large pre-trained Transformer models (Raffel et al., 2020; Lewis et al., 2020; Zhang et al., 2020; Liu and Lapata, 2019; Bao et al., 2020). With these extremely large models, we can obtain state-of-the-art summarization results, but they are slow for online inference, which makes them difficult to be used in the production environment even with cutting-edge hardware. This paper aims to distill these large Transformer summarization models into smaller ones with minimal loss in performance.

Knowledge distillation is a class of methods that leverage the output of a (large) teacher model to guide the training of a (small) student model. In classification tasks, it is typically done by minimizing the distance between the teacher and student predictions (Hinton et al., 2015). As to Seq2Seq models, an effective distillation method is called pseudo-labeling (Kim and Rush, 2016), where the teacher model generates pseudo summaries for all documents in the training set and the resulting document–*pseudo*-summary pairs are used to train the student model.

In this paper, we argue that attention distributions of a Seq2Seq teacher model might be too sharp. As a result, pseudo labels generated from it are sub-optimal for student models. In the summarization task, we observe that 1) pseudo summaries generated from our teacher model copy more continuous text spans from original documents than reference summaries (56% 4-grams in pseudo summaries and 15% 4-grams in reference summaries are copied from their original documents on CNN/DailyMail dataset); 2) pseudo summaries tend to summarize the leading part of a document (measured on CNN/DailyMail, 74% of sentences in pseudo summaries and 64% of sentences in reference summaries are from the leading 40% sentences in original documents). We obtain the two numbers above by matching each sentence in a summary with the sentence in its original document that can produce maximum ROUGE (Lin, 2004) score between them. We call the two biases above the *copy bias* and the *leading bias*. In order to have an intuitive feeling, we select a rep-

resentative example [1] and visualize its cross attention weights [2] (see the left graph in Figure 1). We observe that attention weights form three "lines", which indicates very time the decoder predicts the next word, its attention points to the next word in the input document. That may be the reason why multiple continuous spans of text are copied. Another phenomenon we observe is that all *high-value* attention weights (in deeper color) concentrate on the first 200 words in the input document, which reflects the leading bias. In either case, the attention distribution is too sharp (i.e., attention weights of the next word position or the leading part is much larger than other positions), which means our teacher model is over-confident.

Based on the observations above, we propose a simple method called PLATE (as shorthand for **P**seudo-labeling with **L**arger **A**ttention **TE**mperature) to smooth attention distributions of teacher models. Specifically, we re-scale attention weights in all attention modules with a higher temperature, which leads to *softer* attention distributions. Figure 1 intuitively shows the effect of using higher attention temperatures. Compared with the left graph, the right graph with higher attention temperature has shorter lines (less copy bias) with high attention weights, and positions of high attention weights extend to the first 450 words (less leading bias). Less *copy bias* in pseudo summaries encourages student models to be more abstractive, while less *leading bias* in pseudo summaries encourages student models to take advantage of longer context in documents.

Experiments on CNN/DailyMail, XSum, and New York Times datasets with student models of different sizes show PLATE consistently outperforms vanilla pseudo-labeling methods. Further empirical analysis shows that, with PLATE, both pseudo summaries generated by teacher models and summaries generated by student models are shorter and more abstractive, which matches the goal of abstractive summarization.

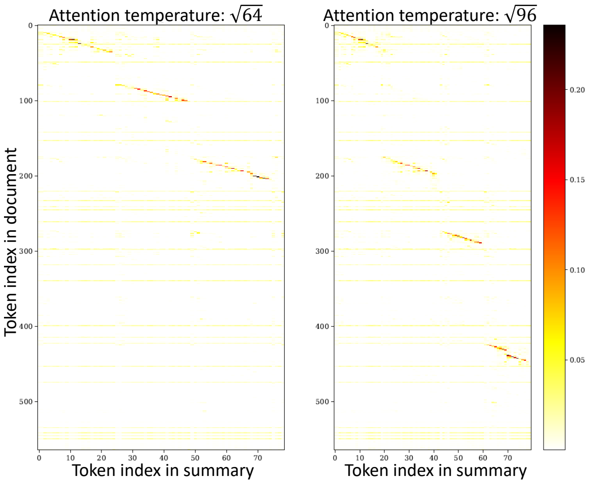

Figure 1: Visualization of teacher cross attention weights when generating pseudo labels with normal (left) and smoothed (right) attention weights. This example is generated by the BART teacher trained on CNNDM (see §4.4). Its training and inference hyperparameters are described in detail in §4.2.

2 Related Work

Large pre-trained Seq2Seq Transformer models largely improve results of generation tasks including text summarization (Song et al., 2019; Lewis et al., 2020; Bao et al., 2020; Raffel et al., 2020; Zhang et al., 2020). These models are pre-trained using unsupervised text-to-text objectives. For example, T5 (Raffel et al., 2020) is pre-trained by predicting corrupted text spans. BART (Lewis et al., 2020) employs denoising auto-encoding objectives such as text infilling and sentence permutation during its pre-training. The pre-training objective of PEGASUS (Zhang et al., 2020) is tailored for the summarization task, which predicts the most "summary worthy" sentences in a document. Our method aims to make these large models faster.

In knowledge distillation, besides learning from gold labels in the training set, student models can learn from soft targets (Ba and Caruana, 2014; Hinton et al., 2015), intermediate hidden states (Romero et al., 2014), attentions (Zagoruyko and Komodakis, 2017; Wang et al., 2020), and target output derivatives (Czarnecki et al., 2017) of teacher models. Recent work for distillation of pre-trained Transformers (e.g., DistilBERT (Sanh et al., 2019), TinyBERT (Jiao et al., 2020), MobileBERT (Sun et al., 2020), BERT-of-Theseus (Xu et al., 2020a), MINILM (Wang et al., 2020)) focuses on natural language understanding tasks such as GLUE (Wang et al., 2018) or SQuAD (Rajpurkar et al., 2016) benchmarks. Most methods above are designed for classification models.

In Seq2Seq learning tasks such as summarization, we can apply distillation methods above to each step of sequence model predictions. However, the sequence-level knowledge of teacher mod-

---

[1] See the detailed example in Appendix E.

[2] We use cross attention because we can see how words in documents are selected during generation.

els is not well utilized. Therefore, Kim and Rush (2016) introduce a sequence-level knowledge distillation method (i.e., *pseudo-labeling*), where a student model is trained with pseudo labels generated by the teacher model using beam search decoding. Kim and Rush (2016) and later work (Kasai et al., 2020; Gu et al., 2017; Denkowski and Neubig, 2017) show *pseudo-labeling* achieves competitive performance for Seq2Seq tasks such as machine translation. Shleifer and Rush (2020) propose the *shrink and fine-tune* (SFT) approach for pre-trained summarization distillation, which re-finetunes a teacher model with some layers removed, and they show SFT outperforms *pseudo-labeling* and a modification of direct knowledge distillation (Jiao et al., 2020) on one of their datasets, but not others. Our method, which builds on top of *pseudo-labeling*, is conceptually simple and improves *pseudo-labeling* across different summarization datasets.

There is an interesting line of work called self-distillation or self-training (Furlanello et al., 2018; Xie et al., 2020; Deng et al., 2009; Liu et al., 2020; He et al., 2019), where the size of the student model is identical to the size of the teacher model. Our method can also be applied in self-distillation and can potentially be combined with the self-distillation methods above.

3 Summarization Distillation

3.1 Transformer based abstractive summarization

Abstractive summarization aims to rewrite a document into its shorter form (i.e., summary), which is a typical Seq2Seq learning problem. We adopt the Seq2Seq Transformer (Vaswani et al., 2017) model. Given a document $X = (x_1, x_2, \dots, x_{|X|})$ and its gold summary $Y = (y_1, y_2, \dots, y_{|Y|})$, we estimate the following conditional probability:

$$p(Y|X;\theta) = \prod_{t=1}^{|Y|} p(y_t|y_{<t}, X; \theta) \qquad (1)$$

where θ is the model parameter and $y_{<t}$ stands for all tokens before position t (i.e., $(y_1, y_2, \dots, y_{t-1})$).

The Seq2Seq Transformer model can be trained by minimizing the negative log-likelihood of gold document-summary pairs:

$$\mathcal{L}_{\text{G}}(\theta) = -\frac{1}{|Y|} \log p(Y|X;\theta) \qquad (2)$$

where $|Y|$ is the number of tokens in summary Y.

3.2 Distillation with pseudo labels

Knowledge distillation refers to the task of transferring knowledge of a large teacher model (or a group of large teacher models) into a small student model. As to Seq2Seq learning tasks such as machine translation and summarization, pseudo-labeling based methods are usually used to imitate teacher predictions at the sequence level. Specifically, suppose we have a document X, and $\hat{Y} = (\hat{y}_1, \hat{y}_2, \dots, \hat{y}_{|\hat{Y}|})$ is a *pseudo* summary generated by a teacher model using beam search. The student can be trained by minimizing the negative log-likelihood of document-to-*pseudo*-summary pairs.

$$\mathcal{L}_{\text{PL}}(\theta) = -\frac{1}{|\hat{Y}|} \sum_{t=1}^{|\hat{Y}|} \log p(\hat{y}_t|\hat{y}_{<t}, X; \theta) \qquad (3)$$

Strictly, all possible *pseudo* summaries from X should be taken into account. Unfortunately, the computational cost is prohibitive. We therefore use a single sample $\hat{Y}$ (which takes a large portion of probability mass from the teacher) instead as in Kim and Rush (2016).

3.3 Re-scaling attention temperatures

Both our teacher and student models are Seq2Seq Transformer models. The core part of a Transformer model is the attention module:

$$\text{Attention}(Q, K, V) = \text{softmax}(\frac{QK^T}{\tau})V \qquad (4)$$

where Q, K, V are linear projections of hidden states of a layer and τ is the temperature of the attention module which is usually $\sqrt{d}$ (d is the hidden dimension size of that attention head).

Our distillation method PLATE works as follows. Assume we have a teacher model trained with $\tau = \sqrt{d}$. When the teacher generates pseudo labels with beam search, we use a higher attention temperature and set $\tau = \sqrt{\lambda\, d}$ where $\lambda > 1$ (λ is the attention temperature coefficient). Note that we only change the teacher's attention temperature during inference time. When we train our student model with pseudo labels, we still use a normal temperature (i.e., $\tau = \sqrt{d}$). We find that adjusting the student's attention temperature does not work. Probably because the student can easily adapt to the scaled attention temperature during training.

We find that $\lambda = 1.5$ or $\lambda = 2.0$ usually works well in practice. To encourage teacher models to generate pseudo labels with more diversity, we further propose to use a random λ for each input document ($\lambda \sim U[a,b]$). Note that $U[a,b]$ is a uniform distribution and we typically set $a = 1.0$ and $b = 2.0$.

4 Experiments

4.1 Datasets

We conduct our experiments on three popular document summarization datasets: CNN/DailyMail (Hermann et al., 2015), XSum (Narayan et al., 2018), and New York Times (Sandhaus, 2008). All datasets are tokenized with the GPT-2 tokenizer (Radford et al., 2019), which is based on UTF-8 BPE (Sennrich et al., 2016).

CNNDM The CNN/DailyMail dataset (CNNDM; Hermann et al., 2015) contains online news articles from the CNN and DailyMail websites paired with their associated highlights as reference summaries. We follow the standard pre-processing steps described in See et al. (2017); Liu and Lapata (2019). [3] The resulting numbers of document-summary pairs for training, validation, and test are 287,227, 13,368, and 11,490, respectively.

XSum The XSum dataset is collected by harvesting online articles from the BBC with single sentence summaries, which is professionally written. The summaries are *extremely* abstractive. We use the official splits of Narayan et al. (2018). There are 204,045 articles for training; 11,332 articles for validation; and 11,334 articles for test.

NYT The New York Times dataset (NYT; Sandhaus, 2008) is composed of articles published by New York Times, and the summaries are written by library scientists. After applying the pre-processing procedures described in Durrett et al. (2016); Liu and Lapata (2019), we first obtain 110,540 articles with abstractive summaries. The test set is constructed by including the 9,076 articles published after January 1, 2007. The remaining 100,834 articles are further split into training and validation sets. After removing articles with summaries less than 50 words, we obtain the final dataset with 38,264 articles for training; 4,002 articles for validation; and 3,421 articles for test.

Model	# Param.	Latency (Millisecond)		
		CNNDM	XSum	NYT
`BART`	406M	1975	903	3272
`BART 12-6`	306M	1279	438	1692
`BART 12-3`	255M	924	289	1488
`Transformer`	70M	1028	406	1462

Table 1: Latency (in Milliseconds) on a V100 GPU and number of parameters (million) of our models.

4.2 Implementation details

Teacher/Student model settings We use `BART` Large (Lewis et al., 2020) as our teacher model, which has 12 layers in the encoder and decoder. The hidden size of each layer is 1024, and each layer contains 16 attention heads with a hidden size of 64. We have four kinds of student models. The first three student models are initialized from BART weights (therefore, their hidden sizes are the same as that of BART). All the three students have the 12 layers of BART encoder and differ in the number of decoder layers. They are denoted by `BART 12-6`, `BART 12-3`, and `BART 12-12` with 6, 3, and 12 decoder layers, respectively. For `BART 12-6` (or `BART 12-3`), the decoder is initialized from the first 6 (or 3) layers or the maximally spaced 6 (or 3) layers of `BART` decoder. The fourth student is the Transformer base model (Vaswani et al., 2017), which has 6 layers in each of the encoder and decoder. Each layer has a hidden size of 512 and 8 attention heads. This student is randomly initialized and denoted by `Transformer`. The latency statistics (Milliseconds) and numbers of parameters of above four models are in Table 1.

Training and inference Hyper-parameters for `BART`, `BART 12-6`, `BART 12-3`, and `BART 12-12` are similar. Specifically, all models are optimized using Adam (Kingma and Ba, 2014) with $\beta_1 = 0.9, \beta_2 = 0.999$. Learning rates are tuned on validation sets (choose from 1e-5, 3e-5, 5e-5, 7e-5). We truncate all documents and summaries to 1024 sub-word tokens. We use a batch size of around 80 documents (we limit the max number of tokens on each GPU to 2048) and train our models for 20,000/15,000/6,000 steps with 500 warmup steps for CNNDM, XSum, and NYT, respectively. We also employ a weight decay of 0.01. For `Transformer`, the hyper-parameters of the Adam optimizer is a bit different, and we use $\beta_1 = 0.9, \beta_2 = 0.98$. Learning rates are picked from 1e-4, 3e-4, 5e-4, 7e-4 accord-

---

[3] Scripts are available at `https://github.com/abisee/cnn-dailymail`.

ing to validation sets. The weight decay is set to 0.0001. The warmup step we use is 4000. We train `Transformer` for 100 epochs and select the best model w.r.t. their ROUGE scores on validation sets. For all models above we apply a label smoothing of 0.1 to prevent overfitting (Pereyra et al., 2017).

During inference, as common wisdom, we apply beam search. The beam size, length penalty, and minimal length are 4, 2.0, and 55 on CNNDM; 6, 0.1, and 1 on XSum; and 4, 0.7, and 80 on NYT, respectively. All our models are trained on 8 NVIDIA V100 GPUs. The training is fairly fast. Training on CNNDM with the teacher model (i.e., `BART`) is most time-consuming. It takes about 45 minutes for one epoch, and we need 6 epochs in total.

4.3 Evaluations

We evaluate the quality of different summarization systems using ROUGE. On CNNDM and XSum datasets, we report full-length F1 based ROUGE-1 (R1), ROUGE-2 (R2), and ROUGE-L (RL) scores. Following Durrett et al. (2016); Liu and Lapata (2019), we report limited-length recall based ROUGE-1, ROUGE-2, and ROUGE-L, where generated summaries are truncated to the lengths of gold summaries. All ROUGE scores are computed using the `ROUGE-1.5.5.pl` script[4].

Summaries generated by abstractive models may be ungrammatical or unfaithful to the original document. Additionally, we also measure the quality of generated summaries by eliciting human judgements. We randomly sample 50 documents from the test set of CNNDM. 12 annotators are invited (they are either native English speakers or graduate students with IELTS test score over 6.5). In the evaluation, participants are presented with a document and a list of outputs by different models. First, they are asked to evaluate the summaries on three dimensions: *fluency* (is the summary grammatically correct?), *faithfulness* (is the summary faithful to the original document?), and *coverage* (does the summary coverage important information of the document?). Then, they are asked to rank the summaries from best to worst as a way of determining the overall quality of summaries. Each document is ensured to be annotated by 3 different subjects.

4.4 Results

Our main results are shown in Table 2. The first block includes several recent abstractive summarization models based on large pre-trained Transformers. BERTSUM (Liu and Lapata, 2019) employs BERT (Devlin et al., 2019) as its encoder and uses randomly initialized decoder. T5 (Raffel et al., 2020), PEGASUS (Zhang et al., 2020) and BART (Lewis et al., 2020) are three popular large Seq2Seq Transformer models with different pretraining objectives. Our own fine-tuning version of BART (BART (ours)) is comparable or slightly better than the original reported BART results, and we use it as the teacher model on the three datasets.

The second block presents results of student models. Shleifer and Rush (2020) compare pseudo-labeling (BART-PL), knowledge distillation using both output and intermediate layers (BART-KD) as well as shrink and fine-tuning (BART-SFT) methods. They also use BART as teacher models. Note their settings of student models are `BART 12-6` on CNNDM and `BART 12-3` on XSum.

Results of our `BART 12-3` and `BART 12-6` student models are in the third and fourth block. We present results of students trained with gold labels (Gold) and regular pseudo labels (Regular) as well as pseudo labels with higher and random attention temperatures (PLATE$^{\text{B12-3}}_{\lambda=1.5}$, PLATE$^{\text{B12-3}}_{\lambda=2.0}$ and PLATE$^{\text{B12-3}}_{\text{rnd}}$). PLATE$^{\text{B12-3}}_{\lambda=1.5}$ means that the student uses attention temperature coefficient $\lambda = 1.5$ with architecture setting `BART 12-3`. PLATE$^{\text{B12-3}}_{\text{rnd}}$ means that we use random attention temperature of $\lambda \sim U[1.0, 2.0]$. We observe that using pseudo-labeling methods with higher attention temperatures consistently improves over its counterpart with normal attention temperatures (Regular) across all three datasets, and the differences between them are almost always significant measured with the ROUGE script[5] (see details in Table 2). Interestingly, our student models PLATE$^{\text{B12-3}}_{\lambda=2.0}$ and PLATE$^{\text{B12-6}}_{\lambda=2.0}$ outperform all models in comparison (including student models and even the teacher model) on CNNDM. Our best performing student model PLATE$^{\text{B12-3}}_{\lambda=1.5}$ outperforms BART-PL, BART-SFT, and BART-KD on XSum. Meanwhile, our method is conceptually simpler and can further be combined with their methods with additional train-

Table 2: Results of various models on CNNDM, XSum, and NYT datasets. ROUGE scores on CNNDM and XSum are F1 based; and ROUGE scores on NYT are limited-length recall based. BART (ours) is our own implementation of BART fine-tuning. * indicates the model significantly outperforms the regular pseudo-labeling model (Regular).

ing objectives.

In Section 3.3, we also propose a variant of our method, which employs random attention temperatures (PLATE$_{\text{rnd}}$ in Table 2). We can see that though random temperature based method is not as good as our best fixed-temperature method, it in general produces decent results. Therefore, we recommend using this method when the computing budget is limited. Note that we also tried more extreme λ values as shown in Appendix B, and we find the value of 1.5 or 2.0 works better than others.

In the fifth block, we additionally conduct self-distillation experiments, which is not the focus of this work. Our method improves the teacher model on CNNDM; ROUGE-2/L scores are improved on XSum; while on NYT, there are improvements on ROUGE-1/L.

Results with the `Transformer` student (the sixth block) follow a similar trend, although the improvements are smaller. It may because the modeling power of `Transformer` without pre-training is not large enough to effectively model the differences in pseudo labels. It is also interesting to see that students distilled with pseudo-labeling do improve gold label based students using randomly initialized `Transformer`, but not with pre-trained models (i.e., `BART 12-6` and `BART 12-3`), which may also be due to the strong modeling power of large pre-trained Transformers.

PLATE$_{\lambda=2.0}$ (Ours)	44.84	21.95	41.77

Table 5: Comparison with sampling and output layer temperature based distillation methods.

regular pseudo-labeling model (Regular), another model PLATE$^{\text{B12-6}}_{\lambda=1.5}$ and human reference (Ref). We ask human judges to rank the outputs of these models from best to worst. We convert the ranks to rank ratings (rank i to $5 - i$) and further conduct student t-test on these ratings. As shown in Table 3, PLATE$^{\text{B12-6}}_{\lambda=2.0}$ obtains the best ranking score and the difference between PLATE$^{\text{B12-6}}_{\lambda=2.0}$ and the regular pseudo-labeling based method Regular is significant ($p < 0.05$), which indicates our proposed method PLATE indeed produces better summaries.

Ablation study In a Transformer, there are three types of attention modules (i.e., encoder self-attention, decoder self-attention and decoder cross-attention), and we can scale attention temperatures for all of them or some of them. Let λ_{enc}, λ_{cross}, and λ_{dec} denote the attention temperature coefficient of the encoder self-attention module, the decoder cross-attention module, and the decoder self-attention module, respectively. As shown in Table 4, using large attention temperature coefficients (2.0) for all three types of attention modules leads to the best result. When setting the coefficient of the cross attention module to $\lambda_{\text{cross}} = 1.0$, the ROUGE scores drop most. Perhaps this is not surprising, since cross attentions are directly related to the selection of document contents for summarization. Besides, the attention temperature of the decoder self-attention is also crucial but not as important as the cross-attention (see the fourth row).

Comparison with sampling and tuning output layer temperature Sampling based methods can produce more diverse and richer outputs than its beam search based counterpart and has been proven useful in back translation (Edunov et al., 2018). We implement the sampling method in Edunov et al. (2018) and Nucleus Sampling (Holtzman et al., 2019), a more advanced sampling method, to generate pseudo labels for distillation. We use the `BART 12-6` as the student model, and the distillation results on CNNDM are in Table 5. As can be seen, both of the sampling based methods above perform worse than the regular beam search based pseudo-labeling method (Regular), let alone ours. Besides the attention temperatures, we can also tune the temperature T in the decoder output softmax layer. With a proper T (i.e., $T = 0.5$) during pseudo label generation, the resulting student model slightly outperforms the baseline student model with regular pseudo labeling method on ROUGE-2/L (see Table 5), but worse than PLATE$_{\lambda=2.0}$. More results with different Ts are in Appendix C.

4.5 Analysis

Why does our distillation method work? To answer this question, we first try to analyze the reasons from both the external characteristics of the summaries generated by the teacher model and the internal characteristics of the teacher's attention mechanism. Then, we will give an in-depth explanation.

Length and novel n-grams We first analyze the pseudo summaries generated by the teacher models. We calculate novel n-grams and lengths of generated summaries. Note that if an n-gram appears in the summary, but not in the original document, we call it a novel n-gram. Proportions of novel n-grams are used to measure the abstractiveness of summaries (See et al., 2017; Liu and Lapata, 2019). As shown in Table 6, when using a larger λ, pseudo summaries are shorter [6] and contain a larger portion of novel n-grams. It indicates that the teachers can produce more concise and abstractive summaries, which matches the goal of abstractive summarization. *Are these pseudo summaries of good quality?* The performance of the teacher with different attention temperatures on CNNDM test

---

[6] We also try changing the length penalty during teachers' inference to make pseudo summaries shorter, but we find this method does not help summarization distillation (see Appendix D for more details).

Table 6: Statistics on outputs of teachers and students with different attention temperature coefficient λ. The student models are all with the `BART 12-6` setting. Inference hyper-parameters on the same dataset are the same.

λ	R1	R2	RL
1.0	44.71	21.52	41.44
1.5	44.92	21.72	41.84
2.0	44.38	21.02	41.50

Table 7: ROUGE of teacher models with different attention temperature coefficient λ on test set of CNNDM.

set is shown in Table 7. Their results are all decent and close to each other (at least for ROUGE-1 and ROUGE-L). Interestingly, compared with $\lambda = 1.0$, the performance of the teacher with $\lambda = 2.0$ is worse, but the resulting student is much better (see Table 2). Perhaps not surprisingly, the styles of summaries from students are similar with these from their teachers. Concise and abstractive teachers lead to concise and abstractive students (see Table 6). Conciseness and abstractiveness are good properties for summarization, which however may not be the case for other generation tasks such as machine translation. We apply PLATE to the WMT16 (Bojar et al., 2016) English-German translation task and use Transformer-big as the teacher and Transformer-base as the student. With $\lambda = 1.5$, we obtain a BLEU of 27.90, while the result of the regular pseudo-labeling is 27.79 (more details are in Appendix A).

Attention We have shown earlier in Figure 1 that with higher attention temperature, cross-attention modules of a teacher can attend to later parts in documents. We observe that students behave similarly, and we put more cross attention visualization of students in Appendix F. To obtain corpus-level statistics, we further calculate the *evident* cross-attention weight distributions of the teacher when generating pseudo labels on the training set of CNNDM. Note that an attention weight is evident if it is greater than 0.15, and these evident attention weights account for around 15% of all attention weights. Specifically, we normalize the token positions of each document to $(0.0, 1.0]$ and divide the normalized positions into five bins. The mean proportions of *evident* attentions for all bins are shown in Figure 2. Compared to the teacher with normal attention temperature (pink bar), teachers with higher attention temperatures (blue and green bars) attend less on the heading parts of documents while more on the tail parts of documents.

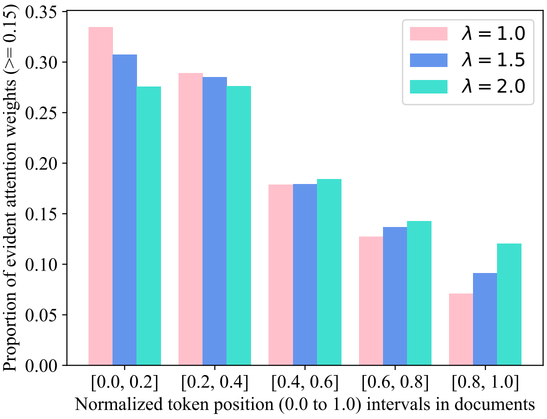

Figure 2: Distributions of *evident* cross attention weights (≥ 0.15) when teachers generate pseudo labels with different attn. temperatures w.r.t. token positions.

To sum up, teachers with higher attention temperatures can generate more concise and abstractive pseudo summaries, which makes the teacher provide more *summary-like* pseudo labels to students. High-temperature teachers can alleviate the leading bias problems by providing pseudo labels with better coverage of source documents to students.

More explanation According to the study of Xu et al. (2020b), the prediction entropy correlates strongly with whether the model is copying or generating, as well as where in the sentence the token is (content selection). The decoder tends to copy when the model has a low prediction entropy and generate novel bigrams when the model has a high prediction entropy. They also find that high entropy of attention distribution strongly correlates with the model's high prediction entropy.

Our method with a higher attention temperature makes attention distributions of the teacher model smoother and leads to a higher entropy of attention distributions, which results in a higher prediction entropy. Therefore, the model with higher attention temperature tends to copy less and generate more novel tokens. The conclusion from Xu et al. (2020b) is in accordance with our observation in Table 6.

5 Conclusions

In this work, we propose a simple but effective extension of pseudo-labeling method PLATE for summarization distillation. Experiments on three datasets demonstrate that our method can consistently outperform the vanilla pseudo-labeling method. Further empirical analysis shows that by using our method, teacher models can generate more concise and abstractive summaries. As a result, summaries produced by student models also become more concise and abstractive. In the future, we would like to explore our method to other generation tasks as well as self-training with unlabeled data. We are also interested in combining our method with other distillation methods and extending our method for better teacher model training.

Model	λ	BLEU
`Transformer-Big` (teacher)	–	28.51
Student		
`Transformer-Base`	1.0	27.79
`Transformer-Base`	1.5	27.90
`Transformer-Base`	2.0	27.85

Table 8: Results of WMT En-De machine translation task on newstest2014. Student models are distilled from pseudo labels generated by the teacher with different attention temperatures (λ).

A Experiments of Applying PLATE to the Machine Translation Task

We apply our method on the WMT16 En-De translation task. We use `Transformer-Big` model as the teacher and `Transformer-Base` as the student. Our results on newstest2014 are shown in Table 8. The student models with our method ($\lambda = 1.5$ and $\lambda = 2.0$) slightly outperform the student with regular pseudo-labeling method ($\lambda = 1.0$). Note that the improvement is not as significant as in summarization tasks.

We speculate the reason may be that, unlike summarization, outputs of the machine translation task are relatively fixed. The strength of our method–conciseness and abstractiveness are good properties for summarization but seem not very beneficial to the translation task.

B Experiments of More λ Values

Besides the λ values of 1.5 and 2.0, we also try more values in a broader range. Table 9 shows the distillation performance of `BART 12-6` student models with more values of λ we try on CNNDM dataset (we also include the values of 1.0, 1.5, and 2.0 in table for convenient comparison). As can be seen, both lower and larger λ values are not helpful to the distillation. Though the suitable λ values may vary across datasets, we recommend considering the λ value 1.5 or 2.0 firstly in most cases.

C Experiments of Changing the Softmax Temperature in the Final Decoder Layer

It's a more direct idea to change the softmax temperature in the final decoder layer rather than attention temperatures, namely changing the T in equation 5 to some other values rather than the default value 1.0.

λ	R1	R2	RL
0.75	43.13	20.60	39.62
1.0	44.00	21.08	40.29
1.5	44.29	21.57	41.13
2.0	44.84	21.95	41.77
2.5	43.99	21.19	41.21
3.0	42.32	19.28	39.67

Table 9: ROUGE scores of `BART 12-6` student models with more values of λ on CNNDM dataset.

T	R1	R2	RL
0.5	43.80	21.20	40.59
1.0	44.00	21.08	40.29
1.5	42.81	20.43	39.56
2.0	42.76	20.34	39.53
Regular	44.00	21.08	40.29
PLATE$_{\lambda=2.0}$ (Ours)	44.84	21.95	41.77

Table 10: Distillation experiment results of changing the softmax temperature in the final decoder layer.

$$q_i = \frac{\exp(z_i/T)}{\sum_j \exp(z_j/T)} \tag{5}$$

However, our experiments demonstrate that this method does not help summarization distillation much. We use `BART` teacher models with different softmax temperatures in the final decoder layers to generate pseudo summaries and use the `BART 12-6` as student models. The experiment results are shown in table 10.

D Experiments of Shorter Pseudo Summaries with Smaller Length Penalty

Our method can make pseudo summaries shorter and more abstractive, so one natural idea is that whether just changing the inference hyperparameter length penalty to a smaller value, which can also make pseudo summaries shorter, can benefit abstractive summarization distillation. The experiment results are shown in Table 11, where the teacher is `BART`, and the student is `BART 12-6`. As can be seen from the table, teachers with smaller length penalty (i.e., 1.0 or 0.5) cannot teach better students than the Regular pseudo-labeling or our method.

Length Penalty	Avg. Len.	R1	R2	RL
1.0	64.39	42.96	20.67	39.76
0.5	60.26	43.49	20.89	40.14
Regular	64.78	44.00	21.08	40.29
PLATE$_{\lambda=2.0}$ (Ours)	52.16	44.84	21.95	41.77

Table 11: Distillation results of changing the teacher’s inference hyper-parameter length penalty on CNNDM dataset. Avg. Len. represents the average length of the teacher generated pseudo summaries.

E The Example in Section 1

We present the detailed content of the example in Section 1 in table 12.

F Attention Visualization

We present more examples of student models’ outputs and cross attention visualization here. The student models are with the `BART 12-6` setting and are trained on CNNDM and the following examples are from the validation set of CNNDM.

Example 1 Table 13 shows system outputs from different student models and Figure 3 illustrates the corresponding cross attention weights of these student models. Compared with the regular pseudo-labeling method (`[Regular]`), the summary generated by our method PLATE$^{\text{B12-6}}_{\lambda=1.5}$ omits the modifier "Nirvana frontman" and "Nirvana bassist" of the person "Kurt Cobain" and "Krist Novoselic", respectively and the resulting summary is shorter and more abstractive. The summary generated by our method PLATE$^{\text{B12-6}}_{\lambda=2.0}$ contains the text "will premiere on HBO on May 4", which is at the end of the source document and included in the reference (i.e., summary worthy), but is ignored by `[Regular]`. It indicates that our method can alleviate the leading bias problem. Figure 3 also shows that PLATE$^{\text{B12-6}}_{\lambda=2.0}$ can access the tail part of the document.

Example 2 The second example is shown in Table 14 (outputs) and Figure 4 (attention visualization). In this example, the source document is relatively long (over 700 words). As shown in Figure 4, the summary generated with the regular pseudo-labeling method `Regular` mainly focuses on the heading part of the source document (around the first 150 words), but our method PLATE$^{\text{B12-6}}_{\lambda=2.0}$ takes into account the tokens in the front, middle and tail of the source document. In Table 14, the summary from PLATE$^{\text{B12-6}}_{\lambda=2.0}$ contains the key sentence "Peter Bergen: Pilots are not different from other people, but they can be careless, lazy, inattentive and reckless", which is similar to the reference sentence "Peter Garrison: Pilots don’t exist on different moral plane than the rest of us". The sentence "the human mind is the blackest of boxes" in the reference, which appears at the tail of the source document, is also included in summaries of PLATE$^{\text{B12-6}}_{\lambda=2.0}$. This example again demonstrates that our method can alleviate the leading bias problem and can make the generated summary have better coverage of source documents.

Abstract

This paper demonstrates that multilingual pre-training and multilingual fine-tuning are both critical for facilitating cross-lingual transfer in zero-shot translation, where the neural machine translation (NMT) model is tested on source languages unseen during supervised training. Following this idea, we present SixT+, a strong many-to-English NMT model that supports 100 source languages but is trained with a parallel dataset in only six source languages. SixT+ initializes the decoder embedding and the full encoder with XLM-R large and then trains the encoder and decoder layers with a simple two-stage training strategy. SixT+ achieves impressive performance on many-to-English translation. It significantly outperforms CRISS and m2m-100, two strong multilingual NMT systems, with an average gain of 7.2 and 5.0 BLEU respectively. Additionally, SixT+ offers a set of model parameters that can be further fine-tuned to other unsupervised tasks. We demonstrate that adding SixT+ initialization outperforms state-of-the-art explicitly designed unsupervised NMT models on Si↔En and Ne↔En by over 1.2 average BLEU. When applied to zero-shot cross-lingual abstractive summarization, it produces an average performance gain of 12.3 ROUGE-L over mBART-ft. We conduct detailed analyses to understand the key ingredients of SixT+, including multilinguality of the auxiliary parallel data, positional disentangled encoder, and the cross-lingual transferability of its encoder.

1 Introduction

Neural machine translation (NMT) systems (Sutskever et al., 2014; Bahdanau et al., 2015; Vaswani et al., 2017) have demonstrated superior performance with large amounts of parallel data. However, the performance of most existing NMT systems will degrade when the labeled data is limited (Koehn and Knowles, 2017; Goyal et al., 2021). To address this problem, unsupervised NMT, in which no parallel corpora are available, is drawing increasing attention.

Some prior work (Johnson et al., 2017; Chen et al., 2017; Gu et al., 2019; Zhang et al., 2020) use pivot-based methods for zero-shot translation between unseen language pairs. In this setting, both source and target languages have parallel data with a pivot language. However, these approaches are infeasible for rare languages where a parallel dataset of any kind is hard to collect. Another line of work (Guzmán et al., 2019; Ko et al., 2021; Garcia et al., 2021) build unsupervised NMT through back-translation and further enhance its performance by cross-lingual transfer from auxiliary languages. These methods are usually complicated with multiple iterations of back-translation and a combination of various training objectives. Moreover, their models can only support one or several pre-specified translation directions. Recently, Chen et al. (2021) propose SixT, a transferability-enhanced fine-tuning method that better adapts XLM-R (Conneau et al., 2020) for translating unseen source languages. SixT is trained once to support all languages involved in the XLM-R pre-training as the source language. However, they focus on exploring a proper fine-tuning approach and build SixT with the parallel dataset from one auxiliary language, which heavily limits the model's zero-shot translation performance.

In this paper, we present SixT+, a strong many-to-English NMT model that can support as many as 100 source languages with parallel datasets from only six language pairs. SixT+ is trained by applying SixT to multilingual fine-tuning with large-scale data. We first initialize the encoder and embeddings of SixT+ with XLM-R and then train it with a two-stage training method. At the first stage, we only train the decoder layers, while at the second stage, we disentangle the positional informa-

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 142 - 157

tion of the encoder and jointly optimize all parameters except the embeddings. SixT+ improves over SixT by keeping the decoder embeddings frozen during the whole training process, which speeds up the model training while reducing the model size. SixT+ is trained once to support all source languages and can be further extended to many-to-many NMT that can support multiple target languages. It is not only a strong multilingual NMT model but can also be fine-tuned for other unsupervised tasks, including unsupervised NMT, zero-shot cross-lingual transfer for natural language understanding (NLU), and natural language generation (NLG) tasks.

Extensive experiments demonstrate that SixT+ works remarkably well. For translating to English, SixT+ significantly outperforms all baselines across 17 languages, including CRISS and m2m-100, two strong unsupervised and supervised multilingual NMT models trained with 1.8B and 7.5B sentence pairs. The many-to-many SixT+ gets better performance than m2m-100 in 6 out of 7 target languages on the Flores101 testset. When serving as a pretrained model, SixT+ also performs impressively well. For unsupervised NMT of rare languages, SixT+ initialization achieves better unsupervised performance than various explicitly designed unsupervised NMT models with an average gain over 1.2 BLEU. For zero-shot cross-lingual transfer for NLU, it significantly outperforms XLM-R on sentence retrieval tasks, while maintaining the performance on most other tasks. On the zero-shot cross-lingual abstractive summarization task, SixT+ improves mBART-ft by 12.3 average ROUGE-L across 5 zero-shot directions. Finally, we conduct detailed analyses to understand the key ingredients of SixT+, including multilinguality of the auxiliary parallel data, positional disentangled encoder, and the cross-lingual transferability of its encoder.[1]

2 SixT+

SixT+ aims at building a strong many-to-English NMT model, especially for the zero-shot directions. We argue that multilingual pretraining and multilingual fine-tuning are both critical for this goal. Therefore, we initialize SixT+ with XLM-R large and fine-tune SixT+ on the multilingual parallel dataset with a simple two-stage training method.

2.1 Data: AUX6 corpus

We utilize De, Es, Fi, Hi, Ru, and Zh as the auxiliary source languages, which are high-resource languages from different language families. We do not add more auxiliary languages to limit the computation cost and the training data size. The training data is from the WMT and CCAligned dataset, consisting of 120 million sentence pairs. We concatenate the validation sets of auxiliary languages for model selection. We denote this dataset as *AUX6*. More dataset details are in the appendix. Following Conneau and Lample (2019), sentences of the i^{th} language pair are sampled according to the multinomial distribution calculated as follows:

$$q_i = \frac{p_i^\alpha}{\sum_j p_j^\alpha}, \tag{1}$$

where p_j is the percentage of each language in the training dataset and we set the hyper-parameter α to be 0.2. In all experiments, all texts are tokenized with the same sentencepiece (Kudo, 2018) tokenizer as XLM-R.

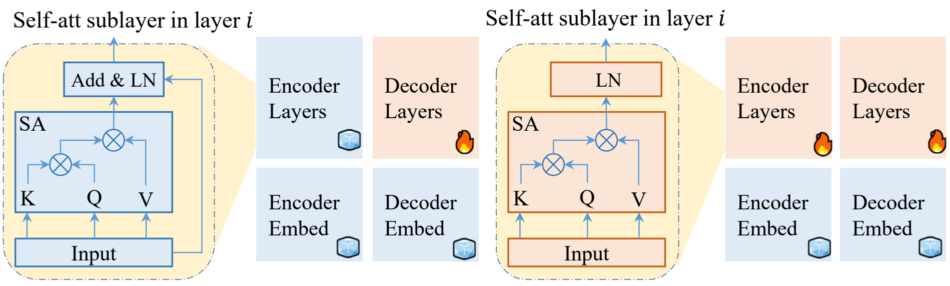
2.2 Model

Architecture SixT+ is a Transformer-based NMT model with $\sim$0.7B model parameters. To initialize the encoder with XLM-R large, our encoder has the same configuration as XLM-R large, i.e., 24 encoder layers, hidden state dimension of 1024, feed-forward dimension of 4096, and head number of 16. For the decoder, we follow the suggestion in Chen et al. (2021), which has 12 decoder layers, a hidden state dimension of 1024, feed-forward dimension of 3072, and head number of 16. We use the same vocabulary as XLM-R and tie the encoder embeddings, decoder embeddings, and decoder output projection to reduce the model size.

Learning We first initialize the encoder and embeddings with XLM-R large and then fine-tune the model on the auxiliary parallel dataset. Compared with fine-tuning XLM-R for NLU tasks like text classification, the prediction space for SixT+ is much larger and it has to learn much more randomly initialized parameters. Directly fine-tuning all parameters may degrade the cross-lingual transferability which is learned in XLM-R. Therefore, following Chen et al. (2021), we train SixT+ with a two-stage training framework, as shown in Figure 1.

---

[1] The code and pretrained models are available at `https://github.com/ghchen18/acl22-sixtp`.



(1) Training at the first stage

(2) Training at the second stage

Figure 1: Our proposed two-stage training framework (TransF) for building cross-lingual NLG model with XLM-R. The blue icy blocks are initialized with XLM-R and frozen, while the red fiery blocks are initialized randomly or from the first stage. 'SA' denotes the self-attention sublayer. We remove the residual connection at the 23th (penultimate) encoder layer at the second stage, namely $i = 23$ in the figure.

Stage 1: Decoder Training. To preserve the cross-lingual transferability of XLM-R, we first train the decoder by keeping the encoder frozen:

$$\mathcal{L}_{\boldsymbol{\theta}_{\text{dec}}} = \sum_{D_i \in D} \sum_{\langle \mathbf{x},\mathbf{y} \rangle \in D_i} \log P(\mathbf{y}|\mathbf{x};\,,\boldsymbol{\theta}_{\text{dec}}), \tag{2}$$

where $D = \{D_1; ...; D_K\}$ is a collection of parallel dataset in K auxiliary languages, $\langle \mathbf{x}, \mathbf{y} \rangle$ is a parallel sentence pair with source language i and $\boldsymbol{\theta}_{\text{dec}}$ is the parameter set of the decoder layers.

Stage 2: Fine-tuning. Freezing the encoder parameters limits the NMT model capacity, especially for the large-scale training data. Therefore, we jointly train the full model in another stage:

$$\mathcal{L}_{\boldsymbol{\theta}} = \sum_{D_i \in D} \sum_{\langle \mathbf{x},\mathbf{y} \rangle \in D_i} \log P(\mathbf{y}|\mathbf{x};\boldsymbol{\theta}), \tag{3}$$

where $\boldsymbol{\theta}$ is the parameter set of both encoder and decoder layers.

Different from SixT which fine-tunes the decoder embedding, we keep the embeddings fixed during the whole training process (see Figure 1). Our preliminary experiments find that this strategy leads to higher computational efficiency without degrading the performance.

Positional Disentangled Encoder Positional Disentangled Encoder (PDE) is reported to improve zero-shot NMT in the previous work (Liu et al., 2021; Chen et al., 2021). The positional correspondence between the input tokens and the encoder representations is one of the factors that makes the encoder representations language-specific. PDE relaxes such correspondence by removing residual connections in an encoder layer. We refer the readers to Liu et al. (2021); Chen et al. (2021) for more details. In SixT+, we remove the residual connection after the self-attention sublayer of the 23th (penultimate) encoder layer at the second training stage, as suggested by Chen et al. (2021). For simplicity, we denote the two-stage training method with PDE as *TransF* in the following sections.

3 Zero-Shot Neural Machine Translation

3.1 Experiment Settings

For the many-to-English translation task, we evaluate the performance of SixT+ on the test sets of 23 language pairs from 9 various language groups[2]: German group (De, Nl), Romance group (Es, Ro, It), Uralic and Baltic group (Fi, Lv, Et), Slavic group (Ru, Pl), Arabic group (Ar, Ps), Indo-Aryan group (Hi, Ne, Si, Gu), Turkic group (Tr, Kk), East Asian group (Zh, Ja, Ko) and Khmer group (My, Km). The dataset details are in the appendix. For decoding, we use beam-search with beam size 5 for all translation directions and do not tune length penalty. We report detokenized BLEU for all directions using sacrebleu[3].

We compare SixT+ with SixT and four other baselines. Among the four baselines, XLM-R ft-all and mBART-ft use the same training data as SixT+, while CRISS and m2m-100 are trained on 1.8B and 7.5B sentence pairs. As SixT+, CRISS, and m2m-100 have different model sizes, support different numbers of languages and are trained with different training datasets, the comparisons are not completely fair, but the results can still demonstrate

---

[2] We refer to the language groups information in Table 1 of Fan et al. (2020).

Table 1: BLEU comparison with baselines on many-to-English test sets. '# Sent' is the training data size. 'Param.' is the model size. '−' indicates the language is not supported by CRISS. † is the average BLEU across the source languages supported by CRISS. SixT+ (1st) is the SixT+ after the first training stage. The best BLEU is bold and underlined. The last three utilize the same multilingual pretrained language model (XLM-R large) but with a different fine-tuning method.

the strong performance of SixT+.

- CRISS (Tran et al., 2020). This model is the state-of-the-art unsupervised many-to-many multilingual NMT model. It is initialized with mBART and fine-tuned on 180 translation directions from CCMatrix. It only supports 25 input languages.
- m2m-100 (Fan et al., 2020). This model is a strong supervised many-to-many multilingual NMT model. It is a large Transformer trained on huge parallel data across 2200 translation directions and with 7.5B parallel sentences from CCMatrix and CCAligned as well as additional back-translations. The official 1.2B model is evaluated.
- SixT (Chen et al., 2021). This model motivates SixT+. The SixT model trained with XLM-R large on WMT19 De-En is evaluated and compared.
- mBART-ft (Liu et al., 2020; Tang et al., 2020). mBART[4] is a strong pretrained multilingual seq2seq model. We follow their setting and directly fine-tune all model parameters on the AUX6 corpus.
- XLM-R ft-all (Conneau and Lample, 2019). This method is the same as SixT+ but utilizes a different fine-tuning method that directly optimizes all model parameters.

3.2 Main Results

As shown in Table 1, SixT+ outperforms all baselines with an average gain of 5.0-7.2 BLEU. The performance of SixT+ is impressive given that it does not use any other monolingual or parallel texts except the 0.12B parallel sentence pairs. First, the significant improvement over mBART-ft demonstrates that the multilingual pretrained encoder XLM-R can also build a strong zero-shot many-to-one translation model if fine-tuned properly. Second, SixT+ is significantly better than XLM-R ft-all and SixT+ (1st), proving that a proper fine-tuning method is important for zero-shot translation. Finally, the gain of SixT+ over SixT shows that adding more auxiliary languages and more parallel data benefits the performance.

SixT+ achieves new state-of-the-art performance on unsupervised many-to-English translation. It is significantly better than CRISS in all 14 unsupervised directions. When comparing with supervised models, SixT+ improves over m2m-100 on 17 out of 23 translation directions. Although CRISS and m2m-100 are many-to-many NMT models that may face the *insufficient modeling capacity* problem (Zhang et al., 2020), they are strong many-to-English baselines trained with much more data (1.8

---

[4] We use mBART50 from Tang et al. (2020).

Target Lang.	En	De	Es	Fi	Hi	Ru	Zh	Avg.
m2m-100	23.6	15.9	15.2	**11.3**	14.1	14.3	19.9	16.3
SixT+ m2m	**29.8**	**17.4**	**15.3**	10.2	**15.5**	**14.6**	**25.2**	**18.3**

Table 2: Averaged BLEU comparison of SixT+ m2m and m2m-100 on zero-shot translations. The detailed results are in the Table 12 of the appendix.

billion for CRISS and 7.5 billion for m2m-100) and computation cost. Moreover, the model size of m2m-100 is much larger than SixT+.

Different from previous unsupervised NMT models built with back-translation on monolingual data (Lample et al., 2018a,b) or parallel data mining (Tran et al., 2020), SixT+ illustrates that better unsupervised NMT can be achieved by cross-lingual transfer from auxiliary languages. It improves on the test sets whose languages are in the same family as the auxiliary languages. For languages that are not in the same family of auxiliary languages, SixT+ also works well. For instance, it improves My→En from 6.7 to 15.3 BLEU, Ps→En from 10.9 to 14.9 BLEU, and Kk→En from 20.7 to 27.3 BLEU.

3.3 Analysis

Many-to-Many SixT+ The SixT+ can be extended to support other or multiple target languages. Following Zhang et al. (2020), we build a many-to-many SixT+ (SixT+ m2m) model and switch between different target languages by a target-language-aware linear projection layer between the encoder and the decoder. The linear layers are randomly initialized and trained in both training stages. The model is also trained on AUX6, but additionally includes the En→{De,Es,Fi,Hi,Ru,Zh} translation directions during supervised training and validation. All the other training details are the same. We evaluate the performance of SixT+ m2m on the Flores 101 testset (Goyal et al., 2021), which is a multilingual aligned benchmark that covers 101 different languages. Following previous work (Fan et al., 2020), we report tokenized BLEU when Hindi[5] and Chinese[6] are the target language and the detokenized BLEU for other target languages. We compare it with the m2m-100 (1.2B) model, as shown in Table 2. Detailed results on each source language are in Table 12 of the appendix.

Data	Size	Hi	Ne	Si	Gu	Avg.
De-En	8M	17.3	13.7	11.9	16.0	14.7
4 Aux. Langs	8M	20.9	16.6	15.1	20.9	18.4

Table 3: BLEU comparison of SixT+ trained with the same size of training data that consists of different number of auxiliary languages. '4 Aux. Langs' is a combination of {De,Es,Fi,Ru}-En parallel datasets.

Data	Europarl (1.9M)	WMT19 (41M)	AUX6 (120M)
SixT+	21.5	26.3	32.9
SixT+ w/o PDE	20.5	26.1	32.9

Table 4: The average BLEU of SixT+ with and without positional disentangled encoder (PDE). Note that AUX6 includes more source languages. The detailed scores are in the Table 13 of the appendix.

Overall, our model outperforms m2m-100 in 6 out of 7 target languages. This is impressive given that our model is unsupervised. The SixT+ m2m performs more evenly in different source languages (see Table 12 in the appendix). In contrast, the performance of m2m-100 varies across languages. Our model learns to translate through effective cross-lingual transfer, while m2m-100 relies heavily on the scale and quality of the direct parallel dataset. We also compare SixT+ m2En and SixT+ m2m for translating to English on this testset and get an average BLEU of 30.5 and 29.8, respectively (see Table 12 in the appendix). The results demonstrate that SixT+ m2m successfully supports seven target languages while keeping most of the performance of SixT+ m2En on the many-to-English testset.

Effect of the Multilinguality of Auxiliary Languages Previous studies report that adding more parallel data and more auxiliary languages improves performance for unsupervised NMT (García et al., 2020; Bai et al., 2020; Garcia et al., 2021). In this experiment, we examine whether increasing multilinguality under a fixed data budget improves the zero-shot performance of SixT+. We fix the amount of auxiliary parallel sentence pairs to 8 mil-

Table 5: XTREME benchmark results of our models and baselines. The results for individual languages can be found from Table 14 to Table 20 in the appendix.

lion and vary the number of auxiliary languages. We report the results in Table 3. It is observed that the model trained with four auxiliary languages (De, Es, Fi, Ru, each has the same data size) outperforms that of one auxiliary language (De), with an average gain of 3.7 BLEU. Note that for both cases, we use auxiliary languages which are not in the Indo-Aryan group to remove the impact of language similarity. This observation demonstrates the necessity of utilizing multiple auxiliary languages in the training dataset.

Effect of Positional Disentangled Encoder In this part, we conduct a comprehensive study on the effect of the positional disentangled encoder (PDE) (Liu et al., 2021; Chen et al., 2021). Table 4 presents the results. We find that on the small-scale Europarl dataset, PDE improves the zero-shot performance with an average gain of 1.0 BLEU. However, when the training data goes large or/and becomes more multilingual, the gain decreases (see results on WMT19 and AUX6). To confirm this, we also conduct experiments on SixT+ m2m (see Table 12 in the appendix). For translating to English, the models with and without PDE perform comparably well. However, for translating to other languages, PDE improves in 5 out of 6 directions, with an average gain of 0.4 BLEU. This is expected as these directions include only one source language (En) and much less training data (7M∼41M) than translating to English (120M). In summary, when large-scale multilingual training data are available for all target languages, it is fine to remove PDE. We suspect the model has already learned language-agnostic encoder representations in this case. Otherwise, PDE benefits zero-shot performance.

Performance on Cross-lingual NLU Tasks To better understand the encoder representation produced by SixT+, we evaluate the zero-shot cross-lingual transfer performance of the SixT+ encoder on the XTREME benchmark (Hu et al., 2020). The XTREME includes 9 target tasks of natural language understanding. We do not report results on XQuAD and MLQA as they have no held-out test data (Phang et al., 2020). For all other XTREME tasks, we follow the training and evaluation protocol in Hu et al. (2020) and implement with the jiant toolkit (Phang et al., 2020). As NMT training can be regarded as an intermediate task (Pruksachatkun et al., 2020), we include previous results on using English intermediate NLU tasks to improve XLM-R on XTREME as a reference (Phang et al., 2020). Table 5 provides the average results for each task. The detailed results are in the appendix.

Overall, SixT+ encoders achieve 8.3% and 31.6% performance gain over XLM-R and XLM-R ft-all across the seven tasks, which verifies that our model learns a more language-agnostic encoder representations. Our encoder may learn better sentence-level representation and capture better semantic alignments among parallel sentences through multilingual NMT training, therefore it generally performs better on sentence pair (XNLI and PAWS-X) and sentence retrieval tasks (BUCC and Tatoeba). The results show the potential of leveraging NLG task as the intermediate task for improving performance on XTREME. We leave a more detailed exploration of why NMT training as well as other NLG intermediate tasks could be beneficial for a given NLU task as future work.

4 SixT+ as a Pretrained Model

SixT+ learns language-agnostic encoder representation and performs impressively well on translating various source languages. In this part, we extend SixT+ to two cross-lingual NLG tasks where the direct labeled data is scarce, namely unsupervised NMT for low-resource languages and zero-shot cross-lingual abstractive summarization.

4.1 Unsupervised NMT for Low-resource Language

Given a low-resource language pair where the parallel dataset is unavailable, early work on unsupervised NMT build the translation model by training denoising autoencoding and back-translation concurrently (Lample et al., 2018b,a; Artetxe et al., 2018). However, these methods may lack robustness when languages are distant (Kim et al., 2020; Marchisio et al., 2020). For example, Guzmán et al. (2019) report BLEU scores of less than 1.0 on distant language pair Nepali-English using the method in Lample et al. (2018b). Recent work improves by better initializing the unsupervised NMT model either with a multilingual pretrained language model (Liu et al., 2020; Song et al., 2019; Ko et al., 2021, MulPLM) or a multilingual NMT model (Lin et al., 2020). In this part, we follow this line and offer an alternative initialization option for building strong unsupervised NMT models.

We first initialize the L_{LR}→En model with SixT+. As SixT+ only supports En as the target language, we initialize the En→L_{LR} model with XLM-R following how SixT+ is initialized. Then we iteratively improve these two models with back-translation. For simplicity, we do not update the L_{LR}→En model and only train the reverse model once. We train it with a synthetic back-translation dataset from L_{LR} monolingual data using the two-stage training method[7]. We do not apply other unsupervised NMT techniques, such as iterative back-translation (Lample et al., 2018b), cross-translation (Garcia et al., 2021) or iterative mining of sentence pairs (Tran et al., 2020). These methods could be complementary to our method. We leave the in-depth exploration as future work.

Experimental Settings We evaluate our method on Ne and Si, two commonly used benchmark languages for evaluating low-resource language translation. The monolingual dataset of Ne and Si consists of 7 million sentences that are sampled from CC100 and CCNet dataset. The test sets are from the Flores dataset (Guzmán et al., 2019). We set the beam size to 5 during the offline back-translation and select the model with unsupervised criterion in Lample et al. (2018a). We compared with state-of-the-art supervised and unsupervised baselines. Please refer to the appendix for more details.

ID	Method	Ne-En →	Ne-En ←	Si-En →	Si-En ←
Supervised approach					
(1)	m2m-100	5.2	0.4	15.3	4.6
(2)	Guzmán et al. (2019)†	<u>21.5</u>	8.8	15.1	6.5
(3)	Liu et al. (2020)†	21.3	<u>9.6</u>	<u>20.2</u>	<u>9.3</u>
Unsupervised approach

(8)	Ours (SixT+)	**23.7**	**10.1**	**17.5**	**8.2**

Table 6: BLEU comparison of different models on the low-resource language translation. Results with '†' are quoted from the original paper. The best unsupervised method for each translation direction is bold, while the best supervised method is underlined.

Results The results are illustrated in Table 6. Our model outperforms all unsupervised baselines for all translation directions, improving the best performing unsupervised baseline with an average gain of 1.2 BLEU. In addition, it even outperforms all supervised baselines and achieves new state-of-the-art performance on Ne→En and En→Ne translations. It is impressive given that the supervised baselines Guzmán et al. (2019) and Liu et al. (2020) are very strong. Both methods are trained on around 600k parallel corpus and more than 70M monolingual corpora with supervised translation and iterative back-translation. Our method is also computationally efficient and easy to implement. As SixT+ offers a ready-to-use L_{LR} →En NMT model, we only run back-translation once for building the reverse model. However, for the baselines (ID 2-3, 5-7), they run iterative back-translation for no less than two rounds and involve cross-translation, denoising autoencoding, or adversarial loss. They are much more complex and computational costly compared with our method.

4.2 Zero-shot Cross-lingual Generation

In zero-shot generation with the source-side transfer, the NLG model is directly tested on unseen source languages during supervised training. As cross-lingual labeled data are scarce, such zero-shot generation is useful in the cross-lingual generation where the languages of input and output text are different. In this experiment, we focus on utilizing SixT+ for zero-shot cross-lingual abstractive summarization (ZS-XSUM). We believe such a framework can be easily extended to other

---

[7] We do not use PDE here as PDE may harm the supervised performance of the reverse model.

zero-shot cross-lingual generation tasks.

The ZS-XSUM task is challenging, as we require the model to summarize (from document to abstract), translate (from input language to output language) and transfer (from auxiliary input language to target input language) at the same time. SixT+ already has the ability to translate and transfer, thus it offers a set of initialization parameters that can ease the learning of the ZS-XSUM model. Specifically, we initialize the ZS-XSUM model with SixT+ (1st)[8] and then train on labeled data of abstractive summarization with the TransF method. The trained model is tested on the cross-lingual summarization in a zero-shot manner where the source language is unseen during training.

Experiment Settings To build a strong ZS-XSUM model, we collect 1.2 million public document-summary pairs to form the training dataset, where the document is in the languages among En/De/Es/Fr/It/Pt/Ru and the summary is in En. We evaluate the performance on the Wikilingua dataset with Hi/Zh/Cs/Nl/Tr as source languages and English as the target language. All the test languages are unseen during training and validation. The dataset details are in the appendix. We compare the proposed method with the mBART-ft method which directly fine-tunes all mBART parameters and our proposed method in building SixT+ which is denoted as 'Ours w/o NMT pretraining'.

Results As shown in Table 7, both of our methods outperform mBART-ft on all zero-shot directions by an average gain of 8.1 and 12.3 ROUGE-L. This is impressive given that mBART is a widely used MulPLM for the cross-lingual generation. We also observe that initializing with SixT+ is much better than XLM-R with the same TranF training method, demonstrating that the NMT pretraining is beneficial for the ZS-XSUM task. To build a cross-lingual generation model without labeled data, previous works usually resort to the translate-and-train or translate-and-test approaches or their extensions (Shen et al., 2018; Duan et al., 2019). For these approaches, an NMT system is required to translate either at the training or testing time. However, translate-and-train can only develop models for a few pre-specified source languages, while the decoding speed of translate-and-test is slow, especially for summarization where the input text is long. Besides, both approaches rely heavily on the performance of the NMT system. SixT+ shows that it is possible to build a strong universal cross-lingual NLG model that can support 100 source languages. This is promising, especially for low-resource languages which the NMT system translates poorly. Our model can also serve as a start point which can be further improved by fine-tuning on genuine or synthesized (produced by an NMT system) cross-lingual corpus. We leave more in-depth exploration as future work.

5 Related Work

5.1 Multilingual Neural Machine Translation

Early works on multilingual NMT show its zero-shot translation capability, where the tested translation direction is unseen during supervised training (Johnson et al., 2017; Ha et al., 2016). To further improve the zero-shot performance, one direction is to learn language-agnostic encoder representations and make the most of cross-lingual transfer. Some approaches modify the encoder architecture to facilitate language-independent representations.

---

[8] Preliminary experiments show that this setting leads to slightly better performance than initialization with SixT+.

Lu et al. (2018) incorporate an explicit neural interlingua after the encoder. Liu et al. (2021); Chen et al. (2021) remove the residual connection at an encoder layers to relax the positional correspondence. Some other works introduce auxiliary training objectives to encourage similarity between the representations of different languages (Arivazhagan et al., 2019; Al-Shedivat and Parikh, 2019; Pham et al., 2019; Pan et al., 2021). For example, Pan et al. (2021) utilize contrastive loss to explicitly align representations of a bilingual sentence pair. Recently, multilingual pretraining has demonstrated to implicitly learn language-agnostic representation (Liu et al., 2020; Conneau et al., 2020; Hu et al., 2020). Inspired by this, some studies initialize multilingual NMT with the MulPLM or introducing the training objectives of MulPLM to multilingual NMT (Gu et al., 2019; Ji et al., 2020; Liu et al., 2020; Chen et al., 2021; Garcia et al., 2021). Our work follows the last line but improves over them by making the most of MulPLM with a simple yet effective fine-tuning method and large-scale multilingual parallel dataset.

5.2 Zero-shot Translation with Multilingual Pretrained Language Model

For NLG tasks like neural machine translation, most work leverage multilingual pretrained seq2seq language models such as mBART (Liu et al., 2020), mT5 (Xue et al., 2021) and ProphetNet-X (Qi et al., 2021) for cross-lingual transfer. For example, Liu et al. (2020) fine-tune mBART with the parallel dataset of one language pair and test on unseen source languages. Considering the great success of the multilingual pretrained encoder (MulPE) such as XLM-R (Conneau et al., 2020) and mBART (Wu and Dredze, 2019) in zero-shot cross-lingual transfer for NLU tasks (Hu et al., 2020), their use for cross-lingual transfer in NLG tasks is still underexplored. Wei et al. (2021) fine-tunes their proposed MulPE to conduct zero-shot translation but use the `[CLS]` representation as the encoder output.

Our work is most similar to SixT (Chen et al., 2021), as indicated by the name itself. However, since SixT focuses on designing a novel fine-tuning method, it conducts experiments with one auxiliary language, which heavily limits the model's performance. In addition, SixT only works on NMT, while SixT+ can not only perform translation but also serve as a pretrained model for various zero-shot cross-lingual generation tasks, such as low-resource NMT and cross-lingual abstractive summarization.

6 Conclusion

In this paper, we introduce SixT+, a strong many-to-English NMT model that supports 100 source languages but is trained once with the parallel dataset from only six source languages. Our model makes the most of cross-lingual transfer by initializing with XLM-R and conducting multilingual fine-tuning on the large-scale dataset with a simple yet effective two-stage training method. Extensive experiments demonstrate that SixT+ outperforms all baselines on many-to-English translation. When serving as a pretrained model, adding SixT+ initialization achieves new state-of-the-art performance for unsupervised NMT of low-resource and significantly outperforms mBART and XLM-R on zero-shot cross-lingual summarization.

A Dataset

A.1 Machine Translation Dataset

The AUX6 dataset is from WMT translation task and CCAligned corpus[9]. The validation and test sets are from newstest, WAT21 translation task[10], IWSLT17 testset[11], Flores Testset[12] and Tatoeba test sets[13]. We use the first 20M sentence pairs of the CCAligned corpus for Es-En and Ru-En language pairs as training data. The Europarl De-En dataset is only used in the experiment of Table 4. All texts are tokenized by the same XLM-R sentencepiece (Kudo, 2018) model. The source sentence length is limited to 512, which is the maximum source sentence length supported by XLM-R. More details are shown in Table 8 and Table 9.

A.2 Unsupervised NMT dataset

The monolingual dataset of Ne and Si consists of 7 million sentences that are sampled from CC100 (Conneau et al., 2020) and CCNet (Wenzek et al., 2020) datasets. We select the best model with an unsupervised criterion based on the BLEU score of a 'round-trip' translation following (Lample et al., 2018a) by using 3000 monolingual Ne/Si sentences sampled from CC100 and CCNet datasets. The testsets of Ne and Si are from Flores testset (Guzmán et al., 2019) [14].

A.3 Abstractive Summarization Dataset

The training data of abstractive summarization task is from CNN/DailyMail,[15] XSum,[16] Wikihow[17] and WikiLingua[18] dataset. In total, the training set contains 1189k document-summary pairs. The average context length after performing sentencepiece is 669 tokens. We randomly sample 2000 Fr-En pairs and 3000 pairs for each test language from the WikiLingua dataset as the validation and test sets. As the maximum length of input tokens for XLM-R is 512, we just keep the first 512 to-

Table 11: Languages used in this paper.

B Language Code

We refer to the language information in Table 1 of Fan et al. (2020). The languages used in this paper are shown in Table 11.

C Model and Training Details

Since the SixT+ embeddings are initialized with XLM-R, all texts are tokenized with the same sentencepiece (Kudo, 2018, SPM) tokenizer as XLM-R. The tokenizer is learned on the full Common Crawl data that includes 250k sentencepiece tokens. We do not apply additional preprocessing, such as true-casing or normalizing punctuation/characters. Following XLM-R, we add the `[BOS]` and `[EOS]` tokens at the head and tail of the input sentence, respectively.

SixT+ is trained on 128 Nvidia V100 GPUs (32GB) with 100k and 10k steps for the first and second training stage. The batch size is 4096 for each GPU. We use the Adam optimizer (Kingma and Ba, 2015) with $\beta_1 = 0.9$ and $\beta_2 = 0.98$. At the first stage, the learning rate is 0.0005 and the warmup step is 4000, while at the second stage, we set the learning rate as 0.0001 and do not use warmup. The dropout probabilities are set to be 0.1. All experiments are done with the fairseq toolkit (Ott et al., 2019).

D Comparison on the Many-to-many Translation

The many-to-many SixT+ model is trained with AUX6 dataset using supervision from 12 translation directions. The m2m-100 model is the official 1.2B model[19] from Fan et al. (2020). The results are shown in Table 12.

E Effect of Positional Disentangled Encoder

We compare the SixT+ with and without (w/o) positional disentangled encoder (PDE) on different training datasets: Europarl (1.9M), WMT19 (41M), and AUX6 (120M). The results are shown in Table 13. We also conduct experiments on SixT+ m2m, as shown in Table 12.

F Unsupervised NMT with SixT+

In addition to CRISS and m2m-100, we compare with the state-of-the-art unsupervised and supervised baselines from the literature on these two languages. Most of these additional baselines are not multilingual and are explicitly designed for low-resource language translation.

• Unsupervised baselines. We include the results of three unsupervised methods. Guzmán et al. (2019) utilize Hi as auxiliary language and train with auxiliary supervised translation and iterative back-translation. Garcia et al. (2021) utilize six languages as auxiliary languages and present a

Table 12: BLEU comparison of our many-to-many NMT model (SixT+ m2m) with m2m-100 on zero-shot translations. We use a target-language-aware linear projection layer to generate different target languages for the SixT+ m2m model. Ours (m2En) is the many-to-English SixT+ model trained with the AUX6 dataset. We include the result of SixT+ m2m w/o PDE to help study the effect of PDE. The best average BLEU for each target language is bold and underlined.

three-stage method with various loss functions, including auxiliary supervised translation, iterative back-translation, denoising autoencoding and cross translation. Ko et al. (2021) fine-tune mBART on the parallel dataset from Hi and monolingual data in an iterative manner with auxiliary supervised translation, back-translation, denoising autoencoding and adversarial objective. Note that these methods utilize much more monolingual data than ours.

• Supervised baselines. We report the supervised results in mBART (Liu et al., 2020) and the FLoRes dataset benchmarks (Guzmán et al., 2019) for reference. These two methods are very strong. Both methods are trained on around 600k parallel corpus and more than 70M monolingual corpora with supervised translation and iterative back-translation. Liu et al. (2020) initialize the model with mBART while Guzmán et al. (2019) use auxiliary parallel corpus from related language for the `Ne↔En` translations.

G XTREME benchmark results

All models are evaluated on the XTREME benchmark (Hu et al., 2020) with jiant toolkit[20]. We follow the same settings with Phang et al. (2020) for fine-tuning and testing. The detailed results for each languages on each task are shown in Table 14 to Table 20.

Abstract

Processing open-domain Chinese texts has been a critical bottleneck in computational linguistics for decades, partially because text segmentation and word discovery often entangle with each other in this challenging scenario. No existing methods yet can achieve effective text segmentation and word discovery simultaneously in open domain. This study fills in this gap by proposing a novel method called TopWORDS-Seg based on Bayesian inference, which enjoys robust performance and transparent interpretation when no training corpus and domain vocabulary are available. Advantages of TopWORDS-Seg are demonstrated by a series of experimental studies.

1 Introduction

Due to absence of word boundaries in Chinese, Chinese natural language processing (CNLP) faces a few unique challenges, including text segmentation and word discovery. When processing open-domain Chinese corpus containing many unregistered words and named entities, these challenges become more critical as they often entangle with each other: we usually cannot segment Chinese texts correctly without knowing the underlying vocabulary; on the other hand, it is often difficult to precisely discover unregistered words and named entities from open-domain corpus without guidance on text segmentation.

Most methods for CNLP in the literature assume that the underlying vocabulary is known and focus on improving performance of text segmentation in closed test. The first category of methods along this research line are simple methods based on *Word Matching* (Chen and Liu, 1992; Geutner, 1996; Chen, 2003; Shu et al., 2017), which segment a Chinese sentence by matching sub-strings in the sentence to a pre-given vocabulary in a forward or reserve order. The second category of methods utilize manually segmented corpus or large-scale pretraining corpus to train statistical models such as *Maximum Entropy* (Berger et al., 1996; McCallum et al.; Low et al., 2005), HMM (Sproat et al., 1994; Zhang et al., 2003) and CRF (Lafferty et al., 2001; Xue, 2003; Peng et al., 2004; Luo et al., 2019), or deep learning models including CNN (Wang and Xu), LSTM (Chen et al., 2015), Bi-LSTM (Ma et al., 2018) and BERT (Yang, 2019), or hybrid models like Bi-LSTM-CRF (Huang et al., 2015) and LSTM-CNNs-CRF (Ma and Hovy, 2016), to achieve text segmentation directly or indirectly. Methods of this category have led to popular toolkits for processing Chinese texts, including Jieba (Sun, 2012), StanfordNLP (Manning et al., 2014), THULAC (Sun et al., 2016), PKUSEG (Luo et al., 2019), and LTP (Che et al., 2021). A popular strategy adopted by some of these toolkits is to segment the target texts into sequences of basic words first, and capture unregistered words and named entities, which are often word compounds consisting of basic words, later via chunking and syntactic analysis. Although such a strategy can equip these toolkits with some ability on word discovery, it is apparently sub-optimal, because we may mis-segment basic words at the first place without realizing the existence of potential technical words, making it impossible to discover technical word compounds correctly in post analysis such as chunking and syntactic analysis.

On the other hand, unsupervised methods are also developed to achieve text segmentation when no pre-given vocabulary and manually segmented training corpus are available. Some methods of this research line segment texts based on local statistics of the target texts, including *Description Length Gain* (Kit and Wilks, 1999), *Mutual Information* (Chang and Lin, 2003), *Accessor Variety* (Feng et al., 2004), *Evaluation-Selection-Adjustment Process* (Wang et al., 2011), and *Normalized Variation*

of Branching Entropy (Magistry and Sagot, 2012). The others, however, rely on generative statistical models whose parameters can be estimated from the target texts only, including *Hierarchical Dirichlet Process* (Goldwater et al., 2009), *Nested Pitman-Yor Process* (Mochihashi et al., 2009), *Bayesian HMM* (Chen et al., 2014), TopWORDS (Deng et al., 2016) and GTS (Yuan et al., 2020).

In general, methods based on word matching and unsupervised learning cannot produce high-quality text segmentation (Zhao and Kit, 2011), although some unsupervised methods are successful on word discovery (Deng et al., 2016). Methods based on supervised learning can achieve excellent performance in closed test (Emerson, 2005), but often suffer from dramatic performance degradation when applied to open-domain Chinese corpus containing many unregistered words and named entities (Liu and Zhang, 2012; Wang et al., 2019). Methods based on deep learning are usually more robust under the "pre-training and fine-tuning" framework, but still suffer from unstable performance and often fail to correctly segment technical words, which play a key role in deciphering the meaning of domain-specific texts, when applied to open-domain texts (Zhao et al., 2018; Fu et al., 2020). There are also some efforts in the literature to integrate supervised and unsupervised methods for improved performance (Zhao and Kit, 2007, 2008, 2011; Wang et al., 2019; Yang et al., 2019). But, these methods either heavily depend on manually labelled corpus for model training, or suffer from unbalanced emphasis on text segmentation and word discovery, resulting in limited improvement for CNLP in open domain. These facts make processing open-domain Chinese texts a critical bottleneck in computational linguistics even for today.

Many factors contribute to the stagnation on development of efficient tools for processing open-domain Chinese texts. From the methodology point of view, we do not have a proper learning framework yet to connect the text segmentation problem to the word discovery problem and deal with them at the same time effectively. From the practical point of view, the lack of proper evaluation criterion in open domain places a critical barrier for fair comparison of different methods and discourages researchers from looking for potential solutions.

This study tries to provide solutions to these critical issues. First, we propose a novel Bayesian framework to integrate TopWORDS, an effective word discoverer (Deng et al., 2016), and PKUSEG, a strong text segmenter, leading to a more efficient text segmenter called TopWORDS-Seg, which can achieve effective text segmentation and word discovery simultaneously in open domain. Next, we design a cocktail strategy for method evaluation and comparison by measuring the overall performance of a target method on both text segmentation in benchmark corpus and technical word discovery and segmentation in open-domain corpus. Experimental studies demonstrate that the proposed TopWORDS-Seg outperforms existing methods with a significant margin for CNLP in open domain.

2 TopWORDS-Seg

Proposed by Deng et al. (2016), TopWORDS is a general approach for offline natural language processing based on unsupervised statistical learning. Assuming that sentences are generated by randomly sampling and concatenating words from an underlying word dictionary (i.e., unigram language model), TopWORDS starts with an over-complete initial word dictionary $\mathcal{D}$ containing all plausible word candidates in the target texts, and gradually simplifies the model by removing non-significant word candidates from $\mathcal{D}$ based on statistical model selection principles, with the unknown word usage frequencies estimated by EM algorithm (Dempster et al., 1977).

TopWORDS is closely related to methods widely used in neural machine translation for constructing sub-word dictionary, and can be viewed as an advanced version of *WordPiece* (Schuster and Nakajima, 2012), *Byte Pair Encoding* (Sennrich et al., 2016) and *Unigram Language Model* (Kudo, 2018). In practice, TopWORDS is particularly effective on discovering words, technical terms and phrases from open-domain Chinese texts, but tends to segment texts with coarser granularity at phrase instead of word level.

In this section, we upgrade TopWORDS from a weak text segmenter with strong ability on word discovery to a more powerful tool enjoying balanced ability on both dimensions via Bayesian inference.

2.1 The Bayesian Framework

Following the setting in Deng et al. (2016), let $\mathcal{T} = \{T_1, \cdots, T_n\}$ be a collection of unsegmented Chinese text sequences to process, $\mathcal{A} = \{a_1, a_2, \cdots, a_M\}$ be the set of Chinese characters involved in $\mathcal{T}$, and $\mathcal{D}_{\mathcal{T}}$ be the underlying vocabulary behind $\mathcal{T}$ unknown to the investigator. We aim to discover $\mathcal{D}_{\mathcal{T}}$ from $\mathcal{T}$, and predict the invisible *word boundary profile* $B_j = (b_{j1}, \cdots, b_{jL_j})$ for each piece of unsegmented Chinese text $T_j = a_{j1}a_{j2}\cdots a_{jL_j}e$, where $b_{jl} = 1$ if there is a word boundary behind the l-th position of T_j and 0 otherwise, and e is a special end mark indicating the end of text sequence.

To learn $\mathcal{D}_{\mathcal{T}}$, we starts with an over-complete initial word dictionary $\mathcal{D} = \{w_1, w_2, \ldots, w_N, e\}$ covering all plausible word candidates in $\mathcal{T}$ (i.e., all sub-strings in $\mathcal{T}$ whose length $\leq \tau_L$ and frequency $\geq \tau_F$) and the end mark e. For simplicity, we always assume that $\mathcal{D}_{\mathcal{T}} \subset \mathcal{D}$ and all characters in $\mathcal{A}$ are covered by $\mathcal{D}$.

Under the unigram language model, we have the following likelihood function for a piece of unsegmented text T_j given B_j and $\mathcal{D}$:

$$\mathbb{P}(T_j \mid \mathcal{D}, \boldsymbol{\theta}, B_j) = \prod_{w \in \mathcal{D}} (\theta_w)^{n_w(B_j)}, \quad (1)$$

where $\boldsymbol{\theta} = \{\theta_w\}_{w\in\mathcal{D}}$ with θ_w being the usage frequency of word w in $\mathcal{T}$, and $n_w(B_j)$ counts the number of occurrences of word w in the segmented version of T_j based on B_j. Let $\boldsymbol{B} = \{B_1, \cdots, B_n\}$ being the word boundary profiles of the n text sequences in $\mathcal{T}$. We have

$$\begin{aligned}\mathbb{P}(\mathcal{T} \mid \mathcal{D}, \boldsymbol{\theta}, \boldsymbol{B}) &= \prod_{j=1}^{n} \mathbb{P}(T_j \mid \mathcal{D}, \boldsymbol{\theta}, B_j) \\ &= \prod_{w\in\mathcal{D}} (\theta_w)^{n_w(\boldsymbol{B})}, \quad (2)\end{aligned}$$

where

$$n_w(\boldsymbol{B}) = \sum_{j=1}^{n} n_w(B_j).$$

In this study, we propose to specify a joint prior distribution $\pi(\boldsymbol{\theta}, \boldsymbol{B})$ for $(\boldsymbol{\theta}, \boldsymbol{B})$ to integrate prior preference on word usage and text segmentation into the learning procedure. According to the Bayes Theorem, we have the following posterior distribution of $(\boldsymbol{\theta}, \boldsymbol{B})$ given $\mathcal{T}$ and $\mathcal{D}$:

$$\mathbb{P}(\boldsymbol{\theta}, \boldsymbol{B} \mid \mathcal{T}, \mathcal{D}) \propto \pi(\boldsymbol{\theta}, \boldsymbol{B}) \cdot \mathbb{P}(\mathcal{T} \mid \mathcal{D}, \boldsymbol{\theta}, \boldsymbol{B}),$$

which leads to the following marginal and conditional posterior distributions:

$$\begin{aligned}\mathbb{P}(\boldsymbol{\theta} \mid \mathcal{T}, \mathcal{D}) &= \int \mathbb{P}(\boldsymbol{\theta}, \boldsymbol{B} \mid \mathcal{T}, \mathcal{D}) d\boldsymbol{B}, \\ \mathbb{P}(\boldsymbol{B} \mid \mathcal{T}, \mathcal{D}, \boldsymbol{\theta}) &\propto \mathbb{P}(\boldsymbol{\theta}, \boldsymbol{B} \mid \mathcal{T}, \mathcal{D}).\end{aligned}$$

Based on $\mathbb{P}(\boldsymbol{\theta} \mid \mathcal{T}, \mathcal{D})$, model parameters $\boldsymbol{\theta}$ can be estimated by the posterior mode, i.e,

$$\hat{\boldsymbol{\theta}} = \arg\max_{\boldsymbol{\theta}} \mathbb{P}(\boldsymbol{\theta} \mid \mathcal{T}, \mathcal{D}). \quad (3)$$

Given $\hat{\boldsymbol{\theta}}$, we can further infer $\boldsymbol{B}$ according to $\mathbb{P}(\boldsymbol{B} \mid \mathcal{T}, \mathcal{D}, \hat{\boldsymbol{\theta}})$ to achieve text segmentation.

2.2 Specification of Prior Distribution

There are various ways to specify the prior distributions $\pi(\boldsymbol{\theta}, \boldsymbol{B})$. In this study, we choose to use the independent conjugate prior below for conceptual and computational convenience:

$$\pi(\boldsymbol{\theta}, \boldsymbol{B}) = \pi(\boldsymbol{\theta}) \cdot \pi(\boldsymbol{B}),$$

where

$$\begin{aligned}\pi(\boldsymbol{\theta}) &= Dirichlet(\boldsymbol{\theta} \mid \boldsymbol{\alpha}), \\ \pi(\boldsymbol{B}) &= \prod_{j=1}^{n} \pi(B_j) = \prod_{j=1}^{n}\prod_{l=1}^{L_j} \pi(b_{jl}), \\ \pi(b_{jl}) &= Binary(b_{jl} \mid \rho_{jl}),\end{aligned}$$

with $\boldsymbol{\alpha} = \{\alpha_w\}_{w\in\mathcal{D}}$ and $\boldsymbol{\rho} = \{\rho_{jl}\}$ being the hyper-parameters controlling the strength of prior information.

In this study, we choose to specify

$$\alpha_w = 1, \ \forall\, w \in \mathcal{D}, \quad (4)$$

leading to a flat prior distribution for $\boldsymbol{\theta}$, but adopt a non-flat prior distribution for $\boldsymbol{\rho}$ by smoothing the word boundary profiles $\boldsymbol{B}^* = \{B_j^*\}_{1\leq j\leq n}$ predicted by a pre-given text segmenter $\mathcal{S}^*$:

$$\rho_{jl} = \begin{cases}(1-\kappa)\cdot b_{jl}^* + \kappa\cdot\rho, & l < L_j, \\ 1, & l = L_j,\end{cases} \quad (5)$$

where b_{jl}^* is the location-specific binary segmentation indicator predicted by $\mathcal{S}^*$, $\kappa \in (0,1)$ is the smoothing parameter, and $\rho > 0$ highlights the probability to place a word boundary at each location by a pseudo segmenter that places boundaries randomly in the text sequence.

Here, we set $\rho = 0.5$ by default, and leave κ as a hyper-parameter that can be tuned to fit different application scenarios, leading to the following joint prior distribution:

$$\pi_\kappa(\boldsymbol{\theta}, \boldsymbol{B}) \propto \prod_{j=1}^{n}\prod_{l=1}^{L_j} (\rho_{jl})^{b_{jl}}(1-\rho_{jl})^{1-b_{jl}}. \quad (6)$$

2.3 Word Discovery

Given the prior distribution $\pi_\kappa(\boldsymbol{\theta}, \boldsymbol{B})$ specified previously, the posterior distribution becomes:

$$\begin{aligned} & \mathbb{P}(\boldsymbol{\theta}, \boldsymbol{B} \mid \mathcal{T}, \mathcal{D}) \\ \propto\ & \pi_\kappa(\boldsymbol{\theta}, \boldsymbol{B}) \cdot \mathbb{P}(\mathcal{T} \mid \mathcal{D}, \boldsymbol{\theta}, \boldsymbol{B}) \\ \propto\ & \prod_{j=1}^{n} \left[\pi_\kappa(B_j) \cdot \prod_{w \in \mathcal{D}} (\theta_w)^{n_w(B_j)} \right], \end{aligned} \tag{7}$$

where

$$\pi_\kappa(B_j) = \prod_{l=1}^{L_j} (\rho_{jl})^{b_{jl}} (1 - \rho_{jl})^{1 - b_{jl}}$$

is a deterministic function of κ, as ρ_{jl}'s degenerate to constants for fixed κ based on (5). Under such a Bayesian model, the problem of word discovery can be naturally converted into a statistical model selection problem, as only word candidates whose usage frequency θ_w is significantly larger than 0 could be meaningful words. We estimate $\boldsymbol{\theta}$ by the posterior mode $\hat{\boldsymbol{\theta}}$ as defined in (3), which can by obtained via the EM algorithm (Dempster et al., 1977) with $\boldsymbol{B}$ as the missing data. Details of the EM algorithm are described in Appendix A.

Once the EM algorithm gets converged, we can evaluate the statistical significance of a word candidate w by the likelihood-ratio statistics between the full model and a reduced model with w removed:

$$\psi_w = \log \left(\frac{\mathbb{P}(\mathcal{T} \mid \mathcal{D}, \hat{\boldsymbol{\theta}})}{\mathbb{P}(\mathcal{T} \mid \mathcal{D}, \hat{\boldsymbol{\theta}}_{[w=0]})} \right), \tag{8}$$

where $\hat{\boldsymbol{\theta}}_{[w=0]}$ is the modification of $\hat{\boldsymbol{\theta}}$ by setting $\hat{\theta}_w = 0$ with other elements unchanged. Apparently, a larger ψ_w suggests that word candidate w is more important for fitting the observed texts, and thus is more likely to be a meaningful word. Because $-2\psi_w \sim \chi^2$ asymptotically under the null hypothesis that the reduced model with w removed is the true model, we can filter out word candidates whose $\psi_w < \tau_\psi$, where threshold τ_ψ is the $(1 - \frac{0.05}{N})$-quantile of the χ^2 distribution, following the Bonferroni correction principle for multiple hypothesis testing. As demonstrated by Deng et al. (2016), such a model selection strategy can effectively filter out most meaningless word candidates and results in a concise final dictionary containing meaningful words and phrases only.

Considering that

$$\psi_w = -\sum_{j=1}^{n} \log\left(1 - r_{wj}\right),$$

where

$$\begin{aligned} r_{wj} &= \mathbb{P}_\kappa\left(w \sim B_j \mid T_j, \mathcal{D}, \hat{\boldsymbol{\theta}}\right) \\ &= \sum_{B_j \in \mathcal{B}_j} I\left(w \sim B_j\right) \cdot \mathbb{P}_\kappa(B_j \mid T_j, \mathcal{D}, \hat{\boldsymbol{\theta}}), \end{aligned} \tag{9}$$

with notation "$w \sim B_j$" meaning that word candidate w appears in the segmented version of T_j based on B_j, we can get ψ_w by calculating r_{wj} for each T_j.

2.4 Text Segmentation

Given $\hat{\boldsymbol{\theta}}$, plausible text segmentation of T_j can be obtained by optimizing B_j according to $\mathbb{P}_\kappa(B_j \mid T_j, \mathcal{D}, \hat{\boldsymbol{\theta}})$, i.e., segment T_j according to

$$\hat{B}_j = \max_{B \in \mathcal{B}_j} \mathbb{P}_\kappa(B \mid T_j, \mathcal{D}, \hat{\boldsymbol{\theta}}). \tag{10}$$

Alternatively, we can also calculate the posterior probability of existing a word boundary at position (j, l) as

$$\gamma_{jl} = \sum_{B \in \mathcal{B}_j} b_{jl} \cdot \mathbb{P}_\kappa(B_j \mid T_j, \mathcal{D}, \hat{\boldsymbol{\theta}}), \tag{11}$$

and segment T_j based on

$$\tilde{B}_j = I(\boldsymbol{\gamma}_j \geq \tau_S), \tag{12}$$

where $\boldsymbol{\gamma}_j = (\gamma_{j1}, \cdots, \gamma_{jL_j})$ and τ_S is a pre-given threshold with 0.5 as the default value. Here, we choose to use the second segmentation strategy, because it leads to more robust results in practice.

2.5 TopWORDS-Seg Algorithm

Integrating the dictionary initialization stage via sub-string enumeration, the prior construction stage guided by a pre-given segmenter $\mathcal{S}^*$ (i.e., PKUSEG by default), the word discovery stage empowered by EM algorithm and likelihood-ratio tests, and the text segmentation stage based on conditional probability inference, into a united framework, we come up with the TopWORDS-Seg algorithm as demonstrated in Figure 1. Computation issues involved in the algorithm are detailed in Appendix B.

A collection of hyper-parameters, including τ_L, τ_F, κ, ρ and τ_S, are associated with the TopWORDS-Seg algorithm, and need be specified to initiate the algorithm. We recommend to set $\tau_L = 15$, $\tau_F = 2$ and $\rho = \tau_S = 0.5$ by default. The specification of hyper-parameter κ is a bit complicated. To capture unregistered words from open-domain texts more efficiently, we would like to

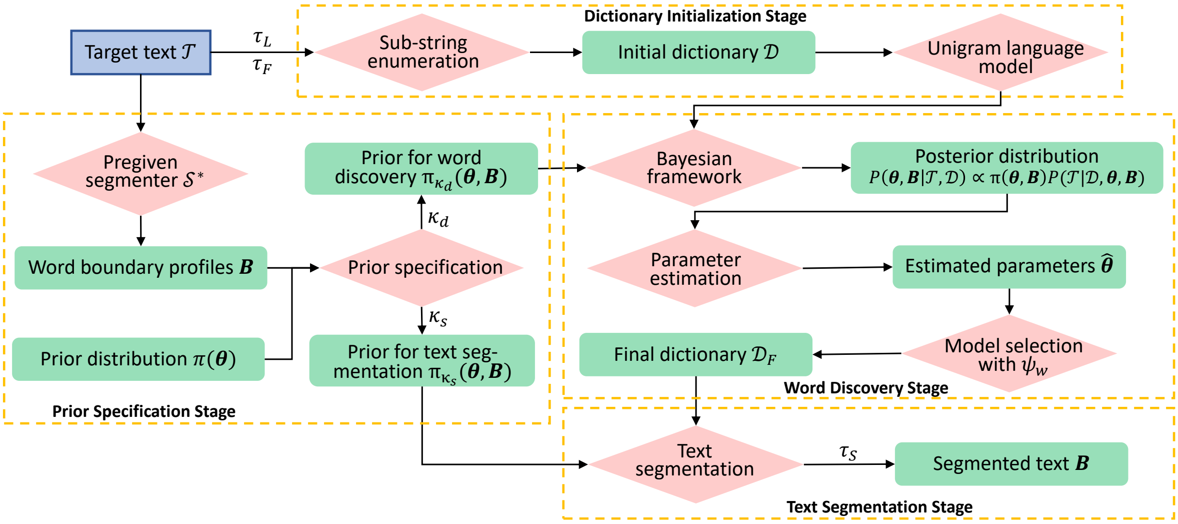

Figure 1: Flow chart of the TopWORDS-Seg

choose a larger κ to encourage word discovery. To segment regular texts more precisely, however, we would like to choose a smaller κ instead to better utilize the prior information. To get rid of the dilemma, we allow to specify κ with different values in different tasks, i.e., using a large κ (referred to as κ_d) in the word discovery stage and a small κ (referred to as κ_s) in the text segmentation stage. Based on a wide range of experimental studies, we suggest to set $\kappa_d = 0.5$ and $\kappa_s = 0.001$ by default.

3 Experimental Study on Wikipedia

Composed of over 10 billion Chinese character tokens from 3.6 million webpages, Chinese Wikipedia (`https://dumps.wikimedia.org/`) is one of the largest open-source Chinese corpus. Containing rich contents of various domains and millions of technical terms highlighted by hyperlinks, the Chinese Wikipedia is an ideal corpus for studying CNLP in open domain.

Considering that it's computationally expensive to processing all webpages in Chinese Wikipedia, we randomly picked up 1,500 webpages involving 8 million Chinese character tokens (referred to as Chinese Wiki-Rand, or $\mathcal{T}_{W\text{-}R}$) as the representative samples of the general texts in Chinese Wikipedia. Moreover, we selected two collections of special webpages from Chinese Wikipedia with label "电影" (referred to as Chinese Wiki-Film, or $\mathcal{T}_{W\text{-}F}$) or "物理" (referred to as Chinese Wiki-Physics, or $\mathcal{T}_{W\text{-}P}$), involving ~5 million Chinese character tokens for each, as the representatives of the domain-specific texts in Chinese Wikipedia. Figure 2 (a) and (b) demonstrates a typical Wikipedia web page and histograms for term length and appearance frequency of technical terms involved in $\mathcal{T}_{W\text{-}R}$.

In this section, we apply TopWORDS-Seg to process these Wikipedia corpora separately, and compare its performance to 6 existing methods, including Jieba (Sun, 2012), StanfordNLP (Manning et al., 2014), THULAC (Sun et al., 2016), PKUSEG (Luo et al., 2019), LTP (Che et al., 2021), and TopWORDS (Deng et al., 2016) itself, from various aspects.

3.1 Performance Evaluation Criteria

Due to the lack of gold standard, it is not straightforward to evaluate and compare the performance of different methods on open-domain corpus like Chinese Wikipedia. Here, we propose a cocktail strategy for method evaluation by measuring the overall performance of each method on both open-domain corpuora and benchmark corpus.

Let V_t be the collection of frequent technical terms in a particular Wikipedia corpus (terms with hyperlinks appear at least 2 times), with n_w be the number of occurrences for each $w \in V_t$. Suppose V is the discovered vocabulary reported by a particular method $\mathcal{M}$, and m_w is the number of successful catches of w by $\mathcal{M}$. Taking advantage of the self-labelled technical terms with hyperlinks in Wikipedia webpages, it is straightforward to measure *discovery recall* R_d and *segmentation recall* R_s for technical terms in V_t as below:

$$R_d = \frac{|V_t \cap V|}{|V_t|} \quad \text{and} \quad R_s = \frac{\sum_{w \in V_t} m_w}{\sum_{w \in V_t} n_w}. \quad (13)$$

Together, R_d and R_s reflect the ability of method

$\mathcal{M}$ to deal with technical terms in open-domain texts.

Because it is difficult to directly evaluate the perform of a method $\mathcal{M}$ on segmenting non-technical contents of the Wikipedia corpus, we retreat to indirect evaluation by evaluating its performance on segmenting the PKU corpus $\mathcal{T}_P$, a benchmark corpus with gold standard released by SIGHAN 2005 Bake-Off (Emerson, 2005), instead. Let F_s be the F_1 score of method $\mathcal{M}$ on text segmentation for the PKU corpus. Score F_s reflects $\mathcal{M}$'s ability to process general Chinese texts without technical contents.

Apparently, R_d, R_s and F_s measure the strength of a method comprehensively from various aspects, with both word discovery and text segmentation considered for technical as well as non-technical texts. Such a cocktail strategy provide us a principle to evaluate and compare the overall performance of different CNLP methods in open domains. If a method enjoys high R_d, R_s and F_s values across different corpora stably, we would feel comfortable to claim it as a robust tools for CNLP in open domains.

3.2 Results

Figure 2 (c) summarizes the performance of TopWORDS-Seg (with the default setting) and the 6 competing methods on the Wikipedia and PKU corpora in terms of R_d, R_s and F_s, with the size of discovered vocabulary $|V|$ reported as well. Comparing these results, we find that TopWORDS-Seg enjoys robust performance on segmenting classic benchmark corpus ($F_s = 82.2\%$ for $\mathcal{T}_P$), open-domain corpus ($R_s = 76.5\%$ for $\mathcal{T}_{W\text{-}R}$) and domain-specific corpus ($R_s = 76.8\%$ and 70.8% for $\mathcal{T}_{W\text{-}F}$ and $\mathcal{T}_{W\text{-}P}$ respectively), and high efficiency on discovering technical terms ($R_d > 82\%$ for all three Wikipedia corpora). The other methods, however, all suffer from either missing too many technical terms in the Wikipedia corpora (R_d ranging from 45% to 77% as in supervised methods), or segmenting the PKU corpus poorly ($F_s = 50.4\%$ as in TopWORDS). Considering that TopWORDS-Seg reports a vocabulary that is 16K smaller than TopWORDS, it actually outperforms TopWORDS significantly in all dimensions.

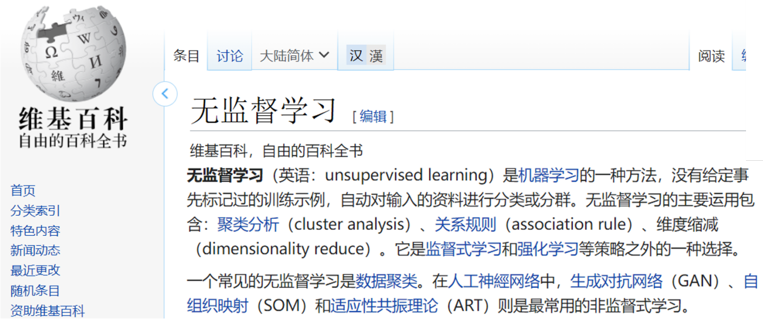
Moreover, considering that both TopWORDS and TopWORDS-Seg tend to segment Chinese texts at coarser granularity with technical terms and phrases preserved as composite words instead of cutting them into smaller language units, the text segmentation standard adopted by the PKU corpus, which tends to segment Chinese texts at finer granularity, may over-punish them. To ease the impact on performance evaluation due to segmentation granularity, we choose to mask part of the PKU corpus $\mathcal{T}_P$ where method $\mathcal{M}$ is not consistent with the standard segmentation only on granularity (with the concrete criteria detailed in Appendix C), and measure the F_1 score of method $\mathcal{M}$ on the masked version of $\mathcal{T}_P$ only, leading to a masked version of F_s referred to as F_m. The proportion of masked corpus (i.e., *mask rate*) is also calculated for each method and reported in Figure 2 (c). TopwORDS-Seg achieves an improved $F_m = 93.7\%$ with a mask rate of 16.6%, suggesting that TopwORDS-Seg actually segments the PKU corpus very well. Meanwhile, a much higher mask rate of 50.4% is obtained for TopWORDS, which is consistent to our impression that TopWORDS tends to preserve too many sub-phrases in text segmentation.

In addition, because some methods based on supervised learning, e.g., Jieba, THULAC and PKUSEG, can receive external vocabulary for processing open-domain corpus, there exists an alternative strategy to integrate TopWORDS with thses methods by simply forwarding the vocabulary discovered by TopWORDS to them. We refer to approaches based on this strategy as TopWORDS-Jieba/THULAC/PKUSEG, and report their performance on both Chinese Wikipedia corpus and PKU corpus in Figure 2 (c) as well. Unfortunately, although this family of approaches achieve a higher R_d in general, they tend to report an over-large vocabulary and segment texts with coarser granularity like TopWORDS does. These results indicate that simply concatenating TopWORDS to other methods does not necessarily lead to an improved approach, and thus imply that the proposed strategy based on Bayesian inference is not trivial.

The heatmaps in Figure 2 (d) demonstrate the similarity on text segmentation of different methods on four different target corpora, where the similarity between any two methods $\mathcal{M}_i$ and $\mathcal{M}_j$ is measured by

$$\phi_{ij} = \frac{\sum_{T \in \mathcal{T}_D} sum(B_T^{(i)} \wedge B_T^{(j)})}{\sum_{T \in \mathcal{T}_D} sum(B_T^{(i)} \vee B_T^{(j)})},$$

with $B_T^{(i)}$ denoting the predicted word boundary vector of text sequence T by method $\mathcal{M}_i$. From the figure, we can see clearly that text segmentation



维基百科

无监督学习 [编辑]

维基百科，自由的百科全书

无监督学习（英语：unsupervised learning）是机器学习的一种方法，没有给定事先标记过的训练示例，自动对输入的资料进行分类或分群。无监督学习的主要运用包含：聚类分析（cluster analysis）、关系规则（association rule）、维度缩减（dimensionality reduce）。它是监督式学习和强化学习等策略之外的一种选择。

一个常见的无监督学习是数据聚类。在人工神經网络中，生成对抗网络（GAN）、自组织映射（SOM）和适应性共振理论（ART）则是最常用的非监督式学习。

(d) Similarity on text segmentation of different methods on four different target corpora. (e) Segmentation results on a typical sentence

reported by TopWORDS-Seg is very similar to the results reported by supervised methods, but is significantly different from the result reported by TopWORDS for all four corpora. Such results confirm the strength of TopWORDS-Seg on text segmentation in addition to word discovery, and provide strong evidences to support TopWORDS-Seg as a powerful tool for processing open-domain Chinese texts.

Figure 2 (e) shows an illustrative example of text segmentation of PKUSEG, TopWORDS and TopWORDS-Seg for a piece of target text, respectively. Apparently, PKUSEG segments the target text almost perfectly except for chopping the technical term *allotropes* (同素异形体) into three substrings by mistake, due to the lack of ability to recognize unregistered words. TopWORDS, however, successfully recognizes and segments the technical term *allotropes* correctly, but segments the other part of the target text with coarser granularity leaving phrases like *physical properties* (物理特性) and *extremely different* (差异极大) as unsegmented language units. TopWORDS-Seg, as expected, segments the target text perfectly, with

the technical term *allotropes* correctly recognized and the rest part segmented with proper granularity.

4 Processing the Book of *Deep Learning*

Written by Goodfellow et al. (2016), the book *Deep Learning* has become a classic tutorial for deep learning. In 2017, its Chinese version was published in China (see Figure 3 (a) for the book's cover), which is composed of more than 400,000 Chinese character tokens (referred to as $\mathcal{T}_D$). Covering rich technical contents in the domain of machine learning, including over 800 technical terms as listed in the Index Table at the end of the book, such a book is an ideal target for testing the performance of the proposed TopWORDS-Seg in real application.

Feeding full text of the book to TopWORDS-Seg and competing methods respectively, we obtained results as summarized in Figure 3. Figure 3 (b) shows that TopWORDS-Seg discovers 84.1% technical terms listed in the Index Table of the book with a vocabulary of 10.7K discovered words. TopWORDS achieves a slightly higher $R_d = 85.0\%$ at the price of a larger vocabulary with 12.8K discovered words. Other methods based on supervised learning result in much lower R_d with the vocabulary size varying between 6.8K to 12.2K. Figure 3 (d) shows the most frequent words discovered by TopWORDS-Seg. Figure 3 (e) displays part of the technical terms captured by TopWORDS-Seg but missed by all supervised methods, which are all meaningful technical terms like *unsupervised learning* (无监督学习) and *stochastic gradient decent* (随机梯度下降). Figure 3 (f) summarizes typical pseudo words and phrases reported by TopWORDS but eliminated by TopWORDS-Seg, which are all common collocations widely used but usually not treated as words in Chinese, e.g., *in the model* (模型中) and *it is because of* (是因为). These results suggest that TopWORDS-Seg is indeed more effective than competing methods on word discovery.

In terms of text segmentation, the heatmap in Figure 3 (c) visualizes the similarity between TopWORDS-Seg and other approaches on this corpus in a similar fashion as in Figure 2 (d). Again, the performance of TopWORDS-Seg is very similar to the supervised methods, and demonstrates significant difference from TopWORDS, suggesting that TopWORDS-Seg is a robust tool with balanced ability on processing open-domain Chinese texts.

5 Conclusions and Discussions

In this paper, we proposed TopWORDS-Seg, a powerful tool for processing open-domain Chinese texts based on Bayesian inference with balanced ability on text segmentation and word discovery. A series of experimental studies confirm that TopWORDS-Seg can discover unregistered technical terms in open-domain texts effectively, and achieve high-quality text segmentation on both benchmark and open-domain corpora. Taking advantage of the Bayesian framework, TopWORDS-Seg is ready to process large scale open-domain Chinese texts without extra training corpus or pre-given domain vocabulary, leading to an ideal solution to a critical bottleneck existing in computational linguistics for decades. Moreover, combing the strong points of PKUSEG and TopWORDS via Bayesian inference, TopWORDS-Seg enjoys transparent reasoning process, and is fully interpretable to most people. In practical applications, such a property is very attractive to many researchers and practicers.

Meanwhile, TopWORDS-Seg also suffers from a few obvious limitations. For example, although the current learning framework is effective to discover frequent words, it tends to miss many rare words that appear only a few times in the texts. For another instance, because PKUSEG is more reliable on segmenting general texts, but less reliable on segmenting technical texts, in the ideal case we should adopt prior information provided by PKUSEG adaptively when processing texts of different types. Unfortunately, TopWORDS-Seg does not take such a natural idea into consideration yet, and simply use the PKUSEG prior at the same intensity everywhere. These deficiencies partially explain why TopWORDS-Seg still misses about 15% technical terms in both experimental studies reported in this paper. More research efforts are needed to fill in these gaps in future.

A EM Algorithm for Estimating $\hat{\boldsymbol{\theta}}$

Given $\boldsymbol{\theta}^{(t)}$, the current estimation of $\boldsymbol{\theta}$, the E-step computes the Q-function below:

$$\begin{aligned} & Q(\boldsymbol{\theta}, \boldsymbol{\theta}^{(t)}) \\ = \; & \mathbb{E}\left(\log\left(\mathbb{P}(\boldsymbol{\theta}, \boldsymbol{B} \mid \mathcal{T}, \mathcal{D})\right) \mid \mathcal{T}, \mathcal{D}, \boldsymbol{\theta}^{(t)}\right) \\ = \; & C + \sum_{w \in \mathcal{D}} \left(\log \theta_w \cdot n_w(\boldsymbol{\theta}^{(t)})\right), \qquad (14) \end{aligned}$$

where C is constant that does not change with $\boldsymbol{\theta}$,

$$n_w(\boldsymbol{\theta}^{(t)}) = \sum_{j=1}^{n} n_{w,j}(\boldsymbol{\theta}^{(t)}), \qquad (15)$$

$$\begin{aligned} n_{wj}(\boldsymbol{\theta}^{(t)}) &= \mathbb{E}\left(n_w(B_j) \mid T_j, \mathcal{D}, \boldsymbol{\theta}^{(t)}\right) \\ &= \sum_{B_j \in \mathcal{B}_j} n_w(B_j) \cdot \mathbb{P}_\kappa\left(B_j \mid T_j, \mathcal{D}, \boldsymbol{\theta}^{(t)}\right), \qquad (16) \end{aligned}$$

$$\begin{aligned} & \mathbb{P}_\kappa\left(B_j \mid T_j, \mathcal{D}, \boldsymbol{\theta}^{(t)}\right) \\ = \; & \frac{\mathbb{P}(T_j \mid \mathcal{D}, \boldsymbol{\theta}^{(t)}, B_j) \cdot \pi_\kappa(B_j)}{\sum_{B \in \mathcal{B}_j} \mathbb{P}(T_j \mid \mathcal{D}, \boldsymbol{\theta}^{(t)}, B) \cdot \pi_\kappa(B)}, \qquad (17) \end{aligned}$$

and $\mathcal{B}_j$ stands for the collection of all possible word boundary profiles of T_j. The M-step updates $\boldsymbol{\theta}^{(t)}$ by maximizing $Q(\boldsymbol{\theta}, \boldsymbol{\theta}^{(t)})$ with respect to $\boldsymbol{\theta}$, leading to the updating function below:

$$\theta_w^{(t+1)} = \frac{n_w(\boldsymbol{\theta}^{(t)})}{\sum_{w \in \mathcal{D}} n_w(\boldsymbol{\theta}^{(t)})}, \; \forall\, w \in \mathcal{D}. \qquad (18)$$

Along the updating procedure of the EM algorithm, word candidates with low estimated usage frequency (e.g., $\hat{\theta}_w < \tau_\theta = 10^{-8}$) can be gradually removed from $\mathcal{D}$ to simplify the model. When EM algorithm gets converged, we can get the estimation of posterior mode, $\hat{\boldsymbol{\theta}}$.

B Computational Details

Considering that

$$\psi_w = -\sum_{j=1}^{n} \log\left(1 - r_{wj}\right),$$

where

$$\begin{aligned} r_{wj} &= \mathbb{P}_\kappa\left(w \sim B_j \mid T_j, \mathcal{D}, \hat{\boldsymbol{\theta}}\right) \\ &= \sum_{B_j \in \mathcal{B}_j} I\left(w \sim B_j\right) \cdot \mathbb{P}_\kappa(B_j \mid T_j, \mathcal{D}, \hat{\boldsymbol{\theta}}), \end{aligned} \tag{19}$$

with notation "$w \sim B_j$" meaning that word candidate w appears in the segmented version of T_j based on B_j, we can get ψ_w by calculating r_{wj} for each T_j.

Thus, to implement the TopWORDS-Seg algorithm, we need to calculate n_{wj} in (15), r_{wj} in (19), $\hat{B}_j$ in (10) or γ_{jl} in (12) for $\forall\ T_j \in \mathcal{T}$. For a specific $T_j = T = a_1 \cdots a_L$, we define $T_{[t:s]} = a_t \cdots a_s$. It can be showed that n_{wj}, r_{wj} and γ_{jl}, which are all functions of T_j, have the formulation below:

$$\begin{aligned} n_w(T) &= \frac{1}{p(T)} \sum_{1 \le t < s \le L} \Big[p(T_{[<t]}) \cdot p(T_{[>s]}) \\ &\quad \cdot \theta_w \cdot \prod_{t \le l < s} (1-\rho_l) \cdot \rho_s \cdot I(T_{[t:s]} = w) \Big], \\ r_w(T) &= \frac{1}{p(T)} \sum_{t=1}^{\tau_L} \Big[r_w(T_{[>t]}) \cdot I(T_{[1:t]} \neq w) + \\ I(T_{[1:t]} = w) \Big] &\cdot \theta_{T_{[\le t]}} \cdot \prod_{1<l<t} (1-\rho_l) \cdot \rho_t \cdot p(T_{[>t]}), \\ \gamma_l(T) &= \frac{p(T_{[\le l]}) \cdot p(T_{[>l]})}{p(T)}, \end{aligned}$$

where

$$\begin{aligned} p(T_{[t:s]}) &= \mathbb{P}_\kappa(T_{[t:s]} \mid \mathcal{D}, \boldsymbol{\theta}) \\ &= \sum_{B \in \mathcal{B}_{[t:s]}} \mathbb{P}(T_{[t:s]} \mid B, \mathcal{D}, \boldsymbol{\theta}) \cdot \pi_\kappa(B), \end{aligned}$$

with $\mathcal{B}_{[t:s]}$ being the truncated version of $\mathcal{B}$ according to the position window $[t:s]$.

As $p(T_{[<t]})$ and $p(T_{[>t]})$ can be derived in linear time via dynamic programming based on the following recursion:

$$\begin{aligned} p(T_{[<t]}) &= \sum_{1 \le s \le \min(t-1, \tau_L)} \Big[p(T_{[<t-s]}) \\ &\quad \cdot \theta_{T_{[t-s:t-1]}} \cdot \prod_{t-s \le l < t-1} (1-\rho_l) \cdot \rho_{t-1} \Big], \\ p(T_{[>t]}) &= \sum_{1 \le s \le \min(L-t, \tau_L)} \Big[p(T_{[>t+s]}) \\ &\quad \cdot \theta_{T_{[t+1:t+s]}} \cdot \prod_{t+1 \le l < t+s} (1-\rho_l) \cdot \rho_{t+s} \Big], \end{aligned}$$

all computation issues involved can be efficiently resolved.

C Criteria for Masking PKU Corpus

For a specific text sequence $T = a_1 \cdots a_L \in \mathcal{T}_W$, let $B^* = (b_1^*, \cdots, b_L^*)$ be the standard segmentation adopted by the PKU corpus, while $B = (b_1, \cdots, b_L)$ be its word boundary profile predicted by a segmentation method $\mathcal{M}$. For each sub-string $S = a_{i_1} \cdots a_{i_2}$ of T, we say method $\mathcal{M}$ segments S with a coarser granularity with respect to B^* (denoted as $S \in \mathcal{G}_{\mathcal{M},B^*}$), if

$$b_{i_1-1} = b^*_{i_1-1} = 1 = b^*_{i_2} = b_{i_2}, \text{ and}$$

$$\sum_{i_1<l<i_2} b_l = 0 \text{ and } \sum_{i_1<l<i_2} b_l^* > 0.$$

Masking all sub-string $S \in \mathcal{G}_{\mathcal{M},B^*}$, we obtain the masked version of $\mathcal{T}_W$.

An Unsupervised Multiple-Task and Multiple-Teacher Model for Cross-lingual Named Entity Recognition

Abstract

Cross-lingual named entity recognition task is one of the critical problems for evaluating the potential transfer learning techniques on low resource languages. Knowledge distillation using pre-trained multilingual language models between source and target languages have shown their superiority in transfer. However, existing cross-lingual distillation models merely consider the potential transferability between two identical single tasks across both domains. Other possible auxiliary tasks to improve the learning performance have not been fully investigated. In this study, based on the knowledge distillation framework and multi-task learning, we introduce the similarity metric model as an auxiliary task to improve the cross-lingual NER performance on the target domain. Specifically, an entity recognizer and a similarity evaluator are first trained in parallel as two teachers from the source domain. Then, two tasks in the student model are supervised by these teachers simultaneously. Empirical studies on the three datasets across 7 different languages confirm the effectiveness of the proposed model.

1 Introduction

Named entity recognition, NER in short, refers to identifying entity types, i.e. location, person, organization, etc., in a given sentence. The exploiting of deep neural networks, such as Bi-LSTM-CRF (Lample et al., 2016), Bi-LSTM-CNN (Chiu and Nichols, 2016) makes this task achieve significant performances. However, since deep neural networks highly rely on a large amount of labelled training data, the annotation acquiring process is expensive and time consuming. This situation is more severe for zero-resource languages. With the help of transfer learning (Ruder et al., 2019) and multilingual BERT (short as mBERT) (Devlin et al., 2019), it is possible to transfer the annotated training samples or trained models from a rich-resource domain to a zero-resource domain.

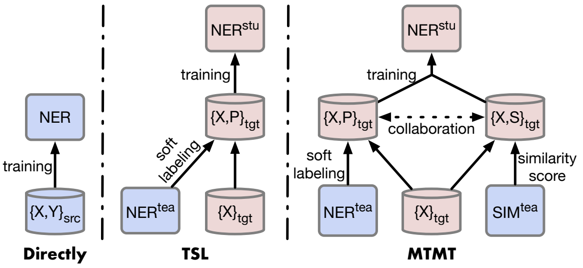

Figure 1: Comparison between previous cross-lingual NER models. **Directly**: direct model transfer; **TSL**: teacher-student learning model; **MTMT**: proposed multiple-task and multiple-teacher Model. NER / NER^{tea}: learned NER model for source language; NER^{stu}: learned NER model for target language; SIM^{tea} learned similarity model for source language; $\{X, Y\}_{src}$: labeled data in source language; $\{X\}_{tgt}$: unlabeled data in target language; $\{X, P\}_{tgt}$: labeled data in target language with probability; $\{X, S\}_{tgt}$: labeled data in target language with entity similarity score.

Many studies have been done to solve this cross-lingual NER problem. Existing models can be separated into three categories, shared feature space based, translation based and knowledge distillation based. Shared feature space based models exploit language-independent features, which lacks the domain-specific features for the target language (Tsai et al., 2016; Wu and Dredze, 2019; Keung et al., 2019). Translation based models generate pseudo labeled target language data to train the cross-lingual NER model, but the noise from translation process restrains its performance. (Mayhew et al., 2017; Xie et al., 2018; Wu et al., 2020b). Knowledge distillation based models train a student model using soft labels of the target language (Wu et al., 2020a,b; Chen et al., 2021; Liang et al.,

Volume 1: Long Papers, pages 170 - 179
May 22-27, 2022

2021).

Although the above-mentioned models solve the cross-lingual NER problem to some extent, the auxiliary tasks, as in multi-task learning, have not been studied in this problem. Due to the distributed representation of natural languages, the relatedness among the embedding of target languages, which is measured by the similarity, can be utilized to further boost the learned encoder and improve the final NER performance on target languages.

Here we give a concrete example to illustrate the importance of similarity between every two tokens under the situation when only the English data is labeled. Given a Spanish sentence "*Arévalo (Avila), 23 may (EFE).*", the token "*Arévalo*" is recognized as ORG type using the learned model from the English domain. In the meantime, the token "*Arévalo*" has high similarity scores with the Spanish tokens "*Viena*" from sentence "*Viena, 23 may (EFE).*", and "*Madrid*" from sentence "*Madrid, 23 may (EFE).*". Also, the tokens "*Viena*" and "*Madrid*" are recognized correctly as LOC type using the same English model mentioned above. Then "*Arévalo*" can be recognized correctly as LOC type under the supervisory signal using the similarity between "*Viena*" and "*Madrid*".

To leverage the similarity between the tokens of the source languages, we design an multiple-task and multiple-teacher model (short as MTMT, as shown in Figure 1), which helps the NER learning process on the target languages. Specifically, we first introduce the knowledge distillation to build entity recognizer and similarity evaluator teachers in the source language and transfer the learned patterns to the student in the target language. In the student model, we then borrow the idea of multi-task learning to incorporate a similarity evaluation task as an auxiliary task into the entity recognition classifier. During the student learning process, we input unlabelled samples from the target languages into the entity recognizer and evaluator, and take output pesudo labels as supervisory signals for these two tasks in the student model. Note that a weighting strategy is also provide therein to take into consideration of the reliability of the teachers.

We validate the model performance on the three commonly-used datasets across 7 languages and the experimental results show the superiority of our presented MTMT model.

Our main contributions are as follows:

- We propose an unsupervised knowledge distillation framework for cross-lingual named entity recognition and develop a teaching and learning procedure under this framework.
- We present a novel multiple-task and multiple-teacher model that introduces an entity similarity evaluator to boost the performance of student recognizer on target languages.
- We conduct extensive experiments on 7 languages compared with state-of-the-art baselines and the results confirm the effectiveness of the presented model.

2 Related Work

Our approach is closely related to the existing works on cross-lingual NER, knowledge distillation, and siamese network.

Cross-Lingual NER aims to extract entities from a target language but assumes only source language is annotated. The existing models can be categorized to a) Shared feature space based models, b) Translation based models, c) Knowledge distillation based models.

Shared feature space based models generally train a language-independent encoder using source and target language data (Tsai et al., 2016). Recently, the pre-trained multilingual language model is effective to address the challenge (Devlin et al., 2019). Moreover, some research introduces new components on top of the mBERT by directly transferring the model learned from the labeled source language to that of target languages (Keung et al., 2019). The performance is still weak due to the lack of annotations of target languages.

Translation based models generally generate pseudo-labeled target data to alleviate target data scarcity. For example, (Wu et al., 2020b; Zhang et al., 2021) gain an improvement by translating the labeled source language to the target language word-by-word. Our model achieves considerable improvement by learning entity similarity in target language data without translation.

Knowledge distillation based models include a teacher model and a student model (Wu et al., 2020c). The teacher model is trained on the labeled source language. The student model learns from the soft label predicted by the teacher model on unlabeled target language data. Therefore, the student model can capture the extra knowledge about target languages. In our work, the student model not only learns the recognizer teacher knowledge, but also learns the entity similarity knowledge inspired by multi-task learning.

Siamese Network is originally introduced by (Bromley et al., 1994) to treat signature verification as a matching problem. It has been successfully applied to transfer learning such as one-shot image recognition (Koch et al., 2015), text similarity (Neculoiu et al., 2016). However, there is a dilemma to adapt the siamese network to token-level recognition tasks such as NER. Siamese network assumes the input is a pair, and the output is a similarity score. To handle this issue, we reconstruct the data to pair format. To the best of our knowledge, we are the first to learn the entity similarity by siamese network.

3 Framework

In this section, we introduce our framework and its detailed implementation. Our framework is consist of two models: *teacher training model* learned from the source language and *teacher-student distillation learning model* learned from the target language. In the teacher training model, there are two sub-models, i.e. an entity recognizer teacher and a similarity evaluator teacher. These two models are two parallel tasks, wherein the entity recognition teacher focuses on identifying the named entities and the similarity evaluator teacher is to decide if two tokens are in the same type.

We then present a teacher-student distillation learning model to learn from the two learned teacher models simultaneously. We note that, in this learning process, such a knowledge distillation makes the student model combine the advantages of both source language patterns of entity recognition and entity similarity evaluation. During the learning process, the samples from the target language are fed into the teacher model and the outputs are taken as the supervisory signal for two tasks in the student model. To guarantee the student learning performance, we assign weights for each supervisory signal correspond to the output confidence of teacher sub-models. We argue that the student entity recognition task and the student entity similarity evaluation task improve the representation learning of the student encoder in the siamese structure.

3.1 Problem Definition

Following standard practice, we formulate cross-lingual NER as a sequence labeling task. Given a sentence $\boldsymbol{x} = \{x_i\}_{i=1}^{L}$ with L tokens, a NER model produces a sequence of labels $\boldsymbol{y} = \{y_i\}_{i=1}^{L}$, where x_i is the i-th token and y_i is the corresponding label of x_i. In the source language, we denote the labeled training data as $\mathcal{D}_{train}^{S} = \{(\boldsymbol{x}, \boldsymbol{y})\}$ and test data as $\mathcal{D}_{test}^{S}$. In the target language, we denote the unlabeled train data as $\mathcal{D}_{train}^{T} = \{\boldsymbol{x}\}$ and the test data as $\mathcal{D}_{test}^{T}$. Formally, our goal is to train a model with $\mathcal{D}_{train}^{S}$ and $\mathcal{D}_{train}^{T}$ to perform well on $\mathcal{D}_{test}^{T}$.

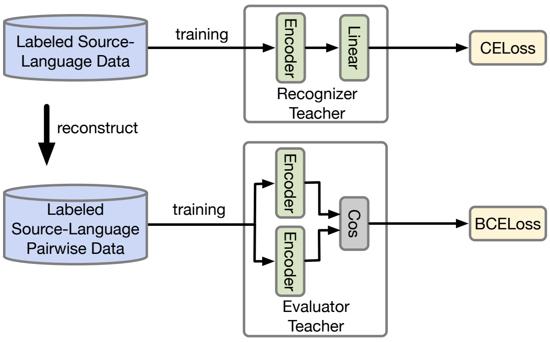

Figure 2: The training process of teacher models.

3.2 Teacher Models

Here we first consider the training of two teacher models. For every two tokens, we define *Entity Similarity Metric* as a score which is the probability that two tokens belong to the same entity type. We aim to find entity similarity to help the cross-lingual NER model in the target language. It is a non-trivial task since we lack golden labels to help us distinguish target named entities. To address this challenge, we propose a binary classifier called similarity evaluator to leverage the labeled source language data for similarity prediction. Our similarity evaluator model, inspired by siamese network (Koch et al., 2015), are able to acquires more powerful features via capturing the invariances to transformation in the input space. Figure 2 illustrated the two teacher models training. The following subsections will illustrate the two teacher models sequentially.

3.2.1 Entity Recognizer

Since the cross-lingual NER task, we unitize multilingual mBERT (Wu and Dredze, 2019) as basic sequence feature extractor backbone to derive the sequence embedding representation throughout this paper. And a linear classifier with softmax upon the pre-trained mBERT output. The model network structure could be formulated as,

$$\begin{aligned} \boldsymbol{h} &= \text{mBERT}(\boldsymbol{x}) \\ \hat{y}_i &= \text{softmax}(W h_i + b) \end{aligned}$$

where $\boldsymbol{h} = \{h_i\}_{i=1}^{L}$ and h_i denotes the output of the pre-trained mBERT that corresponds to the input token x_i. $\hat{y}_i$ denotes the predicted probability distribution for x_i. W and b are trainable parameters. For some sentence sample $(\boldsymbol{x}, \boldsymbol{y}) \in \mathcal{D}^{S}_{train}$ and an entity token query index i, the loss function is,

$$\mathcal{L}_{ER}(\boldsymbol{x}, \boldsymbol{y}, i) = \mathcal{L}_{CE}(y_i, \hat{y}_i)$$

We train this entity recognition teacher model on the source lingual training corpus $\mathcal{D}^{S}_{train} = \{(\boldsymbol{x}, \boldsymbol{y})\}$ directly.

3.2.2 Siamese Entity Similarity Evaluator

To leverage the entity similarity to boost the unsupervised cross-lingual NER performance, we will present our entity pairs construction method and the siamese network model in the following.

Entity Similarity Pairs Construction According to entity labels, we randomly select sentences pair $< \boldsymbol{x}, \boldsymbol{x'} >$ with their some token pair $< x_i, x'_j >$ and associated labels $< y_i, y'_j >$ in $\mathcal{D}^{S}_{train}$, to form the siamese supervision training dataset, $\mathcal{D}^{S-siam}_{train} = \{(\boldsymbol{x}, \boldsymbol{x'}, i, j, t)\}$ where the target $t = 1$ indicates $y_i = y'_j$, and 0 otherwise. And the testing entity pairs $\mathcal{D}^{S-siam}_{test}$ is constructed likewisely.

Siamese Entity Similarity Network Our similarity backbone model is a siamese neural network with mBERT as feature extraction layer. Wherein $\boldsymbol{h}$ and $\boldsymbol{h'}$ represent latent sequences encoding features derived by the two symmetric twins with respect to input sentence $\boldsymbol{x}$ and $\boldsymbol{x'}$ respectively.

The inter-entities similarity is measured on the hidden representations h_i and h'_j of the tokens queried by the entity indices $< i, j >$ on the sequences representations. The cosine function operator is added to compute on the entity token latent vectors' distance, s to measure the similarity between each siamese twin, which is fed into a single sigmoid output unit for target $\hat{t}$ estimation.

More precisely, for a specific entity pair $(\boldsymbol{x}, \boldsymbol{x'}, i, j, t) \in \mathcal{D}^{S-siam}_{train}$, the siamese network could be formulated as,

$$\begin{aligned} \boldsymbol{h} = &\text{mBERT}(\boldsymbol{x}),\ \boldsymbol{h'} = \text{mBERT}(\boldsymbol{x'}) \\ \hat{t}(&\boldsymbol{x}, \boldsymbol{x'}, i, j) = \sigma(\cos(h_i, h'_j)) \end{aligned}$$

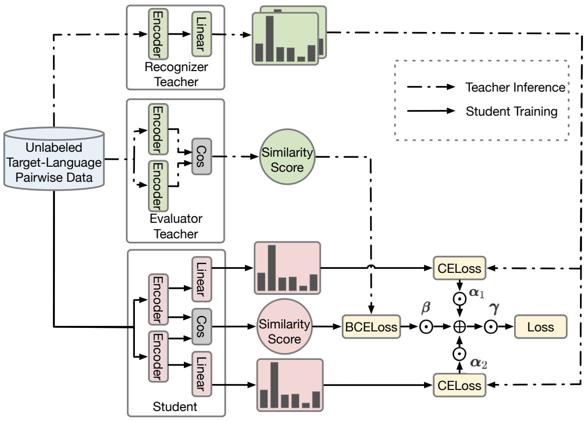

Figure 3: Teacher-student distillation learning.

where cos is the cosine similarity metric function, σ is the sigmoid activation function, $\hat{t} \in [\sigma(-1), \sigma(1)]$ denotes the predicted similarity of two queried tokens pair $< x_i, x'_j >$. Larger $\hat{t}$ value indicates higher similarity between the two queried entities tokens.

The loss function of the similarity prediction can be formulate as,

$$\mathcal{L}_{SIM}(\boldsymbol{x}, \boldsymbol{x'}, i, j, t) = \mathcal{L}_{BCE}(t, \hat{t}).$$

Finally, we can train the siamese entity similarity evaluator on $\mathcal{D}^{S-siam}_{train}$, and evaluate the performance on test dataset $\mathcal{D}^{S-siam}_{test}$. Together with entity recognizer model, this entity similarity evaluator are used as teachers in following knowledge distillation learning process, and transfer knowledge from source to target lingual corpus.

3.3 Teacher-student Distillation Learning

In this section, we consider transferring the named entity type and similarity knowledge learned on labeled source language corpus to unlabeled target language NER task. To this end, we propose a knowledge distillation learning process to train a target language student NER model with its supervisory signals mimicked by the entity type prediction probability by the entity recognizer teacher model and entity representation similarity target by the entity siamese similarity evaluator teacher model. Based on the original unlabeled target sentence training data $\mathcal{D}^{T}_{train}$, we again construct unlabeled target-language siamese pairwise entity data $\mathcal{D}^{T-sim}_{train} = \{(\boldsymbol{x}_T, \boldsymbol{x}'_T, i, j)\}$, with the sentence pair $< \boldsymbol{x}_T, \boldsymbol{x}'_T >$ randomly sample from $\mathcal{D}^{T}_{train}$ and the entity token indices pair $< i, j >$ uniformly sampled from the sentences therein.

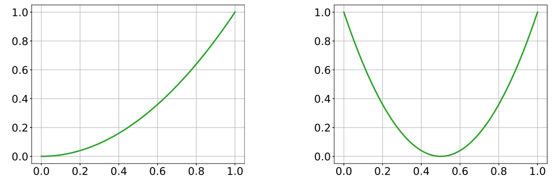
The mBERT is also used as an encoder for the sentence siamese pair, and the entity token feature is queried from the latent sequence encoding representation. Specifically, for a sentence pair $(\boldsymbol{x}_T, \boldsymbol{x}'_T, i, j) \in \mathcal{D}_{train}^{T-sim}$, the student model transform them as follows,

$$
\begin{aligned}
\boldsymbol{h}_T &= \text{mBERT}(\boldsymbol{x}_T) \\
\hat{y}_{T_i} &= \text{softmax}(W h_{Ti} + b) \\
\boldsymbol{h}'_T &= \text{mBERT}(\boldsymbol{x}'_T) \\
\hat{y}'_{T_j} &= \text{softmax}(W h'_{Tj} + b) \\
\hat{t}_T(\boldsymbol{x}_T, \boldsymbol{x}'_T, i, j) &= \sigma(\cos(h_{Ti}, h'_{Tj}))
\end{aligned}
$$

Then for a specific sentence pair sample in the target siamese dataset, the student loss function has three breaches, $\mathcal{L}_{ER}(\boldsymbol{x}_T, \boldsymbol{y}_S, i)$, $\mathcal{L}_{ER}(\boldsymbol{x}'_T, \boldsymbol{y}'_S, j)$, and $\mathcal{L}_{SIM}(\boldsymbol{x}_T, \boldsymbol{x}'_T, i, j, \hat{t}_S)$. Note that supervision information $\boldsymbol{y}_S$, $\boldsymbol{y}'_S$, and $\hat{t}_S$ are taught by the three teacher models. Summering over all the samples in $\mathcal{D}_{train}^{T-sim} = \{(\boldsymbol{x}_T, \boldsymbol{x}'_T, i, j)\}$, the total student model training loss takes form,

$$
\begin{aligned}
\mathcal{L} = \gamma \sum_{(\boldsymbol{x}_T, \boldsymbol{x}'_T, i, j) \in \mathcal{D}_{train}^{T-sim}} &(\alpha_1 \mathcal{L}_{ER}(\boldsymbol{x}_T, \boldsymbol{y}_S, i) \\
&+ \alpha_2 \mathcal{L}_{ER}(\boldsymbol{x}'_T, \boldsymbol{y}'_S, j) \\
&+ \beta \mathcal{L}_{BCE}(\hat{t}_T(\boldsymbol{x}_T, \boldsymbol{x}'_T, i, j), \hat{t}_S))
\end{aligned}
$$

where α_1, α_2, β, and γ are weights in loss function which are set to make the student model learns less noisy knowledge from teachers. The weights are set as follows: $\alpha_1(\alpha_2)$ is an increasing function concerning the output of the entity recognizer teacher as shown in Figure 4. And β is set such that it is high when the output of the entity similarity teacher is close to 0 or 1, and it is low when the output is close to 0.5. γ indicates consistency level between the outputs from two teacher models, e.g. for two input tokens, if the output from entity similarity teacher is high, and the similarity level computed from the outputs of the entity recognizer teacher is low, then their consistency level is low. We want the student model to learn from the two teachers as follows: the higher the prediction of the entity recognizer teacher is (the further away from 0.5 the prediction of the entity similarity teacher is, the higher the consistency level is), the more accurate the prediction is, thus the more attention the student model pays attention to the input tokens, and vice versa. Therefore, we heuristically devises the three weights scheduling as functions of the inputs,



(a) (b)

Figure 4: Weights of loss. (a) indicates the weight $\alpha_{(\cdot)}$ of $\mathcal{L}_{ER}$. (b) indicates the weight β of $\mathcal{L}_{BCE}$.

$$
\begin{aligned}
&\alpha_{(\cdot)} = (max(\hat{y}_{T_i}))^2 \\
&\beta = (2\hat{t}_T(\boldsymbol{x}_T, \boldsymbol{x}'_T, i, j) - 1)^2 \\
&\gamma = 1 - |\sigma(\cos(\hat{y}_{T_i}, \hat{y}'_{T_j})) - \hat{t}_T(\boldsymbol{x}_T, \boldsymbol{x}'_T, i, j)|
\end{aligned}
$$

4 Experiment

In this section, we evaluate our multiple-task and multiple-teacher model for cross-lingual NER and compare our model with a series of state-of-the-art models.

4.1 Dataset

We conducted experiments on three benchmark datasets: CoNLL2002 (Tjong Kim Sang, 2002), CoNLL2003 (Tjong Kim Sang and De Meulder, 2003) and WikiAnn (Pan et al., 2017). CoNLL2002 includes Spanish and Dutch, CoNLL2003 includes English and German, and WikiAnn includes English and three non-western languages: Arabic, Hindi, and Chinese. Each language is divided into a training set, a development set and a test set. All datasets were annotated with four entity types: LOC, MISC, ORG, and PER. Following (Wu and Dredze, 2019), all datasets are annotated using the BIO entity labelling scheme. To imitate the zero-resource cross lingual NER case, following (Wu and Dredze, 2019), we used English as the source language and other languages as the target language. In cross-lingual NER, the training set without entity label of the target language is also available when training the model. We trained the model with the labeled training set of the source language and evaluated the model on the test set of each target language. Table 1 and 2 shows the statistics of all datasets.

4.2 Implementation Details

We use PyTorch 1.7.1 to implement our model. All of the feature encoders mentioned in this paper use

Language	Type	Train	Dev	Test
English-en	Sentence	14,987	3,466	3,684
(CoNLL-2003)	Entity	23,499	5,942	5,648
German-de	Sentence	12,705	3,068	3,160
(CoNLL-2003)	Entity	11,851	4,833	3,673
Spanish-es	Sentence	8,323	1,915	1,517
(CoNLL-2002)	Entity	18,798	4,351	3,558
Dutch-nl	Sentence	15,806	2,895	5,195
(CoNLL-2002)	Entity	13,344	2,616	3,941

Table 1: Statistics of CoNLL.

Language	Type	Train	Dev	Test
English-en	Sentence	20,000	10,000	10,000
	Entity	27,931	14,146	13,958
Arabic-ar	Sentence	20,000	10,000	10,000
	Entity	22,500	11,266	11,259
Hindi-hi	Sentence	5,000	1,000	1,000
	Entity	6,124	1,226	1,228

	Entity	25,031	12,493	12,532

Table 2: Statistics of WikiAnn.

pre-trained mBERT model (Devlin et al., 2019) in HuggingFace Transformer[1], which has 12 Transformer blocks, 12 attention heads, and 768 hidden units.

We set our hyperparameters empirically following (Wu et al., 2020c) with some modifications. We do not freeze any layers and we use the output of the last layer as our hidden feature vector. We set the batch size to be 32, maximum sequence length to be 128, dropout rate to be 0.2, and we use Adam as optimizer (Kingma and Ba, 2014). For the training of recognition teacher model and similarity teacher model, we set the learning rate to be 1e-5 and 5e-6 separately. For knowledge distillation, we use a learning rate of 1e-6 for the student models training. Note that if a word is divided into several subwords after tokenization, then only the first subword is considered in the loss function. Following (Tjong Kim Sang, 2002), we use the entity level F1-score as the evaluation metric. Moreover, we conduct each experiment 5 times and report the mean F1-score.

4.3 Comparison

Table 3 and 4 report the zero-resource cross-lingual NER results of different models on 6 target languages.

Model	de	es	nl
Wiki(Tsai et al., 2016)	48.12	60.55	61.56

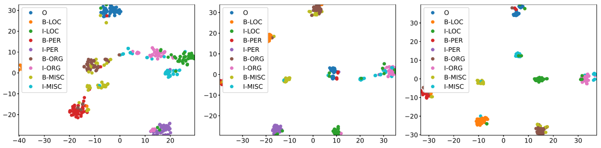
Table 6: Case study on cross-lingual NER. The GREEN (RED) highlight indicates a correct (incorrect) label. The real-valued numbers indicate the entity similarity score.



(a) (b) (c)

Figure 5: t-SNE plot of embeddings of teacher and student models. (a) Entity recognizer teacher. (b) Entity similarity evaluator teacher. (c) Student.

TSL (Wu et al., 2020c) proposes a teacher-student learning model for cross-lingual NER.
Unitrans (Wu et al., 2020b) unifies a data transfer and model transfer for cross-lingual NER.
AdvPicker (Chen et al., 2021) proposes a adversarial discriminator for cross-lingual NER.
RIKD (Liang et al., 2021) develops a reinforced iterative knowledge distillation for cross-lingual NER.
TOF (Zhang et al., 2021) transfers knowledge from three aspects for cross-lingual NER.

It can be seen that our model outperforms the state-of-the-arts. Specifically, compared with the remarkable RIKD, AdvPicker, and Unitrans, which also use knowledge distillation but ignore the entity similarity knowledge, our model obtains significant and consistent improvements in F1-score ranging from 0.23 for German[de] to 6.81 for Arabic[ar]. That demonstrates the benefits of our proposed MTMT model, compared to direct model transfer (Wu and Dredze, 2019).

Note that BERT-f performs better than our model on the Chinese dataset due to their re-tokenization of the dataset. Moreover, compared with the latest model TOF, RIKD, Unitrans, our model requires much lower computational costs for both translation and iterative knowledge distillation, meanwhile reaching superior performance. For a fair comparison, we compare our model against the version of TOF w/o continual learning (Zhang et al., 2021), RIKD w/o IKD (Liang et al., 2021) and Unitrans w/o translation (Wu et al., 2020b) as reported in their paper.

4.4 Ablation Study

To demonstrate the effectiveness of our approach, we designed the following ablation studies. Table 5 presents the results.

(1) *MTST*, which combines the multiple-teacher to single-teacher. That is, the teacher model has the same as the neural network structure of the student model. This causes a performance drop across all languages due to two single teachers cannot make a difference with the combination.

(2) *MTMT w/o weighting*, which set the $\alpha_{(\cdot)}$, β and γ all to be 1 in the loss of student learning. It can be seen that the performance decrease in terms of F1-score ranges from 0.45

for Dutch(nl) to 0.98 for Spanish(es), which validates that weighting loss can bring more confident knowledge to the student model.

(3) *MTMT w/o similarity*, which removes the similarity teacher model. In this case, our approach degrades into the single teacher-student learning model as in TSL (Wu et al., 2020a). Without the similarity knowledge fed into the student model, the performance drops significantly.

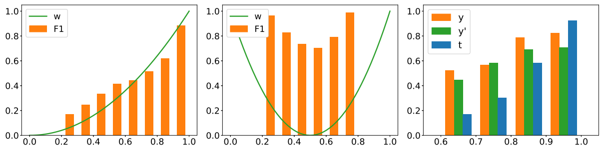
4.5 Case Study

We give a case study to show that the failed cases of baseline models can be corrected by our model. We try to bring up insights on why the proposed multiple-task and multiple-teacher model works.

The proposed MTMT model can help to correct labels using the *Entity Similarity* defined in section 3.2. Specifically, if there is a set of tokens in which every two of them have a high *Entity Similarity* score, and one of the tokens is predicted to have a distinct label while other tokens have identical labels, then the one with the distinct label is predicted wrongly and is corrected by the student model to have the label of all other tokens. As shown in Table 6, in example #1, the entity recognizer teacher fails to identify "*Arévalo*" as B-ORG type, while the student model can correctly predict it. The reason lies in that the entity recognizer teacher predicts "*Viena*"('*Madrid*") as B-LOC type correctly, and the similarity evaluator teacher predicts "*Viena*"("*Madrid*") to have a high similarity score(0.7157, 0.7156) with "*Arévalo*". The student learns from both teachers and predict the correct label for "*Arévalo*". Examples #2 and #3 present the same results with different sentences.

4.6 Embedding Distribution

This section investigates the effect of embeddings of the two different teacher models. It can be seen that the embedding distribution of the student model is close to similarity evaluator teacher, as illustrated in Figure 5. We conjecture that the student model captures similarity knowledge from the similarity evaluator teacher, i.e. the same class of examples tend to cluster and the different class of examples tend to segregate in the embedding distribution. This validates the proposed MTMT model not only transfers cross-lingual NER knowledge from source language, but also learns the similarity knowledge of target language data.



(a) (b) (c)

Figure 6: Weights analysis of student learning. (a) α, F1-score in different probability interval. (b) β, F1-score in different similarity score interval. (c) F1-score of y_S, y'_S, and $\hat{t}_S$ in different γ interval.

4.7 Effect of Weights

In this section, we evaluate the effectiveness of weight loss in student learning from a quantitative perspective. All of the following experiments are conducted on Spanish(es) data.

For α analysis, we calculate the F1-score in different probability intervals of entity recognizer teacher, we find that the recognizer teacher tends to predict more correct in higher probability interval, as illustrated in Figure 6a. Therefore, the student model is better suited to the target language with learning fewer low-confidence misrecognitions for the target language.

For β analysis, we observe that F1-score are increasing with the entity similarity score from 0.5 to both sides 0 and 1 in Figure 6b. The encoder of the student model obtains the clustering information of the target language with the help of β.

For γ analysis, we consider the consistency of recognition results and similarity score by teachers. The F1-score and similarity score of teachers are all higher in the higher γ intervals, as shown in Figure 6c. The student model learns less from unreasonable results, and it can make more accurate entity recognition for the target language.

5 Conclusion

In this paper, we propose an unsupervised multiple-task and multiple-teacher model for cross-lingual NER. The student model learns two source language patterns of entity recognition and entity similarity evaluation. Moreover, to guarantee the student learning performance, we also propose a weighting strategy to take into consideration the reliability of the teachers. Our experimental results show that the proposed model yields significant improvements on six target language datasets and outperforms the existing state-of-the-art approaches.

Abstract

Although current state-of-the-art Transformer-based solutions succeeded in a wide range for single-document NLP tasks, they still struggle to address multi-input tasks such as multi-document summarization. Many solutions truncate the inputs, thus ignoring potential summary-relevant contents, which is unacceptable in the medical domain where each information can be vital. Others leverage linear model approximations to apply multi-input concatenation, worsening the results because all information is considered, even if it is conflicting or noisy with respect to a shared background. Despite the importance and social impact of medicine, there are no ad-hoc solutions for multi-document summarization. For this reason, we propose a novel discriminative marginalized probabilistic method (DAMEN) trained to discriminate critical information from a cluster of topic-related medical documents and generate a multi-document summary via token probability marginalization. Results prove we outperform the previous state-of-the-art on a biomedical dataset for multi-document summarization of systematic literature reviews. Moreover, we perform extensive ablation studies to motivate the design choices and prove the importance of each module of our method.[1]

1 Introduction

The task of multi-document summarization aims to generate a compact and informative summary from a cluster of topic-related documents, which represents a very challenging natural language processing (NLP) application due to the presence of redundant and sometimes conflicting information among documents (Radev, 2000). In the medical domain, in which machine learning plays an increasingly significant role (Domeniconi et al., 2014a; di Lena et al., 2015), multi-document summarization finds application in the generation of systematic literature reviews, a biomedical paper that summarizes results across many studies (Khan et al., 2003). DeYoung et al. (2021) are the first that address this task, showing the related issues.

State-of-the-art approaches leverage two leading solutions: hierarchical networks that capture cross-document relations via graph encodings (Wan and Yang, 2006; Liao et al., 2018; Li et al., 2020; Pasunuru et al., 2021) or hidden states aggregation (Fabbri et al., 2019; Liu and Lapata, 2019a; Jin et al., 2020), and long-range neural models that apply multi-input concatenation (Xiao et al., 2021). While effective, these solutions struggle to process clusters of many topic-related documents in low computational resource scenarios (Moro and Ragazzi, 2022) because they need to truncate the inputs. Moreover, pre-trained state-of-the-art Transformers are not leveraged despite showing strong performance when fine-tuned in downstream tasks such as single-document summarization (Liu and Lapata, 2019b; Lewis et al., 2020a; Raffel et al., 2020; Beltagy et al., 2020; Zaheer et al., 2020).

Multi-document summarization requires models to have more robust capabilities for analyzing the cluster to discriminate the correct information from noise and merge it consistently. In this work, we propose a discriminative marginalized probabilistic neural method (DAMEN) that selects worthy documents in the cluster with respect to a shared background and generates the summary via token probability marginalization.

The marginalization of the probability has been successfully applied in past NLP models such as pLSA (Hofmann, 1999) to learn the word probability distribution in documents by maximizing the likelihood. Recently, new deep neural models that use probability marginalization approaches have been proposed for the question-answering task, where, however, each input/output sentence is generally several orders of magnitude shorter than sets of documents in multi-document summarization

Volume 1: Long Papers, pages 180 - 189

(Guu et al., 2020; Lewis et al., 2020b).

To the best of our knowledge, we are the first that propose such a method for multi-document summarization. To this aim, we conduct experiments on the only medical dataset for multi-document summarization of systematic literature reviews (MS2). Besides, we perform extensive ablation studies to motivate the design choices and prove the importance of each component of our method.

To sum up, our contributions are as follows:

- We propose a novel probabilistic neural method for multi-document summarization (DAMEN) that discriminates the summary-relevant information from a cluster of topic-related documents and generates a final summary via token probability marginalization.

- We advance the research in the medical domain, experimenting with a biomedical multi-document summarization dataset about the generation of systematic literature reviews.

- We show that our solution outperforms previous state-of-the-art solutions, achieving better ROUGE scores. Furthermore, we extensively prove the contribution of each module of our method with ablation studies.

2 Related Work

We describe related works on multi-document summarization categorized on model architectures.

Flat solutions. Flat concatenation is a simple yet powerful solution because the generation of the multi-document summary is treated as a single-document summarization task, thus it can leverage state-of-the-art pre-trained summarization models. Consequently, processing all documents as a flat input requires models capable of handling long sequences. As previously experimented by DeYoung et al. (2021), Xiao et al. (2021) proposed to leverage the Longformer-Encoder-Decoder model (Beltagy et al., 2020) pre-trained with a novel multi-document summarization specific task. They proved that a long-range Transformer that encodes all documents is a straightforward yet effective solution, and they achieved new state-of-the-art results in several multi-document summarization datasets. However, such models may struggle to handle a massive cluster of topic-related documents since they need to truncate them because of architectural limits. Further, processing all documents in a cluster could be noisy if some of them are not relevant or factual with respect to the summary.

Hierarchical solutions. To better preserve cross-document relations and obtain semantic-rich representations, hierarchical concatenation solutions leverage graph-based techniques to work from word and sentence-level (Wan and Yang, 2006; Liao et al., 2018; Nayeem et al., 2018; Antognini and Faltings, 2019; Li et al., 2020) to document-level (Amplayo and Lapata, 2021). Other hierarchical approaches include multi-head pooling and inter-paragraph attention architectures (Liu and Lapata, 2019a), attention models with maximal marginal relevance (Fabbri et al., 2019), and attention across different granularity representations (Jin et al., 2020). Such models are often dataset-specific because of the custom architecture, so they struggle to adapt to other datasets and effectively leverage pre-trained state-of-the-art Transformers.

Our solution. In this work, we show how the summary-relevant information can be discriminated from a cluster of medical documents by a probabilistic neural method trained end-to-end. In detail, our solution fully leverages pre-trained state-of-the-art Transformers without applying input truncation that causes performance drop and discards important contents, unacceptable for a high-social impact domain such as the medical one.

3 Method

We introduce DAMEN, a discriminative marginalized probabilistic neural method for the multi-document summarization of medical literature based on three components:

- ***Indexer***: it is a neural language model based on BERT architecture (Cohan et al., 2020) that creates a dense representation of documents in the cluster, according to the best practices for information retrieval systems.

- ***Discriminator***: it leverages a BERT model to create the background embedding, which is used to compute a distance score between the embedding of each document in the cluster in order to select the top K ones.

- ***Generator***: it uses a BART model (Lewis et al., 2020a) to produce the final summary via token probability marginalization from the top K documents combined with the background.

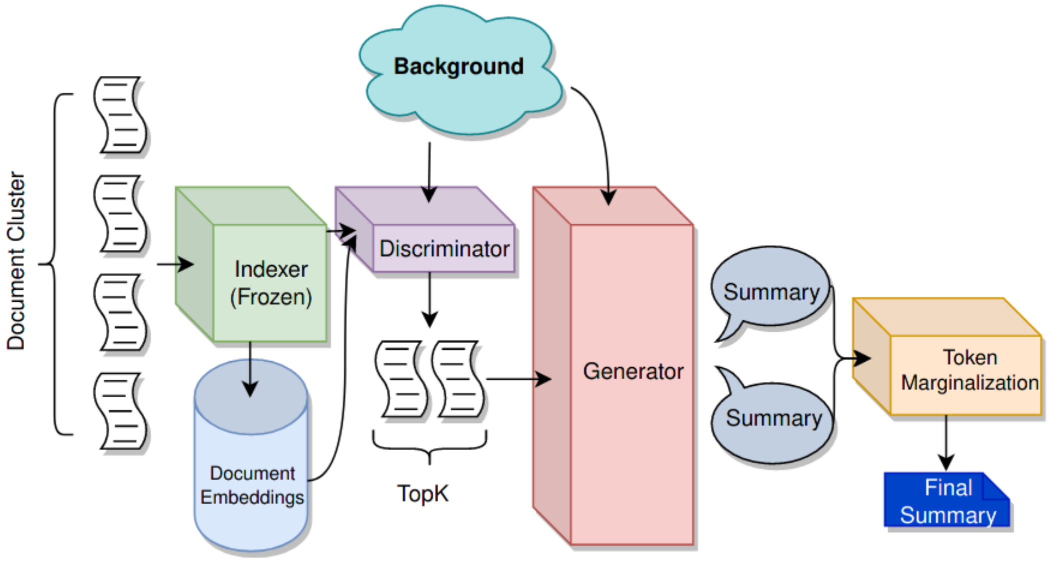

Figure 1: The overview of DAMEN, our probabilistic neural method for multi-document summarization of medical literature. First, two BERT models (i.e., *Indexer* and *Discriminator*) encode the background and documents in the cluster, creating dense embedding representations. Then, the *Discriminator* selects the top K documents via inner product with the background. Afterward, the background is concatenated with each document retrieved and the new textual inputs are given to BART to generate the multi-document summary by marginalizing the token probability distribution at decoding time.

While the *Indexer* is a frozen pre-trained model based on BERT, the *Discriminator* and *Generator* are trained end-to-end during the learning phase (Fig. 1). The overall task can be mathematically formalized as follows. The training tuple is composed of three elements $(y_i, x_i, \mathbf{C}_i)$, where y_i is the ground-truth target summary, $\mathbf{C}_i$ is the cluster of documents used to generate the multi-document summary, and x_i is the background, which is a textual context shared by all $c_j \in \mathbf{C}_i$ used as input of the method, similar to the query in the query-focused multi-document summarization (Su et al., 2020). The whole pipeline is trained end-to-end to maximize the conditional probability of generating y_i from x_i and $\mathbf{C}_i$ through gradient descend:

$$p(y_i|x_i, \mathbf{C}_i) \tag{1}$$

3.1 Indexer

In this phase, we index each document in the cluster with an embedding generated by a BERT-based model. Such a pre-trained language model is the state-of-the-art in semantic modeling from textual data thanks to the vast knowledge learned during pre-training (Chen et al., 2019), achieving groundbreaking results across an extensive range of NLP downstream tasks even without fine-tuning. For this reason, we use it to create a dense latent representation of each document, called document embedding, which is a vector of continuous numbers that indicates a point in a latent semantic space. The technique we use is known as dense passage retriever (DPR) (Karpukhin et al., 2020), and it is widely adopted in the information retrieval domain (e.g., Lin et al., 2021; Moro and Valgimigli, 2021). We choose the DPR method because it does not interrupt the backpropagation, differently from other solutions, e.g., BM25, TF-IDF (Domeniconi et al., 2014b) or LSA (Domeniconi et al., 2016a).

We formalize this step as $B_\beta(\mathbf{C}_i) = E$, where B is a BERT-based model, β represents its parameters, and E is a matrix of shape $(len(\mathbf{C}_i), 768)$, where each row j of the matrix is the latent representation of the document c_j.

3.2 Discriminator

The main idea of the *Discriminator* is to discriminate the critical information from noise in a cluster of topic-related documents with respect to a shared background without breaking the backpropagation chain. For this reason, we use a probabilistic deep neural model to draw a probability distribution over documents in the cluster $< c_0, c_1, ..., c_n > \in \mathbf{C}_i$, with the following formula:

$$p_\theta(\mathbf{C}_i|x_i) \tag{2}$$

where θ represents the parameters of the neural network. Even in this case, the neural model is

		MS2	
Statistic	Background	Document	Summary
# average num. of tokens	125.75	546.90	74.52
# average num. of abstracts per background		23.30	
# backgrounds		13982	

Table 1: The dataset statistics. All values are mean over the whole dataset except for the "# backgrounds" row.

a BERT-based pre-trained language model as the one used for indexing, but this is trained during the learning process while the first is frozen. In detail, the *Discriminator* creates a latent projection for each background, which is used to fetch the more related documents in the cluster. More precisely, it applies the inner product to create a score for each document and selects the top K ones.

3.3 Generator

We use the pre-trained encoder-decoder generative Transformer BART (Lewis et al., 2020a) to summarize the $\mathbf{C}_i$ weighted by the *Discriminator*. This component is trained to predict the next output token, creating a probability distribution over the dictionary for each $c_j \in \mathbf{C}_i$ before marginalizing. The process is then repeated for all the target tokens.

Before giving the documents to the model, we concatenate them with the background x_i, creating $c'_{ij} = [x_i, tok, c_{ij}]$, where tok is a special text separator token (<*doc*>) we add between x_i and c_{ij} to make BART aware of the background text boundary. The behavior of the *Generator* can be formally defined as follows:

$$p(y_i|c'_{ij}) = \prod_{z}^{N} p_\gamma(y_{iz}|c'_{ij}, y_{i,1:z-1}) \tag{3}$$

where γ are the *Generator* parameters, $N = |y_i|$ is the target length, and $y_{i,1:z}$ are the tokens from position 1 to z of the target y_i.

3.4 Model

The entire model aims to draw the probability distribution over the dictionary to generate the output tokens y_i conditioned by x_i and $\mathbf{C_i}$ that we formally define as:

$$p(y_i|x_i, \mathbf{C}_i) = \prod_{z}^{N} \sum_{c \in top-k} p_\theta(c_i|x_i) p_\gamma(y_{iz}|c'_i, y_{i,1:z-1}) \tag{4}$$

We train the whole model by minimizing the negative marginal log-likelihood of each target with the following loss:

$$-\sum \log p(y|x, \mathbf{C}) \tag{5}$$

4 Experiments

This section starts with describing the dataset in §4.1 and training details in §4.2. We then analyze model performance in §4.3 and finally conduct ablation studies in §4.4.

4.1 Dataset

We tested and evaluated our proposed method on the only medical dataset for multi-document summarization, as far as we know, about the generation of systematic literature reviews: the MS2 dataset. The dataset is provided in DeYoung et al. (2021), and it is freely distributed.[2] It contains over 470K document abstracts and 20K summaries derived from the scientific literature. Each sample of the dataset is composed of three elements: i) the *background* statement, which is a short text that describes the research question or topic shared by all documents in the cluster, ii) the *target* statement, which is the multi-document summary to generate, and iii) the *studies*, also defined as cluster for consistency with our notation, which is a set of abstracts of medical studies related to the topic covered in the background statement.

The problem can be formalized as follows: we have a target statement to generate about the background source, containing the topic specifications, and a cluster of related document abstracts from which to fetch and discriminate helpful knowledge with respect to the background. From here on, we use the terms "document" and "abstract" interchangeably since the elements in the cluster are just the abstracts of medical documents.

We report the dataset statistics in Table 1.

Table 2: The results on MS2 for multi-document summarization of systematic literature reviews. The results of previous state-of-the-art are taken from DeYoung et al. (2021). Better ROUGE scores are bolded.

4.2 Training Details

We trained our solution for 3 epochs using a batch size of 1 and a learning rate with a linear schedule set to 1×10^{-5}. We set the number of K equal to 6 because it gave best results and used 1024 tokens as the max input size for the *Generator*. During the evaluation, we adopted a beam size of 4 with a min and a max length set to 32 and 256, respectively.

We implemented the code using PyTorch for tensor computations and Hugging Face[3] for language model checkpoints. We performed the experiments on a workstation with a GPU Nvidia RTX 3090 of 24GB memory, 64GB of RAM, and a processor Intel(R) Core(TM) i9-10900X CPU @ 3.70GHz.

4.3 Results

Table 2 shows the results on multi-document summarization of systematic literature reviews, comparing our method with two solutions proposed in DeYoung et al. (2021). The $\text{BART}_{\text{HIERARCHICAL}}$ solution is trained to encode each document independently and then concatenate the representation of hidden states before decoding, whereas LED_{FLAT} takes as input all documents concatenated as a single document. Experimental results show we outperform the state-of-the-art in all the ROUGE metrics, proving better capability to discriminate relevant information across many related documents and merge it consistently (Fig. 2).

4.4 Ablations

We conducted ablation studies on the MS2 dataset to prove the importance of each module of our method. In detail, for all experiments we trained our solution for 1 epoch with the same training details reported in §4.2, and we performed the evaluation on the first 400 instances of the test set.

The importance of a highly abstractive large-sized Generator. We report in Table 3 the performance using several pre-trained checkpoints of the *Generator* that differ in size and training. In detail, we tested two $\text{BART}_{\text{BASE}}$ checkpoints and three $\text{BART}_{\text{LARGE}}$ checkpoints:

- ***facebook/bart-base***: the actual BART model pre-trained with a denoising masked language modeling.
- ***gayanin/bart-mlm-pubmed***: the BART model pre-trained exclusively on scientific corpora.
- ***facebook/bart-large***: the same BART model as the base version with a large architecture.
- ***facebook/bart-large-cnn***: the large BART fine-tuned on single-document summarization on the CNN/DailyMail dataset (Nallapati et al., 2016).
- ***facebook/bart-large-xsum***: the large BART fine-tuned on single-document summarization on the XSum dataset (Narayan et al., 2018).

Results prove that a large-sized BART model already fine-tuned on a summarization task achieves better performance. More precisely, the checkpoint fine-tuned on the XSum dataset obtains better results thanks to the higher abstractiveness and the shortness of the target summaries, which are made up of just 1-2 sentences, similar to the MS2 dataset.

The importance of a full-sized chunked representation of documents in the cluster. Table 4 reports experiments with three cluster configurations, where each document is treated with a different text representation, described as follows:

- ***Document-level***: the simpler configuration that considers the entire abstracts in the cluster. We truncated documents taking only the first 512 tokens before encoding by the *Indexer*.
- ***Sentence-level***: we considered the sentences of each document obtained using the state-of-the-art tokenizer PySBD (Sadvilkar and Neumann, 2020). The sentences are encoded up to 128 tokens in length and they are then treated as individual textual units.
- ***Chunk-level***: our configuration, where each document is split into chunks of exact 512 tokens to consider all text information without

Table 3: The ablations to validate the contribution of the *Generator*. Better ROUGE scores are bolded.

input truncation. This configuration is similar to the "sentence-level" one but with the difference that each textual unit is 512 tokens in length and not 128.

The results prove the better performance on a cluster with chunked documents. By considering 512 tokens for each document, we fully leverage the capability of BERT language modeling without truncating any information. Input truncation required by the "document-level" configuration plays an important role in final accuracy because it discards and ignores potential summary-relevant information, leading to a performance drop. The "sentence-level" setting lets us increase the top K sentences to retrieve, but it worsens the final summary because single sentences are too fine-grained.

model checkpoints for the *Indexer* and *Discriminator*. First, we leveraged the checkpoint "*sentence-transformers/allenai-specter*" (Cohan et al., 2020), which is a scientific BERT-based model trained to create document embeddings by using paper citations. Thus, we used this pre-trained model for both the *Indexer* and *Discriminator*. Second, we used two different checkpoints with a specific DPR training, such as "*facebook/dpr-question_encoder-single-nq-base*" for encoding the background and "*facebook/dpr-ctx_encoder-single-nq-base*" for encoding each document in the cluster.

Results prove the importance of the DPR checkpoints for both the *Indexer* and *Discriminator*.

5 Conclusion

We proposed a novel probabilistic method based on the combination of three language models to tackle multi-document summarization in the medical domain. This task is characterized by redundant information, noise, and the possible presence of vital information in each sentence that makes arbitrary input truncation unacceptable. For this reason, we proposed a multi-document summarization method able to discriminate salient contents from irrelevant before summarizing. In detail, the solution first leverages a BERT-based model (*Indexer*) for creating dense indices for each chunk of each document in the cluster. Then, a second BERT-based model (*Discriminator*) is used to process the shared background and select only the most relevant chunks. The final BART model is trained to perform a probability marginalization over each token prediction for each selected chunk. In this way, our solution reads all document information and selects just the most relevant chunks, discarding noise before feeding the *Generator*. The *Discriminator* and *Generator* are trained end-to-end, backpropagating the probability distribution as explained in §3. The *Indexer* is frozen; training would lead to some problems, such as the time to learn improved embeddings at each iteration and the larger memory occupation to save the gradient for each document.

We tested our method on MS2, the only dataset on systematic literature reviews, and compared it with state-of-the-art models, finding that our novel approach outperforms competitors on the ROUGE evaluation metrics. Further, we performed extensive ablation studies to highlight the contribution of each component and motivate the design choices.

5.1 Future works

At the edge of our knowledge, this is the first work that applies a probability marginalization method for multi-document summarization. We believe this work can inspire novel research towards end-to-end multi-model collaboration instead of solutions with a single large model addressing the entire task. According to the *divide et impera* pattern, each model learns a specific sub-task, creating a more efficient and transparent cooperating solution. Tasks such as related work generation or text generation from multi-sourced inputs can get the most from our method, improving pre-existing solutions to discriminate helpful knowledge from noise.

Further possible directions to deal with multi-inputs are the following: i) extracting relevant snippets from documents with term weighting techniques (Domeniconi et al., 2015) or semantic relations with unsupervised methods (Domeniconi et al., 2016b, 2017) to better model interpretable representations based on knowledge graph learning techniques (Frisoni and Moro, 2020; Chen et al., 2021a,b) or event extraction methods (Frisoni et al., 2021); ii) training models to write and read cross-document information with self-supervised representation learning methods (Domeniconi et al., 2014c) and memory-based neural layers (Moro et al., 2018; Cui and Hu, 2021).

6 Ethical Considerations

The advancement of deep neural network architectures and the availability of large pre-trained language models has led to significant improvements for the multi-document summarization task, which has applications in high-impact domains, particularly in the medical one. Here, systematic literature reviews play an essential role for the medical and scientific community, and for that reason, they require strong guarantees about the factuality of the output summary. Current state-of-the-art NLP solutions cannot establish such assurance, so we do not believe our solution, like previous ones, is ready to be deployed. The research should explore more effective evaluation measures for text summarization to make it happen, and large-scale accuracy guarantees by medical experts are still needed. Finally, if the method will be applied to sensitive data such as medical patient records, it should also include privacy-preserving policies (da Silva et al., 2006).

Acknowledgments

We thank the Maggioli Group[4] for granting the Ph.D. scholarship to L. Ragazzi and L. Valgimigli. The solution presented in this work has been designed by G. Moro.

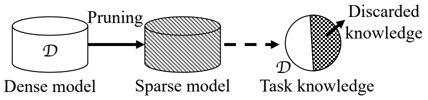
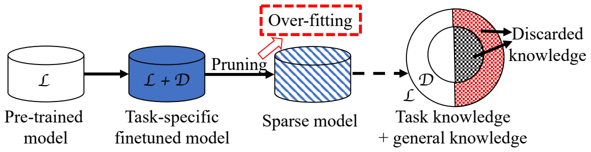
Abstract

Conventional wisdom in pruning Transformer-based language models is that pruning reduces the model expressiveness and thus is more likely to underfit rather than overfit. However, under the trending pretrain-and-finetune paradigm, we postulate a counter-traditional hypothesis, that is: pruning increases the risk of overfitting when performed at the fine-tuning phase. In this paper, we aim to address the overfitting problem and improve pruning performance via progressive knowledge distillation with error-bound properties. We show for the first time that reducing the risk of overfitting can help the effectiveness of pruning under the pretrain-and-finetune paradigm. Ablation studies and experiments on the GLUE benchmark show that our method outperforms the leading competitors across different tasks.

1 Introduction



(a) Pruning under non-pretrain-and-finetune paradigm (e.g., CNN, LSTM, GNN)



(b) Pruning under pretrain-and-finetune paradigm

Figure 1: Pruning under non-pretrain-and-finetune vs. pruning under pretrain-and-finetune. In the subfigures, the cylinders on the left describe the pruning process, and the circles on the right represent the knowledge analysis of the sparse model.

Recently, the emergence of Transformer-based language models (using pretrain-and-finetune paradigm) such as BERT (Devlin et al., 2019) and GPT-3 (Brown et al., 2020) have revolutionized and established state-of-the-art (SOTA) records (beyond human-level) on various natural language (NLP) processing tasks. These models are first pre-trained in a self-supervised fashion on a large corpus and fine-tuned for specific downstream tasks (Wang et al., 2018). While effective and prevalent, they suffer from redundant computation due to the heavy model size, which hinders their popularity on resource-constrained devices, e.g., mobile phones, smart cameras, and autonomous driving (Chen et al., 2021; Qi et al., 2021; Yin et al., 2021a,b; Li et al., 2021; Choi and Baek, 2020).

Various weight pruning approaches (zeroing out certain weights and then optimizing the rest) have been proposed to reduce the footprint requirements of Transformers (Zhu and Gupta, 2018; Blalock et al., 2020; Gordon et al., 2020; Xu et al., 2021; Huang et al., 2021; Peng et al., 2021). Conventional wisdom in pruning states that pruning reduces the overfitting risk since the compressed model structures are less complex, have fewer parameters and are believed to be less prone to overfit (Ying, 2019; Wang et al., 2021; Tian et al., 2020; Gerum et al., 2020). However, under the pretrain-and-finetune paradigm, most pruning methods understate the overfitting problem.

In this paper, we postulate a counter-traditional hypothesis, that is: model pruning increases the risk of overfitting if pruning is performed at the fine-tuning phase. As shown in Figure 1b, the pretrain-and-finetune paradigm contains two types of knowledge, the general-purpose language knowledge learned during pre-training ($\mathcal{L}$) and the task-specific knowledge from the downstream task data ($\mathcal{D}$). Compared to conventional pruning that only discards task-specific knowledge (Figure 1a), pruning under pretrain-and-finetune (Figure 1b) discards extra knowledge (red area) learned in pre-training phase. Thus, to recover both the extra discarded general-purpose knowledge and the discarded task-specific knowledge, pruning under

(a) Sparsity=0 (b) Sparsity=0.8 (c) Sparsity=0.95

Figure 2: Visualization of the overfitting problem when pruning weight matrices of $\text{BERT}_{\text{BASE}}$ on MRPC at the fine-tuning phase. The overfitting problem becomes more severe with the increasing of sparsity.

pretrain-and-finetune increases the amount of information a model needs, which results in relative data deficiency, leading to a higher risk of overfitting. To empirically verify the overfitting problem, we visualize the training and evaluation performance on a real-world task data of MRPC (Devlin et al., 2019) in Figure 2. From Figure 2 (b), it is observed that the evaluation accuracy on the training dataset remains improved while it keeps the same for the validation set through the training process. From Figure 2 (c), the difference in performance becomes more significant when the pruning rate becomes higher and the performance on the validation set even becomes worse after 2,000 training steps. All these observations verify our hypothesis.

The main question this paper attempts to answer is: how to reduce the risk of overfitting of pre-trained language models caused by pruning? However, answering this question is challenging. First, under the pretrain-and-finetune paradigm, both the general-purpose language knowledge and the task-specific knowledge are learned. It is nontrivial to keep the model parameters related to both knowledge when pruning. Second, the amount of data for downstream tasks can be small, such as the data with privacy. Thus, the overfitting problem can easily arise, especially in the face of high pruning rate requirements. A little recent progress has been made on addressing overfitting associated with model compression. However, their results are not remarkable and most of them focus on the vision domain (Bai et al., 2020; Shen et al., 2021).

To address these challenges, we propose SPD, a sparse progressive distillation method, for pruning pre-trained language models. We prune and optimize the weight duplicates of the backbone of the teacher model (a.k.a., student modules). Each student module shares the same architecture (e.g., the number of weights, the dimension of each weight) as the duplicate. We replace the corresponding layer(s) of the duplicated teacher model with the pruned sparse student module(s) in a progressive way and name the new model as a grafted model. We validate our proposed method through the ablation studies and the GLUE benchmark. Experimental results show that our method outperforms the existing approaches.

We summarize our contributions as follows:

- We postulate, analyze, and empirically verify a counter-traditional hypothesis: pruning increases the risk of overfitting under the pretrain-and-finetune paradigm.
- We propose a sparse progressive pruning method and show for the first time that reducing the risk of overfitting can help the effectiveness of pruning.
- Moreover, we theoretically analyze that our pruning method can obtain a sub-network from the student model that has similar accuracy as the teacher.
- Last but not least, we study and minimize the interference between different hyperparameter strategies, including pruning rate, learning rate, and grafting probability, to further improve performance.

2 Related Work

To summarize, our contribution is determining the overfitting problem of pruning under the pretrain-and-finetune paradigm and proposing the sparse progressive distillation method to address it. We demonstrate the benefits of the proposed framework through the ablation studies. We validate our method on eight datasets from the GLUE benchmark. To test if our method is applicable across

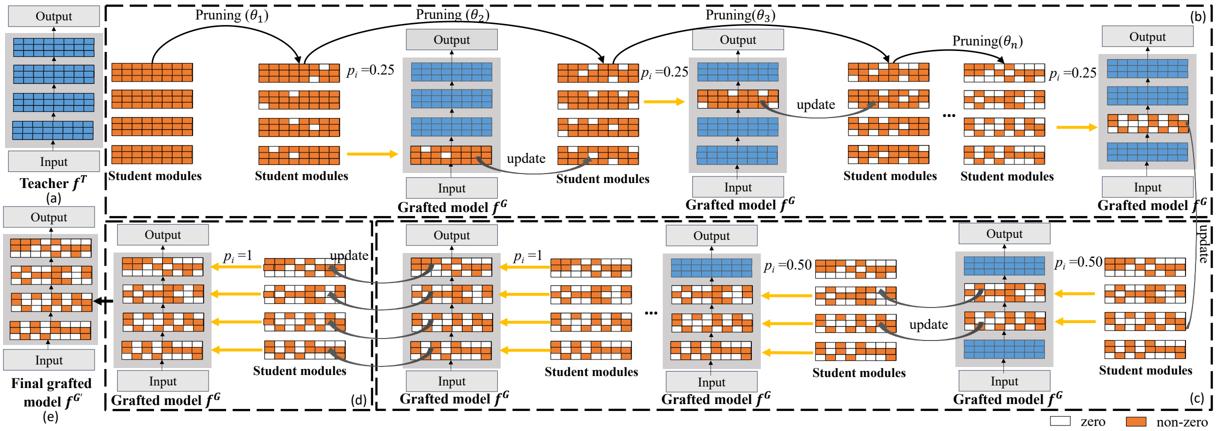

Figure 3: An overview of our sparse progressive distillation method. (a) Teacher model. (b) Pruning to target sparsity. (c) Module grafting with increasing probability. (d) Fine-tuning. (e) Final grafted model.

tasks, we include the tasks of both single sentence and sentence-pair classification. Experimental results show that our method outperforms the leading competitors by a large margin.

Network Pruning. Common wisdom has shown that weight parameters of deep learning models can be reduced without sacrificing accuracy loss, such as magnitude-based pruning and lottery ticket hypothesis (Frankle and Carbin, 2019). (Zhu and Gupta, 2018) compared small-dense models and large-sparse models with the same parameters and showed that the latter outperforms the former, showing the large-sparse models have better expressive power than their small-dense counterparts. However, under the pretrain-and-finetune paradigm, pruning leads to overfitting as discussed.

Knowledge Distillation (KD). As a common method in reducing the number of parameters, the main idea of KD is that the small student model mimics the behaviour of the large teacher model and achieves a comparable performance (Hinton et al., 2015; Mirzadeh et al., 2020). (Sanh et al., 2019; Jiao et al., 2020; Sun et al., 2020) utilized KD to learn universal language representations from large corpus. However, current SOTA knowledge distillation methods are not able to achieve a high model compression rate (less than 10% remaining weights) while achieving an insignificant performance decrease.

Progressive Learning. The key idea of progressive learning is that student learns to update module by module with the teacher. (Shen et al., 2021) utilized a dual-stage distillation scheme where student modules are progressively grafted onto the teacher network, it targets the few-shot scenario and uses only a few unlabeled samples to achieve comparable results on CIFAR-10 and CIFAR-100. (Xu et al., 2020) gradually increased the probability of replacing each teacher module with their corresponding student module and trained the student to reproduce the behavior of the teacher. However, the performance on Transformer-based models of the aforementioned first method is unknown while the second method has an obvious performance drop with a low sparsity (50%).

3 Methodology

3.1 Problem Formulation

The teacher model and the grafted model (shown in Figure 3) are denoted as f^S and f^G, respectively. Both models have $N+1$ layers (i.e., the first N layers are encoder layers, and the $(N+1)$-th layer is the output layer). Denote $f_i^{\mathrm{T}}(\cdot)$, $f_i^{\mathrm{G}}(\cdot)$ as the behaviour function induced from the i-th encoder of the teacher model, and the grafted model, respectively. As shown in Figure 4, we utilize layer-wise knowledge distillation (KD), where we aim to bridge the gap between $f_i^{\mathrm{T}}(\cdot)$ and $f_i^{\mathrm{G}}(\cdot)$.

The grafted model is trained to mimic the behavior of the teacher model. During training, we minimize the summation loss $\mathcal{L}$:

$$\mathcal{L} = \sum_{\mathbf{x}\in\mathcal{X}} \sum_{i=1}^{N+1} \lambda_i \mathcal{L}_{\mathrm{KD}}(f_i^T(\mathbf{x}) f_i^G(\mathbf{x})), \qquad (1)$$

where $\mathcal{X}$ denotes the training dataset, λ_i is coefficient of i-th layer loss, $\mathcal{L}_{\mathcal{D}}$ is the distillation loss of the layer pair, x_i is the input of the i-th layer.

During KD, each student module mimics the behavior of the corresponding teacher layer. Similar to (Jiao et al., 2020), we take the advantage

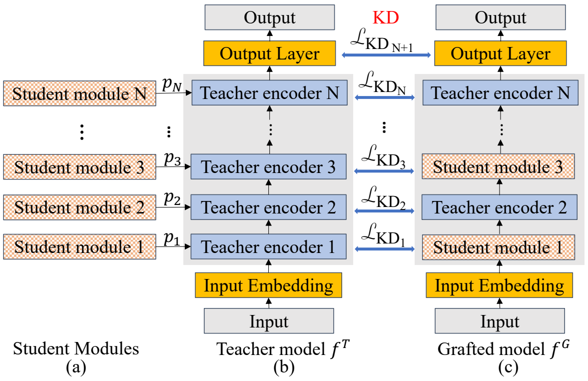

Figure 4: An overview of the layer-wise KD in SPD. (a) N sparse student modules have probabilities of p_1, p_2, p_3, ..., p_N to substitute the corresponding teacher layers separately. (b) Teacher model. (c) Grafted model. L_{KD_i} denotes the distillation loss between the i-th layer of the teacher and i-th layer of the grafted model.

of abundant knowledge in self-attention distribution, hidden states of each Transformer layer, and the final output layer's soft logits of teacher model to help train the student model. Specifically, we design the KD loss as follows

$$\mathcal{L}_{\text{KD}} = \begin{cases} \mathcal{L}_{hidn} + \mathcal{L}_{attn} & 1 \leq i \leq N \\ \mathcal{L}_{pred} & i = N+1 \end{cases} \tag{2}$$

where $\mathcal{L}_{hidn}$ = MSE(H_i^T, H_i^S) ($1 \leq i \leq N$) indicates the difference between hidden states, $\mathcal{L}_{attn}$ = MSE(A_i^T, A_i^S) indicates the difference between attention matrices. MSE($\cdot$) is the mean square error loss function and i is the index of Transformer layer. $\mathcal{L}_{pred}$ = -softmax(z^T) $\cdot$ log_softmax(z^S / $temp$) indicates the difference of soft cross-entropy loss, where z^T and z^S are the soft logits of teacher and student model, respectively. T is the temperature hyper-parameter.

We further reduce the number of non-zero parameters in the weight matrix while maintaining accuracy. We denote $\{\mathbf{W}_j\}_{j=1}^{j=i}$ as the collection of weights in the first i layers, θ_j as the sparsity of the j-th layer. Then, the loss function of sparse knowledge distillation becomes

$$\mathcal{L} = \sum_{\mathbf{x}\in\mathcal{X}} \sum_{i=1}^{N+1} \lambda_i \mathcal{L}_{\text{KD}}(f_i^T(\mathbf{x}, \{\mathbf{W}_j\}_{j=1}^{j=i}), f_i^G(\mathbf{x}, \{\mathbf{W}_j\}_{j=1}^{j=i}))$$
$$s.t. \;\; sparsity(\mathbf{W}_j) \leq \theta_j \text{ for } j = 1, ..., N \tag{3}$$

After training, we find the sparse weight matrix W_j^* using

$$\mathbf{W}_j^* = \Pi_{S_j}(\mathbf{W}_j) \text{ for } j = 1, ..., N, \tag{4}$$

where $\Pi_{S_j}(\cdot)$ denotes the Euclidean projection onto the set $S_j = \{\mathbf{W}_j \mid sparsity(\mathbf{W}_j) \leq \theta_j\}$.

3.2 Our Methods

3.2.1 Error-bound Analysis

Our pruning method is similar to finding matching subnetworks using the lottery ticket hypothesis (Frankle and Carbin, 2019; Pensia et al., 2020) methodology. We analyze the self-attention (excluding activation). Some non-linear activation functions has been analyzed in (Pensia et al., 2020).

Feed-forward layer. Consider a feed-forward network $f(x) = w \cdot x$, and $g(x) = (\sum_{i=1}^{n} w_i)\, x$. Lueker *et al.* (Lueker, 1998) and Pensia *et al.* (Pensia et al., 2020) show that existing a subset of w_i, such that the corresponding value of $g(x)$ is very close to $f(x)$.

Corollary: When $w_1^*, ..., w_n^*$ belongs to i.i.d. uniform distribution over [-1,1], where $n \geq C \log \frac{2}{\delta}$, $\delta \leq \min\{1, \epsilon\}$. Then, with probability at least 1-δ, we have

$$\exists G_{\textbf{spd}} \subset \{1, 2, ..., n\}, \forall w \in [-0.5, 0.5],$$
$$s.t \left| w - \sum_{i\in G_{\textbf{spd}}} w_i^* \right| \leq \epsilon \tag{5}$$

Analysis on self-attention. The self-attention can be presented as:

$$\mathbf{Z} = \text{attention}(\mathbf{Q}, \mathbf{K}, \mathbf{V}) = \text{softmax}(\frac{\mathbf{Q} \cdot \mathbf{K}^T}{\sqrt{d_k}}) \cdot \mathbf{V}. \tag{6}$$

Consider a model $f(x)$ with only one self-attention, when the token size of input x is 1, softmax($\frac{\mathbf{Q}\cdot\mathbf{K}^T}{\sqrt{d_k}}$) = 1, we have $\mathbf{Z} = \mathbf{V}$, where $\mathbf{V} = w^{\mathbf{V}} x$.

Consider $f^G(x) = \left(\sum_{i=1}^{d} w_i^G\right) x$ and a pruning sparsity θ, base on ***Corollary***, when $d \geq C \log 4/\epsilon$, there exists a pattern of w_i^G, such that, with probability $1 - \epsilon$,

$$\forall w \in [-1, 1], \exists \theta_i \in \{0, 1\},$$
$$s.t. \left| w - (\sum_{i\in[1,d]} w_i^G \mathbb{I}(\theta_i)) \right| < \epsilon \tag{7}$$

where $\mathbb{I}(\theta_i)$ is the indicator to determine whether w_i^G will be remained.

In general, let the token x's size be n. so $\mathbf{x} = (x_1, x_2, ..., x_n)$. Consider a teacher model $f^T(x)$

with a self-attention, then

$$\begin{aligned} f^T(x_i) &= \text{softmax}(\frac{\mathbf{Q} \cdot \mathbf{K}^T}{\sqrt{(d_k)}}) \cdot \mathbf{V}_i \\ &= (\frac{\sum_j e^{c_{ij}}}{\sum_i \sum_j (e^{c_{ij}})}) \cdot \mathbf{V}_i \\ &= (\frac{\sum_j e^{c_{ij}}}{\sum_i \sum_j (e^{c_{ij}})}) w^{\mathbf{V}_i} x_i \\ &= w^{c_{i\cdot}} x_i \end{aligned} \tag{8}$$

where c_{ij} is the $(i, j)^{th}$ element of the matrix $\frac{\mathbf{Q} \cdot \mathbf{K}^T}{\sqrt{(d_k)}}$.

Base on ***Corollary***, when $d \geq C \log 4/\epsilon$, there exists a pattern of w_i^G, such that, with probability $1 - \epsilon$,

$$\begin{aligned} &\forall w^{c_{i\cdot}} \in [-1, 1], \exists \theta_k \in \{0, 1\}, \\ s.t. &\left| w^{c_{i\cdot}} - (\sum_{k \in [1,d]} w_k^G \mathbb{I}(\theta_k)) \right| < \epsilon \end{aligned} \tag{9}$$

In summary:

$$\forall i \in \{1, 2, ..., n\}, \left| f^T(x_i) - f^G(x_i) \right| < \epsilon \tag{10}$$

3.2.2 Progressive Module Grafting

To avoid overfitting in the training process for the sparse Transformer model, we further graft student modules (scion) onto the teacher model duplicates (rootstock). For the i-th student module, we use an independent Bernoulli random variable $\mathbb{I}(\theta_i)$ to indicate whether it will be grafted on the rootstock. To be more specific, $\mathbb{I}(\theta_i)$ has a probability of p (grafting probability) to be set as 1 (i.e., student module substitutes the corresponding teacher layer). Otherwise, the latter will keep weight matrices unchanged. Once the target pruning rate is achieved, we apply linear increasing probability to graft student modules which enable the student modules to orchestrate with each other.

Different from the model compression methods that update all model parameters at once, such as TinyBERT (Jiao et al., 2020) and DistilBERT (Sanh et al., 2019), SPD only updates the student modules on the grafted model. It reduces the complexity of network optimization, which mitigates the overfitting problem and enables the student modules to learn deeper knowledge from the teacher model. The overview is described in Algorithm 1. We will further demonstrate the effectiveness of progressive student module grafting in 4.2.

Algorithm 1 Sparse Progressive Distillation

```
Input: Teacher model $f^T$ (fine-tuned BERT$_{\text{BASE}}$); grafted model $f^G$: duplicates of teacher model.
Set $t_1, t_2, t_3$ as the final number of training steps of pruning, progressive module grafting, and finetuning, respectively.
Set $p$ as the grafting probability
Output: Student model
$p \leftarrow p_0$
for t = 0 to $t_3$ do
    if 0 $\leq$ t $<$ $t_1$ then
        Prune student modules and generate mask $M$
        Graft student modules with $p_0$
    end if
    if $t_1 \leq$ t $<$ $t_2$ then
        Graft student modules with $p \leftarrow k(t - t_1) + p_0$
    end if
    Calculate distillation loss $\mathcal{L}$ in Eqn. (3)
    For $f^G$, update sparse weights $w\prime \leftarrow w \cdot M$
    Duplicate sparse weight(s) on $f^G$ to corresponding student module(s)
end for
return $f^G$
```

4 Experiments

4.1 Experimental Setup

Datasets. We evaluate SPD on the General Language Understanding Evaluation (GLUE) benchmark (Wang et al., 2018) and report the metrics, i.e., accuracy scores for SST-2, QNLI, RTE, and WNLI, Matthews Correlation Coefficient (MCC) for CoLA, F1 scores for QQP and MRPC, Spearman correlations for STS-B.

Baselines. We first use 50% sparsity (a widely adopted sparsity ratio among SOTA), and compare SPD against two types of baselines – non-progressive and progressive. For the former, we select BERT-PKD (Sun et al., 2019), DistilBERT (Sanh et al., 2019), MiniLM (Wang et al., 2020), TinyBERT (Jiao et al., 2020), SparseBERT (Xu et al., 2021) and E.T. (Chen et al., 2021), while for the latter, we choose Theseus (Xu et al., 2020). We further compare SPD against other existing works under higher sparsity, e.g., TinyBERT (Jiao et al., 2020), SparseBERT (Xu et al., 2021) and RPP (Guo et al., 2019).

SPD Settings. We use official BERT$_{\text{BASE}}$, uncased model as the pre-train model and the fine-tuned pre-train model as our teacher. Both BERT$_{\text{BASE}}$ and teacher model have the same architecture (i.e., 12 encoder layers (L = 12; embedding dimension d_{model} = 768; self-attention heads H = 12)). We finetune BERT$_{\text{BASE}}$ using best performance from $\{2e^{-5}, 3e^{-5}, 4e^{-5}, 5e^{-5}\}$ as the learning rate. For SPD model training, the number of pruning epochs, linear increasing module grafting epochs, finetuning epochs vary from [10, 30], [5, 20], [5, 10], respectively. For pruning, we use AdamW (Loshchilov and Hutter, 2018) as the optimizer and run the experiments with an initial grafting probability from {0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9}. The probability with the best performance will be adopted. After pruning, we adjust the slope of the grafting probability curve so that the grafting probability equals 1 at the end of module grafting. For module grafting and finetuning, an AdamW optimizer is used with learning rate chosen from $\{3e^{-5}, 1e^{-4}, 3.2e^{-4}, 5e^{-4}, 6.4e^{-4}\}$. The model training and evaluation are performed with CUDA 11.1 on Quadro RTX6000 GPU and Intel(R) Xeon(R) Gold 6244 @ 3.60GHz CPU.

4.2 Experimental Results

Accuracy vs. Sparsity. We do experiments on eight GLUE benchmark tasks (Table 1). For non-progressive baselines, SPD exceeds all of them on QNLI, SST-2, CoLA, STS-B, and MRPC. For RTE, TinyBERT$_6$ has a 1.6% higher accuracy than SPD. However, TinyBERT$_6$ used augmented data while SPD does not use data augmentation to generate the results in Table 1. On average, SPD has 6.3%, 5.6%, 1.2%, 1.7%, 3.7% improvement in performance than BERT$_6$-PKD, DistilBERT, TinyBERT$_6$, SparseBERT, E.T. respectively. Furthermore, on CoLA, SPA achieves up to 25.9% higher performance compared to all non-progressive baselines. For the progressive baseline, we compare SPD with BERT-of-Theseus. Experimental results show that SPD exceeds the latter on all tasks. SPD has a 3.9% increase on average. Among all the tasks, CoLA and RTE have 20.2% and 5.9% gain respectively. For the comparison with sparse and non-progressive baseline, SPD has an improvement of 16.8%, 5.5%, 3.2%, 2.7%, 2.0%, 1.9%, 1.6%, 1.6% on CoLA, RTE, MNLI, QNLI, QQP, MRPC, STS-B, SST-2, respectively.

On all listed tasks, SPD even outperforms the teacher model except for RTE. On RTE, SPD retains exactly the full accuracy of the teacher model. On average, the proposed SPD achieves a 1.1% higher accuracy/score than the teacher model. We conclude the reason for the outstanding performance from three respects: 1) There is redundancy in the original dense BERT model. Thus, pruning the model with a low pruning rate (e.g., 50%) will not lead to a significant performance drop. 2) SPD decreases the overfitting risk which helps the student model learn better. 3) The interference between different hyperparameter strategies is mitigated, which enables SPD to obtain a better student model.

We also compare SPD with other baselines (i.e., 4-layer TinyBERT (Jiao et al., 2020), RPP (Guo et al., 2019), and SparseBERT (Xu et al., 2021)) under higher pruning rates. Results are summarized in Table 2. For the fairness of comparison, we remove data augmentation from the above methods. We mainly compare the aforementioned baselines with very high sparsity (e.g., 90%, 95%) SPD. For the comparison with TinyBERT$_4$, both SPD (90% sparsity) and SPD (95% sparsity) win. SPD (90% sparsity) has 63.4% and 9% higher evaluation score than TinyBERT$_4$ on CoLA and MRPC, respectively. For the setting of 95% sparsity, SPD outperforms TinyBERT$_4$ with 41.3% and 7.6% higher performance, respectively. Compared to RPP, both SPD (90% sparsity) and SPD (95% sparsity) show higher performance on MRPC, with 9.8% and 8.3% higher F1 score, respectively. For SparseBERT, SPD exceeds it on all tasks in Table 2. Especially on CoLA, SPD (90% sparsity) and SPD (95% sparsity) have 2.69× and 2.33× higher Mcc score on CoLA, respectively. SparseBERT has competitive performance with SOTA when using data augmentation. The reason for the performance drop for SparseBERT may because its deficiency of ability in mitigating overfitting problems.

Overfitting Mitigation. We explore the effectiveness of SPD to mitigate the overfitting problem. Depending on whether progressive, grafting, or KD is used, we compare 4 strategies: (a) no progressive, no KD; (b) progressive, no KD; (c) no progressive, KD; (d) progressive, KD (ours). We evaluate these strategies on both training and validation sets of MRPC. The results are summarized in Figure 5. From (a) to (d), the gap between the evaluation results of the training set and the dev set is reduced, which strongly suggests that the strategy adopted by SPD, i.e., progressive + KD, outperforms other strategies in mitigating the overfitting problem. Figure 5 (a), (b), and (c) indicate that compared to progressive only, KD has a bigger impact on mitigating overfitting, as the performance gap between the training set and the dev set decreases more from (a) to (c) than from (a) to (b). From Figure 5 (a), (b) and (c), we also observe that compared to no progressive, no KD, either using progressive (Figure 5 (b)) or KD (Figure 5 (c)) is very obvious to help mitigate the overfitting prob-

lem. Figures 5 (b), (c) and (d) indicate that the combination of progressive and KD brings more benefits than only using progressive or KD as Figure 5 (d) has the smallest performance gap between the training set and the dev set. Combined with Table 1 and Table 2, Figure 5 shows that SPD mitigates overfitting and leads to higher performance.

4.3 Ablation Studies

In this section, we justify the three schedulers used in our method (i.e., grafting probability, pruning rate, and learning rate), and study the sensitivity of our method with respect to each of them.

Study on Components of SPD. The proposed SPD consists of three components (i.e., sparse, knowledge distillation, and progressive module grafting). We conduct experiments to study the importance of each component on GLUE benchmark tasks with the sparsity of 50% and results are shown in Table 3. Compared to both sparse + KD and sparse + progressive, SPD achieves gains on performance among all tasks.

Effects of Grafting Probability Strategy. In our method, we set the grafting probability greater than 0 during pruning, to allow student modules to learn deeper knowledge from the teacher model. To verify the benefit of this design, we change the grafting probability to zero and compare it with our

Model	#Param	MNLI Acc	QQP F1	QNLI Acc	SST-2 Acc	CoLA Mcc	STS-B Spea	MRPC F1	RTE Acc	Avg.
Fine-tuned BERT$_{\text{BASE}}$ (teacher)	109M	84.0	91.4	91.6	92.9	57.9	89.1	90.2	72.2	83.7
Sparse + KD	67M	84.2	91.1	91.5	92.1	57.1	89.4	89.5	70.0	83.1

Table 3: The performance comparison of different strategies on the dev set of GLUE. Mcc refers to Matthews correlation coefficient and Spea refers to Spearman correlation coefficient.

method. The result on RTE is shown in Figure 6. Pruning with grafting (the red curve) shows better performance than pruning without grafting, which justifies the existence of grafting during pruning. In addition, we study the sensitivity of our method to grafting probability (Figure 7). It is observed that $p_0 = 0.6$ achieves the best performance, and the progressive design is better than the non-progressive.

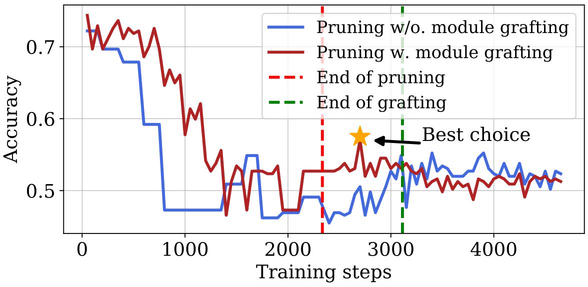

Figure 6: Pruning w/ module grafting vs. Pruning w/o. module grafting on RTE (dev set).

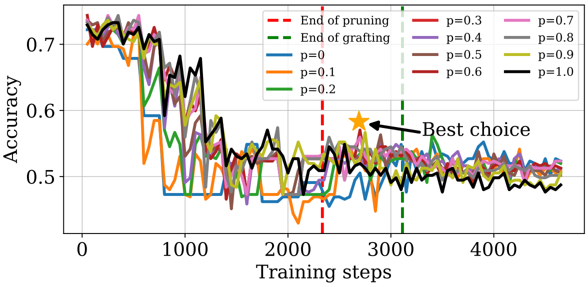

Figure 7: Sensitivity analysis of grafting probability on RTE (dev set).

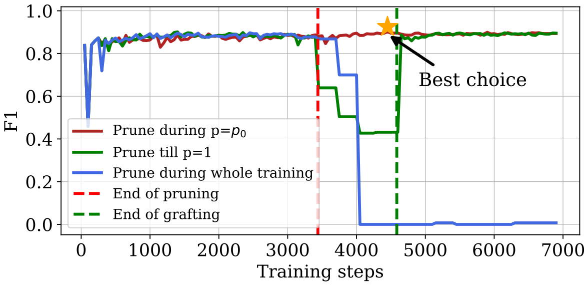

Figure 8: Effects of different pruning ending strategies on MRPC (dev set).

Effects of Pruning Rate Strategy. For the pruning rate scheduler, we compare the strategies with different pruning ending steps. The results are shown in Figure 8. It is observed that the pruning during when grafting probability $p = p_0$ has a higher F1 score than other strategies on MRPC.

Effects of Optimizer Strategy. We also compare our strategy with the strategy that only has one learning rate scheduler. The results (Figure 9) indicate that our strategy (i.e., two independent optimizers) is better. We also evaluate different learning rates with the pruning rate of 0.9 and the grafting probability of 0.8.

5 Conclusion

In this paper, we postulate a counter-traditional hypothesis that pruning increases the risk of overfitting under the pretrain-and-finetune paradigm. We analyze and empirically verify this hypothesis, and propose a sparse progressive pruning method to address the overfitting problem. We theoretically analyze that our pruning method can obtain a subnetwork from the student model that has a similar accuracy as the teacher. We study and minimize the interference between different hyperparameter strategies, including pruning rate, learning rate, and grafting probability. A number of ablation studies and experimental results on eight tasks from the GLUE benchmark demonstrate the superiority of our method over the leading competitors.

Appendix

We provide the sensitivity analysis of learning rate on RTE and STS-B (dev set) and the evaluation curves of four tasks (CoLA, STS-B, MRPC, and RTE) with the target pruning rate of 0.95.

Sensitivity Analysis of Learning Rate. The analysis results on RTE and STS-B are shown in Figure 10 and Figure 11, respectively. Results vary with different learning rate settings. Among the eight learning rates listed in the legend of Figure 10, $3.2 \times e^{-4}$ achieves the best performance. For STS-B, $4.0 \times e^{-4}$ gives the best performance among the learning rate choices in Figures 11.

Evaluation Curves of Four Tasks at Target Pruning rate of 0.95. We plot the evaluation curves of CoLA (Figure 12), STS-B (Figure 13), MRPC (Figure 14), RTE (Figure 15) to further demonstrate the advantages of our proposed method SPD. In each figure, the x-axis is the training steps while the y-axis represents evaluation metrics. To obtain the curves, we use the same settings as Table 2.

Moreover, we describe the hyper-parameters settings in detail. For CoLA, we set the max sequence length as 128, the learning rate as $5.0e^{-4}$, the grafting probability during pruning as 0.8, the number of training epochs as 60, and the number of pruning epochs as 30. For STS-B, we use the same setting as CoLA. For MRPC, we set the max sequence length as 128, the learning rate as $6.4 \times e^{-4}$, the grafting probability during pruning as 0.8, the number of training epochs as 60, and the number of pruning epochs as 30. For RTE, we set the max sequence length as 128, the learning rate as $3.0 \times e^{-5}$, the grafting probability during pruning as 0.6, the number of training epochs as 60, and the number of pruning epochs as 30.

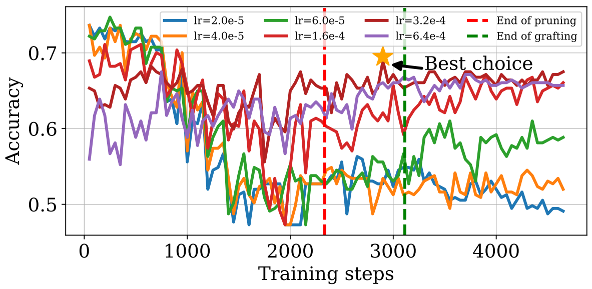

Figure 10: Sensitivity analysis of learning rate on RTE (dev set).

Abstract

We propose a novel data-augmentation technique for neural machine translation based on ROT-k ciphertexts. ROT-k is a simple letter substitution cipher that replaces a letter in the plaintext with the kth letter after it in the alphabet. We first generate multiple ROT-k ciphertexts using different values of k for the plaintext which is the source side of the parallel data. We then leverage this enciphered training data along with the original parallel data via multi-source training to improve neural machine translation. Our method, `CipherDAug`, uses a co-regularization-inspired training procedure, requires no external data sources other than the original training data, and uses a standard Transformer to outperform strong data augmentation techniques on several datasets by a significant margin. This technique combines easily with existing approaches to data augmentation, and yields particularly strong results in low-resource settings.[1]

1 Introduction

> One naturally wonders if the problem of translation could conceivably be treated as a problem in cryptography. [...] frequencies of letters, letter combinations, [...] etc., [...] are to some significant degree independent of the language used (Weaver, 1949)

Indeed, to a system which treats inputs as atomic identifiers, the alphabet behind these identifiers is irrelevant. Distributional properties are of sole importance, and changes in the underlying encoding should be transparent provided these properties are preserved. In light of this, a bijective cipher such as ROT-k (Figure 1) is in effect invisible to modern NLP techniques: distributional features are invariant under such a cipher, guaranteeing that the meaning of an enciphered text is the same as the un-enciphered text, given the key. This work exploits this fact to develop a novel approach to data augmentation which is completely orthogonal to previous approaches.

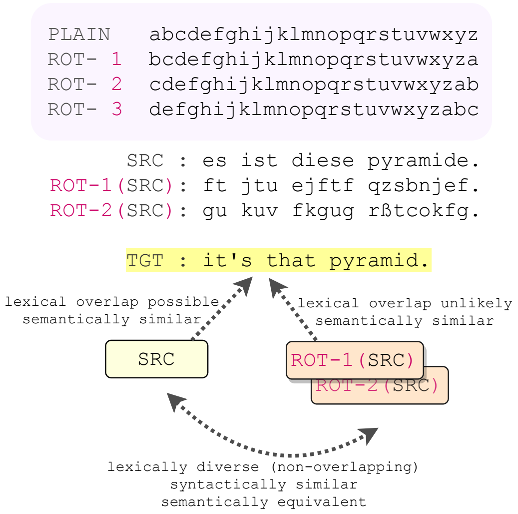

Figure 1: ROT-k encipherment. The *plaintext* `SRC` is enciphered to generate the *ciphertexts* ROT-1(`SRC`) and ROT-2(`SRC`), which share distributional features with the plaintext but use a new encoding.

Data augmentation is a simple regularization-inspired technique to improve generalization in neural machine translation (NMT) models. These models (Bahdanau et al., 2015; Vaswani et al., 2017) learn powerful representational spaces (Raganato and Tiedemann, 2018; Voita et al., 2019; Kudugunta et al., 2019) which scale to large numbers of languages and massive datasets (Aharoni et al., 2019). However, in the absence of data augmentation, their complexity makes them susceptible to memorization and poor generalization.

Data augmentation for NMT requires producing new, high-quality parallel training data. This is not trivial as slight modifications to a sequence can have drastic syntactic or semantic effects, and changes to a source sentence generally require corresponding changes to its translation. Existing techniques suffer various limitations: back-translation (Sennrich et al., 2016b; Edunov et al., 2018; Xia

May 22-27, 2022

et al., 2019a; Nguyen et al., 2019) can yield semantically poor results due to its use of trained models that are susceptible to errors (Edunov et al., 2018). Word replacement approaches (Gao et al., 2019; Liu et al., 2021; Takase and Kiyono, 2021; Belinkov and Bisk, 2018; Sennrich et al., 2016a; Guo et al., 2020a; Wu et al., 2021a) may ignore context cues or fracture alignments between sequences.

This paper overcomes these limitations by exploiting the invariance of distributional features under ROT-k ciphers. We contribute a novel data augmentation technique which creates enciphered copies of the source side of a parallel dataset. We then leverage this enciphered training data along with the original parallel data via multi-source training to improve neural machine translation. We also provide a co-regularization-inspired training procedure which exploits this enciphered data to outperform existing strong NMT data augmentation techniques across a wide range of experiments and analyses. Our technique can be flexibly combined with existing augmentation techniques, and does not rely on any external data.

2 Ciphertexts for Data Augmentation

A ROT-k cipher (Figure 1) produces a *ciphertext* by replacing each letter of its input (*plaintext*) with the kth letter after it in the alphabet. Past work (Dou and Knight, 2012; Dou et al., 2014) has explicitly used decipherment techniques (Kambhatla et al., 2018) to improve machine translation. We emphasize that decipherment itself is *not* the purpose of the present work: rather, we use ciphers simply to re-encode data while preserving its meaning. This is possible because ROT-k is a 1:1 cipher where each ciphertext symbol corresponds to a unique plaintext symbol; this means it will preserve distributional features from the plaintext. This makes ROT-k cryptographically weak, but suitable for use in data augmentation.

Concretely, given a set of n training samples $\mathcal{D} = \{(x_i, y_i)\}_{i=1}^n$ and a set of keys K, we use Algorithm 1 to generate $|K|n$ new samples; giving $(|K| + 1)n$ samples when added to the training set.

Algorithm 1 Cipher-Augment Training Data

```
Training data $\mathcal{D} = \{x_i, y_i\}_{i=1}^n$
Set of cipher keys $K = \{k_1, k_2, .., k_m\}$
procedure ENCIPHER($\mathcal{D}$, $K$)
    for $k$ in $K$ do
                    ▷ encipher source sentences with ROT-$k$
        $\mathcal{D}_k \leftarrow \{\text{ROT-}k(x_i), y_i\}_{i=1}^n$
                    ▷ target sentences remain unchanged
        assert $|\mathcal{D}| = |\mathcal{D}_k|$
    return $\{\mathcal{D}_k \forall k \in K\}$
```

2.1 The Naive Approach

The ciphertexts produced by Algorithm 1 are guaranteed to be lexically diverse, not only from the plaintext but also from one another. Given this fact, we can naively regard each $\mathcal{D}_k$ as a different *language* and formulate a multilingual training setting (Johnson et al., 2017). For a plaintext sample x_i, ciphertext samples $\{\text{ROT}-k_j(x_i), ..., \text{ROT}-k_{|K|}(x_i)\}$, and target sequence y_i, the *multi-source model* is trained by minimizing the cross-entropy

$$\mathcal{L}^i_{NLL} = -\log p_\Theta(y_i|x_i) - \sum_j^{|K|} \log p_\Theta(y_i|\text{ROT-}k_j(x_i)) \tag{1}$$

where $|K|$ is the number of distinct keys used to generate ciphertexts.

While this yields a multilingual model, this formulation does not allow explicit interaction between a plaintext sample and the corresponding ciphertexts. To allow such interactions, we design another model that relies on inherent pivoting between sources and enciphered sources. We achieve this by adding ROT-k(*source*) $\rightarrow$ *source* as a translation direction; following Johnson et al. (2017) we prepend the appropriate target token to all source sentences and train to minimize the objective

$$\begin{aligned}\mathcal{L}^i_{NLL} &= -\log p_\Theta(y_i|x_i) \\ &\quad - \sum_j^{|K|} [\ \log p_\Theta(y_i|\ \text{ROT-}k_j(x_i)) \\ &\quad + \log p_\Theta(x_i|\ \text{ROT-}k_j(x_i))\ ]\end{aligned} \tag{2}$$

We refer to (2) as the *naive* model.

Discussion. In this setting the decoder must learn the distributions of both the true target language and the source language. This may lead to quicker saturation of the decoder and sub-optimal use of its capacity, which must now be shared between two languages; this is a notorious property of many-to-many multilingual NMT (Aharoni et al., 2019).

2.2 CipherDAug: A Better Approach

To better leverage the equivalence between plain- and ciphertext data, we take inspiration from multi-view learning (Xu et al., 2013). We rethink enciphered samples as different *views* of the authentic source samples which can be exploited for co-training (Blum and Mitchell, 1998). This is motivated by the observation that plain and enciphered samples have identical sentence length, grammar, and (most importantly) sentential semantics.

Given an enciphered source *cipher*(x_i) we model the loss for a plaintext sample (x_i, y_i) as

$$\begin{aligned}\mathcal{L}^i = \; & \underbrace{\alpha_1 \, \mathcal{L}^i_{NLL}(\, p_\Theta(\, y_i | x_i)\,)}_{\text{anchor source x-entropy}} \\ + \; & \underbrace{\alpha_2 \, \mathcal{L}^i_{NLL}(\, p_\Theta(\, y_i | \, \textit{cipher}(x_i))\,)}_{\text{cipher source x-entropy}} \\ + \; & \underbrace{\beta \, \mathcal{L}^i_{dist}(\, p_\Theta(\, y_i|x_i), \; p_\Theta(\, y_i|\textit{cipher}(x_i))\,)}_{\text{agreement loss, see (4)}}\end{aligned} \tag{3}$$

where the original source language sentence x_i is called the *anchor* here since it is always paired with each enciphered version. The first two terms are conventional negative log-likelihoods, to encourage the model to generate the appropriate target for both x_i and *cipher*(x_i).

The third term is the *agreement loss*, measured as the pairwise symmetric KL divergence[2] between the output distributions for x_i and *cipher*(x_i):

$$\begin{aligned}& \mathcal{L}^i_{dist}(\, p_\Theta(\, y_i|x_i), \; p_\Theta(\, y_i|\textit{cipher}(x_i))\,) \\ & = \frac{1}{2}[\, D^i_{KL}(\, p^{flat}_\Theta(\, y_i|x_i) \; || \; p_\Theta(y_i| \, \textit{cipher}(x_i))\,) \\ & + D^i_{KL}(\, p^{flat}_\Theta(y_i| \, \textit{cipher}(x_i)) \; || \; p_\Theta(y_i|x_i))\,]\end{aligned} \tag{4}$$

This term allows explicit interactions between plain- and ciphertexts by way of *co-regularization*. Co-regularization relies on the assumption "that the target functions in each view agree on labels of most examples" (Sindhwani et al., 2005) and constrains the model to consider only solutions which capture this agreement.

In cases where there are many output classes and the model predictions strongly favour certain of these classes, (4) may have an outsized influence on model behaviour. As a precautionary measure, we use a softmax temperature τ to flatten the model predictions, based on a similar technique in knowledge distillation (Hinton et al., 2015) and multi-view regularization (Wang et al., 2021). The flattened prediction for an (x, y) pair is given by

$$p^{flat}_\Theta(x \,|\, y) = \frac{\exp(z_y)/\tau}{\sum_{y^j} \exp(z_{y^j})/\tau} \tag{5}$$

where z_y is the logit for the output label y. A higher value of τ produces a softer, more even distribution over output classes.

The overall training procedure, which we dub CipherDAug, is summarized in Algorithm 2.

Algorithm 2 CipherDAug Training Algorithm

```
Training data $\mathcal{D} = \{x_i, y_i\}_{i=1}^n$
Set of cipher keys $K = \{k_1, k_2, .., k_m\}$
Randomly initialized NMT model $\Theta$

procedure MULTISOURCE TRAIN ($\Theta$, $\mathcal{D}$, $K$)
    $\mathcal{D}_{anchor} = \mathcal{D}$          ▷ plaintexts act as anchor dataset
    while $\Theta$ not converged do
        for each $\mathcal{D}_{cipher} \in$ ENCIPHER($\mathcal{D}$, $K$) do ▷ Algo. 1
            $(cipher(x_i), y_i) \sim \mathcal{D}_{cipher}$
            $(x_i, y_i) \sim \mathcal{D}_{anchor}$          ▷ same index $i$
                                                  ▷ same target $y_i$
            $\mathcal{L}^i_{NLL} \leftarrow \mathcal{P}(y_i|x_i)$
            $\mathcal{L}^i_{NLL} \leftarrow \mathcal{P}(y_i|cipher(x_i))$
            $\mathcal{L}^i_{dist} \leftarrow \mathcal{P}(y_i|x_i) \parallel \mathcal{P}(y_i|cipher(x_i))$
                                                  ▷ using eq (4)
            update $\Theta$ by minimizing $\mathcal{L}^i$        ▷ using eq (3)
```

3 Experiments and Results

3.1 Experimental Setup

Datasets We use the widely studied IWSLT14 De↔En and IWSLT17 Fr↔En language pairs as our small-sized datasets.[3] For high-resource experiments, we evaluate on the standard WMT14 En→De set of 4.5M sentence pairs.[4] We also extend our experiments to the extremely low-resource pair Sk↔En from the multilingual TED dataset (Qi et al., 2018) with 61k training samples, and dev and test splits of size 2271 and 2245 respectively.

Ciphertext Generation and Vocabularies. We use a variant of ROT-k which preserves whitespace, numerals, special characters, and punctuation. As a result, these characters appear the same in both plain- and ciphertexts.

For our *naive* approach, we encipher the German side of the IWSLT14 dataset with up to 20 keys `{1,2,3,4,5,...,20}`. For our main experiments, we encipher the source side of every translation direction[5] with key `{1}` for WMT experiments and keys `{1,2}` for the rest.[6]

We use `sentencepiece` (Kudo and Richardson, 2018) to tokenize text into byte-pair encodings

---

[2] Other metrics such as regular (asymmetric) KL divergence or JS divergence can also be used in (4), but we find that symmetrized KL divergence yields the best results.

[3] The De↔En data has a train/dev/test split of about 170k/7k/7k. The Fr↔En data has a 236k/890/1210 split using `dev2010` and `tst2015`.

[4] Following Vaswani et al. (2017), we validate on `newstest2013` and test on `newstest2014`

[5] In all generated ciphertexts, the source alphabet is preserved, only the distribution of characters is changed. The target side is never altered.

[6] The dictionaries for enciphered data are produced using only the training dataset, and then applied to the train/dev/test splits, in the same manner that BPE is learned and applied.

(BPE; Sennrich et al. 2016c) by jointly learning subwords on the source, enciphered-source, and target sides. We tune the number of BPE merges as recommended by Ding et al. (2019); the resulting subword vocabulary sizes for each dataset are tabulated in Table 1.

→	src	tgt	s∪t	1(src)	2(src)	total
De→En	9k	6.7k	11.8k	6.7k	6.5k	20k
En→De	7.3k	9.7k	12.7k	6.6k	6.4k	20k
Fr→En	7k	6k	10.4k	5.2k	5.2k	16k
En→Fr	7.5k	6.5k	11k	5k	5k	16k
En→Sk	5.2k	7.1k	10k	4.6k	4.5k	16k
En→De	25k	24k	36k	16k	16k	60k

Table 1: Approximate subword vocabularies for the IWSLT14 (top), IWSLT17, TED, and WMT (bottom) datasets. 1(src) and 2(src) denote ROT-1 and ROT-2 encipherments, respectively.

In all experiments, we set the loss weight hyperparameters α_1, α_2 to 1, and β to 5. Section 4.1 shows an ablation over β to justify this setting. We find that softmax temperature $\tau = 1$ works well for all experiments; $\tau = 2$ results in more stable training for larger datasets.

Evaluation We evaluate on BLEU scores[7] (Papineni et al., 2002). Following previous work (Vaswani et al., 2017; Nguyen et al., 2019; Xu et al., 2021), we compute tokenized BLEU with `multi_bleu.perl`[8] for IWSLT14 and TED datasets, additionally apply compound-splitting for WMT14 En-De[9] and `SacreBLEU`[10] (Post, 2018) for IWSLT17 datasets. For all experiments, we perform significance tests based on bootstrap resampling (Clark et al., 2011) using the `compare-mt` toolkit (Neubig et al., 2019).

Baselines Our main baselines are strong and widely used data-augmentation techniques that do not use external data. We compare CipherDAug to back-translation-based data-diversification (Nguyen et al., 2019), word replacement techniques like SwitchOut (Wang et al., 2018), WordDrop (Sennrich et al., 2016a), and RAML (Norouzi et al., 2016), and the subword-regularization technique BPE-Dropout (Provilkov et al., 2020).

See supplemental sections A.1 and A.2 for further baseline and implementation details.

Model	**De → En**	
Transformer	34.91	
+ Word Dropout	34.83	
+ SwitchOut	34.82	
+ RAML	35.11	
+ RAML + Switchout	35.17	
+ RAML + WordDrop	35.47	
Naive Multi-Source	*Equation (1)*	*Equation (2)*
2 keys	35.45	35.85
5 keys	35.65	35.98
10 keys	33.70	35.42
20 keys	32.95	34.75
5 keys + RAML + Switchout	-	36.17
5 keys + RAML + WordDrop	-	36.63
CipherDAug - 1 key	36.21	
CipherDAug - 2 keys	**37.60**	

Table 2: Results on the IWSLT14 De-En validation set comparing the naive approach and CipherDAug.[11]

3.2 Results from the Naive Approach

Table 2 shows our results using the naive method on the IWSLT14 De→En dev set. Simply using 2 enciphered sources gives a BLEU score of 35.45, which nearly matches the performance of the best baseline, RAML+SwitchOut, at 35.47. Adding the ROT-k(source) → source direction further improves the score to 35.85. Adding the ROT-k(source) → source direction consistently yields better results than the vanilla multi-source model, but increasing the number of keys has a less consistent effect. We hypothesize that more keys are generally beneficial, but that the model becomes saturated when too many are used. Based on these observations, we limit later experiments to 2 keys.

We observe further gains by combining the naive method with the two best performing baselines. This emphasizes that ciphertext-based augmentation is orthogonal to other data-augmentation methods and can be seamlessly combined with these to yield greater improvements.

3.3 Main Results

We present our main results in Table 3. While using a single key improves significantly over the Transformer model, augmenting with 2 keys outperforms *all* baselines. Table 4 shows additional comparisons against approaches that introduce architectural improvements to the transformer (such as MAT; Fan et al. 2020) or that require large pretrained models, like BiBERT (Xu et al., 2021).

Table 3: IWSLT14 De↔En (left), IWSLT17 Fr↔En (center) and WMT14 En→De (right). All baselines were reproduced except for Mixed-Repr. (Wu et al., 2020) which we report from literature. Our numbers are median results over three runs. Statistical significance is indicated by * ($p < 0.001$) and ** ($p < 0.05$) vs. the baseline, and † ($p < 0.001$) vs. 1 key. See A.1 for additional details.

our method yields stronger improvements over the standard Transformer than any other data augmentation technique (Table 3). This includes strong methods such RAML+SwitchOut and data diversification, which report improvements as high as 1.8 and 1.9 BLEU points respectively. Data diversification involves training a total of 7 different models for forward and backward translation on the source and target data. By contrast, CipherDAug trains a single model, and improves the baseline transformer by 2.9 BLEU points on IWSLT14 De→En and about 2.2 BLEU points on the smaller datasets.

Model	$\lvert\Theta\rvert$	**De → En**
Transformer	44M	34.71
Macaron Net (2020)	1x	35.40
BERT Fuse (Zhu et al., 2020)	1x(+BERT)	36.11
MAT (Fan et al., 2020)	0.9x	36.22
UniDrop (Wu et al., 2021b)	1x	36.88
R-DROP (Liang et al., 2021)	1x	37.25
BiBERT (Xu et al., 2021)	1x(+BERT)	37.50
CipherDAug-2 keys (Ours)	1.2x	**37.53**

Table 4: Results on IWSLT14 De-En test set with non-data-augmentation methods that are fundamentally different. CipherDAug has 1.2x parameters because of the slightly larger embedding layer size owing to the combined cipher vocabulary. See A.3.1 for comparisons against a Transformer with 1.2x parameters.

On WMT14 En→De, our method using 1 key improves by 0.6 BLEU over the baseline transformer and significantly outperforms word replacement methods like SwitchOut and WordDropout.

Low-resource setting The Sk↔En dataset is uniquely challenging as it has only 61k pairs of training samples. This dataset is generally paired with a related high-resource language pair such as Cs-En (Neubig and Hu, 2018), or trained in a massively multilingual setting (Aharoni et al., 2019) with 58 other languages from the multilingual TED dataset (Qi et al., 2018). Xia et al. (2019b) introduced a generalized data augmentation technique that works in this multilingual setting and leverages over 2M monolingual sentences for each language using back-translation. Applying CipherDAug to this dataset (Table 5) yields significant improvements over these methods, achieving 32.62 BLEU on Sk→En and 24.61 on En→Sk.

	Sk-En	**En-Sk**
1-1(Neubig and Hu; Aharoni et al.)	24	5.80
Sk (61k) always paired with Cs (103k)

CipherDAug - 2 keys	**32.62**†	**24.61**†

Table 5: Results on the low-resource TED (Qi et al., 2018) Sk-En pair. Our model is trained on Sk-En only and does not require additional parallel data from a related high resource language (HRL) pair.

Discussion On the relatively larger WMT14 dataset (4.5M), despite improving significantly over the baseline Transformer, the Base model

---

[12] Wu et al. 2020 introduce a new model architecture for mixing subword representations that involves a two-stage training process. CipherDAug, on the other hand, only uses a vanilla Transformer that is trained end-to-end.

	|src∪tgt|	|vocab|	D_{emb}	EmbΘ	TrainΘ	BLEU
Transformer-256	12k	12k	256	3M	37M	34.40
Transformer-512	12k	12k	512	6.1M	44M	34.64
Transformer-256	20k	20k	256	5.1M	42M	34.19
Transformer-512	20k	20k	512	10.1M	52M	34.39
CipherDAug-1key	11.8k	16k	256	4.1M	40M	36.25
CipherDAug-1key	11.8k	16k	512	8.2M	47M	36.19
CipherDAug-2keys	11.8k	20k	256	5M	42M	36.90
CipherDAug-2keys	11.8k	20k	512	10.1M	52M	**37.53**

Table 6: Results on IWSLT14 De→En with baseline Transformer and CipherDAug using different vocabulary sizes and embedding dimensions. Except for the embedding layers, the rest of the network configuration is exactly the same across all settings with 31M parameters. The column **Train**Θ denotes total number of trainable parameters (approx. 31M + 2.**Emb**Θ). Transformer-512 denotes the baseline transformer model used in our experiments.

(68M params) approaches saturation when ∼9M enciphered sentences (2 keys) are added. Upgrading to Transformer Big (218M) may be viable, but would be an unfair comparison with other models. The model capacity becomes a bottleneck with larger datasets when the model is optimised to translate each of the source sentences (4.5M plain and 9M enciphered) individually (single-source) as well as together (multi-source) through the co-regularization loss. The results indicate that our proposed approach works best in small and low resource data settings.

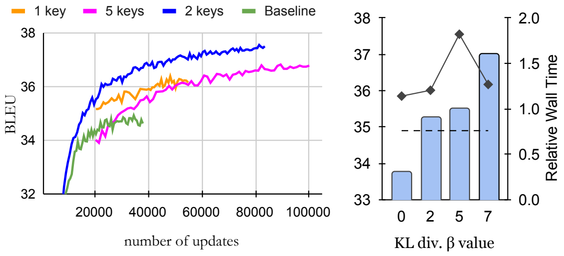

Figure 2: Ablation over number of distinct keys (left) and weight β of agreement loss (right). Wall times (run times) are measured to convergence/early stopping, relative to $\beta = 5$ with 2 cipher keys which is our setting of choice. The dashed line (right) shows baseline BLEU score.

4 Analysis

4.1 Ablations

Number of Keys Figure 2 (left) shows the effect of adding different amounts of enciphered data. We obtain the best performance using just 2 different keys. Using more or fewer degrades performance, though both cases still outperform the baseline. As noted in Section 3.2, the model may become saturated when too many keys are used.

Agreement Loss Figure 2 (right) shows an ablation analysis on the agreement loss. We find that CipherDAug is sensitive to the weight β given to this term: increasing or decreasing it from our default setting $\beta = 5$ incurs a performance drop of nearly 2 BLEU. Despite the performance gains attendant to this term, it is equally clear that agreement loss cannot fully account for CipherDAug's improvements over the baseline: in the naive setting where $\beta = 0$, CipherDAug still outperforms the baseline by approximately 1 BLEU.

Learning BPE vocabularies jointly vs. separately From Table 7, we see that there is no significant impact on BLEU if we learn BPE vocabularies separately for each language or enciphered language from IWSLT14 De→En. This is consistent with results from Neubig and Hu (2018) in the context of mutilingual NMT.

	|s∪t|	rot-1(s)	rot-2(s)	|V|	BLEU
sep	12k	6.5k	6.5k	21.2k	37.65
joint	11.8k	6.7k	6.5k	20k	37.53

Table 7: Comparison of BPE vocabularies learnt jointly vs. separately for CipherDAug-2 keys. The 'separate' setting uses the union of BPEs learnt separately on the bitext and two ciphertexts. The difference in BLEU scores is not statistically significant.

Note that it is preferable to learn the BPEs jointly as this allows us to limit the total vocabulary size. When learned separately, we cannot control the combined vocabulary size which may result in a larger or smaller vocabulary (and therefore, a different number of embedding parameters) than intended.

Disentangling the effects of increased parameters in the embedding layer CipherDAug leverages the combined vocabularies of the original parallel bitext and enciphered copies of the source text. This necessarily increases in the number of parameters in the embedding layer even though the rest of the network remains identical.

To understand the effect of these extra parameters, we compare CipherDAug against the baseline Transformer model with different vocabulary and embedding sizes. Results from different settings are shown in Table 6. [13]

As we reduce the embedding dimension of our best model (CipherDAug with 2 keys) from 512 to 256, we observe a small change of -0.6 BLEU in the final scores. With 1 cipher key, however, our model exhibits a slight (statistically insignificant) improvement of +0.06 BLEU. These results show that the few extra embedding parameters in CipherDAug do not have an outsized impact on model performance, but we emphasize that reducing the dimensionality of the embedding layer diminishes its expressivity and is therefore not a completely fair comparison.

4.2 Hallucinations

The attention mechanism of a model might not reflect a model's true inner reasoning (Jain and Wallace, 2019; Moradi et al., 2019, 2021). To better analyze NMT models, Lee et al. (2018) introduce the notion of *hallucinations*. A model hallucinates when small perturbations in its input cause drastic changes in the output, implying it is not actually attentive to this input.

Using Algorithm 2 of Raunak et al. (2021), Table 8 shows the number of hallucinations on the IWSLT14 De-En test set for the baseline and CipherDAug models. We use the 50 most common subwords as perturbations. CipherDAug sees a 40% reduction in hallucinations relative to the baseline, suggesting it is more resilient against perturbations and more attentive to the content of its input.

Model	Hallucinations
Transformer	23
CipherDAug-2 keys (Ours)	**14**

Table 8: Number of distinct sentences which cause hallucinations in the baseline and CipherDAug models.

4.3 Effect on Rare Subwords

We argue that CipherDAug is effective in part because it reduces the impact of rare words. On average, the rarest subword in a ROT-k enciphered sentence is significantly more frequent than the rarest subword in a plaintext sentence. This is apparent in an example like the following:

```
hier ist es nötig, das, was wir
unter politically correctness        (6)
verstehen, immer wieder anzubringen.
```

Figure 3 plots the frequency of each subword in this sentence and its ROT-k enciphered variants. In the plaintext, we observe a series of rare subwords `ically`, `_correct`, and `ness` coming from the English borrowing. After encipherment, however, these are replaced by a variety of more common subwords `jd`, `bmm`, `_d`, and so on. The result is that the enciphered sentences have fewer rare subwords; this allows them to share more information with other sentences, and allows the more common enciphered tokens to inform the model's encoding of less common plaintext tokens.

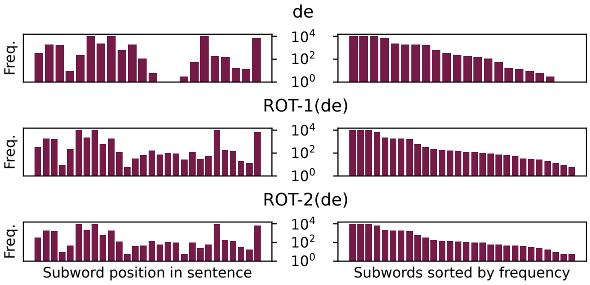

Figure 3: Frequencies of subwords in (6) and its ROT-k enciphered variants. Encipherment replaces rare subwords with more common ones.

We reiterate that this trend holds across the whole corpus, and highlights the value of an augmentation scheme that allows a model to see many different segmentations of each input.

This is not the *only* mechanism by which CipherDAug improves performance: we find improvements for tokens in every frequency bucket, not simply those which are rare (Figure 4).

4.4 Multi-view Learning

In Section 2.2, we argue that the agreement loss in (4) acts as a co-regularization term in a multi-view learning setting. Multi-view learning works best when the different views capture distinct information. In CipherDAug, this is accomplished by

---

[13] Note that in Table 6, the BPE vocabularies from the original source and target remain approximately same across the baseline (12k) and CipherDAug (11.8k) even though the final vocabulary sizes of our models vary with the addition of the enciphered source(s).

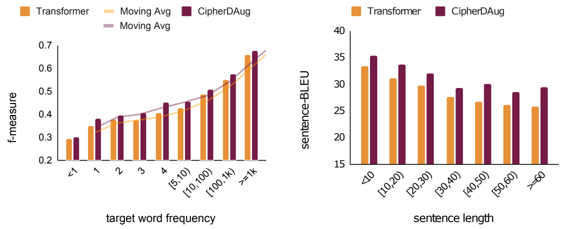

Figure 4: CipherDAug yields improvements for tokens of all frequencies and sentences of every length. (a) F-measure between model outputs and reference tokens, bucketed by frequency of the reference token. (b) Sentence BLEU bucketed by target sentence length.

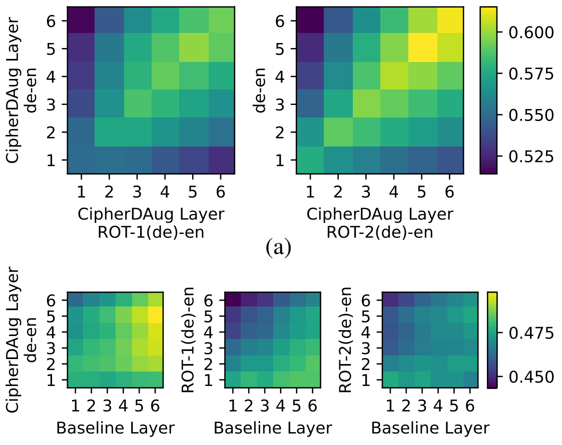

(a)

(b)

Figure 5: PWCCA between encoder states at different layers. All correlations exceed the value expected from a random baseline (0.27). (a) Impact of key on CipherDAug encoder states. (b) Comparison between CipherDAug and baseline, showing different distributions of information across models and input encodings.

allowing enciphered inputs to receive different segmentations than plaintext inputs. As evidence that the different views capture distinct information, we note that even after training with co-regularization the model remains sensitive to the choice of input encoding, as seen in cases such as Figure 6 where the model may produce any of three distinct outputs depending on whether it is given plain- or ciphertext as input. If all of the input views captured identical information we should expect no such variation, especially after training with an explicit co-regularization term.

4.5 Canonical Correlation Analysis

To further analyze CipherDAug, we turn to canonical correlation analysis (CCA; Hardoon et al. 2004; Raghu et al. 2017), which finds a linear transform to maximize correlation between values in two high dimensional datasets. As detailed in Raghu et al. 2017, it is useful for measuring correlations between activations from different networks.

For each IWSLT14 De-En test sentence, we save the activations from each layer of our baseline and CipherDAug models. For the CipherDAug model, we save activations on plaintext and enciphered inputs. For every pair of layers, we compute the projection weighted[14] CCA (PWCCA) between activations from those layers. If this value is high (relative to a random baseline), this means that there is a linear transformation under which the activations from those layers are linearly correlated, implying that the layers capture similar information.

Figure 5 plots the PWCCA between encoder states from the baseline and CipherDAug models, and between CipherDAug encoder states with different input encodings. It is immediately clear that CipherDAug learns similar, but not identical, representations for plain- and ciphertext inputs: the state of a layer in the de→en setting is generally predictive of the state of that same layer in the ROT-1(de)→en and ROT-2(de)→en settings.

We emphasize, however, that representations for plain- and ciphertexts are not identical, as can be seen by comparing against the baseline model. Here, some layers in one model show a moderate correlation to *every* layer of the other model; other layers show a strong correlation with a *different* layer from the other model. This implies that, while the two models extract some of the same information, they do so at different depths in the encoder. Moreover, CipherDAug states from enciphered inputs present an entirely different pattern of correlations than plaintext inputs. This implies that CipherDAug not only learns different information than the baseline, but that these differences are distinct for plaintexts and ciphertexts. These results strengthen Section 4.4's claim that plain- and ciphertexts capture distinct information.

5 Related Work

Data-augmentation (Sennrich et al., 2016b) can be broadly categorized into back-translation based methods and those which perturb or change the input (Wang et al., 2018). Back-translation (Sennrich et al., 2016b) is arguably the *de-facto* data augmentation method for NMT. Besides back-translating

---

[14] See Raghu et al. 2017 for an explanation of CCA variants including PWCCA. We choose PWCCA as it has been found to be most robust against noise and because it does not require explicitly tuning the number of dimensions to analyze.

external monolingual data (Edunov et al., 2018), Li et al. (2019) forward-translate the source (Zhang and Zong, 2016) and/or backward-translate the target side (Sennrich et al., 2016a) of the original (in-domain) parallel data. Our technique produces lexically diverse samples using only the original source data, rather than relying on model predictions which may be of limited quality. Belinkov and Bisk (2018) showed that NMT models can be sensitive to orthographic variation, and that training with noise improves their robustness (Khayrallah and Koehn, 2018). Common noising techniques include token dropping (Zhang et al., 2020), word replacement (Xie et al., 2017; Wu et al., 2021a), Word-Dropout (randomly zeroing out word embeddings; Sennrich et al. 2016a; Gal and Ghahramani 2016) and adding synthetic noise by swapping random characters or replacing words with common typos (Karpukhin et al., 2019). Adding enciphered data is distinct from noising as the ciphertexts are generated deterministically and follow the same distribution as the underlying natural language, simply using shifted letters of the same alphabet.[15]

To extend the support of the empirical data distribution, Norouzi et al. (2016) introduced RAML on the target side; Wang et al. (2018) proposed SwitchOut as a more general method which they applied to the source side. Special cases of SwitchOut include Word-Dropout and sequence-mixing (Guo et al., 2020a), which exchanges words between similar source sentences to encourage compositional behaviour. Such methods generate several different samples for each sentence because of the large vocabulary to choose replacements from; they often give poor coverage despite this. In contrast, CipherDAug guarantees lexically diverse examples with semantic equivalence to the source sentences without having to *choose* specific replacements.

Adversarial techniques (Gao et al., 2019) perform soft perturbations of tokens or spans (Takase and Kiyono 2021, Karpukhin et al. 2019). An advantage of soft replacements over hard ones is that they take into account the context of the tokens being replaced (Liu et al., 2021; Mohiuddin et al., 2021). These methods require architectural changes to a model whereas CipherDAug does not.

Ciphertext-based augmentation is orthogonal to most other data-augmentation methods and can be seamlessly combined with these to jointly improve neural machine translation.

6 Conclusion

We introduce CipherDAug, a novel technique for augmenting translation data using ROT-k enciphered copies of the source corpus. This technique requires no external data, and significantly outperforms a variety of strong existing data augmentation techniques. We have shown that an agreement loss term, which minimizes divergence between representations of plain- and ciphertext inputs, is crucial to the performance of this model, and we have explained the function of this loss term with reference to co-regularization techniques from multi-view learning. We have also demonstrated other means by which enciphered data can improve model performance, such as by reducing the impact of rare words. Overall, CipherDAug shows promise as a simple, out-of-the-box approach to data augmentation which improves on and combines easily with existing techniques, and which yields particularly strong results in low-resource settings.

A Appendix

A.1 Baselines

To compare model performance on the small and mid-sized datasets, we re-implemented most baselines:

- we used the pseudocode in appendix A6 along with proofs in appendices A1 and A2 of the SwitchOut paper (Wang et al., 2018) to implement SwitchOut, WordDrop (Sennrich et al., 2016a), RAML (Norouzi et al., 2016), RAML+SwitchOut and RAML+WordDrop as special cases of SwitchOut. The hyperparameter τ was tuned on the dev set for each language pair. The respective τ values are 0.9 and 0.95 for De-En and 0.85 and 0.95 for Fr-En.

- we followed the instructions on the official open-sourced repository to reproduce BPE-Dropout (Provilkov et al., 2020) [16] with the recommended value of p=0.1 using the `sentencepiece` tokenizer. We trained models on our `Fairseq` codebase for IWSLT14 De↔En and WMT14 En→De. We reported the SacreBLEU numbers for IWSLT17 Fr↔En from literature.

- experiments on data-diversification (Nguyen et al., 2019) were reproduced using the official open-sourced implementation on top of the `Fairseq` toolkit. For WMT14 En-De, we use a Transformer Base (68M parameters) for a fair comparison across methods, whereas the original implementation employs a Transformer Big model (210M parameters). [17]. Note that this method requires training 7 individual models and has a total effective data size 7 times the original size to produce best results.

We reported the performance of Mixed-Representation (Wu et al., 2020) baseline for IWSLT14 De→En from the literature as we could reproduce the experiemnts. However, to the best of our knowledge, we employ settings identical to Mixed-Repr. baseline for IWSLT14 De→En in our model – the same tokenizer (`SentencePiece`), vocabulary size (12k), model size (`transformer_iwslt_de_en`), decoding hyper-parameters (beam 5, len-pen 1.0) and evaluation script (`multi-bleu.perl`).

A.2 CipherDAug: Models and Hyperparameters

The smaller datasets (IWSLT14 De↔En [18], IWSLT17 Fr↔En[19] and TED Sk↔En[20]) are trained with the `transformer_iwslt_de_en` config with 6 layers of encoder and decoder with 4 attention heads, embedding size of 512, feed-forward size of 1024, network dropout 0.3 and attention dropout 0.1. The peak learning rate is $6e-4$ with 8000 warmup steps.

For training the on WMT14 En→De dataset[21], we use Transformer Base config, dubbed `transformer_wmt_en_de` in `fairseq` toolkit, with 6 layers of encoder and decoder with 8 attention heads, embedding size of 512, feed-forward size of 2048, dropout 0.1. The peak learning rate is $7e-4$ with 4000 warmup steps.

Following conventional training of Transformers, we use Adam optimizer with betas (0.9, 0.98) and $\epsilon = 10^{-9}$ and `inverse_sqrt` learning rate scheduler. Label smoothing is set to 0.1.

We also set an `agreement_loss_warmup` to 2000 steps. This signifies that until the specified number of steps, the model will train with regular cross-entropy loss without computing KL divergence. This is done to let the model gain some confidence before we start applying co-regularization. This does not improve or worsen model performance, but we find that this helps the model converge slightly faster.

The `transformer_iwslt_de_en` models (for IWSLT14, IWSLT17 and TED datasets) were run on 2 Titan RTX GPUs while the `transformer_wmt_en_de` model for WMT14 En-De was run on 8 A6000 GPUs. All models were run until convergence with an early stopping patience of 15 validation steps. While smaller models converged within 100k updates,

Table 9: Results on IWSLT14 De→En with baseline Transformer and CipherDAug using ALONE embeddings (Takase and Kobayashi, 2020). The column **TrainΘ** denotes the approx. total number of **trainable** parameters. The filter vectors for ALONE embeddings are constructed using real valued vectors. Using the ALONE embeddings disentangles the effect of increased vocabulary in CipherDAug by building embeddings largely independent of the vocabulary sizes and ensures that it has the same number of net trainable parameters as the baseline Transformer. See Table 10 for details.

the model on WMT14 dataset was force stopped at 400k updates while the model was still improving (at a very slow rate).

For producing translations, the decoder beam size is set to 4 and length penalty 0.6 for WMT, and 5 and 1.0 for all other experiments. We evaluate on BLEU scores (Papineni et al., 2002). Following previous work (Vaswani et al., 2017; Nguyen et al., 2019; Xu et al., 2021), we compute tokenized BLEU with `multi_bleu.perl`[22] for IWSLT14 and TED datasets, additionally apply compound-splitting for WMT14 En-De[23] and `SacreBLEU` (Post, 2018) (Signature: `nrefs:1|case:mixed|eff:no|tok:13a|smooth:exp|version:2.0.0` for IWSLT17 datasets.

Finally, all results are reported on translations obtained after averaging the last 5 checkpoints.

A.3 Additional Experiments

A.3.1 Disentangling the effects of increased parameters in the embedding layer

Additional experiment based on results from Sec. 4.1 – Table 6. CipherDAug uses the combined vocabularies of the original parallel bitext and enciphered copies of the source text. This necessarily increases in the number of parameters in the embedding layer even though the rest of the network remains identical.

Using embeddings largely independent of the vocabulary size. To completely disambiguate the effects of the different sizes of vocabularies in the baseline and CipherDAug transformers, we replace the embedding layer with ALONE embeddings (Takase and Kobayashi, 2020).

While the conventional embedding layer requires an embedding matrix $E \in \mathbb{R}^{D_{emb} \text{ x } V}$ where V is the vocabulary size, ALONE lets different words in the vocabulary share a vector element with each other. To concretely obtain a word representation for w, ALONE computes an element-wise product of the base embedding $o \in \mathbb{R}^{1 \text{ x } D_O}$ and a filter vector, and then applies a feed-forward network of dimension D_{inter} to increase its expressiveness.

	|Θ|
conventional	D_{emb} x V
ALONE	$D_O + D_{inter}$ x $(D_O + D_{emb}) + M$ x D_O x c

Table 10: Number of parameters in conventional embeddings vs. **ALONE embeddings**. In our experiments, base emb. dim $D_O = 512$, emb. dim $D_{emb} = 512$, number of column vectors $M = 8$, and number of source matrices $c = 64$. Refer to Takase and Kobayashi (2020) for details.

See Takase and Kobayashi (2020) for more details on ALONE embeddings. We integrated the officially released code[24] with our implementation. Table 10 compares parameter counts with and without ALONE, and Table 9 details the result of using ALONE embeddings with CipherDAug.

A.3.2 Effect of different dropout probabilities

To further study the efficacy of our method in under-regularized scenarios, we compare the baseline transformer model with CipherDAug for the

---

[24] `https://github.com/takase/alone_seq2seq`

dropout values of 0 (no regularization), 0.1, 0,2 and 0.3 in Table 11. Evidently, our method shows consistent gains over the baseline. While a dropout value of 0.3 is optimal for both models, CipherDAug records a BLEU of +4.5 against the base model with dropout set to 0 which removes regularization as well any stochasticity from the model. This suggests that the variation in input data introduced by CipherDAug can yield improvements for transformer models, with similar effects to adding dropout (albeit to a lesser degree).

dropout →	**0**	**0.1**	**0.2**	**0.3**
Transformer	22.79	31.12	33.70	34.64
CipherDAug	27.10	36.45	36.90	37.53

Table 11: Results on IWSLT14 De→En with baseline Transformer and CipherDAug using different dropout values.

A.3.3 Complimenting data-diversification with CipherDAug

To further support our claim that our method can be combined with existing data-augmentation techniques, we extend CipherDAug into the data-diversification (Nguyen et al., 2019) framework.

Data-Diversification: This is a simple technique that employs the following steps to augment data without changing the model architecture:

Algorithm 3 Data-diversification

```
1: Train 3 randomly initialized forward (s→t) models
2: Train 3 randomly initialized backward (t→s) models
3: Translate original bitext with the forward models → $D_1, D_2, D_3$
4: Translate original bitext with the backward models → $D_4, D_5, D_6$
5: Combine all data $D = D_0 \cup D_1 \cup D_2 \cup D_3 \cup D_4 \cup D_5 \cup D_6$
   where $D_0$ = original bitext
6: Train final model on the augmented data $D$
```

We adapt Algo 3 to incorporate CipherDAug by modifying steps 1 and 2 – we replace the forward models with one CipherDAug model with 2 keys trained on IWSLT14 De→En and the backward models with a CipherDAug model with 2 keys trained on IWSLT14 En→De. We leverage the observation that CipherDAug often produces lexically diverse translations for the source and enciphered-source sentences (Figure 6; Figure 9 in Appendix). Following Step 5 above, we finally combine the 3 forward translations and the 3 backward translations with the original parallel data, and train a final model on the resulting augmented data. The results in Table 12 demonstrate that the combination is more effective than data diversification on its own.

model	**base**	**bwd.**	**fwd.**	**bidir.**
data-diverse	34.7	35.8	35.94	37.0
CipherDAug+	34.64	36.20	36.66	**37.95**

Table 12: Results on IWSLT14 De→En with data-diversification and CipherDAug-2keys in the data-diversification framework. The best results in this setting outperform both the baseline data-diverse model and CipherDAug in isolation. Note that we did not tune our model for this experiment. This further strengthens our claim that our method is complimentary to most existing techniques. (We borrowed the ablation results from Nguyen et al. (2019).)

A.4 Comparison with other methods

We show a comparison of our method CipherDAug with a variety of data-augmentation methods as well as other methods that introduce architectural changes for better neural machine translation in Table 13.

Model	**De → En**

Overlap-based Vocabulary Generation Improves Cross-lingual Transfer Among Related Languages

Vaidehi Patil *1 **Partha Talukdar**†2 **Sunita Sarawagi**‡1
1Indian Institute of Technology Bombay, India
2Google Research, India

Abstract

Pre-trained multilingual language models such as mBERT and XLM-R have demonstrated great potential for zero-shot cross-lingual transfer to low web-resource languages (LRL). However, due to limited model capacity, the large difference in the sizes of available monolingual corpora between high web-resource languages (HRL) and LRLs does not provide enough scope of co-embedding the LRL with the HRL, thereby affecting the downstream task performance of LRLs. In this paper, we argue that *relatedness* among languages in a language family along the dimension of lexical overlap may be leveraged to overcome some of the corpora limitations of LRLs. We propose **Overlap BPE** (**OBPE**), a simple yet effective modification to the BPE vocabulary generation algorithm which enhances overlap across related languages. Through extensive experiments on multiple NLP tasks and datasets, we observe that OBPE generates a vocabulary that increases the representation of LRLs via tokens shared with HRLs. This results in improved zero-shot transfer from related HRLs to LRLs without reducing HRL representation and accuracy. Unlike previous studies that dismissed the importance of token-overlap, we show that in the low-resource related language setting, token overlap matters. Synthetically reducing the overlap to zero can cause as much as a four-fold drop in zero-shot transfer accuracy.

1 Introduction

Zero-shot cross-lingual transfer is the ability of a model to learn from labeled data in one language and transfer the learning to another language without any labeled data. Transformer (Vaswani et al., 2017) based multilingual models pre-trained on unlabeled data from multiple languages are the state-of-the-art means for cross-lingual transfer (Ruder et al., 2019; Devlin et al., 2019a). While pre-training based cross-lingual transfer holds great promise for low web-resource languages (LRLs), such techniques are found to be more effective for transfer within high web-resource languages (HRLs) (Wu and Dredze, 2020).

Vocabulary generation is an important step in multilingual model training, where vocabulary size directly impacts model capacity. Usually, the vocabulary is generated from a union of HRL and LRL data. This often results in under-allocation of vocabulary bandwidth to LRLs, as LRL data is significantly smaller in size compared to HRL. This under-allocation of model capacity results in lower LRL performance (Wu and Dredze, 2020), as mentioned previously. In response, prior research has explored development of region-specific models (Antoun et al.; Khanuja et al., 2021), generating vocabulary specific to language clusters (Chung et al., 2020), and exploring relatedness among languages to build better LMs for LRLs (Khemchandani et al., 2021). However, none of these methods have utilized relatedness among languages for better vocabulary generation during multilingual pre-training.

In this paper, we hypothesize that exploiting language relatedness can result in an overall more effective vocabulary, which is also better representative of LRLs. Closely related languages (e.g., languages belonging to a single family) have common origins for words with similar meanings. We show some examples across three different families of related languages in Table 10. Morphological inflections of the root word lead to lexically overlapping tokens across languages. Learning representations for such subwords in lexically overlapping words shared across HRL and its related LRLs can enable better transfer of supervision from HRL to LRLs. During Masked Language Modelling (MLM) pre-training (Devlin et al., 2019a), the shared tokens can serve as anchors in learning contextual representations of neighboring tokens. However, choos-

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 219 - 233

Language and Token frequencies	English: University (10), versity (6); German: Universitaten (2); Dutch: Universiteit (1); Western Frisian: Universiteiten (1)
Starting Vocab	Uni, versit, U,n,i,v,e,r,s,i,t,y,a
BPE Vocab	versity, Uni, versit, U,n,i,v,e,r,s,i,t,y,a
OBPE Vocab	Universit, Uni, versit, U,n,i,v,e,r,s,i,t,y,a

Table 1: First row shows lexically overlapping tokens in four different languages with their corpus frequencies (in brackets), with English (En) as the High Web-Resource Language (HRL). From a starting vocabulary shown in the second row, BPE merges tokens based on greater overall frequency, adding new vocabulary item *versity* as it has the highest overall frequency (16). OBPE instead adds *Universit* since it also rewards cross-lingual overlap, even though *Universit* has lower overall frequency (15).

ing the correct granularity of sharing automatically is tricky. On one extreme, we can choose a vocabulary which favours longer units frequent in HRL without regard for sharing, thereby leading to better semantic representation of the tokens but no cross-lingual transfer. On the other extreme, we can choose character-level vocabulary (Ma et al., 2020), where every token is shared across languages but have no semantic significance.

Given text from a mix of high and low Web-resource languages (HRL and LRL, respectively), Byte Pair Encoding (BPE) (Sennrich et al., 2016) and its variants like Wordpiece (Schuster and Nakajima, 2012) and Sentencepiece (Kudo and Richardson, 2018) prefer frequent tokens, most of those from the HRLs. This would cause most long HRL tokens to get included, leaving only a limited budget of short tokens for the LRL. Any sub-token level overlap between HRL and LRL could get lost in this process. In a zero-shot setting, since available supervision is HRL based, this creates a bottleneck when transferring supervision from HRL to LRLs. Oversampling LRLs is a common strategy to offset this imbalance but that hurts HRL performance as shown in (Conneau et al., 2020a).

In this paper, we propose Overlap BPE (OBPE). OBPE chooses a vocabulary by giving token overlap among HRL and LRLs a primary consideration. OBPE prefers vocabulary units which are shared across multiple languages, while also encoding the input corpora compactly. Thus, OBPE tries to balance the trade-off between cross-lingual subword sharing and the need for robust representation of individual languages in the vocabulary. This results in a more balanced vocabulary, resulting in improved performance for LRLs without hurting HRL accuracy. Table 1 shows an example to highlight this difference between OBPE and BPE.

Recently K et al. (2020); Conneau et al. (2020b) concluded that token overlap is unimportant for cross-lingual transfer. However, they studied language pairs where either both languages had a large corpus, or where the languages were not sufficiently related. We focus on related languages within a family and observe drastic drop in zero-shot accuracy when we synthetically reduce the overlap to zero (58% F1 drops to 17% for NER, 71% drops to 30% for text classification).

This paper offers the following contributions

- We present OBPE, a simple yet effective modification to the popular BPE algorithm to promote overlap between LRLs and a related HRL during vocabulary generation. OBPE uses a generalized mean based formulation to quantify token overlap among languages.
- We evaluate OBPE on twelve languages across three related families, and show consistent improvement in zero-shot transfer over state-of-the art baselines on four NLP tasks. We analyse the reasons behind the gains obtained by OBPE and show that OBPE increases the percentage of LRL tokens in the vocabulary without reducing HRL tokens. This is unlike over-sampling strategies where increasing one reduces the other.
- Through controlled experiments on the amount of token overlap on a related HRL-LRL pair, we show that token overlap is extremely important in the low-resource, related language setting. Recent literature which conclude that token overlap is unimportant may have overlooked this important setting.

The source code for our experiments is available at https://github.com/Vaidehi99/OBPE.

2 Related Work

Transformer-based multilingual language models such as mBERT (Devlin et al., 2019b) and XLM-R (Conneau et al., 2020a) are now established as the de-facto method for zero-shot cross-lingual transferability, and thus hold promise for low resource domains. However, recent studies have indicated that even the current state-of-the-art models such as XLM-R (Large) do not yield reasonable transfer performance across low resource target languages with limited data (Wu and Dredze, 2020). This has led to a surge of interest in enhancing cross-lingual transfer of multilingual models to the low-resource setting. We categorize existing work based on the stage of the pre-training pipeline where it is relevant:

Input Data In the data creation stage, Conneau et al. (2020a) propose over-sampling of LRL documents to improve LRL representation in the vocabulary and pre-training steps. Khemchandani et al. (2021) specifically target related languages and propose transliteration of LRL documents to the script of related HRL for greater lexical overlap. We deploy both these tricks in this paper.

Tokenization Rust et al. (2021) study that even the tokenization step could have a crucial impact on performance accrued to each language in a multilingual models. They propose the use of dedicated tokenizer for each language instead of the automatically generated multilingual mBERT tokenizer. However, they continue to use the default mBERT vocabulary generator.

Vocabulary Generation Sennrich et al. (2016) highlighted the importance of subword tokens in the vocabulary and proposed use of the BPE algorithm (Gage, 1994) for efficiently growing such a vocabulary incrementally. Variants like Wordpiece (Schuster and Nakajima, 2012) and Sentencepiece (Kudo and Richardson, 2018) either build on top of BPE or follow a very similar process. Kudo (2018) is a variant method that chooses tokens based on unigram LM score. We obtained better results with BPE and continued with that. All these BPE variants incrementally add subwords based on overall frequency in the combined corpus, and they all ignore language boundaries. Chung et al. (2020) observed that such a combined approach could under-represent several languages, and proposed instead to separately create vocabularies for clusters of related languages and take a union of each cluster-specific vocabulary. However, within each cluster they continue to use the default vocabulary generator. Our approach can be used as a drop-in replacement to further enhance the quality of the cluster-specific vocabulary that they obtain. Wang et al. (2019); Gao et al. (2020) propose a soft-decoupled encoding approach for exploiting subword overlap between LRLs and HRLs. However, their focus is NMT models and does not easily integrate in existing multilingual models such as mBERT. (Maronikolakis et al., 2021) targets tokenization compatibility based purely on vocabulary size and does not focus on choosing the tokens that go in the vocabulary.

Pre-Training and Adaptation Several previous works have proposed to include additional alignment loss between parallel (Cao et al., 2020) or pseudo-parallel (Khemchandani et al., 2021) sentences to co-embed HRLs and LRLs. Another approach is to design language-specific Adapter layers (Pfeiffer et al., 2020a,b; Artetxe et al., 2020; Üstün et al., 2020) that can be easily fine-tuned for each new language. Pfeiffer et al. (2021) leverages the pre-trained embeddings of lexically overlapping tokens between the vocabulary of pre-trained model and that of unseen target language to initialize the corresponding embeddings of target language. However, they did not attempt to increase the fraction of such tokens in the vocabulary.

We are not aware of any prior work that explicitly promotes overlapping tokens between LRLs and HRLs in the vocabulary of multilingual models.

3 Overlap-based Vocabulary Generation

We are given monolingual data $D_1, ..., D_n$ in a set of n languages $\mathcal{L} = \{L_1, ..., L_n\}$ and a vocabulary budget V. Our goal is to generate a vocabulary $\mathcal{V}$ that when used to tokenize each D_i in a multilingual model would provide cross-lingual transfer to LRLs from related HRLs. We use $\mathcal{L}_{\text{LRL}}$ to denote the subset of the n languages that are low-resource, the remaining languages $\mathcal{L} - \mathcal{L}_{\text{LRL}}$ are denoted as the set $\mathcal{L}_{\text{HRL}}$ of high resource languages.

Existing methods of vocabulary creation start with a union D of monolingual data $D_1, ..., D_n$, and choose a vocabulary $\mathcal{V}$ that most compactly represents D. We first present an overview of BPE, a popular algorithm for vocabulary generation.

3.1 Background: BPE

Byte Pair Encoding (BPE) (Gage, 1994) is a simple data compression technique that chooses a vocabulary $\mathcal{V}$ that minimizes total size of $D = \cup_i D_i$ when encoded using $\mathcal{V}$.

$$\mathcal{V} = \operatorname*{argmin}_{S:|S|=\text{V}} \sum_{i=1}^{n} |\text{encode}(D_i, S)| \qquad (1)$$

The size of the encoding $|\text{encode}(D_i, S)|$ can be alternately expressed as the sum of frequency of tokens in S when D_i is tokenized using S. This motivates the following efficient greedy algorithm to implement the above optimization (Sennrich et al.,

Algorithm 1 Overlap based BPE (OBPE)

```
for $i \in \{1, 2, ..., n\}$ do
    Split words in $D_i$ into characters $C_i$ with a special marker after every word
end for
$\mathcal{V} = \cup_{i=1}^{n} C_i$
while $|\mathcal{V}| < \mathrm{V}$ do
    Update token and pair frequency on $\{D_i\}, \mathcal{V}$
    Add to $\mathcal{V}$ token $k$ formed by merging pairs $u, v \in \mathcal{V}$ with the largest value of
        $(1-\alpha)\sum_j f_{kj} + \alpha \sum_{i \in \mathcal{L}_{\text{LRL}}} \max_{h \in \mathcal{L}_{\text{HRL}}} \left(\frac{f_{ki}^p + f_{kh}^p}{2}\right)^{\frac{1}{p}}$
end while
```

2016). Let f_{ki} denote the frequency of a candidate token k in the corpus D_i of language L_i. The BPE algorithm grows $\mathcal{V}$ incrementally. Initially, $\mathcal{V}$ comprises of characters in D. Then, until $|\mathcal{V}| \leq \mathrm{V}$, it chooses the token k obtained by merging two existing tokens in $\mathcal{V}$ for which the frequency in D is maximum.

$$\mathcal{V} = \mathcal{V} \cup \operatorname*{argmax}_{k=[u,v]:u,v \in \mathcal{V}} \sum_i f_{ki} \tag{2}$$

A limitation of BPE on multilingual data is that tokens that appear largely in low-resource D_i may not get added to $\mathcal{V}$, leading to sentences in L_i being over-tokenized. For a low resource language, the available monolingual data D_i is often orders of magnitude smaller than another high-resource language. Models like mBERT and XLM-R address this limitation by over-sampling documents of low-resource languages. However, over-sampling LRLs might compromise learned representation of HRLs where task-specific labeled data is available. We propose an alternative strategy of vocabulary generation called OBPE that seeks to maximize transfer from HRL to LRL.

3.2 Our Proposal: OBPE

The key idea in OBPE is to maximize the overlap between an LRL and a closely related HRL while simultaneously encoding the input corpora compactly as in BPE. When labeled data D_h^T for a task T is available in an HRL L_h, then a multilingual model fine-tuned with D_h^T is likely to transfer better to a related LRL L_i when L_i and L_h share several tokens in common. Thus, the objective that OBPE seeks to optimize when creating a vocabulary is:

$$\begin{aligned}\mathcal{V} = \operatorname*{argmin}_{S:|S|=\mathrm{V}} \Bigg[&(1-\alpha)\sum_{i=1}^{n} |\text{encode}(D_i, S)| \\ &- \alpha \sum_{i \in \mathcal{L}_{\text{LRL}}} \max_{j \in \mathcal{L}_{\text{HRL}}} \text{overlap}(L_i, L_j, S) \Bigg]\end{aligned} \tag{3}$$

where $0 \leq \alpha \leq 1$ determines importance of the two terms. The first term in the objective compactly represents the total corpus, as in BPE's (Eq (1)). The second term additionally biases towards vocabulary with greater overlap of each LRL to one HRL where we expect task-specific labeled data to be present. There are several ways in which we can measure the overlap between two languages with respect to a current vocabulary. First, we encode each of D_i and D_j using the vocabulary S, which then yields a multiset of tokens in each corpus. Inspired by the literature on fair allocation (Barman et al., 2021), we explore a continuously parameterized function that expresses overlap between two languages' encoding as a generalized mean function as follows:

$$\text{overlap}(L_i, L_h, S) = \sum_{k \in S} \left(\frac{f_{ki}^p + f_{kh}^p}{2}\right)^{\frac{1}{p}}, \quad p \leq 1 \tag{4}$$

where f_{ki} denotes the frequency of token k when D_i is encoded with S. For different values of p, we get different tradeoffs between fairness to each language and overall goodness. When $p = -\infty$, generalized mean reduces to the minimum function, and we get the most egalitarian allocation. However, this ignores the larger of the two frequencies. When $p = 1$, we get a simple average which is what the first term in Equation (3) already covers. For $p = 0, -1$, we get the geometric and harmonic means respectively. Due to smaller size of LRL monolingual data, the frequency of a token which is shared across languages is likely to be much higher in HRL monolingual data as compared to that in LRL monolingual data, Hence, setting p to large negative values will increase the weight given to LRLs and thus increase overlap. We will present an exploration of the effect of p on zero-shot transfer in the experiment section.

The greedy version of the above objective that controls the candidate vocabulary item to be in-

Family	HRL	LRLs	Number of HRL Docs	
			BALANCED	SKEWED
West Germanic	English (en)	German (de), Dutch (nl), Western Frisian (fy)	0.16M	1.00M
Romance	French (fr)	Spanish (es), Portuguese (pt), Italian (it)	0.16M	0.50M
Indo-Aryan	Hindi (hi)	Marathi (mr), Punjabi (pa), Gujarati (gu)	0.16M	0.16M

Table 2: Twelve Languages *simulated* as HRLs and LRLs across with two different corpus distribution: BALANCED and SKEWED. Number of documents in languages simulated as LRLs is 20K.

	Lang	Number of sentences			
Dataset split		NER	POS	TC	XNLI
Train:HRL	hi	5.0	53.0	25.0	
	en	10.5	18.0	10.0	393.0
	fr	7.5	16.5	10.0	393.0
Validation:HRL	hi	1.0	3.0	4.0	
	en	6.0	4.0	10.0	2.5
	fr	4.0	2.0	10.0	2.5
Test data	hi	0.2	12.0	7.0	
	en	6.0	4.6	10.0	5.0
	fr	4.0	4.1	10	5.0
	mr	0.8	9.5	6.5	-
	pa	0.2	13.4	7.9	-
	gu	0.3	14.0	8.0	-
	de	12.0	19.3	10.0	5.0
	nl	8.0	1.0	-	-
	fy	0.8	-	-	-
	es	5.0	3.1	10.0	5.0
	pt	4.0	2.5	-	-
	it	5.0	3.4	-	-

Table 3: Task-specific data sizes. Number of sentences in thousands.

ducted in each iteration of OBPE is thus:

$$\mathcal{V} = \mathcal{V} \cup \underset{k=[u,v]:u,v\in\mathcal{V}}{\operatorname{argmax}} \; (1-\alpha)\sum_{j} f_{kj} + \alpha \sum_{i\in\mathcal{L}_{\text{LRL}}} \max_{h\in\mathcal{L}_{\text{HRL}}} \left(\frac{f_{ki}^{p} + f_{kh}^{p}}{2}\right)^{\frac{1}{p}} \quad (5)$$

The data structure maintained by BPE to efficiently conduct such merges can be applied with little changes to the OBPE algorithm. The only difference is that we need to separately maintain the frequency in each language in addition to overall frequency. Since the time and resources used to create the vocabulary is significantly smaller than the model pre-training time, this additional overhead to the pre-training step is negligible.

4 Experiments

We evaluate by measuring the efficacy of zero-shot transfer from the HRL on four different tasks: named entity recognition (NER), part of speech tagging (POS), text classification(TC), and Cross-lingual Natural Language Inference (XNLI). Through our experiments, we evaluate the following questions:

1. Is OBPE more effective than BPE for zero-shot transfer? (Section 4.2)
2. What is the effect of token overlap on overall accuracy? (Section 4.3)
3. How does increased LRL representation in the vocabulary impact accuracy? (Section 4.4)

We report additional ablation and analysis experiments in Section 4.5.

4.1 Setup

Pre-training Data and Languages As our pre-training dataset $\{D_i\}$, we use the Wikipedia dumps of all the languages as used in mBERT. We pre-train with 12 languages grouped into three families of four related languages as shown in Table 2. In each family, we simulate as HRL the most populous language, and call the remaining as LRLs. The number of documents for languages simulated as LRLs is set to 20K. For the HRLs, we consider two corpus distributions:

- BALANCED : all three HRLs get 160K documents each
- SKEWED : English gets one million, French half million, and Hindi 160K documents

We evaluate twelve-language models in each of these settings, and present results for separate four language models per family in Table 12 in the Appendix. For the Indo-Aryan languages set, the monolingual data of Punjabi and Gujarati is transliterated to Devanagari, the script of Hindi and Marathi. We use libindic's indictrans library (Bhat et al., 2015) for transliteration. Languages in the other two sets do not require transliteration as they have a common script. Thus, all four languages in each set are in the same script so their lexical overlap can be leveraged.

Pre-Training Details To ensure that LRLs are not under-represented, we over-sample using exponentially smoothed weighting similar to multilingual BERT (Devlin et al., 2019b) with exponentiation factor 0.7. We perform MLM pretraining on a BERT base model with 110M parameters from scratch. We generate a vocabulary of size of 30k. We chose batch size as 2048, learning rate as 3e-5 and maximum sequence length as 128. Pre-training of BERT was done with duplication factor 5 for for 64k iterations for HRLs. For all LRLs, duplication factor was 20 and training was done for 24K iterations. MLM pre-training was done on Google v3-8 Cloud TPUs where 10K iterations required 2.1 TPU hours.

Task-specific Data We evaluate on four downstream tasks: (1) NER: data from WikiANN (Pan et al., 2017) and XTREME (Hu et al., 2020), (2) XNLI: data from (Conneau et al., 2018), (3) POS: data from XTREME (Hu et al., 2020) and TDIL[1], and (4) Text Classification (TC): data from TDIL and XGLUE (Liang et al., 2020). We downsampled the TDIL data for each language to make them class-balanced. The POS tagset for Indo-Aryan languages used was the BIS Tagset (Sardesai et al., 2012). Table 3 presents a summary. The test set to compute LRL perplexity was formed by sampling 10K sentences from Samanantar corpus(Ramesh et al., 2021) for Indic languages and from Tatoeba corpus[2] for other languages. The perplexity reported for a language is the average of sentence perplexity over all the sentences sampled from that language's corpus.

Task-specific fine-tuning details We perform task-specific fine-tuning of pre-trained BERT on the task-specific training data of HRL and evaluate on all languages in the same family. Here we used learning-rate 2e-5 and batch size 32, with training duration as 16 epochs for NER, 8 epochs for POS and 3200 iterations for Text Classification and XNLI. The models were evaluated on a separate validation dataset of the HRL and the model with the minimum validation loss, maximum F1-score, accuracy and minimum validation loss was selected for final evaluation for XNLI, NER, POS and Text Classification respectively. All fine-tuning experiments were performed on Google Colaboratory. The results reported for all the experiments are an average of 3 independent runs.

4.2 Effectiveness of OBPE

We evaluate the impact of OBPE on improving zero-shot transfer from HRLs to LRLs within the same family across four different tasks. We compare with four existing methods that represent different methods of vocabulary creation and allocation of budget across languages:

Methods compared

1. **BPE** (Sennrich et al., 2016), the existing default method of vocabulary generation.
2. **Clustered vocabulary (CV)** (Chung et al., 2020) Since the paper uses a SentencePiece unigram for vocabulary, we followed the same approach for this comparison. We allocate each family equal number of vocabulary tokens which is V/3.
3. **BPE-dropout (BPE-dp)** (Provilkov et al., 2020) uses the vocabulary generated by BPE but tokenizes the text using a dropout rate of 0.1. This allows the training of tokens that are subsumed by larger tokens in the vocabulary.
4. **Compatibility of Tokenizations (Tok-Comp)** (Maronikolakis et al., 2021) uses a method to select meaningful vocabulary sizes in an automated manner for all language using compression rates. Since their best performances are found, when the compression rates are similar, we choose a size for each language corresponding to compression rate of 0.5. The tokenizer used in this method is WordPiece. .
5. **OBPE** (Ours) with default $\alpha = 0.5, p = -\infty$. We also do ablation on these.

In Table 4 we observe that across all four tasks, zero-shot LRL accuracy improves compared to BPE. For example, the average accuracy on XNLI for the LRL languages improves from 55.6 to 58.1 just by changing the set of tokens in the vocabulary. These gains are obtained without compromising HRL performance on the tasks. The Clustered Vocabulary (CV) approach is much worse than BPE. These experiments are on the Balanced-12 model. In the supplementary section, we report the results on the Skewed-12 (Table 5) and Balanced-4 models (Table 12) and show similar gains even with these models. In this table, we averaged the gains over nine LRLs, and in the Supplementary Table 14 we show consistent gains for individual languages.

In addition to improving zero-shot transfer from HRLs to LRLs on downstream tasks, OBPE also leads to better intrinsic representation of LRLs. We validate that by measuring the pseudo-perplexity (Salazar et al., 2020) of a test set of LRL sentences. We find that average perplexity of LRL

Table 4: Zero-shot performance of models in the Balanced-12 setting trained on 9 LRL and 3 HRL languages. Performance is measured on four tasks: NER (F1), Text Classification (Accuracy), POS (Accuracy), and XNLI (Accuracy). For all metrics, higher is better (↑). Zero-shot transfer to LRL improves without hurting HRL accuracy. P-value of paired-t-test between BPE and OBPE LRL gains has values $0.01, 0.04, 0.02, 0.01$ for each of the 4 tasks establishing statistical significance. Detailed results for each language is pesented in Table 14. Section 4.2 has further discussion.

Method	LRL Performance (↑)				HRL Performance (↑)			
	NER	TC	XNLI	POS	NER	TC	XNLI	POS
BPE (Sennrich et al., 2016)	52.91	51.68	48.57	74.79	81.78	80.04	64.96	95.03
CV (Chung et al., 2020)	52.73	54.40	44.28	76.70	79.84	77.74	57.18	94.60
OBPE (This paper)	**55.09**	**55.37**	**50.01**	**75.05**	**82.94**	**80.31**	**65.57**	**95.09**

Table 5: Zero-shot performance of models in the Skewed-12 setting of Table 2 on same four tasks as Table 4. OBPE shows gains here too. Detailed numbers in Table 11 of Supplementary. Section 4.2 has further discussion.

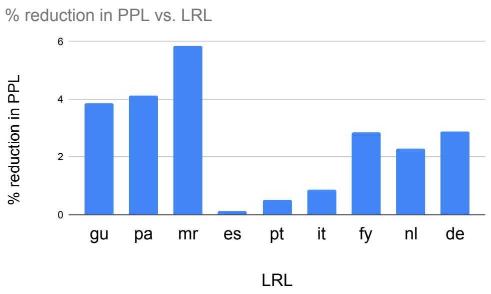

Figure 1: Percentage reduction in Pseudo perplexity (Salazar et al., 2020) for different LRLs as we go from BPE to OBPE vocabulary. (Section 4.2)

sentences drops by 2.6% when we go from the BPE to OBPE vocabulary. More details on this experiment appear in Figure 1.

In order to investigate the reasons behind the OBPE gains, we first inspected the percentage of tokens in the vocabulary that belong to LRLs, HRLs, and in their overlap. We find that with OBPE both LRL tokens and overlapping tokens increase. Either of these could have led to the observed gains. We analyze the effect of each of these factors in the following two sections.

4.3 Effect of Token Overlap

We present the impact of token overlap via two sets of experiments: first, a controlled setup where we synthetically vary the fraction of overlap and second where we measure correlation between overlap and gains of OBPE on the data as-is.

	en-es	
	High (es: 1 GB)	Low: (es: 20K)
NER	-1.4	-11.7
XNLI	0.7	-1.3
	hi-mr	
	High (mr: 110K)	Low (mr: 20K)
NER	-12.2	-41.6
TC	-2.7	-41.3
POS	-6.6	-7.8

Table 6: Drop in Accuracy of Zero-shot transfer when we synthetically reduce token overlap to zero. Transfer is from English (en) as HRL to Spanish (es) and from Hindi (hi) as HRL to Marathi (mr) in two settings: (1) High where es, mr have sizes comparable to the HRL and (2) Low where their sizes are only 20K. Token overlap is important in the low-resource and related language setting (Section 4.3)

For the controlled setup we follow (K et al., 2020) for synthetically controlling the amount of overlap between HRL and LRL. We trained a bilingual model between Hindi (HRL 160K) and Marathi (LRL 20K) — two closely related languages in the Indo-Aryan family. To find the set of overlapping tokens between Hindi and Marathi, we first run OBPE on Hindi-Marathi language pair to generate a vocabulary and label all tokens present

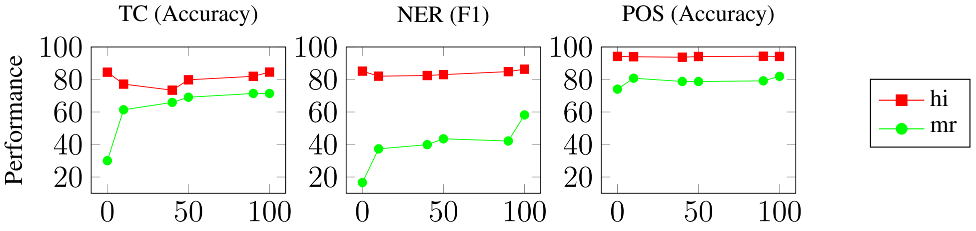

Figure 2: Zero-shot performance vs Overlap of models trained on unicode shifted HRL data to simulate increasing overlap between HRL (SynthHindi) and LRL (mr). Performance is measured on three tasks: Text Classification (Accuracy), NER (F1) and POS (Accuracy). On TC and NER observe the huge drop in LRL accuracy as we decrease overlap from 100 down to 0. Further discussions in Section 4.3.

in both languages as *overlapping tokens*. We then incrementally sample 10%, 40%, 50%, 90% of the tokens from this set. We shift the Unicode of the entire Hindi monolingual data except the set of sampled tokens so that there are no overlapping tokens between Hindi (hi) and Marathi (mr) monolingual data other than the sampled tokens. Let us call this Hindi data **SynthHindi**. We then run OBPE on SynthHindi-Marathi language pair to generate a vocabulary to pretrain the model. The task-specific Hindi data is also converted to SynthHindi during fine-tuning and testing of the model.

Figure 2 shows results with increasing overlap. We observe increasing gains in LRL accuracy as we go from no overlap to full overlap on all three tasks. NER accuracy increases from 17% to 58% for the LRL (mr) even while the HRL (hi) accuracy stays unchanged. For TC we observe similar gains. For POS, even without token overlap, we get good cross-lingual transfer because POS tags are more driven by structural similarity, and Hindi and Marathi follow similar structure.

Our results contradict the conclusions of (K et al., 2020) which claimed that token overlap is unimportant for cross-lingual transfer. However, there are two key differences with our setting: (1) unlike (K et al., 2020), we explore low-resource settings, and (2) except for English-Spanish, the other language pairs they considered are not linguistically related. To explain the importance of both these factors, in Table 6 we present accuracy of English-Spanish in a simulated low-resource setting where we sample 20K Spanish documents and 160K English documents. Also, we repeat our Hindi-Marathi experiments where Marathi is not low-resource. We observe that (1) Spanish as LRL benefits significantly on overlap with English. (2) Marathi gains from token overlap with Hindi even in the high resource setting.

Thus, we conclude that as long as languages are related, token overlap is important and the benefit from overlap is higher in the low resource setting.

Overlap Vs Gain: Real data setup We further substantiate our hypothesis that the shared tokens across languages favoured by OBPE enable transfer of supervision from HRL to LRL via statistics on real-data. In Table 9 we show the Pearson product-moment correlation coefficient between overlap gain and performance gain within LRLs of the same family and task. We get a high positive correlation coefficient, with an average of 0.644.

4.4 Effect of Increased LRL representation

We next investigate the impact of increased representation of LRL tokens in the vocabulary. OBPE increases LRL representation by favoring overlapping tokens, but LRL tokens can also be increased by just over-sampling LRL documents. We train another BALANCED12 model but with further oversampling LRLs with exponentiation factor of 0.5 instead of 0.7. We observe in Figure 8 that this increases LRL fraction but reduces HRL tokens in the vocabulary. Table 7 also shows the comparison of zero-shot transfer accuracy with oversampled BPE against over-sampled OBPE. We find that OBPE even with default exponentiation factor achieves highest LRL gains, whereas aggressively over-sampled BPE hurts HRL accuracy. Within the same sampling setting, OBPE is better than corresponding BPE.

4.5 Ablation study

We conducted experiments for different values of p that controls the amount of overlap in the generalized mean function (Equation (5)). Figure 3 and Table 14 show the results for various p. Setting $p = 1$ gives the original BPE algorithm. Setting $p = 0, -1$ gives geometric and harmonic mean respectively, setting $p = -\infty$ gives minimum. We

Method	LRL Performance (↑)				HRL Performance (↑)			
	NER	TC	XNLI	POS	NER	TC	XNLI	POS
BPE	64.5	65.5	52.1	84.6	83.3	**82.1**	62.7	**95.2**
+overSample	64.4	67.6	52.1	84.6	82.4	82.0	62.0	95.2
OBPE	**65.7**	**68.0**	**54.0**	**85.3**	**84.0**	81.9	**66.3**	95.1
+overSample	64.6	67.9	53.5	85.1	82.7	81.7	65.7	94.8

Table 7: Zero-shot performance of models in the same setting as Table 4 but comparing default sampling with oversampling (exponentiation factor S=0.5). Note, even if BPE_overSamp improves LRL somewhat, it causes HRL to drop. OBPE with default sampling is best for both LRLs and HRLs. Also OBPE_overSampled is better than BPE_overSampled (Section 4.4).

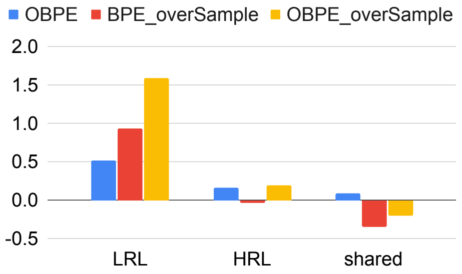

Table 8: Percentage rise over BPE in representation of LRL, HRL and Shared (percentage of tokens shared between HRL and LRL weighted by frequency) in vocabulary generated by OBPE and BPE_overSample and OBPE_overSample (Section 4.4).

Lang family	Task	Pearson Correlation
Indo-Aryan	NER	0.835
	POS	0.690
West Germanic	NER	0.387
	POS	0.348
Romance	NER	0.946
	POS	0.595

Table 9: Correlation coefficient between performance gain and overlap gain within languages in a family for various tasks. (Section 4.3).

compare the task-specific results for different values of p as shown in Table 14 and find that the gains we obtain are highest in the $p = -\infty$ (minimum) setting (Figure 3).

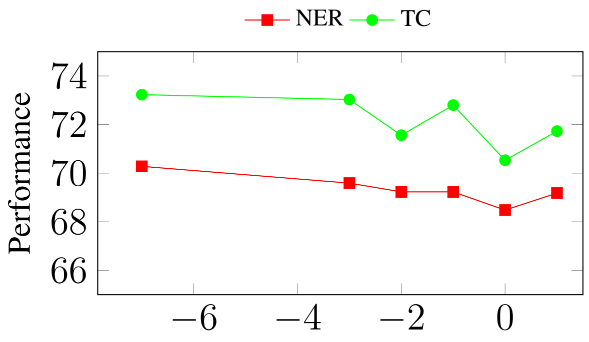

Figure 3: Zero-shot LRL performance of models in the same setting as Table 4 for different values of p evaluated on NER and Text Classification. Best results at $p = -\infty$.(Section 4.5)

We also experiment with $\alpha = 0.7$, and find that for most languages the results were not better than our default $\alpha = 0.5$.

5 Conclusion

In this paper, we address the problem of cross-lingual transfer from HRLs to LRLs by exploiting relatedness among them. We focus on lexical overlap during the vocabulary generation stage of multilingual pre-training. We propose Overlap BPE (OBPE), a simple yet effective modification to the BPE algorithm, which chooses a vocabulary that maximizes overlap across languages. OBPE encodes input corpora compactly while also balancing the trade-off between cross-lingual subword sharing and language-specific vocabularies. We focus on three sets of closely related languages from diverse language families. Our experiments provide evidence that OBPE is effective in leveraging overlap across related languages to improve LRL performance. In contrast to prior work, through controlled experiments on the amount of token overlap between two related HRL-LRL language pairs, we establish that token overlap is important when a LRL is paired with a related HRL.

Acknowledgements We thank Yash Khemchandani and Sarvesh Mehtani for participating in the early phases of this research. We thank Dan Garrette and Srini Narayanan for comments on the draft. We thank Technology Development for Indian Languages (TDIL) Programme initiated by the Ministry of Electronics Information Technology, Govt. of India for providing us datasets used in this study. The experiments reported in the paper were made possible by a Tensor Flow Research Cloud (TFRC) TPU grant. The IIT Bombay authors thank Google Research India for supporting this research.

A Appendix

A.1 Examples of Token Overlap within Language Families

Table 10 shows examples of overlapping tokens within three different language families, and Figure 4 shows a real example of how OBPE chooses shared tokens.

A.2 Limitations

- Our approach is expected to improve cross-lingual transfer from HRL to LRL only when the HRL and LRL are related linguistically since it relies on the presence of lexically overlapping tokens
- It requires the transliteration of LRL data to the script of its related HRL if LRL does not have the same script.

A.3 Potential risks

Language models may amplify bias in data and also introduce new ones. Multilingual models explored in the paper are not immune to such issues. Detecting such biases and mitigating them is a topic of ongoing research. We are hopeful that our focus on better representation of LRLs in the vocabulary is a step towards more inclusive models.

	Tokens
Hindi	नियुक्ति(Niyukti), नियुक्त(Niyukta)
Panjabi	नियुकत(Niyukata), नियुकतीआं(Niyukatiaa), नियुकती(Niyukati)
Marathi	नियुक्ति(Niyukti), नियुक्त(Niyukta)
Gujarati	नियुक्ति(Niyukti), नियुक्त(Niyukta)
BPE vocab	नियुक्ति(Niyukti), नियुक्त(Niyukta)
OBPE vocab	नियुक्ति(Niyukti), नियुक्त(Niyukta), **नियुक्(Niyuk)**

Figure 4: Similar meaning words with shared root forms across related Indo-Aryan languages. BPE vocabulary does not capture the tokens corresponding to Punjabi as it is a LRL and will thus tokenize Niyukata into multiple tokens which do not captures its meaning whereas Niyukata when tokenized by OBPE tokenizer will contain Niyuk which captures most of the meaning of the token Niyukata whose representation will be learnt when pretraining using Punjabi monolingual data

A.4 Replicability

BERT configuration parameters used in our experiments are as follows:

"attention_probs_dropout_prob": 0.1, "hidden_act": "gelu", "hidden_dropout_prob": 0.1, "hidden_size": 768, "initializer_range": 0.02, "intermediate_size": 3072, "max_position_embeddings": 512, "num_attention_heads": 12, "num_hidden_layers": 12, "type_vocab_size": 2, "vocab_size": 30000 All the task-specific fine-tuning experiments are done using GPUs on Google Colaboratory where each fine-tuning experiment requires 2 GPU hours.

A.5 License

Tatoeba data, GLUE data, Wikipedia dumps use the Creative Commons licenses. TDIL data used for Indic languages uses Research license type and Xtreme dataset uses Apache License 2.0. To the best of our knowledge, the use of scientific artifacts in this work is consistent with their intended use.

Indo-Aryan	Hindi:Vaapariyo, Marathi:Vaapartat , Punjabi:Vaaparan, Gujarati:Vaaparvana Hindi:Jaate, Marathi:Jaaoon , Punjabi:Jaana, Gujarati:Jaao
West-Germanic	English:Category, German:Kategorie, Dutch:Categorie, Western Frisian:Kategory English:University, German:Universitaten, Dutch:Universiteit, Western Frisian:Universiteiten
Romance	French:Association, Spanish:Associacion, Portuguese:Associacao, Italian:Associazione French:Certifie, Spanish:Certificar, Portuguese:Certificado, Italian:Certificato

Table 10: Lexically overlapping tokens with similar meanings across four languages in each of three families. OBPE, our proposed method, exploits such meaning-preserving overlap among related languages to induce vocabulary for multilingual learning.

Table 11: Zero-shot performance of models in the Skewed-12 setting trained on 9 LRL and 3 HRL languages. Performance is measured on four tasks: NER (F1), Text Classification (Accuracy), POS (Accuracy), and XNLI (Accuracy). For all metrics, higher is better . Zero-shot transfer to LRL improves without hurting HRL accuracy. Averages results across HRLs and LRLs are presented in Table 5. OBPE shows gains here too. Section 4.2 has further discussion.

A.6 Data bias

We have used standard Wikipedia corpus, and there have been some studies on bias in such corpus.(Hube, 2017)

	0	62.6	61.5	53.9				

Table 13: Accuracy of Zero-shot transfer from English (En) as HRL to Spanish (Es) and from Hindi(Hi) as HRL to Marathi(Mr) in two settings: (1) High where Es,Mr have sizes comparable to the HRL and (2) Low where their sizes are only 20K. As the percentage of overlapping tokens retained is decreased from 100% to 0%, the accuracy drops but the drop is higher in the low-resource setting. Task-specific accuracy numbers in first column(En-Es-High-es) have been taken from (K et al., 2020). Table 6 contains the reduction in accuracy on decreasing overlap from 100% to 0 % i.e. the difference between the rows corresponding to 100% and 0%

Long-range Sequence Modeling with Predictable Sparse Attention

Yimeng Zhuang, Jing Zhang, Mei Tu
Samsung Research China - Beijing (SRC-B)

Abstract

Self-attention mechanism has been shown to be an effective approach for capturing global context dependencies in sequence modeling, but it suffers from quadratic complexity in time and memory usage. Due to the sparsity of the attention matrix, much computation is redundant. Therefore, in this paper, we design an efficient Transformer architecture, named Fourier Sparse Attention for Transformer (FSAT), for fast long-range sequence modeling. We provide a brand-new perspective for constructing sparse attention matrix, i.e. making the sparse attention matrix predictable. Two core submodules are: (1) A fast Fourier transform based hidden state cross module, which captures and pools L^2 semantic combinations in $\mathcal{O}(L \log L)$ time complexity. (2) A sparse attention matrix estimation module, which predicts dominant elements of an attention matrix based on the output of the previous hidden state cross module. By reparameterization and gradient truncation, FSAT successfully learned the index of dominant elements. The overall complexity about the sequence length is reduced from $\mathcal{O}(L^2)$ to $\mathcal{O}(L \log L)$. Extensive experiments (natural language, vision, and math) show that FSAT remarkably outperforms the standard multi-head attention and its variants in various long-sequence tasks with low computational costs, and achieves new state-of-the-art results on the Long Range Arena benchmark.

1 Introduction

Models based on the Transformer architecture (Vaswani et al., 2017) have been firmly established as state of the art approaches across a range of domains like language (Brown et al., 2020; Clark et al., 2020; Devlin et al., 2018), and vision (Carion et al., 2020; Dosovitskiy et al., 2020). The Transformer architecture perceiving long-range context heavily relies on the multi-head self-attention mechanism, in which the relevance of every token pairs is computed to decide the attention scores and token's representations are the weighted average of all tokens using the attention scores.

Despite its effectiveness, self-attention mechanism's quadratic time and memory complexity about the sequence length is an obstacle to extend Transformer for very long sequences, such as document-level text tasks, high-resolution images, videos, etc. Shen et al. (2021, 2018) elaborate the issue of high computational complexity. For instance, more than 68GB GPU memory and 1.6T multiply-accumulation operations are required for a $64 \times 64 \times 32$ 3D feature volume.

Great efforts have been made to develop Transformer's variants for long-range sequence modeling tasks. Tay et al. (2020c) categorize the researches of efficient Transformers: (a) Fixed patterns or combination of patterns (Beltagy et al., 2020; Zaheer et al., 2020), in which the field to be attended is pre-defined by fixed pattern. (b) Learnable patterns (Kitaev et al., 2020; Tay et al., 2020a), in which tokens are sorted or clustered in a data-driven fashion. (c) Memory (Ma et al., 2021; Lee et al., 2019), in which spacial tokens with global view are introduced to compress the input sequence. (d) Low-rank methods (Tay et al., 2021; Wang et al., 2020), which adopt low-rank approximations of the self-attention matrix. (e) Kernels (Katharopoulos et al., 2020; Choromanski et al., 2020a,b), which view the attention mechanism through kernelization. (f) Recurrence (Rae et al., 2019), which connects multiple segments via recurrence structure. Despite their variety, approximating the quadratic-cost attention matrix by the sparsity of attention matrix is the common idea.

In this paper, we propose predictable sparse attention, and name it as Fourier Sparse Attention for Transformer (FSAT) due to fast Fourier transform is a key operation in our method. FSAT is a brand-new perspective of efficient Transformer, i.e. learning the sparse structure of an attention ma-

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 234 - 243
May 22-27, 2022

trix in end-to-end fashion. Specifically, we firstly compute the semantic relevance of token pairs and then use it to predict the indices of dominant (non-zero) elements of an attention matrix, and finally attention scores are filled according to the predicted sparse structure. In this process, two problems have to be solved: (1) Efficiently capturing semantic relevance of L^2 token pairs where L is the length of an input sequence. (2) Learning discrete indices with gradient descent algorithm. To this end, we propose pooled hidden state cross to efficiently calculate and compress semantic relevance in $\mathcal{O}(L \log L)$ time complexity. For end-to-end training, we get continuous and meaningful gradients for learning discrete indices by reparameterization and gradient truncation. Consequently, FSAT is out of the scope of Tay et al. (2020c)'s taxonomy. It's worth noting that predictable sparse attention is different from the methods of learnable patterns. Although these methods use learnable algorithms to sort or cluster tokens, they still exploit fixed patterns (chunked patterns). Instead, FSAT directly predicts the sparse structure of an attention matrix without any pre-defined pattern.

In order to fit the predicted sparse attention matrix, the key and value vectors in self-attention mechanism are projected from pooled hidden state cross vectors, which can be viewed as 2-order features of the tokens. As an extra benefit, model's expressiveness may increase. Therefore, unlike some efficient Transformer variants which approximate the quadratic-cost attention matrix at the expense of accuracy, FSAT not only reduces computational complexity but also improves model accuracy in some tasks. On Long Range Arena benchmark, FSAT outperforms the Transformer and several recent efficient self-attention methods by a large margin.

To summarize, our contributions are as follows:

- We propose Fourier Sparse Attention for Transformer (FSAT) to extend Transformer for long sequences. The overall complexity about the sequence length is reduced from $\mathcal{O}(L^2)$ to $\mathcal{O}(L \log L)$.
- We introduce the pooled hidden state cross to implement FSAT.
- Empirically, extensive experiments (natural language, vision, and math) demonstrate the advantages of our proposed methods, and new state-of-the-art results are achieved on the Long Range Arena benchmark.

2 Related Works

2.1 Efficient Transformer

Tay et al. (2020c) have provided a comprehensive overview of existing efficient Transformers. Some promising models are compared with our method in the experiments. Big bird (Zaheer et al., 2020) uses random, sliding window and global attention to build hybrid attention pattern. Performer (Choromanski et al., 2020a,b) utilizes orthogonal random features to approximate softmax-attention kernels with linear complexity. Linformer (Wang et al., 2020) achieves linear complexity by adopting random projections based on the JL lemma to compress the attention length to a fix length. Longformer (Beltagy et al., 2020) combines local windowed attention with task-motivated global attention for long documents. Reformer proposed in Kitaev et al. (2020) clusters similar tokens by locality-sensitive-hashing, and dot-product attention is performed inside clusters.

2.2 Feature Crosses

Feature crosses, which synthesize crossing combinations of features, is a widely used technique for extending features' predictive ability in machine learning. For example, Takahashi et al. (2018) demonstrate their gender identification system leveraging synergy of both texts and images by feature cross technique. Yu et al. (2018) and Seo et al. (2016) utilize crossed feature to design a trilinear attention function. Chen et al. (2021) explore how to search the best feature crosses by submodular optimization. More researches involving feature crosses focus on feature selection (Zadeh et al., 2017; Wei et al., 2015; Hoque et al., 2014; Nie et al., 2010; Guyon and Elisseeff, 2003; Kwak and Choi, 2002; Rogati and Yang, 2002; Weston et al., 2000).

2.3 Fourier Transform in Transformer

Recently, Fourier transform in Transformer has garnered interest. Choromanski et al. (2020a,b) propose Performer by approximating softmax attention-kernels via orthogonal random Fourier features. Tamkin et al. (2020) propose BERT + Prism model using spectral filters in the activations of neurons for producing multi-scale representations, and got positive experimental results at

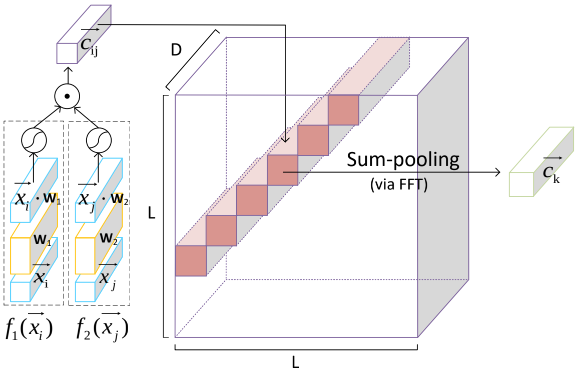

Figure 1: The process of feature mapping, hidden state cross, and sum-pooling along antidiagonals, corresponding to Formula 2.

utterance- and document-level tasks. More radically, Lee-Thorp et al. (2021) reform Transformer by replacing the entire self-attention sub-layer with discrete Fourier transforms along sequence dimension and hidden dimension respectively.

3 Self-attention with Pooled Hidden State Cross

In this section, we start by explaining the motivation of introducing pooled hidden state cross, then introduce how to compute pooled hidden state cross, and finally discuss the way to equip self-attention with pooled hidden state cross.

3.1 Why Pooled Hidden State Cross

Three desiderata motivate our use of pooled hidden state cross: (1) Long-range semantic dependency and relevance can be captured by hidden state crosses, since the combinations of every token pair have been included. Capturing semantic relevance is also the basis of the predictable sparse attention proposed in the next section. (2) Hidden state cross is a way to extract 2-order token features, intuitively it may generate more expressive feature representations. (3) Crossing and pooling hidden states are conducted depth-wisely, so that they can be efficiently implemented via fast Fourier transform.

3.2 Pooled Hidden State Cross

Inspired by the feature cross technique, we propose the concept of hidden state cross. Briefly speaking, feature cross technique (a.k.a feature combination) synthesizes new feature xy by multiplying feature x and feature y. We extend it to the level of hidden state of deep learning models. Specifically, given the hidden states of a token sequence $\vec{x}_0, \cdots, \vec{x}_{L-1}$, we define

$$\vec{c}_{ij} = f_1(\vec{x}_i) \odot f_2(\vec{x}_j) \tag{1}$$

as the crossed hidden state vector of the i-th and the j-th token, where $f(\cdot)$ is a parameterized nonlinear feature mapping function, subscripts indicate containing different parameters, and $\odot$ is the Hadamard product. We expect that the semantic combination of two tokens can be learned and encoded in the crossed hidden state vector.

Problems arise when computing the hidden state crosses of L^2 token pairs. Firstly, the computational complexity is $\mathcal{O}(L^2)$ about the sequence length L, which is computationally prohibitive for long sequences. Secondly, the output should be L^2 vectors which is too large to be attended in the Transformer model. To alleviate the problems, crossed hidden states are sum-pooled in this paper.

$$\vec{c}_k = \sum_{i+j=k} \vec{c}_{ij} = \sum_{i+j=k} f_1(\vec{x}_i) \odot f_2(\vec{x}_j) \tag{2}$$

Figure 1 illustrates the computation. The pooled hidden state cross $\vec{c}_k$ represents the sum of crossed hidden states along the k-th antidiagonal. Therefore, the output vectors are compressed from L^2 vectors, i.e. $\{\vec{c}_{ij}\}_{i,j\in[0,L-1]}$, to $2L-1$ vectors, i.e. $\{\vec{c}_k\}_{k\in[0,2L-2]}$.

3.2.1 Implementation via Fast Fourier Transform

Formula 2 can be efficiently implemented by Fast Fourier Transform (FFT). Specifically, hidden states are firstly non-linearly converted by the feature mapping functions, and then 1D discrete Fourier transform is applied along the sequence dimension to transform the mapped hidden states into frequency domain, crossing and pooling are then conducted via multiplication in frequency domain, finally by applying inverse 1D discrete Fourier transform the pooled hidden state crosses are transformed back from frequency domain. By the Hermitian property, the imaginary part of the output is zero. Thus, we can safely only keep the real part of the output and avoid involving complex numbers into the model. Formally,

$$\mathbf{C}_0 = \Re(\mathcal{F}^{-1}(\mathcal{F}(f_1(\mathbf{X})) \odot \mathcal{F}(f_2(\mathbf{X})))) \tag{3}$$

in which, $\mathbf{X} \in \mathbb{R}^{L\times D}$ denotes the matrix consisting of the L D-dimensional hidden states. $\mathcal{F}$ and $\mathcal{F}^{-1}$

are 1D Fourier transform and inverse 1D Fourier transform respectively. $\Re$ means keeping the real part of complex numbers. $\mathbf{C}_0 \in \mathbb{R}^{(2L-1)\times D}$ is the output matrix of pooled hidden state crosses. The computational complexity about the sequence length is reduced from $\mathcal{O}(L^2)$ to $\mathcal{O}(L \log L)$ by FFT.

3.2.2 Central Token Symmetry

Formula 3 has the output matrix of shape $(2L - 1) \times D$, which doubles the sequence length. To keep the computational complexity of attention not increasing, the length is needed to be reduced. As is shown in Figure 1, sum-pooling along antidiagonal produces a symmetric token combination (cross) about a central token. Specifically, in even-numbered antidiagonals, the central token is the $\frac{k}{2}$-th token. For instance, the token combinations of the 10th antidiagonal include token 5-5, 4-6, 3-7, and so on. In odd-numbered antidiagonals, the symmetric center is between $\lfloor\frac{k}{2}\rfloor$-th token and $\lceil\frac{k}{2}\rceil$-th token. For instance, the 11th antidiagonal includes the token combinations of token 5-6, 4-7, 3-8, etc. Therefore, we can reduce the length by merging the consecutive even-numbered and odd-numbered antidiagonals so that token combinations of near symmetric centers are together. In the previous example, token combinations of the 10th antidiagonal and the 11th antidiagonal are summed up. Besides, token combinations of two same tokens are subtracted, e.g. token combination 5-5. Formally,

$$\mathbf{C} = LN(\mathbf{C}_1 + \mathbf{C}_2 - f_1(\mathbf{X}) \odot f_2(\mathbf{X})) \tag{4}$$

where $\mathbf{C}_1 \in \mathbb{R}^{L\times D}$ (padding a row of zero to align its the length to $\mathbf{C}_2$) and $\mathbf{C}_2 \in \mathbb{R}^{L\times D}$ are the odd-numbered and even-numbered rows of matrix $\mathbf{C}_0$ respectively, LN denotes layer normalization which ensures stable training, $\mathbf{C} \in \mathbb{R}^{L\times D}$ is the output.

3.3 Revise Self-attention

In this section, we revise the multi-head self-attention to utilize our pooled hidden state cross. The output of an attention layer is calculated as follows.

$$\mathcal{A}(\mathbf{X}, \mathbf{C}) = (\prod_{h=1}^{H} \Psi(\frac{\mathbf{Q}^h \mathbf{K}^{h^T}}{\sqrt{d}})\mathbf{V}^h)\mathbf{W}_o \tag{5}$$

where d is the dimension of a single head, superscript h denotes the h-th head, $\prod$ denotes the concatenation operation of H heads along the last dimension, Ψ is a row-wise scoring function (e.g. softmax), $\mathbf{W}_o \in \mathbb{R}^{Hd\times D}$ is the output projection matrix. It's worth noting that the key, and value in attention mechanism are revised.

$$\mathbf{Q}^h = \mathbf{X}\mathbf{W}_Q^h, \quad \mathbf{K}^h = \mathbf{C}\mathbf{W}_K^h, \quad \mathbf{V}^h = \mathbf{C}\mathbf{W}_V^h \tag{6}$$

where $\mathbf{W}_Q^h, \mathbf{W}_K^h, \mathbf{W}_V^h \in \mathbb{R}^{D\times d}$ are the learnable projection matrices.

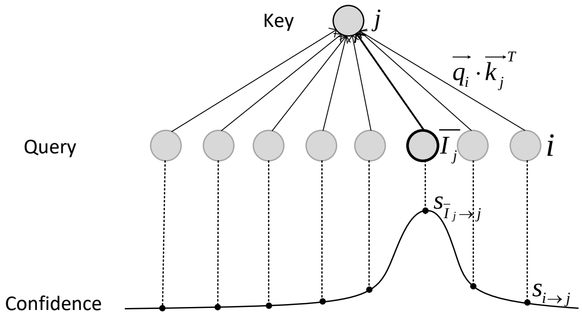

Figure 2: An illustration of the weighted directed graph with a single key vertex, and its in-neighbors. The edge pointing from the bold dominant query vertex to the key vertex corresponds to a dominant attention element in the attention matrix. Decreasing confidences are assigned to the edges away from the dominant query vertex.

4 Predictable Sparse Attention

Due to the sparsity of attention matrix, most elements of the attention matrix are close to zero, for the sake of simplicity, we call those elements, which are much greater than zero, dominant elements. Base on the pooled hidden state cross, we propose predictable sparse attention, which predicts dominant elements of attention matrix, to avoid computing the full attention matrix.

4.1 Sparse Attention

In this section, we describe the predictable sparse attention by a weighted directed sparse graph, in which the vertexes are the L query/key vectors of the input sequence, its directed edges represent that the head vertex attends to the tail vertex in the attention mechanism, and two weights (i.e. attention score and confidence) are assigned to each edge. Figure 2 illustrates a sub-graph with a single key vertex and its in-neighbors. The attention matrix is the adjacency matrix of the graph. For the multi-head attention, each head has a graph computed independently. The i-th output vector of the proposed predictable sparse attention is defined as

$$\mathcal{A}(\mathbf{X},\mathbf{C})_i = (\prod_{h=1}^{H}(\Psi(\frac{\vec{q}_i^{\,h}\mathbf{K}_{N_i^h}^{h^T}}{\sqrt{d}})\odot\vec{s}^{\,h}_{i\to N_i^h})\mathbf{V}^h_{N_i^h})\mathbf{W}_o \tag{7}$$

where row vector $\vec{q}^{\,h}$, and matrices $\mathbf{K}^h, \mathbf{V}^h \in \mathbb{R}^{L\times d}$ are respectively the query, key, and value projected from $\mathbf{X}$ or $\mathbf{C}$ following Formula 6, N_i^h represents the out-neighbors set of the i-th vertex in the h-th head's directed graph, when N_i^h is written at subscript, it means only extracting the matrix's rows corresponding to the vertexes in N_i^h, and $\vec{s}^{\,h}_{i\to N_i^h}$ represents the confidence vector consisting of the confidence scores of the edges pointing from i-th vertex to the vertexes in N_i^h in the h-th head's directed graph.

4.2 Sparse Attention Matrix Estimation

The challenge of the predictable sparse attention is to find out which elements in the attention matrix are dominant under the condition of not computing the full attention matrix. We utilize pooled hidden state cross, because semantic combination vectors contain the information of the relevance of token pairs.

4.2.1 Attention Confidence

We introduce attention confidence to help the model learning the sparse structure of an attention matrix. Specifically, we define the confidence of the i-th query vector $\vec{q}_i$ attending to the j-th key vector $\vec{k}_j$ as

$$s_{i\to j} = \rho(i\,|\,\bar{I}_j, \sigma^2) \tag{8}$$

in which, ρ denotes the probability density function of Gaussian distribution, $\bar{I}_j$ is the index of the dominant query vector, which attends to the key vector $\vec{k}_j$ with a dominant attention score (i.e. edge $\bar{I}_j \to j$ corresponds to a dominant element in the attention matrix), σ^2 is a hyper-parameter representing the variance. We have this definition because of the observation that the query vectors far away from the dominant query vector have decreasing probabilities of attending to the key vector.

4.2.2 Reparameterization

The key to make a sparse attention matrix predictable is how to back-propagate gradients through the predicted discrete indices. In this paper, discrete indices are reparameterized. A dominant index matrix $\bar{\mathbf{I}} \in \mathbb{R}^{L\times M}$ is predicted based on the pooled hidden state cross $\mathbf{C}$:

$$\bar{\mathbf{I}} = \sigma(\mathbf{C}\mathbf{W}_I + \vec{b}_I)\cdot L_{max} \tag{9}$$

where $\mathbf{W}_I \in \mathbb{R}^{D\times M}$ and $\vec{b}_I \in \mathbb{R}^M$ are the learnable weight and bias respectively, $\sigma(\cdot)$ is the sigmoid function, L_{max} is the maximum sequence length that the model supports. Since there may be multiple dominant query vectors for a key vector, the hyper-parameter M presumes the maximum number of dominant query vectors for a single key vector.

Given the sparse graph described by an index matrix $\mathbf{I} \in \mathbb{N}^{L\times M}$, whose value in the j-th row m-th column I_{jm} indicates that there is a directed edge pointing from the I_{jm}-th query vector to the j-th key vector, the confidence score of each edge can be calculated as follows.

$$s_{I_{jm}\to j} = \rho(I_{jm}|\bar{I}_{jm}, \sigma^2) \tag{10}$$

where $\bar{I}_{jm}$ is the m-th predicted dominant index of the j-th key vector predicted by Formula 9. Therefore, applying the chain rule, the gradient of confidence scores from a loss function can continue to be propagated through Formula 9 and Formula 10 to matrix $\mathbf{C}$.

4.2.3 Learning Index

The index matrix $\mathbf{I} \in \mathbb{N}^{L\times M}$ decides which edges are considered and which edges are ignored in the sparse graph. In this paper, two types of index matrix are adopted, a predicted index matrix $\mathbf{I}_p = \lfloor\bar{\mathbf{I}}\rfloor$ and a random index matrix $\mathbf{I}_r \sim \mathcal{U}_{[0,N-1]}$. The process for learning sparse attention matrix can be viewed as a process for searching right indices, it is a process of exploring new knowledge and exploiting existing knowledge. Therefore, in training, the sparse graph is decided by the union of $\mathbf{I}_p$ (exploitation) and $\mathbf{I}_r$ (exploration), and, in inference, only $\mathbf{I}_p$ is used.

4.2.4 Gradient Truncation

When back-propagation, the gradient of attention confidence is truncated into the range $(-\infty, 0]$ for stable convergence. Because, for gradient descent algorithm, positive gradients will decrease the confidence values on edges, it means that the gradients prevent the model from considering these edges in sparse attention mechanism, and tune the model's parameters to change its predicted dominant-indices. But due to the discreteness of indices, changing the predicted dominant-indices

Models	ListOps	Text	Retrieval	Image	Pathfinder	Avg.	Avg. (w/o Text)

Table 1: Experimental results on the Long Range Arena benchmark. Except for Retrieval task, results of models from Local Attention to Performer are cited from Tay et al. (2020b). Fnet, Nyström, and Luna-256 are more recent works, results are from their papers. Average accuracy without the Text task is reported separately. For the Text task, the results of FSAT using different feature mapping (fully-connect structure or depth-wise separable convolution layer) are reported, see the discussion in the body text.

slightly larger or smaller does not ensure moving closer to the correct dominant indices. On the contrary, negative gradients indicate hitting the correct dominant-indices, and the model should be tuned using these gradients.

4.3 Complexity Analysis

In terms of computational complexity, the proposed predictable sparse attention has lower computational cost in time and memory usage. Specifically, the computational complexity for pooled hidden state cross includes the feature mapping $\mathcal{O}(LD^2)$, and fast Fourier transform $\mathcal{O}(LD\log L)$. The computational complexity involved in Formula 7 includes computing attention probability $\mathcal{O}(LMD)$, computing attention confidence $\mathcal{O}(LDM)$, and matrix multiplications about the value matrix and projection matrices $\mathcal{O}(LMD+LD^2)$. The overall computational complexity is $\mathcal{O}(LD^2+LD\log L+LMD)$. Since M is always small (e.g. $M=4$), for long sequences, this complexity is much smaller than $\mathcal{O}(L^2D+LD^2)$ which is the complexity of standard multi-head attention. In memory usage, sparse attention has no need to store the full attention matrix, thus the memory complexity is reduced from $\mathcal{O}(L^2H+LD)$ to $\mathcal{O}(LMH+LD)$.

5 Experiments

We conduct experiments to study the performance of the proposed approach on long sequence modeling tasks.

5.1 Long-context Sequence Modeling

As the primary goal, we evaluate the proposed Fourier Sparse Attention for Transformer (FSAT) on multiple tasks requiring long-context perception. We test our models on the Long Range Arena (LRA) benchmark (Tay et al., 2020b), since it is specifically designed for evaluating the performance of efficient Transformers on various long sequence tasks, and there are quite a number of baseline models evaluated on this benchmark.

5.2 Datasets and Baselines

The LRA benchmark includes five tasks of different kinds and modalities (natural language, vision, and math) in order to simulate meaningful real-world tasks under the long-context scenario.

- **ListOps** This task requires models to compute the output value of mathematical expression with a hierarchical structure and operators. The sequence lengths are up to 2K.
- **Text** A byte-level text classification task to probe the model's reasoning ability with compositional, unsegmented characters. Character

	Steps per second ↑				Peak Memory Usage ↓			
Model	1K	2K	3K	4K	1K	2K	3K	4K
Transformer	1.0	1.0	1.0	1.0	1.00	1.00	1.00	1.00
Local Attention	1.1	1.7	3.2	5.3	0.49	0.29	0.19	0.14
Linformer	1.2	1.9	3.7	5.5	0.44	0.21	0.18	0.1
Reformer	0.5	0.4	0.7	0.8	0.56	0.37	0.28	0.24
Sinkhorn Trans.	1.1	1.6	2.9	3.8	0.55	0.31	0.21	0.16
Synthesizer	1.1	1.2	2.9	1.4	0.76	0.75	0.74	0.74
BigBird	0.9	0.8	1.2	1.1	0.91	0.56	0.4	0.3
Linear Trans.	1.1	1.9	3.7	5.6	0.44	0.22	0.15	0.11
Performer	1.2	1.9	3.8	5.7	0.44	0.22	0.15	0.11
FSAT (ours)	1.1	1.5	2	2.5	0.53	0.27	0.21	0.16

Table 2: The time cost and memory consumption on the Long Range Arena benchmark on byte-level text classification with various input lengths (1K, 2K, 3K and 4K). The speed and memory consumption are shown through the rate with respect to the vanilla Transformer.

sequences are truncated or padded to a fixed maximum length of 4K in this task.

- **Retrieval** A byte-level document retrieval task tests model's ability to compress long sequences into representations suitable for similarity-based matching.
- **Image** An image classification task evaluates a model's performance of perceiving 2D spatial relations between input pixels. Images are flattened to sequences of length 1K pixels.
- **Pathfinder** A binary image classification task tests if a model can capture long-range spatial dependencies by judging if two points are connected by a path consisting of dashes in an image with distractor paths. 32×32 images are flattened to sequences of length 1K pixels.

We compare our model with a number of promising models, including vanilla Transformer(Vaswani et al., 2017), a local attention baseline, Sparse Transformer(Child et al., 2019), Longformer(Beltagy et al., 2020), Linformer(Wang et al., 2020), Reformer(Kitaev et al., 2020), Sinkhorn Transformer(Tay et al., 2020a), Synthesizer(Tay et al., 2021), Big Bird(Zaheer et al., 2020), Linear Transformer(Katharopoulos et al., 2020), Performer(Choromanski et al., 2020a,b), and more recent models, such as FNet(Lee-Thorp et al., 2021), Nsytrömformer(Xiong et al., 2021), and Luan(Ma et al., 2021).

5.3 Implementation details

We run our experiments on the LRA benchmark with the configurations based on Tay et al. (2020b) open source codebase. Specifically, we follow the original data preprocessing, data split, and keep roughly equivalent model parameters for a fair comparison with the baselines reported in Tay et al. (2020b). An exception is that we reproduce the experiments of the Retrieval task for a longer training of 30K steps because models are not fully converged in 5K training steps. Ma et al. (2021); Lee-Thorp et al. (2021); Xiong et al. (2021) also pointed the same issue. We also re-run the vanilla Transformer using our Pytorch implementation.

For the proposed FSAT, the default value of the hyper-parameter M is 4, and the variance σ^2 is empirically set to L_{max} which is the maximum sequence length of each task. To ensure roughly equivalent model parameters, we reduce the dimension of FFN layer from 4 times of the hidden size to 2 times for FSAT to offset the increased parameters of non-linear feature mapping functions (Formula 1). In our code, sparse matrix multiplications involved in FSAT model are implemented via scatter operations at batch-level for better efficiency. Median results of 5 runs are reported in the tables.

5.4 Results

Table 1 summarizes the performance of a number of models on the LRA benchmark. As we can see, the proposed model clearly outperforms all previously published approaches, and achieves new state-of-the-art performance on four of the five datasets, and a 5.8% absolute improvement over average performance, which validates the effectiveness of the proposed FSAT model. It is noteworthy that we separately report the average accuracy

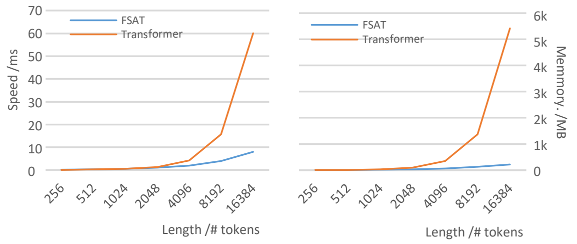

Figure 3: An illustration of the trend of time and memory cost, as the input sequence length increases. The average memory consumption (MB) and training time (ms) for a single sequence is counted.

without the Text task, this is because we find that convolution layers have a significant impact on this task. In the experiment, we adopt a depth-wise separable convolution layer with a kernel size of 5 as the feature mapping function when computing hidden crosses, the accuracy significantly increases from 65.95% to 80.24%. Therefore, considering the particularity of the Text task, we report its result separately. We suspect that the small data size may be the reason of its particularity.

5.5 Efficiency

The time and memory efficiency of our model and competing approaches are summarized in Table 2. Compared with the vanilla Transformer, our FSAT significantly reduces the computational complexity with faster training speed and lower memory usage, which demonstrates that directly predicting the sparse structure of attention matrix is an effective way for building efficient Transformer architecture. The limitation of FSAT is that extra operations (e.g. gathering, slicing) of linear complexity are involved, so that FSAT can not bring parallel superiority into full play. Even so, among all compared Transformer variants, FSAT achieves promising results in time and memory efficiency. The trend of computation complexity increasing is shown in Figure 3. This is in line with expectations, FSAT has a linear rate of increase, its advantage is especially obvious for sequences longer than 4K tokens. This demonstrates the potential of the proposed predictable sparse attention for the tasks with much longer sequences, e.g. 3D feature volume.

5.6 Ablation Study

An ablation study is conducted to verify the necessity of our proposed model components. In Table 3, we report FSAT models with the different number of predicted dominant indices. The results show that for each key vector in the attention mechanism about 4 predicted dominant query vectors are enough for the model to produce high accuracy. We also remove the sparse attention module, and test the architecture of only integrating the pooled hidden state cross into the attention mechanism, corresponding to Formula 5. We call this architecture Fourier Attention for Transformer (FAT). It can be seen from the results of FAT, better results can be obtained with the pooled hidden state cross in some tasks, which supports our hypothesis that the 2-order token feature may generate more expressive feature representations. It is noteworthy that without the gradient truncation, or only using random indices $\mathcal{I}_r$ or $\mathcal{I}_p$, the performance significantly drops. Besides, the depth-wise convolution based feature mapping performs worse than a fully-connected structure base feature mapping.

	ListOps	Retrieval	Image	Avg.
Transformer	37.45	78.38	43.19	53.01
FSAT-2	39.1	76.76	49.64	55.17
FSAT-4	46.85	81.11	49.97	59.31
- No Trunc.	42.65	74.88	47.74	55.09
- Only $\mathbf{I}_r$	37.54	73.84	40.24	50.54
- Only $\mathbf{I}_p$	17.8	56.81	21.58	32.06
+ DConv-5	45.95	81.45	32.23	53.21
FSAT-8	**47.95**	81.29	49.85	59.70
FAT	46.8	**82.46**	**50.14**	**59.77**

6 Conclusion

In this paper, we proposed a new efficient Transformer architecture, FSAT, which directly predicts the sparse structure of attention matrix to avoid computing the quadratic-cost full self-attention. The proposed approach has the advantages in long-range sequence modeling tasks meanwhile reaching a balance between time, memory, and accuracy. We showed the effectiveness of the proposed method in modeling long sequence context using the Long Range Arena benchmark. Experimental results showed that state-of-the-art performance is achieved by our proposed method.

Abstract

In modern recommender systems, there are usually comments or reviews from users that justify their ratings for different items. Trained on such textual corpus, explainable recommendation models learn to discover user interests and generate personalized explanations. Though able to provide plausible explanations, existing models tend to generate repeated sentences for different items or empty sentences with insufficient details. This begs an interesting question: can we immerse the models in a multimodal environment to gain proper awareness of real-world concepts and alleviate above shortcomings? To this end, we propose a visually-enhanced approach named METER with the help of visualization generation and text–image matching discrimination: the explainable recommendation model is encouraged to visualize what it refers to while incurring a penalty if the visualization is incongruent with the textual explanation. Experimental results and a manual assessment demonstrate that our approach can improve not only the text quality but also the diversity and explainability of the generated explanations.

1 Introduction

Explainable recommender systems have recently attracted increasing attention both in industry and in the academic community. Such systems aim to provide high-quality recommendations and simultaneously generate explanations for the recommendations (Zhang et al., 2014; Zhang and Chen, 2020). The explanations not only can bridge the gap between how systems and users perceive the relevance of the recommended items, but also can serve to shed light on the recommendation decision process so as to avoid a black box. To provide appropriate explanations, feature-based (Zhang et al., 2014), graph-based (Xian et al., 2019, 2020; Geng et al., 2022; Fu et al., 2020), sentence-based (Chen et al., 2019a; Li et al., 2020, 2021a, 2022), causality-based (Tan et al., 2021, 2022; Xu et al., 2021a,b) and neural-symbolic (Shi et al., 2020; Chen et al., 2021, 2022) approaches have been explored in recent years. Among them, PETER (Li et al., 2021a) is a representative sentence-based method that directly generates explanation sentences for given user–item pairs based on Personalized Transformer.

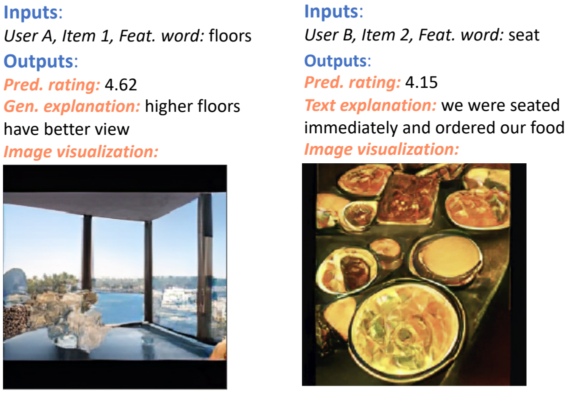

Figure 1: Example cases by the proposed model on TripAdvisor and Yelp datasets respectively.

While PETER outperforms previous methods in terms of both explainability and text quality metrics, it also suffers from several shortcomings: PETER tends to repeat certain universally applicable "safe" sentences as explanations (e.g., "the hotel is very nice"). For the 32,003 records in the test split of the TripAdvisor dataset by Li et al. (2020), PETER only generates around 8,100 unique sentences. The duplicate rate is close to 75%, while in reality, the duplicate rate of the TripAdvisor ground truth explanations is only 5.4%. In addition, such models are trained solely on a textual corpus, lacking real-world experiences to generate more authentic explanations, which may lead to empty sentences with insufficient details. Recently, Vokenization (Tan and Bansal, 2020) demonstrates that language understanding can be improved with token-level visual supervisions. This motivates us to consider enhancing text explanation generation with the aid of real-world images.

In this paper, we present an entirely new form

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 244 - 255
May 22-27, 2022

of explanation generation model that is immersed in a multimodal environment. The goal is to encourage it to perceive real-world signals and generate visually-enhanced explanations to better assist a user's decision. Specifically, we propose the *Multimodally-Enhanced Transformer for Explainable Recommendation* (**METER**) approach for improved text explanations based on conditional image generation and text–image matching. Unlike traditional caption-to-image generation, our training sentences are explanations that are more comprehensive reviews based on user experiences rather than simple abstract descriptions of the image content. We adopt the generation order "rating → text → image" based on the consideration that the generation difficulty should gradually increase. With this approach, we seek to guide the model to understand real-world concepts regarding both item attributes and user interests (e.g., a spacious room or modern decoration). Furthermore, METER is encouraged to visualize what it is talking about for the given user–item pair and is penalized in case of a mismatch between the generated visualization and the textual explanation. This is in line with the spirit of the context token prediction module in Li et al. (2021a). While PETER only predicts text tokens as contextual information, our METER additionally generates visual tokens as a supplement. We claim that if a sentence contains more real-world concepts, it is easier to visualize it as an image with higher fidelity. To this end, we introduce a text–image matching discriminator based on contrastive learning which helps to improve both the diversity and faithfulness of the textual explanations. Beyond an auxiliary task for text generation, another advantage of METER is that the generated image visualizations may provide intuitive visual explanations in addition to rating scores and textual explanations.

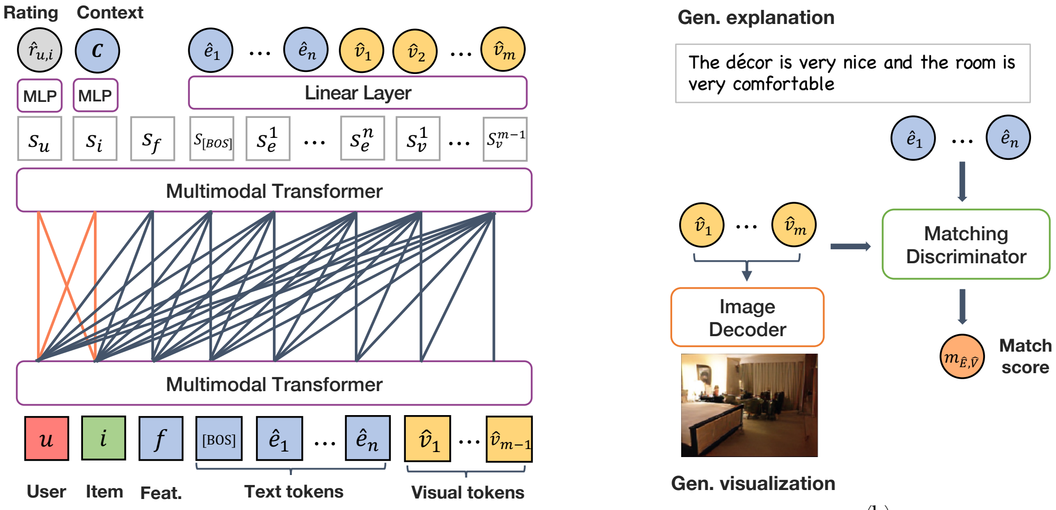
To empirically evaluate our framework, we conduct experiments and user studies on two real-world datasets in terms of diversity and faithfulness of text explanations, as well as consistency and quality of image visualizations. Our results reveal that using the proposed METER leads to improvements on text diversity and faithfulness, and that the generated image visualizations show high fidelity and good consistency. Overall, we make the following key contributions:

- To the best of our knowledge, this is the first exploration of a multimodal explainable recommender system that jointly generates rating scores, textual explanations, and images. The system will also be promising in creative advertising applications.
- By immersing the model into a multimodal environment, we help it explore the real-world concepts mentioned in the text explanations and in turn enable it to generate more diverse and faithful natural language rationales that are consistent with visual grounding.
- Experiments and a user study on real-world datasets demonstrate the superiority of our approach over several strong baselines.

2 Related Work

Visually-Guided Language Learning There have been numerous efforts on utilizing visual information to facilitate language tasks. The general strategy they typically pursue is to obtain cross-modally aligned semantics through visual grounding. Gella et al. (2017); Zhang et al. (2020); Sigurdsson et al. (2020) draw on the visual modality to bridge the gap between languages and conduct visual grounding to improve unsupervised cross-lingual word mapping or machine translation. Vokenization (Tan and Bansal, 2020) assigns each text token with a corresponding voken and improves text-based pretraining with contextualized, visual-grounded supervisions. VidLanKD (Tang et al., 2021) further solves the shortcomings of Tan and Bansal (2020) by first learning a multimodal teacher model on video-language dataset and then transferring knowledge to the student language model through distillation. Shen et al. (2021) discovers visual impressions from text-only corpus to improve open-domain dialog generation. Li et al. (2021b) learns vision–language representations with cross-modal contrastive learning on a combination of pure text corpus and image–text pairs to advance both single modal and multi-modal downstream tasks. Recently, DALL-E (Ramesh et al., 2021) merges text and visual tokens as a single stream of data and employs a universal Transformer to autoregressively model the multimodal stream. The astonishing success of these methods inspires us to guide personalized explanation generation with visual signals.

Generate Explanations for Recommendation Explainable recommendation has been an important task in both research and industry (Zhang and Chen, 2020). Early approaches mainly attempt to



(a) (b)

Figure 2: Architecture of METER framework: (a) Multimodally-Enhanced Transformer, which takes user ID u, item ID i, feature word f as initial condition tokens. Text tokens $\{\hat{e}_t\}_{t=1}^{n}$ are first generated triggered by the [BOS] token, next visual tokens $\{\hat{v}_t\}_{t=1}^{m}$ can be generated conditioned on (u,i,f) triplet and text sequence. (b) Text–image matching discriminator that estimates the match score between the generated text explanation and visualization.

make latent factor models interpretable by aligning each latent dimension with the explicit meaning (Zhang et al., 2014; Chen et al., 2016). In recent years, numerous neural models have been proposed to explain recommendations based on user reviews (Chen et al., 2019c,a). There have also been attempts to generate purely visual explanations (Chen et al., 2019b; Tangseng and Okatani, 2020). Compared with other explanation styles for recommendation, sentence-based methods are more straightforward and have been at the center of attention in recent times. Explanation sentences can either be generated by filling predefined templates (Zhang et al., 2014; Wang et al., 2018) or through flexible natural language approaches such as Attn2Seq (Dong et al., 2017), based on recurrent neural networks, and PETER (Li et al., 2021a), which is powered by a personalized Transformer. NETE (Li et al., 2020) combines the advantage of the two styles and produces template-controlled explanations by learning from sentence templates, which is an early form of prompt-based generation. However, none of the previous work has integrated textual and visual features and provided multimodal explanations. To the best of our knowledge, METER is also the first approach to draw on vision for improved textual explanation generation.

3 Methodology

3.1 Overview and Problem Formulation

The goal of our METER framework is to give an estimated rating score $\hat{r}_{u,i}$ that reflects a user u's preference towards item i and generate a multimodal explanation to justify the estimated rating. The generated multi-modal explanation consists of a text sentence $\hat{E}_{u,i}$ and an image visualization $\hat{V}_{u,i}$. The latter may serve as a supplement to the textual explanation for better explainability when text alone provides insufficient information. Moreover, the METER recommendation explanation model is encouraged to visualize what it is talking about for the user–item pairs and will be punished if the generated visualization does not match its textual explanation. By doing so, we aim to improve the quality, diversity, as well as faithfulness of the generated text explanations through visual grounding.

In the following, we shall first elaborate how to represent visual information into visual tokens and how to encode the positional embeddings for different types of tokens used in METER. Subsequently, we describe the Multimodal Enhanced Transformer for autoregressive multimodal explanation generation. Moreover, we will introduce the text–image matching discriminator, which guides the multimodal Transformer to generate better and more diversified text explanations. Finally, we summarize the training objectives of our framework for rating prediction and explanation generation.

3.2 Visual Encoder

To introduce visual signals into the Transformer structure, we follow the idea of VQ-VAEs (van den Oord et al., 2017) to encode an image $I \in \mathbb{R}^{H\times W\times 3}$ into a sequence of discrete patch-level visual tokens $z_q \in \mathbb{R}^{h \times w \times d}$, where H and W is the original size of the input image, $h \cdot w$ is the number of visual patches, and d is the patch-level feature dimensionality. The visual tokens are constructed by vector-quantization through a learned discrete codebook $\mathcal{Z} = \{z_k\}_{k=1}^{K} \in \mathbb{R}^d$ of visual representations. To balance efficiency and perceptual quality, we adopt VQ-GAN (Esser et al., 2021) as the visual encoder and decoder in our framework. We first pre-train the vector-quantized visual patch encoder $\mathcal{E}$, decoder $\mathcal{G}$, and the discrete codebook $\mathcal{Z}$ on our collected images. With these pretrained components, we can encode an input image I with the encoder $\mathcal{E}$ as $\hat{z} = \mathcal{E}(I) \in \mathbb{R}^{h \times w \times d}$. Next, we serialize $\hat{z}$ and conduct element-wise quantization for individual encoding $\hat{z}_j$ of $\hat{z}$ onto its closest codebook entry z_k:

$$z_q = \left(\underset{z_k \in \mathcal{Z}}{\arg\min} \|\hat{z}_j - z_k\| \right) \in \mathbb{R}^{h \times w \times d}$$

The resulting z_q are served as the encoded visual tokens $\{v_j\}_{j=1}^{m}$ of the input image. As for the sequence of visual tokens $\hat{z}_q = \{\hat{v}_j\}_{j=1}^{m}$ produced by METER autoregressively, we can utilize the decoder $\mathcal{G}$ to transform it back to a generated original size image $\hat{I}$: $\hat{I} = \mathcal{G}(\hat{z}_q) \in \mathbb{R}^{H \times W \times 3}$.

3.3 Input Representation

Five distinct types of input tokens can be distinguished: user ID, item ID, feature word, text tokens for explanation, and visual tokens. With the aforementioned vector-quantized visual patch encoder, we obtain a visual token representation for a given image. For text explanations, we directly tokenize them into text token sequences. Intuitively, the generated explanation should reflect both the user's interest preferences and the item attributes. Hence, we have user IDs and item IDs as two special types of tokens to guide the model to talk about the correct topics. Finally, the feature words can serve as conditional inputs to specialize the topic of explanation.

To represent tokens as embeddings, we prepare four embedding codebooks: $\mathcal{U}$ for user IDs, $\mathcal{I}$ for item IDs, $\mathcal{V}$ for text tokens and feature words, and $\mathcal{Z}$ for visual tokens. We set a fixed length m for visual tokens and a maximum length n for text tokens. Thus, the input sequence $\mathbf{S}_0$ can be represented as $\mathbf{S}_0 = [u, i, f, e_1, \cdots, e_n, v_1, \cdots, v_m]$. Before feeding the token sequence into METER, we provide positional embeddings for non-visual tokens and visual tokens separately. As the visual information has a spatial prior and is organized in a 2-D grid, we adopt an axial positional embedding (Ho et al., 2019) for visual tokens. In addition, we prepare an embedding codebook $\mathcal{P}$ for non-visual tokens. The final input sequence representation is the addition of token embeddings and the corresponding positional embeddings.

3.4 Multimodally-Enhanced Transformer

Given a input sequence, we use a Multimodally-Enhanced Transformer to encode it and predict the next token, which can be either a text or visual token. When the input sequence starts with the special token [BOS] alone, the model also predicts the rating score for the candidate user–item pair and contextual words that could reflect the user's preference and the item's attributes. Suppose our multimodal Transformer has L layers, each with h-head multi-head self-attention, and d is the input embedding dimensionality. Then, for input sequence $\mathbf{S}_l$ at layer $l \in [0, L-1]$, the encoded sequence $\mathbf{S}_{l+1}$ can be computed as follows (specifically $\mathbf{S}_L$ denotes the final-layer output):

$$\mathbf{S}_{l+1} = \mathrm{FFN}_l \left(\mathrm{Attention} \left(\mathbf{S}_l \mathbf{W}_{\mathbf{Q}}, \mathbf{S}_l \mathbf{W}_{\mathbf{K}}, \mathbf{S}_l \mathbf{W}_{\mathbf{V}} \right) \right)$$

Here, $\mathbf{W}_{\mathbf{Q}}, \mathbf{W}_{\mathbf{K}}, \mathbf{W}_{\mathbf{V}} \in \mathbb{R}^{d \times d_h}$ are weight matrices for projecting query, key, and value respectively (Vaswani et al., 2017), $d_h = d/h$ is the dimensionality for each head. FFN_l is a feed-forward module consisting of two fully-connected layers with ReLU in between for the l-th Transformer layer. The $\mathrm{Attention}$ function is defined as

$$\mathrm{Attention}(\mathbf{Q}, \mathbf{K}, \mathbf{V}) = \mathrm{Softmax}\left(\frac{\mathbf{Q}\mathbf{K}^\top}{\sqrt{d_h}} \right) \mathbf{V}$$

with a scaling factor $\sqrt{d_h}$ that maintains the order of magnitude in features. We adopt a similar masking strategy as Li et al. (2021a): the user & item IDs both can attend to all tokens in the sequence, while other non-ID tokens (including feature words, text tokens, and visual tokens) all retain the traditional causal attention masking in order to avoid any leakage of future information. Figure 2 (a) provides an illustration of our masking strategy.

Assuming the final-layer output from the Transformer is $\mathbf{S}_L = [s_u, s_i, s_f, \{s_e\}, \{s_v\}]$, this also serves as a representation of the input sequence for next generation iteration. We can use these vector representations to enable the following four tasks:

Rating prediction The first representation s_u is used to conduct rating score prediction. We regard the score prediction as a regression problem and the goal is to predict the score $\hat{r}_{u,i}$ for the given pair of user/item IDs. Due to the adopted masking strategy, u and i can both attend to each other and capture the correlation between them. Here we make use of a two-layer fully-connected network with sigmoid activation σ to map s_u to a scalar score value: $\hat{r}_{u,i} = \sigma\left(s_u W_1 + b_1\right) W_2 + b_2$, where the dimensionality of input, hidden layer, and output are d, d, and 1 respectively. Mean Squared Error loss (MSE) is used for rating score regression:

$$\mathcal{L}_r = \mathbb{E}_{(u,i)\in\mathcal{T}}\left(r_{u,i} - \hat{r}_{u,i}\right)^2$$

where $r_{u,i}$ is the ground-truth rating score and $\mathcal{T}$ represents the training corpus.

Context token prediction The second representation s_i is designed to predict the context words for a given user–item pair. Similar to s_u, s_i also absorbs the words that are related to a certain user's preference and an item's attributes. Thus, this auxiliary task is able to force the Transformer to exploit the information hidden in the user ID and item ID. Such design can mitigate the problem of identical explanations being generated. By passing s_i into a single fully-connected layer with Softmax activation, we can obtain a probability distribution over the vocabulary $\mathcal{V}$ for the context word: $P_c = \mathrm{Softmax}\left(s_i W_c + b_c\right)$, where the dimensionality of input and output are d and $|\mathcal{V}|$, respectively. The predicted context tokens are the top-n words with the highest probability. If we represent the probabilities of these context words $\mathbf{C}$ as $\{p_c^t\}_{t=1}^n$, then the negative log likelihood (NLL) loss can be computed as:

$$\mathcal{L}_c = \mathbb{E}\left[\frac{1}{n}\sum_{t=1}^{n} -\log p_c^t\right]$$

Explanation/visualization generation The generation of explanation words and visual codes follows the autoregressive style, i.e., decoding one token at a time from left to right. Text generation is triggered by the special [BOS] token, upon which we repeatedly decode words until [EOS] is sampled. If the number of generated text tokens before [EOS] is less than n, we pad the sequence with [PAD]. If the text sequence length is greater than n, we cut it off at length n. To obtain the visual code sequence $\hat{\mathbf{V}}$, we iterate METER for a fixed number of m steps conditioned on the text explanation $\hat{\mathbf{E}}$ and the previously generated visual code sequence. Similar to context word prediction, we adopt a single fully-connected layer for text representations $\{s_e\}$ to produce probability distributions over the text vocabulary $\mathcal{V}$. As for visual representations $\{s_v\}$, we employ another fully-connected layer to produce probability distributions over the discrete visual codebook $\mathcal{Z}$. We can then sample words and visual codes from the obtained probability distributions. For simplicity, we employ greedy decoding as the sampling method to select the word/code with the highest probability. If we denote the probabilities of the sampled words and visual codes as $\{p_e^t\}_{t=1}^n$ and $\{p_v^t\}_{t=1}^m$, respectively, then the token-level language modeling loss for text and visual code generation can be expressed as:

$$\mathcal{L}_e = \mathbb{E}\left[\frac{1}{n}\sum_{t=1}^{n} -\log p_e^t\right] + \alpha\cdot\mathbb{E}\left[\frac{1}{m}\sum_{t=1}^{m} -\log p_v^t\right]$$

where α is a hyperparameter used to balance the training of textual and visual token generation.

Text–image matching METER is capable of generating text–image explanation pairs. However, we still need to know whether and to what degree the generated image visualization matches the text explanation from a global perspective. Hence we adopt a text–image matching discriminator D to measure the degree of congruency. From another aspect, if a generated sentence contains more real-world concepts, it is easier to ground the sentence to corresponding visual tokens and obtain an image visualization with higher fidelity. With contrastive training, we in turn push METER to generate text explanations with more grounded details. Our discriminator is equipped with two separate encoders for the visual token sequence and the text sequence. Assuming the outputs of the two encoders to be $\hat{\mathbf{E}}$ and $\hat{\mathbf{V}}$, we can construct positive training text–image pairs from the ground truth, as well as negative ones through alternate pairings. Thus, the discriminator loss can be written as:

$$\mathcal{L}_\mathrm{d} = \mathbb{E}\left[\log\left(D(\mathbf{E},\mathbf{V})\right)\right] + \mathbb{E}\left[\log\left(1 - D\left(\mathbf{E},\hat{\mathbf{V}}\right)\right)\right] + \mathbb{E}\left[\log\left(1 - D\left(\hat{\mathbf{E}},\mathbf{V}\right)\right)\right]$$

In summary, the overall training objective function $\mathcal{J}$ consists of the aforementioned four losses:

$$\mathcal{J} = \min_{\Theta}\left(\lambda_e\mathcal{L}_e + \lambda_d\mathcal{L}_d + \lambda_r\mathcal{L}_r + \lambda_c\mathcal{L}_c\right)$$

Here, Θ denotes all trainable parameters, while λ_e, λ_d, λ_r, λ_c are regularization weights to help

Figure 3: t-SNE visualization for the top 88 clusters of sentence semantics when threshold is 0.95. For clarity, we only show a subset of centric explanation sentences.

balance the learning of different tasks. METER is then trained on $\mathcal{J}$ in an end-to-end manner.

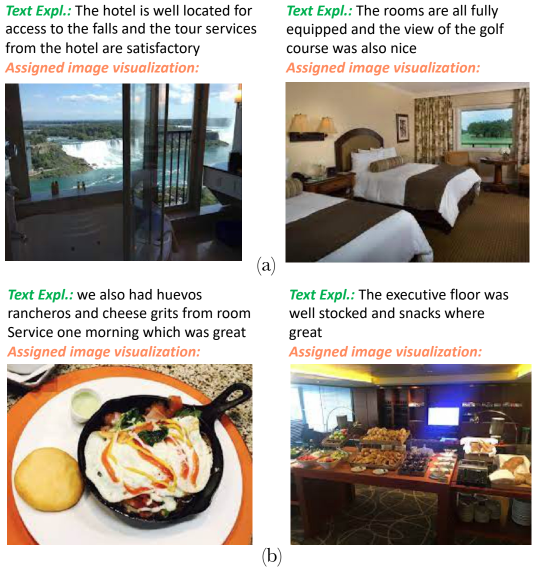
4 Experiments and Discussions

4.1 Building Datasets

To conduct experiments, we adopt two publicly available explainable recommendation datasets proposed in Li et al. (2020). For each dataset, training/validation/testing splits are created following the ratio of $8 : 1 : 1$.

To enable the visually-enhanced model proposed in this paper, we compile a collection of images portraying real-world concepts. The real-world concepts are obtained by clustering sentence semantics with the help of Sentence-BERT (Reimers and Gurevych, 2019). At first, we use Sentence-BERT to compute the embeddings of all text explanation sentences. Since many ground-truth explanations have similar semantic meanings, we conduct fast clustering to aggregate these explanation sentences into different groups representing similar concepts and topics. Figure 3 gives a t-SNE visualization (Van der Maaten and Hinton, 2008) of the top 88 clusters if setting the similarity threshold to 0.95. From the figure, we can have a glimpse of what kinds of topics these explanation typically show. To ensure a proper amount of clusters, we set the threshold to 0.85. Thus we obtain 16,577 clusters consists of the most common 99,066 explanations for TripAdvisor and 64,937 clusters which cover 283,895 explanations for Yelp.

The explanation sentences at cluster centers are then used as query input to search relevant images through Google Images API. For TripAdvisor and Yelp, we retrieve the top 20 and top 10 images for each centric explanation sentence. As a result, we have a visual concept pool of 331,540 and 649,370 images for TripAdvisor and Yelp, respectively.



Text Expl.: The hotel is well located for access to the falls and the tour services from the hotel are satisfactory
Assigned image visualization:

Text Expl.: The rooms are all fully equipped and the view of the golf course was also nice
Assigned image visualization:

Text Expl.: we also had huevos rancheros and cheese grits from room Service one morning which was great
Assigned image visualization:

Text Expl.: The executive floor was well stocked and snacks where great
Assigned image visualization:

(b)

Figure 4: Example ground-truth text explanation–image visualization pairs on (a) TripAdvisor and (b) Yelp datasets.

After collecting enough images about dataset-aware topics, we assign each text explanation the most suitable image visualization by calculating the similarity between the two modalities with CLIP model (Radford et al., 2021). In this way, we build the textual recommendation explanation–image visualization pairs for both datasets and then train METER on the constructed multimodal pairs. In Figure 4, we provide several text explanations with their corresponding assigned image visualizations.

Table 1 shows the statistics of the established multimodal explainable recommendation datasets. Note that the TripAdvisor dataset mainly focuses on the hotel and travel domain, while the majority of the Yelp data is about restaurants. Records in the two datasets consist of: user ID, item ID, rating score (from 1 to 5), feature word, text explanation, and image visualization aligned with the text explanation.

Dataset	**Yelp**	**TripAdvisor**
#users	27,147	9,765
#items	20,266	6,280
#explanations	1,293,247	320,023
#features	7,340	5,069
#images	649,370	331,540

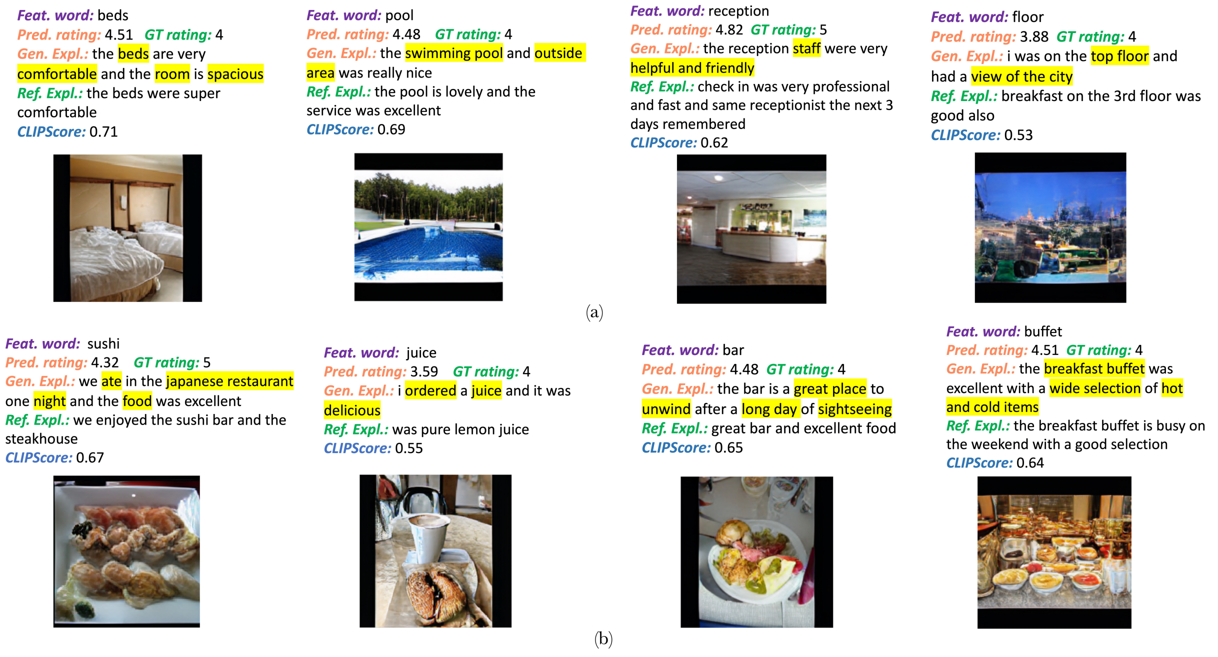
Table 2: Performance comparison on the TEST splits of TripAdvisor & Yelp datasets among several explanation generation methods. The metrics are organized into four groups – text explainability (FMR, FCR), text diversity (DIV, USR), text quality (BLUE, ROUGE), and image consistency (CS). Note that here BLEU and ROUGE scores are percentage values, while the other metrics are absolute values.

(i.e., encoder, decoder, and visual codebook) of VQ-GAN are first pre-trained on the collected images of the two datasets. For image visualization generation, we first sample 32 candidate images conditioned on the corresponding explanations, and then use the trained text–image discriminator to produce match scores. The image with the highest match score is finally selected as output. The embedding size d of METER is set to 256, the dimensionality of the feed-forward network's hidden layer is $1,024$. The maximum text length n of the explanation sequence is set to 15, while the length of the visual token sequence m is set to 256, and the standard image size for VQ-GAN is set to 256×256. We keep the most frequent $20,000$ words as the text vocabulary, while the size of the discrete visual codebook is $1,024$. The Multimodally-Enhanced Transformer uses $L = 8$ layers, each endowed with a multi-head attention with $h = 8$ heads. We set the regularization weights λ_e, λ_d, λ_r, and λ_c to 1.0, 1.0, 0.1, and 1.0, respectively. And we choose 7.0 as the value of the balancing hyperparameter α. The METER model is trained with Adam optimization (Kingma and Ba, 2015) under a batch size of 32, and the learning rate is set to 5×10^{-4}. We conduct all experiments on NVIDIA Quadro RTX 6000 GPUs.

4.3 Evaluation Metrics

We conduct our evaluation from three perspectives – explanation generation performance, text–image matching performance, and rating prediction performance. For each of the three aspects, we adopt both automatic and manual forms of evaluation (see Sec. 4.6). For explanation performance, we measure the text quality, diversity, and explainability of the generated explanations. For the text quality, we adopt BLEU-1 and BLEU-4, as well as ROUGE-1 and ROUGE-2. To overcome the drawbacks of the two traditional metrics, we also employ Unique Sentence Ratio (USR) proposed by Li et al. (2020) to quantify the diversity of the generated sentences. For the diversity in feature word level, we adopt Feature Diversity (DIV) proposed in Li et al. (2020), which measures the intersection of features between any two generated explanations. In explainable recommendation, an explanation will normally be valued more by users if it justifies a recommendation's advantage using certain feature words as specified in the datasets. Thus, we adopt two more metrics tailored for explainability evaluation proposed by Li et al. (2020) – Feature Matching Ratio (FMR) and Feature Coverage Ratio (FCR). Specifically, FMR measures whether a generated explanation contains the feature in the ground-truth, while FCR is computed as the number of distinct features contained in the generated explanations, divided by the total number of features in the whole dataset. To assess the text–image matching, we adopt CLIPScore (CS) proposed by Hessel et al. (2021) as an objective metric to measure the degree of correspondence for cross-modality pairs. For the rating prediction performance, we rely on two standard metrics – Root Mean Square Error (RMSE) and Mean Absolute Error (MAE). By including the recommendation experiment, we merely seek to prove that the rating scores predicted by our method are sufficiently



Feat. word: beds
Pred. rating: 4.51 *GT rating:* 4
Gen. Expl.: the beds are very comfortable and the room is spacious
Ref. Expl.: the beds were super comfortable
CLIPScore: 0.71

Feat. word: pool
Pred. rating: 4.48 *GT rating:* 4
Gen. Expl.: the swimming pool and outside area was really nice
Ref. Expl.: the pool is lovely and the service was excellent
CLIPScore: 0.69

Feat. word: reception
Pred. rating: 4.82 *GT rating:* 5
Gen. Expl.: the reception staff were very helpful and friendly
Ref. Expl.: check in was very professional and fast and same receptionist the next 3 days remembered
CLIPScore: 0.62

Feat. word: floor
Pred. rating: 3.88 *GT rating:* 4

Gen. Expl.: the bar is a great place to unwind after a long day of sightseeing
Ref. Expl.: great bar and excellent food
CLIPScore: 0.65

Feat. word: buffet
Pred. rating: 4.51 *GT rating:* 4
Gen. Expl.: the breakfast buffet was excellent with a wide selection of hot and cold items
Ref. Expl.: the breakfast buffet is busy on the weekend with a good selection
CLIPScore: 0.64

(b)

Figure 5: Qualitative results generated by METER with a conditional feature word as input: (a) is from TripAdvisor, while (b) is from Yelp. The real-world concepts in the generated explanations are highlighted.

strong to merit explanation generation, because if a rating prediction is inaccurate, the generated explanation will be less meaningful.

4.4 Comparison Baselines

For the performance comparison, we consider several baselines with regard to the task of explanation generation: **Attn2Seq** (Dong et al., 2017) learns to encode attributes into vectors, and then invokes an attention mechanism to generate reviews conditioned on the attribute vector. **Transformer** (Vaswani et al., 2017) treats user and item IDs as words and trains on the explanation generation task with a vanilla Transformer structure through language modeling. **NETE** (Li et al., 2020) designed a tailored GRU module to incorporate the given feature into the decoding stage. The system can generate template-like explanations while also making recommendations. **PETER** (Li et al., 2021a) is a simple and effective framework that attempts to use the IDs to predict the words in the target explanation. It is built upon a modified attention mask of the Transformer model. With regard to mere recommendation, we compare with two traditional methods in addition to NETE and PETER: **PMF** (Salakhutdinov and Mnih, 2007) conducts probabilistic matrix factorization in latent space. **SVD++** (Koren, 2008) combines factor and neighborhood models to enhance the accuracy.

4.5 Results and Analysis

In this section, we evaluate the performance of the proposed METER approach on two real-world datasets and compare with several representative explanation generation methods in Table 2 and recommendation models in Table 3. From Table 2, we can see that METER achieves the best FMR and DIV against all other methods, showing that METER can cover more diverse feature words during generation while maintaining good explainability. METER notably improves the USR over PETER but is slightly lower than NETE. Note that NETE is a template-based approach so it naturally achieves high USR scores. Among all methods, METER exhibits the best balance between text quality and text diversity, while being the only method that can produce both text and images, with reasonably high Image Consistency. Since automatic metrics cannot completely reflect the quality and faithfulness of generated text explanations, we also conduct a user study in the next subsection for further verification. Moreover, Table 3 indicates that METER can achieve comparable rating performance to other approaches. In Figure 5, we present several real examples illustrating how METER is able to jointly generate not only high-quality rating scores and text explanations but also image visualizations. Taking the first case in (b) as an example, we observe how METER creates coherent explanations

Methods	Yelp		TripAdvisor	
	RMSE ↓	MAE ↓	RMSE ↓	MAE ↓
PMF	1.09	0.88	0.87	0.70
SVD++	**1.01**	**0.78**	0.80	0.61
NETE	**1.01**	0.79	**0.79**	**0.60**
PETER	**1.01**	**0.78**	0.81	0.63
METER	**1.01**	0.79	0.80	0.61

Table 3: Recommendation performance comparison in terms of RMSE and MAE among several methods.

rather than directly copying the feature word into the generated sentence, leading to greater diversity.

4.6 User Study

To genuinely assess the quality of text explanations generated by METER and whether the image visualization matches the text explanation, we conduct a user study on the faithfulness of the generated text explanations with associated visual grounding. We randomly sampled 500 generated explainable contextual sentences as well as corresponding image visualizations. For comparison, we also randomly pick 500 samples from the baselines and randomly mixed them with the samples from our method. We asked 30 human subjects to provide a rating range from $1-5$, where larger scores represent better faithfulness and diversity. For better evaluation, we also provide the original user/item information and ground-truth explanation sentence for their reference. We consider **Faithfulness** as a criterion to assess the degree of explainability of the text, which encompasses both its readability and its cogency to the human participants. A higher **Diversity** represents more lexically varied generated context. We further consider **Consistency** representing to what extent the generated images match the associated generated sentence, while higher **Quality** scores indicate the generated image contains clearer details and better fidelity. We then calculate the overall scores by averaging the ratings given by each human participant across 500 samples each from both the baseline and from our method. The results are reported in Table 4 and show that our method can generate diverse and faithful explanation sentences of a higher quality than PETER, while also attaining a high image quality and good cross-modal consistency.

4.7 Ablation Study

We also provide an ablation study of the training tasks on TripAdvisor dataset. According to Table 5, the context prediction task has a big influence on the explainability and diversity of the generated explanations. The feature word has a vital role in deciding the topic for the model to consider. Obviously the rating prediction task is important for recommendation performance, while the visual generation task is decisive for the image consistency score. As we expected, the discriminator loss can assist the model to generate both diverse explanations and better image visualizations.

	Sentence		Image	
	Faithfulness	Diversity	Consistency	Quality
Baselines	3.41	2.96	2.54	3.04
Ours	**4.57**	**3.70**	**3.06**	**4.19**

Table 4: Manual evaluation performance between METER and baselines. Note that the baseline for sentence generation is PETER, while for image generation it is METER without VQ-GAN tokenizer pretrained on images of certain dataset. Results are not comparable across two domains (Sentence & Image).

	Expl.		Div.		Qual.	Rec.	Cons.
	FMR	FCR	DIV	USR	B4	RMSE	CS

5 Conclusion

In this paper, we propose METER, the first attempt to jointly generate rating scores, text explanations, and corresponding image visualizations. We immerse our model in a multimodal environment by putting all modalities to one shared Transformer decoder structure. A text–image matching discriminator is further introduced to encourage sentences with more groundable and fine-grained concepts. Experimental results demonstrate that our framework can provide diverse and faithful text explanations, together with image visualizations as additional intuitive explanations. This proves that visual information offers auxiliary knowledge for the explanation generation model to gain awareness of real-world semantics. Our dataset and code are available at `https://github.com/jeykigung/METER`. In the future, we plan to investigate generating visually-enhanced explanations for more domains such as fashion and movie.

Abstract

New intent discovery aims to uncover novel intent categories from user utterances to expand the set of supported intent classes. It is a critical task for the development and service expansion of a practical dialogue system. Despite its importance, this problem remains under-explored in the literature. Existing approaches typically rely on a large amount of labeled utterances and employ pseudo-labeling methods for representation learning and clustering, which are label-intensive, inefficient, and inaccurate. In this paper, we provide new solutions to two important research questions for new intent discovery: (1) how to learn semantic utterance representations and (2) how to better cluster utterances. Particularly, we first propose a multi-task pre-training strategy to leverage rich unlabeled data along with external labeled data for representation learning. Then, we design a new contrastive loss to exploit self-supervisory signals in unlabeled data for clustering. Extensive experiments on three intent recognition benchmarks demonstrate the high effectiveness of our proposed method, which outperforms state-of-the-art methods by a large margin in both unsupervised and semi-supervised scenarios. The source code will be available at `https://github.com/zhang-yu-wei/MTP-CLNN`.

1 Introduction

Why Study New Intent Discovery (NID)? Recent years have witnessed the rapid growth of conversational AI applications. To design a natural language understanding system, a set of expected customer intentions are collected beforehand to train an intent recognition model. However, the pre-defined intents cannot fully meet customer needs. This implies the necessity of expanding the intent recognition model by repeatedly integrating new intents discovered from unlabeled user utterances (Fig. 1).

I haven't got my credit card.

Sorry for that. Your card will be arriving soon.

I recently found my card! Could you help me re-establish it?

Sorry, I don't understand your question.

Figure 1: New Intent Discovery.

To reduce the effort in manually identifying unknown intents from a mass of utterances, previous works commonly employ clustering algorithms to group utterances of similar intents (Cheung and Li, 2012; Hakkani-Tür et al., 2015; Padmasundari, 2018). The cluster assignments thereafter can either be directly used as new intent labels or as heuristics for faster annotations.

Research Questions (RQ) and Challenges. Current study of NID centers around two basic research questions: *1) How to learn semantic utterance representations to provide proper cues for clustering? 2) How to better cluster the utterances?* The study of the two questions are often interwoven in existing research. Utterances can be represented according to different aspects such as the style of language, the related topics, or even the length of sentences. It is important to learn semantic utterance representations to provide proper cues for clustering. Simply applying a vanilla pre-trained language model (PLM) to generate utterance representations is not a viable solution, which leads to poor performance on NID as shown by the experimental results in Section 4.2. Some recent works proposed to use labeled utterances of known intents

for representation learning (Forman et al., 2015; Haponchyk et al., 2018; Lin et al., 2020; Zhang et al., 2021c; Haponchyk and Moschitti, 2021), but they require a substantial amount of known intents and sufficient labeled utterances of each intent, which are not always available especially at the early development stage of a dialogue system. Further, pseudo-labeling approaches are often exploited to generate supervision signals for representation learning and clustering. For example, Lin et al. (2020) finetune a PLM with an utterance similarity prediction task on labeled utterances to guide the training of unlabeled data with pseudo-labels. Zhang et al. (2021c) adopt a deep clustering method (Caron et al., 2018) that uses k-means clustering to produce pseudo-labels. However, pseudo-labels are often noisy and can lead to error propagation.

Our Solutions. In this work, we propose a simple yet effective solution for each research question. **Solution to RQ 1: multi-task pre-training.** We propose a multi-task pre-training strategy that takes advantage of both external data and internal data for representation learning. Specifically, we leverage publicly available, high-quality intent detection datasets, following Zhang et al. (2021d), as well as the provided labeled and unlabeled utterances in the current domain, to fine-tune a pre-trained PLM to learn task-specific utterance representations for NID. The multi-task learning strategy enables knowledge transfer from general intent detection tasks and adaptation to a specific application domain. **Solution to RQ 2: contrastive learning with nearest neighbors.** We propose to use a contrastive loss to produce compact clusters, which is motivated by the recent success of contrastive learning in both computer vision (Bachman et al., 2019; He et al., 2019; Chen et al., 2020; Khosla et al., 2020) and natural language processing (Gunel et al., 2021; Gao et al., 2021; Yan et al., 2021). Contrastive learning usually maximizes the agreement between different views of the same example and minimize that between different examples. However, the commonly used instance discrimination task may push away false negatives and hurts the clustering performance. Inspired by a recent work in computer vision (Van Gansbeke et al., 2020), we introduce neighborhood relationship to customize the contrastive loss for clustering in both unsupervised (i.e., without any labeled utterances of known intents) and semi-supervised scenarios. Intuitively, in a semantic feature space, neighboring utterances should have a similar intent, and pulling together neighboring samples makes clusters more compact.

Our main contributions are three-fold.

- We show that our proposed multi-task pre-training method already leads to large performance gains over state-of-the-art models for both unsupervised and semi-supervised NID.
- We propose a self-supervised clustering method for NID by incorporating neighborhood relationship into the contrastive learning objective, which further boosts performance.
- We conduct extensive experiments and ablation studies on three benchmark datasets to verify the effectiveness of our methods.

2 Related Works

New Intent Discovery. The study of NID is still in an early stage. Pioneering works focus on unsupervised clustering methods. Shi et al. (2018) leveraged auto-encoder to extract features. Perkins and Yang (2019) considered the context of an utterance in a conversation. Chatterjee and Sengupta (2020) proposed to improve density-based models. Some recent works (Haponchyk et al., 2018; Haponchyk and Moschitti, 2021) studied supervised clustering algorithms for intent labeling, yet it can not handle new intents. Another line of works (Forman et al., 2015; Lin et al., 2020; Zhang et al., 2021c) investigated a more practical case where some known intents are provided to support the discovery of unknown intents, which is often referred to as semi-supervised NID.

To tackle semi-supervised NID, Lin et al. (2020) proposed to first perform supervised training on known intents with a sentence similarity task and then use pseudo labeling on unlabeled utterances to learn a better embedding space. Zhang et al. (2021c) proposed to first pre-train on known intents and then perform k-means clustering to assign pseudo labels on unlabeled data for representation learning following Deep Clustering (Caron et al., 2018). They also proposed to align clusters to accelerate the learning of top layers. Another approach is to first classify the utterances as known and unknown and then uncover new intents with the unknown utterances (Vedula et al., 2020; Zhang et al., 2021b). Hence, it relies on accurate classification in the first stage.

In this work, we address NID by proposing a multi-task pre-training method for representation learning and a contrastive learning method for clustering. In contrast to previous methods that rely on ample annotated data in the current domain for pre-training, our method can be used in an unsupervised setting and work well in data-scarce scenarios (Section 4.3).

Pre-training for Intent Recognition. Despite the effectiveness of large-scale pre-trained language models (Radford and Narasimhan, 2018; Devlin et al., 2019; Liu et al., 2019; Brown et al., 2020), the inherent mismatch in linguistic behavior between the pre-training datasets and dialogues encourages the research of continual pre-training on dialogue corpus. Most previous works proposed to pre-train on open domain dialogues in a self-supervised manner (Mehri et al., 2020; Wu et al., 2020; Henderson et al., 2020; Hosseini-Asl et al., 2020). Recently, several works pointed out that pre-training with relavant tasks can be effective for intent recognition. For example, Zhang et al. (2020) formulated intent recognition as a sentence similarity task and pre-trained on natural language inference (NLI) datasets. Vulić et al. (2021); Zhang et al. (2021e) pre-trained with a contrastive loss on intent detection tasks. Our multi-task pre-training method is inspired from Zhang et al. (2021d) which leverages publicly available intent datasets and unlabeled data in the current domain for pre-training to improve the performance of few-shot intent detection. However, we argue that the method is more suitable to be applied for NID due to the natural existence of unlabeled utterances.

Contrastive Representation Learning. Contrastive learning has shown promising results in computer vision (Bachman et al., 2019; Chen et al., 2020; He et al., 2019; Khosla et al., 2020) and gained popularity in natural language processing. Some recent works used unsupervised contrastive learning to learn sentence embeddings (Gao et al., 2021; Yan et al., 2021; Kim et al., 2021; Giorgi et al., 2021). Specifically, Gao et al. (2021); Yan et al. (2021) showed that contrastive loss can avoid an anisotropic embedding space. Kim et al. (2021) proposed a self-guided contrastive training to improve the quality of BERT representations. Giorgi et al. (2021) proposed to pre-train a universal sentence encoder by contrasting a randomly sampled text segment from nearby sentences. Zhang et al. (2021e) demonstrated that self-supervised contrastive pre-training and supervised contrastive fine-tuning can benefit few-shot intent recognition. Zhang et al. (2021a) showed that combining a contrastive loss with a clustering objective can improve short text clustering. Our proposed contrastive loss is tailored for clustering, which encourages utterances with similar semantics to group together and avoids pushing away false negatives as in the conventional contrastive loss.

3 Method

Problem Statement. To develop an intent recognition model, we usually prepare a set of expected intents $\mathcal{C}_k$ along with a few annotated utterances $\mathcal{D}^{\text{labeled}}_{\text{known}} = \{(x_i, y_i)|y_i \in \mathcal{C}_k\}$ for each intent. After deployed, the system will encounter utterances $\mathcal{D}^{\text{unlabeled}} = \{x_i|y_i \in \{\mathcal{C}_k, \mathcal{C}_u\}\}$ from both predefined (known) intents $\mathcal{C}_k$ and unknown intents $\mathcal{C}_u$. The aim of new intent discovery (NID) is to identify the emerging intents $\mathcal{C}_u$ in $\mathcal{D}^{\text{unlabeled}}$. NID can be viewed as a direct extension of out-of-distribution (OOD) detection, where we not only need to identify OOD examples but also discover the underlying clusters. NID is also different from zero-shot learning in that we do not presume access to any kind of class information during training. In this work, we consider both unsupervised and semi-supervised NID, which are distinguished by the existence of $\mathcal{D}^{\text{labeled}}_{\text{known}}$, following Zhang et al. (2021c).

Overview of Our Approach. As shown in Fig. 2, we propose a two-stage framework that addresses the research questions mentioned in Sec. 1. In the first stage, we perform multi-task pre-training (MTP) that jointly optimizes a cross-entropy loss on external labeled data and a self-supervised loss on target unlabeled data (Sec. 3.1). In the second stage, we first mine top-K nearest neighbors of each training instance in the embedding space and then perform contrastive learning with nearest neighbors (CLNN) (Sec. 3.2). After training, we employ a simple non-parametric clustering algorithm to obtain clustering results.

3.1 Stage 1: Multi-task Pre-training (MTP)

We propose a multi-task pre-training objective that combines a classification task on external data from publicly available intent detection datasets and a self-supervised learning task on internal data from the current domain. Different from previous works (Lin et al., 2020; Zhang et al., 2021c), our pre-training method does not rely on annotated data ($\mathcal{D}^{\text{labeled}}_{\text{known}}$) from the current domain and hence can

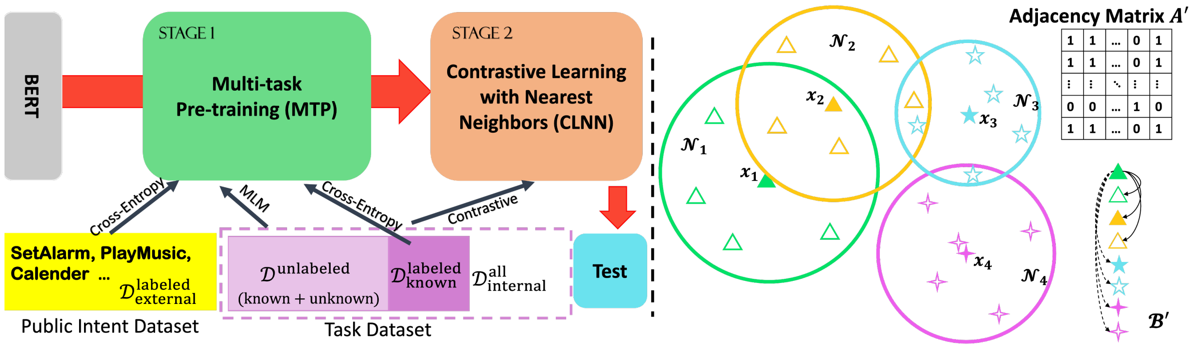

Figure 2: **The left part shows the overall workflow of our method** where the training order is indicated by the red arrow. The datasets and corresponding loss functions used in each training stage are indicated by the black arrows. **The right part illustrates a simple example of CLNN**. A batch of four training instances $\{x_i\}_{i=1}^4$ (solid markers) and their respective neighborhoods $\{\mathcal{N}_i\}_{i=1}^4$ are plotted (hollow markers within large circles). Since x_2 falls within $\mathcal{N}_1$, x_2 along with its neighbors are taken as positive instance for x_1 (but not vice versa since x_1 is not in $\mathcal{N}_2$). We also show an example of adjacency matrix $\mathbf{A}'$ and augmented batch $\mathcal{B}'$. The pairwise relationships with the first instance in the batch are plotted with solid lines indicating positive pairs and dashed lines indicating negative pairs.

be applied in an unsupervised setting.

Specifically, we first initialize the model with a pre-trained BERT encoder (Devlin et al., 2019). Then, we employ a joint pre-training loss as in Zhang et al. (2021d). The loss consists of a cross-entropy loss on external labeled data and a masked language modelling (MLM) loss on all available data from the current domain:

$$\mathcal{L}_{\text{stg1}} = \underbrace{\mathcal{L}_{\text{ce}}(\mathcal{D}^{\text{labeled}}_{\text{external}};\theta)}_{\text{supervised}} + \underbrace{\mathcal{L}_{\text{mlm}}(\mathcal{D}^{\text{all}}_{\text{internal}};\theta)}_{\text{self-supervised}}, \quad (1)$$

where θ are model parameters. For the supervised classification task, we leverage an external public intent dataset with diverse domains (e.g., CLINC150 (Larson et al., 2019)), denoted as $\mathcal{D}^{\text{labeled}}_{\text{external}}$, following Zhang et al. (2021d). For the self-supervised MLM task, we use all available data (labeled or unlabeled) from the current domain, denoted as $\mathcal{D}^{\text{all}}_{\text{internal}}$.

Intuitively, the classification task aims to learn general knowledge of intent recognition with annotated utterances in external intent datasets, while the self-supervised task learns domain-specific semantics with utterances collected in the current domain. Together, they enable learning semantic utterance representations to provide proper cues for the subsequent clustering task. As will be shown in Sec. 4.3, both tasks are essential for NID.

For semi-supervised NID, we can further utilize the annotated data in the current domain to conduct continual pre-training, by replacing $\mathcal{D}^{\text{labeled}}_{\text{external}}$ in Eq. 1 to $\mathcal{D}^{\text{labeled}}_{\text{known}}$. This step is not included in unsupervised NID.

3.2 Stage 2: Contrastive Learning with Nearest Neighbors (CLNN)

In the second stage, we propose a contrastive learning objective that pulls together neighboring instances and pushes away distant ones in the embedding space to learn compact representations for clustering. Concretely, we first encode the utterances with the pre-trained model from stage 1. Then, for each utterance x_i, we search for its top-K nearest neighbors in the embedding space using inner product as distance metric to form a neighborhood $\mathcal{N}_i$. The utterances in $\mathcal{N}_i$ are supposed to share a similar intent as x_i. During training, we sample a minibatch of utterances $\mathcal{B} = \{x_i\}_{i=1}^M$. For each utterance $x_i \in \mathcal{B}$, we uniformly sample one neighbor x'_i from its neighborhood $\mathcal{N}_i$. We then use data augmentation to generate $\tilde{x}_i$ and $\tilde{x}'_i$ for x_i and x'_i respectively. Here, we treat $\tilde{x}_i$ and $\tilde{x}'_i$ as two views of x_i, which form a positive pair. We then obtain an augmented batch $\mathcal{B}' = \{\tilde{x}_i, \tilde{x}'_i\}_{i=1}^M$ with all the generated samples. To compute contrastive loss, we construct an adjacency matrix $\boldsymbol{A}'$ for $\mathcal{B}'$, which is a $2M \times 2M$ binary matrix where 1 indicates positive relation (either being neighbors or having the same intent label in semi-supervised NID) and 0 indicates negative relation. Hence, we can write the contrastive loss as:

$$l_i = -\frac{1}{|\mathcal{C}_i|} \sum_{j \in \mathcal{C}_i} \log \frac{\exp(\text{sim}(\tilde{h}_i, \tilde{h}_j)/\tau)}{\sum_{k \neq i}^{2M} \exp(\text{sim}(\tilde{h}_i, \tilde{h}_k)/\tau)}, \quad (2)$$

$$\mathcal{L}_{\text{stg2}} = \frac{1}{2M}\sum_{i=1}^{2M} l_i, \tag{3}$$

where $\mathcal{C}_i \equiv \{\boldsymbol{A}'_{i,j} = 1 | j \in \{1, ..., 2M\}\}$ denotes the set of instances having positive relation with $\tilde{x}_i$ and $|\mathcal{C}_i|$ is the cardinality. $\tilde{h}_i$ is the embedding for utterance $\tilde{x}_i$. τ is the temperature parameter. $\text{sim}(\cdot, \cdot)$ is a similarity function (e.g., dot product) on a pair of normalized feature vectors. During training, the neighborhood will be updated every few epochs. We implement the contrastive loss following Khosla et al. (2020).

Notice that the main difference between Eq. 2 and conventional contrastive loss is how we construct the set of positive instances $\mathcal{C}_i$. Conventional contrastive loss can be regarded as a special case of Eq. 2 with neighborhood size $K = 0$ and the same instance is augmented twice to form a positive pair (Chen et al., 2020). After contrastive learning, a non-parametric clustering algorithm such as k-means can be applied to obtain cluster assignments.

Data Augmentation. Strong data augmentation has been shown to be beneficial in contrastive learning (Chen et al., 2020). We find that it is inefficient to directly apply existing data augmentation methods such as EDA (Wei and Zou, 2019), which are designed for general sentence embedding. We observe that the intent of an utterance can be expressed by only a small subset of words such as "suggest restaurant" or "book a flight". While it is hard to identify the keywords for an unlabeled utterance, randomly replacing a small amount of tokens in it with some random tokens from the library will not affect intent semantics much. This approach works well in our experiments (See Table 5 RTR).

Advantages of CLNN. By introducing the notion of neighborhood relationship in contrastive learning, CLNN can 1) pull together similar instances and push away dissimilar ones to obtain more compact clusters; 2) utilize proximity in the embedding space rather than assigning noisy pseudo-labels (Van Gansbeke et al., 2020); 3) directly optimize in the feature space rather than clustering logits as in Van Gansbeke et al. (2020), which has been proven to be more effective by Rebuffi et al. (2020); and 4) naturally incorporate known intents with the adjacency matrix.

4 Experiment

4.1 Experimental Details

Datasets. We evaluate our proposed method on three popular intent recognition benchmarks. **BANKING** (Casanueva et al., 2020) is a fine-grained dataset with 77 intents collected from banking dialogues, **StackOverflow** (Xu et al., 2015) is a large scale dataset collected from online queries, **M-CID** (Arora et al., 2020) is a smaller dataset collected for Covid-19 services. We choose **CLINC150** (Larson et al., 2019) as our external public intent dataset in stage 1 due to its high-quality annotations and coverage of diverse domains. The dataset statistics are summarized in Table 1. We use the same splits of BANKING and StackOverflow as in Zhang et al. (2021b). Details about dataset splitting are provided in the Appendix.

Experimental Setup. We evaluate our proposed method on both unsupervised and semi-supervised NID. *Notice that in unsupervised NID, no labeled utterances from the current domain are provided.* For clarity, we define two variables. The proportion of known intents is defined as $|\mathcal{C}_k|/(|\mathcal{C}_k|+|\mathcal{C}_u|)$ and referred to as "**known class ratio (KCR)**", and the proportion of labeled examples for each known intent is denoted as "**labeled ratio (LAR)**". The labeled data are randomly sampled from the original training set. Notice that, KCR $= 0$ means unsupervised NID, and KCR > 0 means semi-supervised NID. In the following sections, we provide experimental results for both unsupervised NID and semi-supervised NID with KCR $= \{25\%, 50\%, 75\%\}$ and LAR $= \{10\%, 50\%\}$.

Evaluation Metrics. We adopt three popular evaluation metrics for clustering: normalized mutual information (NMI), adjusted rand index (ARI), and accuracy (ACC).

Baselines and Model Variants. We summarize the baselines compared in our experiments for both unsupervised and semi-supervised NID. Our

Table 3: Performance on semi-supervised NID with different known class ratio. The LAR is set to 10%. For each dataset, the best results are marked in bold. **Comb** denotes the baseline method combined with our proposed MTP.

implementation is based on Zhang et al. (2021b).[1]

- **Unsupervised baselines.** (1) GloVe-KM and (2) GloVe-AG are based on GloVe (Pennington et al., 2014) embeddings and then evaluated with k-means (MacQueen et al., 1967) or agglomerative clustering (Gowda, 1984) respectively. (3) BERT-KM applies k-means on BERT embeddings. (4) SAE-KM adopts k-means on embeddings of stacked auto-encoder. (5) Deep Embedding Clustering (SAE-DEC) (Xie et al., 2016) and (6) Deep Clustering Network (SAE-DCN) (Yang et al., 2017) are unsupervised clustering methods based on stacked auto-encoder.

- **Semi-supervised baselines.** (1) BERT-KCL (Hsu et al., 2018) and (2) BERT-MCL (Hsu et al., 2019) employs pairwise similarity task for semi-supervised clustering. (3) BERT-DTC (Han et al., 2019) extends DEC into semi-supervised scenario. (4) CDAC+ (Lin

---

[1] For fair comparison, the baselines are re-run with TEXTOIR: `https://github.com/thuiar/TEXTOIR`, and hence some results are different from those reported in Lin et al. (2020); Zhang et al. (2021c).

Figure 4: Ablation study on the effectiveness of MTP. The LAR is set to 10%. SUP stands for supervised pre-training on internal labeled data only. The three columns correspond to results in the three metrics respectively.

et al., 2020) employs a pseudo-labeling process. (5) Deep Aligned Clustering (DAC) (Zhang et al., 2021c) improves Deep Clustering (Caron et al., 2018) by aligning clusters between iterations.

- Our model variants include MTP and MTP-CLNN, which correspond to applying k-means on utterance representations learned in stage 1 and stage 2 respectively. Further, we continue to train a DAC model on top of MTP to form a stronger baseline MTP-DAC for semi-supervised NID.

Implementation. We take pre-trained *bert-base-uncased* model from Wolf et al. (2019)[2] as our base model and we use the *[CLS]* token as the BERT representation. For MTP, we first train until convergence on the external dataset, and then when training on $D_{\text{known}}^{\text{labeled}}$, we use a development set to validate early-stopping with a patience of 20 epochs following Zhang et al. (2021c). For contrastive learning, we project a 768-d BERT embedding to an 128-d vector with a two-layer MLP and set the temperature as 0.07. For mining nearest neighbors, we use the inner product method provided by Johnson et al. (2017)[3]. We set neighborhood size $K = 50$ for BANKING and M-CID, and $K = 500$ for StackOverflow, since we empirically find that the optimal K should be roughly half of the average size of the training set for each class (see Section 4.4). The neighborhood is updated every 5 epochs. For data augmentation, the random token replacement probability is set to 0.25. For model optimization, we use the AdamW provided by Wolf et al. (2019). In stage 1, the learning rate is set to $5e^{-5}$. In stage 2, the learning rate is set to $1e^{-5}$ for BANKING and M-CID, and $1e^{-6}$ for StackOverflow. The batch sizes are chosen based on available GPU memory. All the experiments are conducted on a single RTX-3090 and averaged over 10 different seeds. More details are provided in the Appendix.

4.2 Result Analysis

Unsupervised NID. We show the results for unsupervised NID in Table 2. First, comparing the performance of BERT-KM with GloVe-KM and SAE-KM, we observe that BERT embedding performs worse on NID even though it achieves better performance on NLP benchmarks such as GLUE, which manifests learning task-specific knowledge is important for NID. Second, our proposed pre-

(d) (e) (f)

Figure 5: Analysis on the number of nearest neighbors in CLNN for unsupervised NID. Vertical dashed lines correspond to our empirical estimations of optima. Horizontal dashed lines represent the results of only training with MTP. When the number of nearest neighbors is 0, we simply augment the same instance twice as in conventional contrastive learning (Chen et al., 2020). The three columns correspond to results in the three metrics respectively.

training method MTP improves upon baselines by a large margin. Take the NMI score of BANKING for example, MTP outperforms the strongest baseline SAE-DCN by 14.38%, which demonstrates the effectiveness of exploiting both external public datasets and unlabeled internal utterances. Furthermore, MTP-CLNN improves upon MTP by around 5% in NMI, 10% in ARI, and 10% in ACC across different datasets.

Semi-supervised NID. The results for semi-supervised NID are shown in Table 3. First, MTP significantly outperforms the strongest baseline DAC in all settings. For instance, on M-CID, MTP achieves 22.57% improvement over DAC in NMI. Moreover, MTP is less sensitive to the proportion of labeled classes. From KCR = 75% to KCR = 25% on M-CID, MTP only drops 8.55% in NMI, as opposed to about 21.58% for DAC. The less performance decrease indicates that our pre-training method is much more label-efficient. Furthermore, with our proposed contrastive learning, MTP-CLNN consistently outperforms MTP and the combined baseline MTP-DAC. Take BANKING with KCR = 25% for example, MTP-CLNN improves upon MTP by 4.11% in NMI while surpassing MTP-DAC by 2.63%. A similar trend can be observed when LAR = 50%, and we provide the results in the Appendix.

Visualization. In Fig. 3, we show the t-SNE visualization of clusters with embeddings learned by two strongest baselines and our methods. It clearly shows the advantage of our methods, which can produce more compact clusters. Results on other datasets can be found in the Appendix.

4.3 Ablation Study of MTP

To further illustrate the effectiveness of MTP, we conduct two ablation studies in this section. First, we compare MTP with the pre-training method employed in Zhang et al. (2021c), where only internal labeled data are utilized for supervised pre-training (denoted as SUP).[4] In Fig. 4, we show the results of both pre-training methods combined with CLNN with different proportions of known classes. Notice that when KCR = 0 there is no pre-training at all for SUP-CLNN. It can be seen that MTP-CLNN consistently outperforms SUP-CLNN. Furthermore, the performance gap increases while KCR decreases, and the largest gap is achieved

---

[4] Notice that we make a simple modification to their pre-training to optimize the entire model rather than the last few layers for fair comparison.

	BANKING		StackOverflow		M-CID	
Methods	NMI	ARI	NMI	ARI	NMI	ARI
PUB-CLNN	75.69	44.58	42.22	24.77	73.64	56.94
MLM-CLNN	77.02	47.79	78.62	**68.77**	71.28	53.28
MTP-CLNN	**81.80**	**55.75**	**78.71**	67.63	**79.95**	**66.71**

Table 4: Ablation study of MTP for unsupervised NID.

when KCR $= 0$. This shows the high effectiveness of our method in data-scarce scenarios.

Second, we decompose MTP into two parts: supervised pre-training on external public data (PUB) and self-supervised pre-training on internal unlabeled data (MLM). We report the results of the two pre-training methods combined with CLNN as well as MTP in Table 4. We can easily conclude that either PUB or MLM is indispensable and multi-task pre-training is beneficial.

4.4 Analysis of CLNN

Number of Nearest Neighbors. We conduct an ablation study on neighborhood size K in Fig. 5. We can make two main observations. First, although the performance of MTP-CLNN varies with different K, it still significantly outperforms MTP (dashed horizontal line) for a wide range of K. For example, MTP-CLNN is still better than MTP when $K = 50$ on StackOverflow or $K = 200$ on BANKING. Second, despite the difficulty to search for K with only unlabeled data, we empirically find an effective estimation method, i.e. *to choose K as half of the average size of the training set for each class*[5]. It can be seen that the estimated $K \approx 60$ on BANKING and $K \approx 40$ on M-CID (vertical dashed lines) lie in the optimal regions, which shows the effectiveness of our empirical estimation method.

Exploration of Data Augmentation. We compare Random Token Replacement (RTR) used in our experiments with other methods. For instance, dropout is applied on embeddings to provide data augmentation in Gao et al. (2021), randomly shuffling the order of input tokens is proven to be effective in Yan et al. (2021), and EDA (Wei and Zou, 2019) is often applied in text classification. Furthermore, we compare with a Stop-words Replacement (SWR) variant that only replaces the stop-words with other random stop-words so it minimally affects the intents of utterances. The results in Table 5 demonstrate that (1) RTR and SWR consistently outperform others, which verifies our hypothesis in Section 3.2. (2) Surprisingly, RTR and SWR perform on par with each other. For simplicity, we only report the results with RTR in the main experiments.

	BANKING		StackOverflow		M-CID	
Methods	NMI	ARI	NMI	ARI	NMI	ARI
dropout	79.52	50.83	75.60	57.67	79.64	66.14
shuffle	79.02	49.72	75.70	58.95	79.68	66.09
EDA	78.29	49.02	71.50	49.80	79.73	66.39
SWR(Ours)	82.03	56.18	78.48	67.15	79.23	65.74
RTR(Ours)*	81.80	55.75	78.71	67.63	79.95	66.71

Table 5: Ablation study on data augmentation for unsupervised NID. * is the method used in the main results.

5 Conclusion

We have provided simple and effective solutions for two fundamental research questions for new intent discovery (NID): (1) how to learn better utterance representations to provide proper cues for clustering and (2) how to better cluster utterances in the representation space. In the first stage, we use a multi-task pre-training strategy to exploit both external and internal data for representation learning. In the second stage, we perform contrastive learning with mined nearest neighbors to exploit self-supervisory signals in the representation space. Extensive experiments on three intent recognition benchmarks show that our approach can significantly improve the performance of NID in both unsupervised and semi-supervised scenarios.

There are two limitations of this work. (1) We have only evaluated on balanced data. However, in real-world applications, most datasets are highly imbalanced. (2) The discovered clusters lack interpretability. Our clustering method can only assign a cluster label to each unlabeled utterance but cannot generate a valid intent name for each cluster.

6 Acknowledgments

We would like to thank the anonymous reviewers for their valuable comments. This research was supported by the grants of HK ITF UIM/377 and PolyU DaSAIL project P0030935 funded by RGC.

---

[5] We presume prior knowledge of the number of clusters. There are some off-the-shelf methods that can be directly applied in the embedding space to determine the optimal number of clusters (Zhang et al., 2021c).

A Experimental Details

A.1 Datasets

In this section, we provide more details about the datasets. The development sets are prepared to exclude no unknown intents.

- **BANKING** (Casanueva et al., 2020) is a fine-grained intent detection dataset in which 77 intents are collected for banking dialogue system. The dataset is splitted into 9,003, 1,000 and 3,080 for training, validation, and test sets respectively.
- **StackOverflow** (Xu et al., 2015) is a large scale dataset for online questioning which contains 20 intents with 1,000 examples in each class. We split the dataset into 18,000 for training, 1,000 for validation, and 1,000 for test.
- **M-CID** (Arora et al., 2020) is a small scale dataset for cross-lingual Covid-19 queries. We only use the English subset of this dataset which has 16 intents. We split the dataset into 1,220 for training, 176 for validation, and 349 for test.
- **CLINC150** (Larson et al., 2019) consists of 10 domains across multiple unique services. We use 8 domains [6] and remove the out-of-scope data. We only use this dataset during training stage 1.

A.2 Implementation

The batch size is set to 64 for stage 1 and 128 for stage 2 in all experiments to fully utilize the GPU memory. In stage 1, we first train until convergence on external data and then train with validation on internal data. In stage 2, we train until convergence without early-stopping.

A.3 More Experimental Results

The results on semi-supervised NID when $LAR = 50\%$ are shown in Table 6. It can be seen that our methods still achieve the best performance in this case. In Fig. 6 and Fig. 7, we show the t-SNE visualization of clusters on BANKING and M-CID with embeddings learned by two strongest baselines and our methods. Again, it shows that our methods can produce more compact clusters.

---

[6] The domains “Banking” and “Credit Cards” are excluded because they are semantically close to the evaluation data.

Modeling U.S. State-Level Policies by Extracting Winners and Losers from Legislative Texts

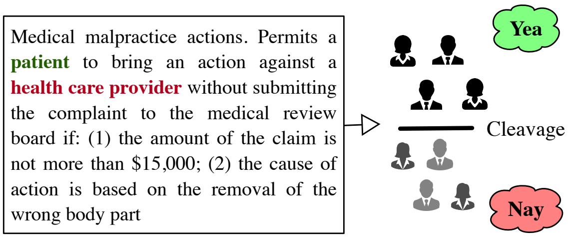
Abstract

Decisions on state-level policies have a deep effect on many aspects of our everyday life, such as health-care and education access. However, there is little understanding of how these policies and decisions are being formed in the legislative process. We take a data-driven approach by decoding the impact of legislation on relevant stakeholders (e.g., teachers in education bills) to understand legislators' decision-making process and votes. We build a new dataset for multiple US states that interconnects multiple sources of data including bills, stakeholders, legislators, and money donors. Next, we develop a textual graph-based model to embed and analyze state bills. Our model predicts winners/losers of bills and then utilizes them to better determine the legislative body's vote breakdown according to demographic/ideological criteria, e.g., gender.

1 Introduction

State-level legislation is the cornerstone of national policies and has long-lasting effects on residents of US states. Thus, decoding the processes that shape state bills is crucial yet involved. State legislatures vote on 23 times more bills than Federal legislatures, exceeding 120K bills per year (King, 2019). In addition, these state bills cover a broader range of local problems as each state possesses lawmaking power effective within its boundaries. E.g., the State of Washington Health Care Committee addresses health service issues including licensing and regulation of health care facilities and providers. Moreover, it regulates pharmacies, pharmaceutical drugs, state public health programs, and private/public insurance markets (House, 2021).

We argue that recent NLP architectures can provide new insights into the state-level legislative efforts. In particular, contextualized graph and text embedding can better represent policies within and across states via a shared political context. However, most of the prior efforts are focused on analyzing congressional bills with traditional techniques, e.g., (Gerrish and Blei, 2011, 2012). A few state-level studies (Eidelman et al., 2018; Davoodi et al., 2020) took great steps in predicting the progression of state bills towards a vote on the floor and the breakdown of votes based on demographic metrics (e.g., gender). But their main downside is they evaluate policies in a limited context and do not capture cross-state patterns.



Medical malpractice actions. Permits a **patient** to bring an action against a **health care provider** without submitting the complaint to the medical review board if: (1) the amount of the claim is not more than $15,000; (2) the cause of action is based on the removal of the wrong body part

Figure 1: *A health bill leading to voting cleavage based on the party metric primarily due to its specific losers (red) and winners (green).*

Winners-Losers analysis. In this work, we take a new data-driven approach to analyzing state legislation. Our key insight is that each state bill inevitably produces some *winners* and *losers* to provide practical solutions to specific in-state and local problems. Thus, we argue that it is important to examine state bills in the larger context of their impact on different population segments as well as commercial and professional stakeholders. To help clarify this idea, consider the example in Figure 1. This state bill makes it easier for patients (*winners)* to take legal actions against healthcare providers (*losers*). This analysis of *winners and losers (WLs)* can foster transparency in legislative efforts in each state, while interconnecting different states through common stakeholders and revealing cross-state patterns. In addition, the context of WLs can enable a new category of NLP models for predicting the roll-call behavior of legislators.

Downstream bill classification tasks. For instance, the political science community sees tremendous value in predicting voting cleavages,

a) Competitive b) Inverse-Competitive

Figure 2: *Two types of gender-based voting cleavages.*

based on the ideological and demographic identities of legislators (Section 2). Each of such metrics (e.g., party, gender, district, ideology) splits legislators into groups. Measuring lack of consensus within and across these groups, which has political and social benefits, can be done using two classification tasks (Section 5): For a given metric, we say a bill is *competitive* (Figure 2) if the majority vote of legislators from a group (e.g., Democrat, male, urban, liberal) is different from that of the opposite group (e.g., Republican, female, rural, conservative). Similarly, a bill is *inverse-competitive* if there is a tie in votes of members of the same group (e.g., liberals). For instance, the health bill in Figure 1 resulted in a party competitive vote. Another example is a state bill on abortion that *"requires... physician performing an abortion to admitting privileges at a hospital in the county"* resulted in a gender competitive vote. We show the context of winners/losers of these bills could hint at such cleavages prior to voting (Sections 4, 6).

Framework overview. To achieve this goal, we address multiple NLP challenges in our proposed framework: *(1) Data:* The legislative process in US states does not track the stakeholders of bills and the impact of bills on them. Thus, we design a reliable crowd-sourcing pipeline to extract and analyze winners and losers of state bills from their text and form a new annotated dataset. *(2) Modeling:* To automate the WL analysis, next, we provide a nationwide graph abstraction to model the state legislative process, as well as a joint text and graph embedding architecture for predicting winners and losers. Our model captures the interplay of different entities, e.g., bills, stakeholders, legislators, and money donors, while maintaining dependencies between their textual attributes. We leverage RGCN (Schlichtkrull et al., 2018), a relational graph convolutional network, to represent diverse relations. We also adopt the RoBERTa transformer (Liu et al., 2019) after performing domain-adaptive pretraining on political texts using the MLM (Masked Language Model) task. *(3) Application:* Finally, we showcase the ability of our WL analysis and prediction model in decoding the voting behavior of state legislators. In summary, we make three *technical contributions*:

- We provide the first definition and realization of winners/losers analysis for state bills using the latest NLP advances. (Sections 2, 3, 4).
- We developed a new joint graph and text embedding model that both predicts winners/losers of bills and legislators' votes. In particular, it incorporates the winners/losers inference into the vote prediction task, to evaluate bills in a broader context (Section 5).
- We operationalized the winners/losers analysis for several legislative topics (e.g., health) and created a new dataset. The extensive evaluation shows our approach delivers a higher F1, than existing models (Sections 3, 6)

2 Related Works

Our work is inspired by some promising studies:

Roll-call classification. Eidelman et al. 2018 associate the bill's text with partisan information of its sponsors to predict the likelihood of a member of the U.S. Congress voting in support of a bill. Similarly, Gerrish and Blei 2011 embed the combined topic and text of Congress bills in the ideological space and develop ideal point models for inferring votes. Peng et al., 2016; Kornilova et al., 2018; Kraft et al., 2016; Patil et al., 2019; Karimi et al., 2019; Pujari and Goldwasser, 2021 augment this model using data on social networks, thus generating better embeddings.

Bill text classification. Instead of leveraging bill text in models to describe the behavior of each legislator, Yano et al. 2012 include the bill's text in a model that directly predicts whether a bill comes out from a standing committee. Particularly, they develop features based on the urgency of the problem being solved by the bill and the set of legislators co-sponsoring the bill. Eidelman et al. 2018 conduct a similar study on US states.

Winners-losers analysis. Analyzing the impact of bills on its stakeholders is a well-studied topic in the political science literature. Gamm and Kousser, 2010 reveal state legislators are more likely to write bills aimed at a particular local stakeholder when the legislative body is dominated by one party. Similarly, Bagashka and Clark, 2016 show state legislators are motivated to introduce particularistic bills designed to help a specific geographical area within their district. Pennock, 1979 analyzes legislation based on its generalized and particularized impact on different interest groups. By leveraging recent NLP advances (e.g., contextualized language models, graph embedding, crowdsourcing), our work extends these studies and provides the first automated framework for the stakeholders analysis on state bills.

Voting cleavages. Research has covered multiple ways that the demographic background of legislators can affect roll-call voting. Frederick 2010 demonstrates gender affects the roll-call vote in the Senate by changing the influence of partisanship for GOP women. Broach 1972 describes that urban-rural voting cleavages happen in less partisan states and on bills that separate urban and rural interests. Similar to us, Davoodi et al. 2020 build a textual graph to predict such cleavages. While our focus is on a different problem, stakeholders analysis, we outperform this prior study by representing bills in a broader context containing their stakeholders.

Graph embedding in NLP. Our work uses Graph convolutional networks (GCNs), which have been applied to various NLP tasks, e.g., Semantic role labeling (SRL) (Marcheggiani and Titov, 2017) and relation classification in clinical narratives (Li et al., 2018). In these tasks, GCNs encode the syntactic structure of sentences. Similarly, Defferrard et al., 2016; Peng et al., 2018; Henaff et al., 2015 use graph neural networks (GNNs) to represent a network of documents based on their references. Similar to our work but for a different problem and objective, Sawhney et al., 2020 analyze speech-level stance of members of the parliament, by performing node classification on graph attention networks (GATs), and Pujari and Goldwasser, 2021 analyze social media content generated by politicians using a graph transformer model.

3 Modeling

We first provide an overview of key players in the state-level legislative process. Then, we model them using an efficient text-based graph abstraction (Figure 3), which will enable us to embed and evaluate state policies in a broad context and perform the stakeholder and roll-call analysis on them.

3.1 Players in State Legislative Process

Our model, unlike prior works, fully captures the interplay of main players in the lawmaking process:

1. Legislators. A state legislature typically consists of two “chambers” [1]: the House and the Senate. The legislative process starts with legislators sponsoring a bill in a chamber. The idea of a bill can come from different sources. Next, the bill goes through multiple roll-call votes in the origin chamber, where it can fail at any stage. It is first referred to the proper committee by the chamber leader. Committee members, before casting their votes, may set up a public hearing with the sponsors and interested parties. If the bill passes out of the committee, it reaches the second reading, where the full chamber debates, amends, and votes on the bill. If the bill passes by a majority vote, it is scheduled for the third reading and final vote. A bill must go through a similar procedure in the other chamber before it is acted on by the governor.

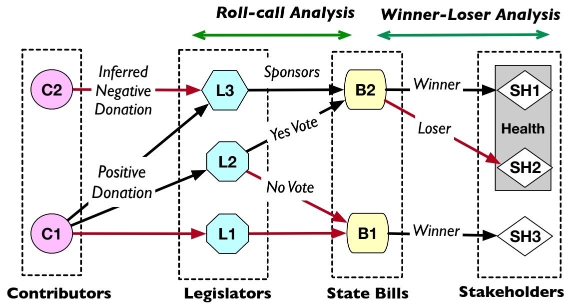

Figure 3: Nationwide, Heterogeneous, and multi-relational graph abstraction for analysis and prediction of winners-losers and roll-calls.

2. Contributors. While legislators navigate through bills, external contributors influence their decisions. Individual and corporate money donors aim at developing changes in the outcome and theme of bills starting from the election times. Lobbyists launch campaigns to persuade legislators towards certain policies. Such efforts inevitably lead to new bills or amendments to existing laws.

3. Stakeholders. A state bill cannot benefit everyone and it produces beneficial or detrimental effects on its stakeholders. Identifying winners and losers of a bill from its text is crucial, which can hint at the fate of a bill. Particularly, legislators do not always write bills themselves. Corporations and interest groups (e.g., ALEC) sell fill-in-the-blank bills to legislators. Thus, we can see voting patterns on bills with the same winners and losers.

---

[1] Nebraska’s legislature is unique in the nation because it has a single-house system.

3.2 Nationwide, Multi-Relational, and Heterogeneous Legislative Graph

To model these players and their interactions, we design a legislative graph with three important properties (Figure 3). First, since each of the players (e.g., stakeholders, legislators) has different textual attributes, our proposed graph supports heterogeneous textual nodes. Second, we form a nationwide graph to capture cross-state patterns (ablation study in Appendix A.2) by building common entities (e.g., stakeholders in Section 4). Finally, our abstraction supports multiple relations between each pair of entities (e.g., legislators voting and sponsoring a bill). With this overview, we present the nodes and relations that we will realize based on the real data:

Node types. The nodes in the legislative graph contain a rich set of textual features: *(1) Bill* nodes embed title, abstract, and body of state bills. *(2) Stakeholder* nodes come with short texts on political interests and constituent entities of stakeholders of policies in bills (will be detailed shortly). *(3) Legislator* nodes contain diverse textual information on legislators, e.g., their biography, political interests, committee assignments, and demographic profile (e.g., party, gender, ideology, and district). *(4) Contributors* nodes have text-based attributes on money donors covering their specific/general business interests, party, and their type (individual or non-individual).

Relation types. Based on the legislative process, legislator and bill nodes participate in *Bill Sponsorship*, *'No' Vote*, and *'Yes' Vote* relations in the graph (See Appendix A.4 for handling abstain votes.) A stakeholder node forms *Winner*, *Loser*, or *Neutral* relations with a bill node, which we will extract it based on the bill text. Similarly, we form two types of relations between contributors and legislators: *Positive Donation* realized based on the real donation data, and *Negative Donation*, which we infer when a contributor shows a lack of interest in a demographic of legislators (e.g., never donates to women). We sample and connect such legislators and the contributor via a negative relation.

4 Data-Driven Stakeholders Analysis

Next, we describe how we build up the legislative graph, by collecting data on legislators, bills, and contributors. US states do not record the impact of bills on relevant stakeholders. Thus, we explain how to derive stakeholders from bill nodes, perform winners-losers analysis on them, and interconnect different US states by forming common stakeholder nodes. We highlight how our analysis can be used (1) to inform the public about the dynamic and direction of state policies, and (2) to determine legislators' roll-call behavior with different demographic and ideological profiles.

4.1 Data Collection & Bootstrapping Graph

Bills. From the LegiScan website (LegiScan, 2019), we collected data on bills introduced in Indiana, Oregon, and Wisconsin from 2011 through 2018 (details in Appendix 7). We developed a crawler that uses the LegiScan API to fetch legislative information on every bill, including: (1) bill metadata, e.g., the bill type, title, description, sponsors, and links to its texts; (2) vote metadata, e.g., legislator's roll-call vote; and (3) legislator metadata, e.g., party and district info. Then, our crawler converts bill texts in PDF format to text files. In total, we collected ∼35k bills and sampled 58% of them that had both roll-call data and full texts. Our focus is on the 2nd/3rd reading, in which the full chambers vote, so we selected 32% of the bills for building the legislative graph (Table 1). In LegiScan, each bill is associated with a main topic (e.g., health), used for referral to a proper committee. For the four most frequent topics (Table 2), we will define a group of generic stakeholders for the winners-losers analysis.

Legislators. Our crawler also used Ballotpedia (Ballotpedia, 2019) to collect text information on each legislator's biography, political interests, and committee assignments. Also, it consumed other publicly available datasets to identify a legislator's demographic profile, e.g., ideology, gender, and district. The ideology scores for legislators (Shor and McCarty, 2011) were grouped into conservatives, moderates, and liberals. The district identifier was combined with GIS census data (Census, 2019) to identify each legislator as representing an urban or

Table 4: *Stakeholders of different bill topics and their frequency distribution as winners (W) and losers (L).*

rural district. Table 3 summarizes the distribution of legislators' demographic profile.

Contributors: FollowTheMoney (FollowTheMoney, 2019) records donations to state legislators and candidates. Our crawler collected the information of donors for each legislator in our dataset (See Table 1). This includes multiple textual attributes for each contributor: type (individual or non-individual), general party, and economic and business information. While the contributor data can be utilized in more sophisticated ways, we focused on major contributors by setting a minimum donation threshold and pruning donors who contributed to a single legislator; We set the fraction of negative donations (Section 3) to 30% of the positive ones extracted from the data.

4.2 Stakeholders Extraction & Annotation

For each select bill topic, we (authors) randomly sampled 10% of bills and carefully analyzed their texts. We recorded entities discussed in the bill texts as well as the detrimental or beneficial impact of the suggested policies on them (regardless of the legislative outcome, i.e., passed in a vote or not). To interconnect different states and optimize the legislative graph, we deduplicated entities and clustered those whose interests align (e.g., surgeons, doctors, dentists, and etc.) into generic ones (e.g., healthcare providers). Table 4 shows the final list of stakeholders for the select topics. With detailed annotation guidelines, we leveraged Amazon MTurk for labeling ∼4k bill texts from these topics (Table 2), where 3-5 workers identified the effect of the suggested policies in each bill on the relevant stakeholders. As will be detailed in Appendix A.1, we ensured the accuracy of the labeled data is 90%+.

4.3 Benefits of Winners-Losers Analysis

Based on the outcomes of the previous two steps, we formed a legislative graph for our target states. We briefly provide two results from the winners-losers analysis on the graph to highlight its importance. First, we show the frequency distribution of the stakeholders as a winner vs. a loser for each topic in Table 4, which would inform the public about the dynamics and directions of state-level policies. E.g., under the education topic, students were the largest winners, while educational institutions were the major losers. For law bills, law enforcement agencies were the top losers given the recent nationwide focus on police use of force.

Legislator Profiles		Education Companies	Educational Institutions	State Edu. Agencies	Teachers, Edu. Workers	Students
Party	*Democrat*	-7.0	-4.0	1.0	6.0	-3.0
	Republican	18	1.0	-14.0	-1.0	24.0
Geography	*Rural*	-3.3	-4.3	1.0	5.9	-2.8
	Urban	4.7	-2.3	-6.3	2.5	9.9
Gender	*Male*	1.8	-3.3	-4.2	3.8	5.6
	Female	4.9	-2.2	-7.7	2.2	12.7
Ideology	*Liberal*	-3.1	-6.3	3.6	4.7	-3.9
	Moderate	14.4	3.2	-5.2	2.0	5.9
	Conservative	-7.4	-5.1	-22.3	5.5	28.1

Table 5: *Capturing policy preferences of different demographic and ideological groups of legislators on education bills, by measuring the change in the rate (%) of 'yes' vote when a stakeholder is a winner and a loser.*

Also, our winners-losers analysis captures the policy preferences of different ideological and demographic groups of legislators. For example, Democrats are more likely to support legislation benefiting teachers, compared to Republicans (GOP). This fact is also reflected in our models predicting voting cleavages in Section 6 (e.g., our naive model, WL-Correlation, outperforming other models in its category). Here, to motivate the need for building such models, we are interested in measuring the rate of 'Yes' votes from each demographic and ideological group of legislators on bills of a given topic, where a stakeholder is a loser and a winner. E.g., on education bills benefiting a stakeholder (e.g., Students) as a winner, we compute, A = [# of yes votes]/[total # of votes] in the GOP legislators. Similarly, on educations bills, where this stakeholder is a loser, we calculate B = [# of yes votes]/[total # of votes] for GOP. We then report the difference, A-B, in Table 5, where a large positive value indicates the stakeholder is being advantaged by the respective group of legislators. E.g., we see GOP has significantly more Yes votes when students are winners, compared to Yes votes when students are losers. By running queries on the legislative graph containing all players (e.g., donors), we were able to see the voting behavior of GOP could be motivated by major donations to this party from corporations representing students (e.g., School Choice).

5 Embedding & Prediction Architecture

The stakeholder analysis based on human data annotation is expensive and time-consuming. To automate the analysis and better leverage its results in other applications, we build up a contextualized embedding architecture and define two classification tasks on the legislative graph:

5.1 Classification Tasks on Legislative Graph

Task 1: winners-losers prediction. Our first task is to predict the relation between a bill node and each relevant stakeholder node (based on its topic in Table 4). Such predicted relations will bring valuable insights into the bills, while also clarifying legislators' roll-call behavior (Section 6). Thus, we define the next task to showcase these benefits.

Task 2: bill cleavage and survival prediction. For a bill, we predict if (1) it shows identifiable voting cleavages and (2) it can advance by getting a pass. We achieve these by predicting and aggregating roll-call relations (between legislators and bills) in the graph. In particular, we assign 9 labels to each bill: *(1) Competitive labels*: For voting cleavages, we split legislators into groups based on their demographic and ideological profiles (party, gender, ideology, and the urban/rural nature of their district as defined in Section 4). For an attribute (e.g., gender), we say a voting round is "competitive" if the majority of legislators from one group (e.g., Women) and the majority of the opposite group (e.g., Men) cast different votes (Figure 2a). *(2) Inverse-competitive labels*: Similarly, for an attribute (e.g., gender), a voting round is inverse-competitive if we identify a partial or complete tie (Appendix A.4) in the vote of legislators of the same group (e.g., Men in Figure 2b). *(3) Survival label*: Finally, a bill passes its current voting round by getting a majority vote.

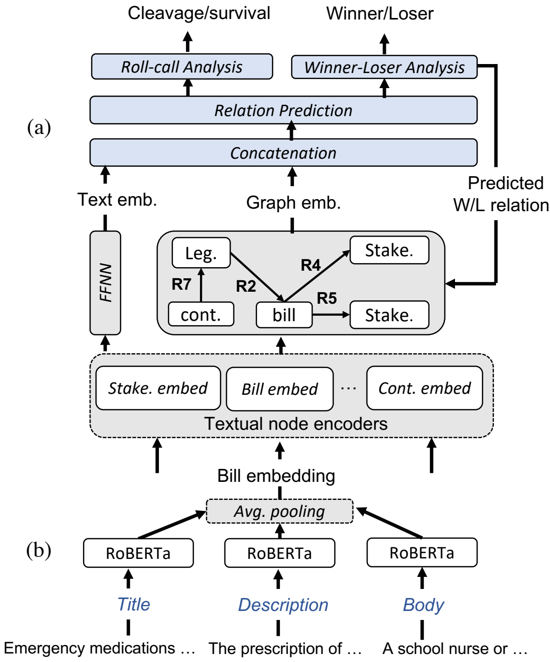

Figure 4: *Joint text-graph embedding model for shared prediction of winners/losers and roll-calls in the legislative graph using RGCN & pretrained RoBERTa.*

5.2 Overview of Embedding & Training

At a high-level, we propose a unified model to jointly embed and classify both roll-call and winner-loser relations in the legislative graph (Figure 4a): (a) We first train our model to predict relations between bill nodes and their stakeholders. One can use the result of this stage for further analysis of state policies (e.g., Section). (b) Our key insight is that knowing winner-loser relations enhances the embedding of nodes in the legislative graph. Thus, we conduct inference on bills that lack such relations (if any) using the pretrained model from step (a) and add these predicted relations to the graph. (c) Next, continue training on the updated graph to fine-tune the model for the roll-call (vote) prediction task. Finally, we aggregate the predicted votes for the bill cleavages/survival analysis. In all these steps, our model generates and jointly optimizes both text and graph embeddings for each node, and consumes them to classify the two types of relations. Thanks to jointly optimizing the tasks over the textual and graph information, our architecture outperforms existing models (Section 6). Hereafter, we detail the layers in our model using a bottom-up approach:

5.3 Contextualized Text Embedding Layers

The lower half of our model generates a contextual embedding for textual attributes of nodes in the legislative graph. We leverage the RoBERTa architecture (Liu et al., 2019). For improved performance, one of our contributions is that we will pretrain RoBERTa on unlabeled bill texts using the MLM task (Section 6). In more detail, for each *bill* node, we feed three pieces of textual information to RoBERTa: title, abstract, and body. RoBERTa does not support input sequences longer than 512 tokens. Thus, we take the representation of each of these components separately (the embedding of their [CLS] token) and do average pooling to output the final representation of the bill. Similarly, the text embedding of *stakeholder*, *legislator*, and *contributor* nodes are the average of the vectors representing their key textual attributes (Section 4).

5.4 Relational Graph Convolutional Layers

On top of the text embedding layer, we place a Relational Graph Convolutional Network (RGCN) to create a graph embedding for each node. The RGCN uses the text embedding of each node to initialize its graph representation. In parallel, we build a feed-forward neural network (FFNN), taking the text embeddings of nodes to a concatenation layer for our joint text-graph optimization. The (non-relational) GCN has multiple layers and each layer performs two operations: *propagation* and *aggregation*. In the propagation, nodes update their neighbors by sharing their features or hidden states. In the aggregation, each node adds up the messages coming to it to update its representation. In GCN, at layer $l+1$, the hidden representation of node i, ${h_i}^{l+1}$, with neighbours N_i is:

$$ {h_i}^{l+1} = \sigma\left(\sum_{j \in N_i} \frac{1}{c_i} W^l h_j^l\right) \qquad (1) $$

GCN uses the same weight matrix in each layer, W^l, and normalization factor, $c_i = |N_i|$, for all relation types in a graph. We choose RGCN as it uses unique parameters for each relation type, thus better handling our multi-relational graph. In RGCN, the embedding of node i in layer $(l+1)$ is:

$$ {h_i}^{l+1} = \sigma\left(W_0^l h_i^l + \sum_{r \in R} \sum_{j \in N_i^r} \frac{1}{c_{i,r}} W_r^l h_j^l\right) \qquad (2) $$

A 3-layer RGCN turns out to be sufficient in our case to capture the 3rd order relations between contributors and stakeholder nodes.

5.5 Relations Prediction Layers

By combining the outputs of the RGCN and FFNN, we train a relation classification layer by using the DistMult scoring function (Schlichtkrull et al., 2018; Yang et al., 2014). For each relation (s, r, d) being predicted, this layer computes $f(s, r, d) = e_s^T W_r e_d$. e_s and e_r are the joint text and graph embeddings of the source and destination nodes and w_r is a diagonal relational weight matrix. Our loss function is $L = L_{CLS} + L_{Text} + L_{Graph}$ enabling us to jointly optimize the text and graph embeddings as well as the relation prediction. L_{CLS} is the cross-entropy loss of the relation classification; L_{Graph} and L_{Text} are the L2 regularization of RGCN's and FFNN's weights, optimizing the graph and text representations, respectively.

6 Experiments

We first evaluate the efficiency of our legislative graph abstraction and text+graph embedding model in the winners-losers prediction. Then, we show the benefits of our combined inference of stakeholders and roll-calls in decoding state bills.

6.1 Experimental Setup

Data Split and metric. We split the legislative graph (Formed in Section 4) based on bill nodes. We randomly select 20% of the bills for testing and keep the rest for training and validation. We study three settings in terms of the winners-losers (stakeholders) information in the graph: (a) *Unknown* winners-losers relations. (b) *Known* relations based on our human-labeled annotation. (c) *Predicted:* 30% of bills in the train graph come with such relations and we predict them for the rest of bills. In Appendix A.3, we will report the results of state- and time-based splits. Finally, given our data is highly skewed, we choose Macro F1 as the main metric over accuracy.

Settings/parameters. We build our joint model (Figure 4) on top of PyTorch, DGL, and spaCy. We set the initial embedding dimension in RoBERTa and RGCN to 1024. The FFNN and RGCN take the embeddings to a 256-dimensional space. We also used Adam optimizer, and for each observed relation (Table 1), we sampled a negative example.

6.2 Baseline Models

We devise robust baselines for both of our tasks:

1. Text-based models. We build a logistic regression (LR) classifier that takes the text embedding of a bill and predicts if it shows a certain cleavage or passes/fails. A similar classifier takes the text embeddings of a bill and a stakeholder to classify their relation. We evaluate three embedding architectures: ***(a) BoW***, where unigram and bigram features (top 5K highest-scoring) are used to represent textual information. ***(b) RoBERTa*** (Liu et al., 2019). ***(c) Pretrained RoBERTa*** that we adapted its domain by applying MLM on 10K unlabeled state bills (39K sentences) (Gururangan et al., 2020). We study two additional variations of these models (only for winners-losers prediction due to limited space): ***Sponsors***, where the bill sponsors are represented using a one-hot vector and concatenated to the bill text representation. ***Roll-Call***, where we concatenate a vector containing cleavage/survival info. of each bill to its text embedding.

2. Graph-based models: We build a relation classifier over edge embeddings, generated by three widely-used graph models, to predict roll-call and winner-loser relations (for the bill cleavages/survival task, we aggregate votes): ***(a) DeepWalk*** (Perozzi et al., 2014) that generates embeddings for nodes and edges by running Skip-Gram on random walks on the graph. ***(b) GCN*** (Kipf and Welling, 2016) is a basic 3-layer GCN model with random node features in its first layer. ***(c) RGCN*** (Schlichtkrull et al., 2018) is the relational GCN handling different relation types in the legislative graph.

3. Naive models. We evaluate three naive classifiers: ***(a) Majority***: A baseline predicting the most frequent class in the train data. ***(b) Sponsor***: An LR classifier that uses the one-hot embedding of bill sponsors to determine bill survival/cleavages (similarly winner/loser relations). ***(c) WL-Correlation*** (solely for the survival/cleavage task) predicts a legislator's vote on a test bill with known winners/losers based on his historical votes on train bills with the same winners/losers.

6.3 Exp 1: *Winners-Losers Prediction*

We compare these models in predicting relations between bills and their relevant stakeholders (Table 6).

Model	*Variation*	*Embedding*	*F1*
Naive	–	*Majority*	40.3
		Sponsor	55.1
Text-based	***Vanilla***	*BoW*	66.2
		RoBERTa	69.1
		Pretrained RoBERTa	69.8
	Sponsors	*BoW*	67.7
		RoBERTa	70.2
		Pretrained RoBERTa	70.8
	Roll-call	*BoW*	66.5
		RoBERTa	68.3
		Pretrained RoBERTa	69.1
Graph-based	–	*DeepWalk*	57.4
		GCN	57.7
		RGCN	63.9
Our Joint Text + Graph	–	*RoBERTa + RGCN*	73.2
		Pretrained RoBERTa + RGCN	**74.1**

Table 6: *Performance of different models in predicting winner-loser relations between bills and stakeholders.*

(1) In the vanilla text-based category, RoBERTa shows 2.9 higher F1 than BoW. Our pretrained RoBERTa generates more efficient contextual embedding for text information of bills and stakeholders (e.g., summary), and thus better determines the impact of a bill on its stakeholders. Including the sponsors' info in the pretrained RoBERTa leads to the best text model. *(2) In the graph-based models*, Deepwalk/GCN exhibits a sharp drop in F1, by ignoring the heterogeneity of relations in the graph and thus producing inefficient representations for them. RGCN overcomes this issue and approaches the best text model with F1 of 63.9. *(3) Our joint text-graph* model combines the strengths of the graph and text models and delivers 3.3 points higher F1.

6.4 Exp 2: *Impact on Bill Cleavage Prediction*

Next, we focus on the performance of different models in determining voting cleavages/survival, with *Unknown*, *Known*, *Predicted* winners-losers in the legislative graph. In Table 7, we report the results for the bill survival and party-based voting cleavages (results for the other cleavages in Appendix, Table 11). We can make a few observations: First, our stakeholder analysis helps all models to better decode state policies, when comparing the same model in the Unknown and Known winners-losers settings: *(1) In the text-based models*, prediction on the textual information of both bills and known winners-losers delivers a higher F1 than only on the text of bills (e.g., Pretrained RoBERTa model gets a 5.4% boost in F1 in predicting party competitive bills). Similarly, *(2) In the graph-based models*: RGCN overcomes

Models			*Pass/ Fail*	*Comp. (Party)*	*Inverse Comp. (Party)*
Type	*Winner/ Loser*	*Embedding*			
Naive	***Unknown***	*Majority*	47.2	43.1	48.3
		Sponsor	50.6	52.3	53.4
	Known	*WL Correlation*	58.7	51.3	54.8
Text-based	***Unknown***	*BoW*	48.1	56.8	48.6
		Pre. RoBERTa	49.8	58.2	49.3
	Known	*BoW*	49.4	61.2	50.1
		Pre. RoBERTa	51.9	63.6	51.8
	Predicted	*BoW*	48.3	59.1	49.3
		Pre. RoBERTa	50.1	61.4	49.8
Graph-based	***Unknown***	*DeepWalk*	59.9	49.1	49.8
		GCN	60.8	50.4	48.2
		RGCN	64.3	52.8	49.8
	Known	*DeepWalk*	62.6	49.6	50.3
		GCN	63.6	52.2	50.3
		RGCN	66.3	53.7	52.4
	Predicted	*DeepWalk*	61.3	47.7	50.1
		GCN	62.3	51.2	49.5
		RGCN	65.6	52.3	52.1
Our Joint Text + Graph	***Unknown***	*Pre. RoBERTa + RGCN*	69.8	69.9	59.1
	Known		73.7	71.8	59.8
	Predicted		70.7	71.6	59.5

Table 7: *Effect of winners/losers information on the graph and text-based models in different downstream vote classification tasks. See the results for other demographic voting cleavages in Table 11.*

the limitations of Deepwalk in handling heterogeneous relation types (winner-loser vs. roll-call) and delivers consistent gains in the setting *Known*. *(3) Our model* has the best performance due to generating and optimizing a joint graph and text representation for legislators, bills, money donors, and stakeholders in the setting with known winners and losers. Second, by focusing on the models with the *Predicted* winners-losers information, we observe: *(5) Our model* still beats the other baselines, due to our unified model for roll-call and winner-loser training as well as our text-based legislative graph abstraction (Section 5). Of course, there is an expected drop in F1 across different models including ours, when we consume predicted winner-loser relations instead of human-labeled ones. This drop could be tolerable in most cases, thus not hindering the automation of our stakeholder analysis and leveraging its results in downstream vote analysis tasks (ethical considerations in Section 7).

7 Conclusion

We took a new data-driven approach to analyze state legislation in the US. We showed that identifying the winners/losers of state bills can (1) inform the public on the directions of state policies, and (2) build a nationwide context for a better understanding of legislators' roll-call behaviors. Thus, we proposed a text-based graph abstraction to model the interplay of key players in the state legislative process, e.g., bills, stakeholders, legislators, and donors to legislators' campaigns. Next, to automate our analysis, we developed a shared text and graph embedding architecture to jointly predict winners/losers of bills and legislators' votes on them. We created a new dataset using different data sources and human annotation and evaluated the strength of our architecture against existing models. We hope this work will provide a starting point for further studies examining the impact of policy decisions on individuals and groups, an important step towards making the democratic process more transparent.

Ethical Considerations

Analyzing state legislation is a sensitive task, where unexpected results of research and deployed ML systems can create misguided beliefs on the government policies on important topics (e.g., health, education). Thus, we would like to discuss some ethical aspects related to our work in terms of data and model (considering potential scenarios suggested by Chandrabose et al., 2021):

1. Selection of data sources. While there can be different inherent imbalances in the state legislature (e.g., gender and party distribution), we were not able to identify that our data sources adding systematic political and social biases to our study, e.g., towards demographic populations of legislators. All our data sources (e.g., LegiScan and FollowTheMoney) are publicly available and have been used by the political science community over the years. LegiScan (LegiScan, 2019) is a nonpartisan and impartial legislative tracking and reporting service for state bills. FollowTheMoney (FollowTheMoney, 2019) is a nonpartisan, nonprofit organization revealing the influence of campaign money on state-level elections and public policy in all US states. Finally, Ballotpedia (Ballotpedia, 2019) is a nonpartisan, nonprofit organization providing a brief introduction, biography, committee assignment, and general information on legislators across different years. Our study combined these data sources for analyzing state bills in a broad context, thus contributing to reduced *data bias* for all models evaluated in this paper.

2. Selection of states. In addition, to help mitigate the risk of data collection bias or topic preference that can be introduced through the choice of specific state legislatures, we randomly picked a "red", a "blue", and a "purple" state (indicating a significant majority for Republicans, Democrats or more balanced state legislature, respectively). There were some restrictions in terms of collecting the data from the above sources (e.g., FollowTheMoney and Ballotpedia). These data sources and services often limit the number of API calls and queries for retrieving the data for educational institutions. Besides this, annotating the data through Amazon MTurk was expensive for us so we conducted our study on four highly discussed topics in state bills (i.e., health, education, agriculture, and law). We will explore ways of expanding our dataset to more states and topics over time.

3. Disguised winners and losers. In theory, the authors of state bills (e.g., interest groups selling fill-in-the-blank bills to legislators) may try to reframe bills (disguise winners or losers) to further their political aims. At the first glance, this could pose a challenge to our bill annotation, dataset, and stakeholder analysis. As described in Section 3, the state legislative process has a multi-stage reviewing process in two chambers (e.g., first reading, second reading, and third reading). Thus, we have observed that it is hard to hide the impact of bills on their relevant stakeholders from our qualified annotators, i.e., the authors and multiple vetted MTurk workers for each example, in practice. In addition, our work on MTurk maps the impact of policies suggested by bills to winners and losers. Thus, it already considers those stakeholders that are not mentioned in the text explicitly (More details in Appendix A.1).

4. Winners and losers analysis. The analysis, aligning demographic cleavages with winners and losers preferences, is done at an aggregate level based on the data we annotated. These preferences could be influenced by other factors beyond demographics. Deriving conclusions from this analysis could require longitudinal studies, capturing the change of these patterns over time, for example when analyzing policies intended to help correct inequities towards marginalized groups. Our goal is to provide a tool for domain experts that would point at nuanced, stakeholder specific, legislative preferences that can be studied further in order to determine their significance.

5. Handling abstain votes. There are abstain (absent and N/A) votes in our dataset. However, we did not include them in our study due to their extremely low frequency (for our proposed model and other baseline models). We leave this evaluation as a future work.

6. Handling other countries and languages. While our dataset is specific to the US, the the problem we studied, stakeholder analysis, can be generalized to legislation from other countries and in different languages. Although we have not evaluated such bills (due to lack of data sources), we expect such legislation to produce winners or losers to provide practical solutions to their local problems. In particular, our framework offers a multi-relational graph abstraction and prediction models to analyze stakeholders of bills (winners/losers) and the voting behavior of legislators. These techniques can support non-US national and state-level legislative processes. To accommodate other languages, one could adopt cross-lingual embedding models, e.g., XLM-R (Conneau et al., 2019) instead of RoBERTa, in our architecture.

A Appendices

A.1 Data Annotation Pipeline

Our analysis on MTurk maps the policy described in the bills to potential winners and losers, i.e., stakeholders that would be positively or negatively impacted if the bill passes. The analysis is for the proposed policy, regardless of the legislative outcome (pass a vote or not). Due to lack of space, we did not mention certain aspects of our bill annotation task on MTurk in Section 4. We referred to it as a pipeline (in Section 4) because we fully automated the whole process (e.g., selection of MTurkers, publishing bills, collecting and analyzing results, and etc.) in Python, based on MTurk APIs and other open-source libraries. Annotation of political bills, particularly our winners/losers analysis, turned out to be a challenging task for typical MTurk workers. Thus, we developed an automated quality assurance scheme to ensure high-quality annotations for our study. In particular, we built the following components in our pipeline:

Questions/Tasks
How many women currently serve on the US Supreme Court?
Which party currently has the majority of seats in the US Senate?
What is the topic of the following legislation? *Prevention and control of, emergency and involuntary commitment for, and treatment programs and services for drug dependence.*
Select the entities that lose benefits from this bill? *Requires Oregon Health Authority to commission independent study of costs and impacts of operating basic health program in Oregon. Specifies parameters of study. Requires a report to Legislative Assembly by November 30, 2014. Appropriates money from General Fund to authority for contract costs to conduct study. Declares emergency, effective on passage.*

Table 8: *Some of the questions used in our Political Science qualification test.*

1. We developed a Political Science Qualification test on MTurk to evaluate candidate MTurk workers. Our test consists of 20 questions (e.g., Sentiment analysis on the US political text, identifying winners and losers of US bills, basic political knowledge questions). Table 8 shows the first four questions in the test.

2. Our pipeline selected 20 qualified English-speaker annotators who successfully completed 80% of the tasks, assigned them our qualification label on Mturk, and added them to our pool. We designed the test such that it must be completed by candidates in 30 minutes and those who failed the test were not allowed to take it again. While location was not a determining metric for us in selectors annotators (instead of focused on evaluating their knowledge of the US policies and politics), most of our qualified annotators were located in the US.

3. Next, for annotating each bill in our dataset, our pipeline randomly chose 3 annotators from the pool to determine the effect of the bill on the relevant stakeholders (generated based on the topic of the bill).

4. After collecting the result, for each bill, it computed the final winners and losers based on the majority rule. For 5% of bills with no agreement among annotators (each annotator selected different winners/losers), we automatically assigned these bills to two additional MTurkers, and then recalculated the final results/labels based on the majority rule.

5. For a small fraction of bills (around 1%) adding new annotators was not sufficient to reach an agreement, and thus we automatically rejected all the results and restarted the process from Step 3 with a new group of annotators. Finally, for a handful of bills, the authors performed the annotation manually.

6. To monitor the accuracy of our annotation, our pipeline sampled labeled bills from each batch of bills and we (authors) performed winners/losers analysis on them to validate the results. We ended up observing that our pipeline generated fully correct labels (all winners and losers) for 90%+ of bills. Figure 5 shows the distribution of winners and losers associated with the bills in our crowd-sourced pipeline.

A.2 Ablation Study: Effect of Nationwide Context

As discussed in Section 3, proposed policies and legislative outcomes at the state level are influenced by the nationwide context. Corporations and lobbying groups coordinate their efforts across multiple states to influence legislators in a similar way. We capture this fact in our graph representation by interconnecting states through common/shared nodes

Model	***Embedding***	***State (Test: IN)***	***State (Test: OR)***	***Time (Test: 20%)***
Naive	***Sponsors***	52.3	52.0	53.2

Table 10: *Effect of winners/losers information on the graph and text-based models in different vote classification tasks, for time-based and state-based data splits.*

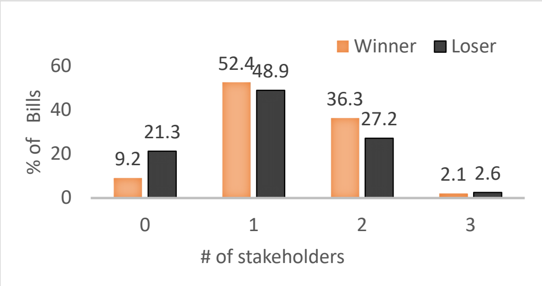

Figure 5: *Distribution of winner and loser relations between bills and their stakeholders. Most of the annotated bills had at least one winner or loser. A small portion of the bills (only 3.5%) had no loser and winner. A bill does not necessarily have both a winner and a loser.*

in Section 3. We conducted an ablation study to show the benefit of building a nationwide legislative graph. We split common nodes in the legislative graph that were shared across states (e.g., stakeholders, money donors) into state-specific nodes. Then, we repeated a handful of experiments in Section 6. In our classification tasks (both winners/losers prediction and bill cleavage/survival), we observed up to 4.3 points drop in the macro F1. This indicated interconnecting states through common nodes (e.g., stakeholders, and money donors) leads to better contextualized textual+graph embedding. In addition, in another ablation study, we measured the effect of different relation types and textual attributes of nodes in the legislative graph. For example, our evaluation showed the donors' information (and relations with legislators) improves the F1 score by at least 2.1 points across different tasks (for graph models listed in Table 6).

A.3 Additional Results: State and Time-based Data Splits

In Section 6, we evaluated all models using a random split based on bill nodes. Here, We further evaluate the best model in each category (from Table 6, Table 7) with two different data splits: (1) Time-based where test bills are selected from 20% of most recently introduced bills. (2) State-based where we choose the test bills from one specific state and train bills from the other two states. In Table 9, we look at the winners/losers prediction task and the performance of the best model in each category (i.e., naive, text-based, graph-based that we discussed in Section 6). Similarly, in Table 10, we study the best models (from Table 7) for classifying party-based competitive bills.

Overall, we make multiple observations. First, our results of the time- and state-based splits still show that our pretrained textual+graph model outperforms other models in both of the tasks (i.e., winners/losers prediction, and voting cleavage classification). Second, we can see a rather sharp drop across all the models in terms of F1 score for these

Models			*Pass/*	*Competitive*				*Inverse-Competitive*

Table 11: *Effect of winners/losers information on the graph and text-based models in different vote classification tasks. Extending the results based on the random split of bills in Table 7.*

two new splits. The reason is that time-based and state-based splits of bills lead to more unseen nodes (e.g., legislators, money donors), challenging graph models more than text models. For the time-based data split, the performance degradation is slightly less as the number of unseen nodes was fewer in the test dataset. Third, when we use Oregon for testing, we observe there is a higher drop in the performance of models, compared to using Indiana for testing; One potential reason is that Wisconsin and Indiana tend to be Republican states, while OR has been a Democratic one. Forth, our graph abstraction and stakeholders analysis (relations) help even baseline models to better decode state policies, when we compare the performance of models in the bill cleavage/survival tasks, with *Unknown*, *Known*, *Predicted* winners and losers in the legislative graph.

A.4 Measuring Disagreement and Labeling Competitive Roll-Calls

As discussed in Section 5, roll-call votes occur when a state-level legislator votes "yea" or "nay" on a bill. In Sections 1 and 5, we defined two types of bill classification tasks to characterize voting cleavages or disagreement across and within different ideological and demographic groups of legislators. Here, we discuss how we measure the disagreement and label bills in each of these tasks: **(1) Inverse-Competitive bills**: Consider a bill where 55% of Men voting Yea and 45% of them voting Nay. We define the disagreement as the percentage of minority votes or 45%. When the disagreement within a group of legislators (e.g, men) is between 40-49%, we consider the bill as an inverse-competitive bill with a partial tie in votes. The disagreement of 50% is a complete tie. **(2) Competitive bills**: Next, consider a bill with 60% of Women voting Yea and 80% Men voting Nay on a roll call. This bill is competitive because the majority of female legislators voted differently than the majority of male legislators (the cross-group disagreement is 20% = 80%-60% in this case.) Conceptually, we do not need to compute the cross-group disagreement to identify competitive bills.

Structural Characterization for Dialogue Disentanglement

Abstract

Tangled multi-party dialogue contexts lead to challenges for dialogue reading comprehension, where multiple dialogue threads flow simultaneously within a common dialogue record, increasing difficulties in understanding the dialogue history for both human and machine. Previous studies mainly focus on utterance encoding methods with carefully designed features but pay inadequate attention to characteristic features of the structure of dialogues. We specially take structure factors into account and design a novel model for dialogue disentangling. Based on the fact that dialogues are constructed on successive participation and interactions between speakers, we model structural information of dialogues in two aspects: 1)speaker property that indicates whom a message is from, and 2) reference dependency that shows whom a message may refer to. The proposed method achieves new state-of-the-art on the Ubuntu IRC benchmark dataset and contributes to dialogue-related comprehension.

1 Introduction

Communication between multiple parties happens anytime and anywhere, especially as the booming social network services hugely facilitate open conversations, such as group chatting and forum discussion, producing various tangled dialogue logs (Lowe et al., 2015; Zhang et al., 2018b; Choi et al., 2018; Reddy et al., 2019; Li et al., 2020a). Whereas, it can be challenging for a new participant to understand the previous chatting log since multi-party dialogues always exhibit disorder and complication (Shen et al., 2006; Elsner and Charniak, 2010; Jiang et al., 2018; Kummerfeld et al., 2019). In fact, it is because of the distributed and random organization, multi-party dialogues are much less coherent or consistent than plain texts. As the example shown in figure 1, the development of a multi-party dialogue has the following characteristics: 1) Random users successively participate in the dialogue and follow specific topics that they are interested in, motivating the development of those topics. 2) Users reply to former related utterances and mention involved users, forming dependencies among utterances. As a result, multiple ongoing conversation threads grow as the dialogue proceeds, which breaks the consistency and hinders both humans and machines from understanding the context, let alone giving a proper response (Jiang et al., 2018; Kummerfeld et al., 2019; Joty et al., 2019; Jiang et al., 2021). In a word, the behavior of speakers determines the structure of a dialogue passage. And the structure causes problems of reading comprehension. Hence, for better understanding, structural features of dialogue context deserve special attention.

(1003) daftykins I meant to the channel and not me, I know nothing about python :)
…
(1009) regum I cant ssh into it until I log in as a user.
(1010) regum it says connetction refused.
(1011) blakdog Do the ubuntu lts versions able to run as a live cd?
(1012) bekks regum: Because the root accoutn is disabled in Ubuntu, by default.
(1013) daftykins blackdog: run as live for testing, yes
(1014) regum which is really inconvenient, as it means I have to plug a keyboard every time I turn it on.
(1015) blakdog thanks
(1016) daftykins regum: so reconfigure SSHd
jancoow daftykins: oh haha sorry

Figure 1: Here is an example piece of multi-party chatting logs from Ubuntu IRC (Kummerfeld et al., 2019). `jancoow` figures out conversation threads, understand the context and reply to the related message (`1003` from `daftykins`), and the dialogue develops.

Disentanglement is worthy of study. Decoupling

messages or clustering conversation threads help with screening concerned parts among contexts, therefore it may be naturally required by passage comprehension, and related downstream dialogue tasks (Elsner and Charniak, 2010; Jia et al., 2020; Liu et al., 2021a), such as response selection, question-answering, etc.

Nevertheless, existing works on dialogue disentanglement (Zhu et al., 2020; Yu and Joty, 2020; Li et al., 2020b) generally ignore or pay little attention to characters of dialogues. Earlier works mainly depend on feature engineering (Kummerfeld et al., 2019; Elsner and Charniak, 2010; Yu and Joty, 2020), and use well-constructed handcrafted features to train a naive classifier (Elsner and Charniak, 2010) or linear feed-forward network (Kummerfeld et al., 2019). Recent works are mostly based on two strategies: 1) two-step (Mehri and Carenini, 2017; Zhu et al., 2020; Yu and Joty, 2020; Li et al., 2020b; Liu et al., 2021a) and 2) end-to-end (Tan et al., 2019; Liu et al., 2020a). In terms of the two-step method, the disentanglement task is divided into *matching* and *clustering*. It means firstly matching utterance pairs to detect reply-to relations and then clustering utterances according to the matching score. In the end-to-end strategy, alternatively, for each conversation thread, the state of dialogue is modeled, and is mapped with a subsequent utterance to update. At the same time, the subsequent utterance is judged to belong to the best-matched thread. Nonetheless, the essence of both strategies is to model the relations of utterance pairs.

Recently, Pre-trained Language Models (PrLMs) (Devlin et al., 2019; an, 2019; Clark et al., 2020) have brought prosperity to numbers of natural language processing tasks by providing contextualized backbones. Various works have reported substantial performance gains with the contextualized information from PrLMs (Lowe et al., 2015; Li et al., 2020a; Liu et al., 2021c; Jia et al., 2020; Wang et al., 2020). Studies on dialogue disentanglement also get benefit from PrLMs (Li et al., 2020b; Zhu et al., 2020), whereas, there is still room for improvement due to their insufficient enhancement of dialogue structure information.

So as to enhance characteristic structural features of tangled multi-party dialogues, we design a new model as a better solution for dialogue disentanglement. Structure of a multi-party dialogue is based on the actions of speakers according to the natural development of dialogues. Hence, we model two structural features to help with the detection of reply-to relationships: 1)user identities of messages, referred to as *speaker property*; and 2) mention of users in messages, called *reference dependency*. With the two features enhanced between encoding and prediction, the model makes progress on dialogue disentanglement. Evaluation is conducted on DSTC-8 Ubuntu IRC dataset (Kummerfeld et al., 2019), where our proposed model achieves new state-of-the-art. Further analyses and applications illustrate the advantages and scalability additionally. Our source code is available [1].

2 Background and Related Work

2.1 Dialogue-related Reading Comprehension

Dialogue understanding brings challenges to machine reading comprehension (MRC), in terms of handling the complicated scenarios from multiple speakers and criss-crossed dependencies among utterances (Lowe et al., 2015; Yang and Choi, 2019; Sun et al., 2019; Li et al., 2020a). A dialogue is developed by all involved speakers in a distributed way. An individual speaker focuses on some topics that are discussed in the conversation, and then declares oneself or replies to utterances from related speakers. Therefore, consistency and continuity are broken by tangled reply-to dependencies between non-adjacent utterances (Li et al., 2020a; Jia et al., 2020; Ma et al., 2021; Li et al., 2021), leading to a graph structure that is different from smooth presentation in plain texts.

PrLMs have made a significant breakthrough in MRC, where various training objectives and strategies (Devlin et al., 2019; Clark et al., 2020; an, 2019; Lan et al., 2020) have achieved further improvement. Devoted to MRC tasks, PrLMs usually work as a contextualized encoder with some task-oriented decoders added (Devlin et al., 2019). And this paradigm may be a generic but suboptimal solution, especially for some distinctive scenarios, such as dialogue.

Recently, numbers of works of dialogue-related MRC have managed to enhance dialogue structural features in order to deal with dialogue passages better (Liu et al., 2021c; Jia et al., 2020; Zhang and Zhao, 2021; Ma et al., 2021; Li et al., 2021),

---

[1] `https://github.com/xbmxb/StructureCharacterization4DD`

which achieve progress compared to methods that were previously proposed for plain texts. This inspiration impacts and promotes a wide range of dialogue-related MRC tasks such as response selection (Gu et al., 2020; Liu et al., 2021c), question answering (Ma et al., 2021; Li et al., 2021), emotion detection (Hu et al., 2021), etc.

2.2 Dialogue Disentanglement

Dialogue disentanglement (Elsner and Charniak, 2010), which is also referred to as conversation management (Traum et al., 2004) , thread detection (Shen et al., 2006) or thread extraction (Adams, 2008), has been studied for decades, since understanding long multi-party dialogues remains to be non-trivial. Thus, dialogue disentanglement methods have been proposed to cluster utterances.

Early works can be summarized as feature encoder and clustering algorithms. Well-designed handcraft features are constructed as input of simple networks that predict whether a pair of utterances are alike or different, and clustering methods are then borrowed for partitioning (Elsner and Charniak, 2010; Jiang et al., 2018). Researches are facilitated by a large-scale, high-quality public dataset, Ubuntu IRC, created by Kummerfeld et al. (2019). And then the application of FeedForward network and pointer network (Vinyals et al., 2015) leads to significant progress, but the improvement still partially relies on handcraft-related features (Kummerfeld et al., 2019; Yu and Joty, 2020). Then the end-to-end strategy is proposed and fills the gap between the *match* and *clustering* (Liu et al., 2020a), where dialogue disentanglement is modeled as a dialogue state transition process. The utterances are clustered by mapping with the states of each dialogue thread. Inspired by achievements of pre-trained language models (Devlin et al., 2019; Clark et al., 2020; an, 2019), latest work use BERT to contextually encode the dialogue context (Zhu et al., 2020; Li et al., 2020b). Liu et al. (2021b) investigates disentanglement from a different perspective. Their end-to-end co-training approach provides a novel unsupervised baseline.

However, attention paid to the characteristics of dialogues seems to be inadequate. Feature engineering-based works represent properties of individual utterances such as time, speakers, and topics with naive handcraft methods, thus ignoring dialogue contexts (Elsner and Charniak, 2010; Kummerfeld et al., 2019). PrLM-based Masked Hierarchical Transformer (Zhu et al., 2020) utilizes the golden conversation structures to operate attentions on related utterances when training models, which results in exposure bias. DialBERT (Li et al., 2020b), a recent architecture including a BERT (Devlin et al., 2019) and an LSTM (Hochreiter and Schmidhuber, 1997), models contextual clues but no dialogue-specific features, and claims a state-of-the-art performance. Our approach draws inspiration from these works and further models structural features for better dialogue understanding.

Unlike the above studies, our work incorporates dialogue-specific characters. We propose a new model considering structural characteristics of dialogues, based on the fact that dialogues are developed according to the behavior of speakers. In detail, we model dialogue structures with two highlights: 1) speaker properties of each utterance and 2) reference of speakers between utterances, which both help with modeling inherent interactions among a dialogue passage.

2.3 Speaker-aware Dialogue Modeling

Speaker role, as a feature of dialogue passage, has received growing attention recently. On the one hand, speaker embedding facilities research of dialogues. Speaker-aware modeling has also made contributions to response retrieval (Gu et al., 2020; Liu et al., 2021c). SA-BERT (Gu et al., 2020) add a speaker embedding to the input of a PrLM, while MDFN (Liu et al., 2021c) modifies self-attention to enhance speaker switches. Persona has been utilized for smoother dialogue generation. In recent work (Liu et al., 2020b), the speaker-aware information is modeled by adding a reward of persona proximity to the reinforcement learning of generation, based on a persona-annotated dataset (Zhang et al., 2018a). On the other hand, speakers role is a valuable research object for personal knowledge analysis, since the persona can be extracted from one's words in dialogues. Relationship prediction task has been better handled through observing interactions of dialogue speakers (Jia et al., 2021; Tigunova et al., 2021). Tigunova et al. (2021) make use of speaker identity by a *SA-BERT* (Gu et al., 2020)-like embedding but in utterance-level representation.

Relations between utterances have been studied for a long time. Earlier works mostly based on pioneer datasets, Penn Discourse TreeBank

(Prasad et al., 2008) and Rhetorical Structure Theory Discourse TreeBank (Mann and Thompson, 1988). In the dialogue field, the much more complex relations contain latent features (Shi and Huang, 2019; Zhang and Zhao, 2021; Jia et al., 2020). Due to the inherent graph structure, Graph Convolutional Network (Kipf and Welling, 2017) is well applied to natural language modeling. Derivations such as Relational-GCN (Schlichtkrull et al., 2018), TextGCN (Yao et al., 2019), LBGCN (Huang et al., 2021), etc, encourage better structural solutions in NLP.

In this work, we aim to inject speaker-aware and reference-aware characteristic features for the motivation of disentanglement, instead of making progress on embedding approaches.

3 Methodology

The definition of the dialogue disentanglement task and details of our model are sequentially presented in this section, illustrating how we make efforts for disentanglement with dialogue structural features.

3.1 Task Formulation

Suppose that we perform disentanglement to a long multi-party dialogue history $\mathbb{D} = \{u_0, u_2, \ldots, u_n\}$, where $\mathbb{D}$ is composed of n utterances. An utterance includes an identity of speaker and a message sent by this user, thus denoted as $u_i = \{s_i, m_i\}$. As several threads are flowing simultaneously within $\mathbb{D}$, we define a set of threads $\mathbb{T} = \{t_0, t_2, \ldots, t_p\}$ as a partition of $\mathbb{D}$, where $t_i = \{u_{i_0}, \ldots, u_{i_k}\}$ denoting a thread of the conversation. In this task, we aim to disentangle $\mathbb{D}$ into $\mathbb{T}$. As indicated before, a multi-party dialogue is constructed by successive participation of speakers, who often reply to former utterances of interest. Thus, a dialogue passage can be modeled as a graph structure whose vertices denote utterances and edges denote reply-to relationships between utterances. Following the two-step method (Mehri and Carenini, 2017), we focus on finding a parent node for each utterance through inference of reply-to relationship, so as to discover edges and then determine the graph of a conversation thread.

3.2 Model Architecture

Figure 2 shows the architecture of the proposed model, which is introduced in detail in this part. The model architecture consists of three modules, including text encoder, structural interaction, and context-aware prediction: 1) The utterances from a dialogue history are encoded with a PrLM, whose output is then aggregated to context-level. 2) The representation is sequentially fed into the structural modeling module, where dialogue structural features are used to characterize contexts. 3) Then in the prediction module, the model performs a fusion and calculates the prediction of reply-to relationships.

3.2.1 Encoder

Pairwise encoding Following previous works (Zhu et al., 2020; Li et al., 2020b), we utilize a pre-trained language model *e.g.* BERT (Devlin et al., 2019) as an encoder for contextualized representation of tokens. Since chatting records are always long and continuous, it is inappropriate and unrealistic to concatenate the whole context as input. Hence, we focus on the pair of utterances with a reply-to relation. An utterance is concatenated with each parent candidate as input to a PrLM. This may sacrifice contextual information between candidates, but we make up for this in 3.2.3.

Assuming that for an utterance u_i, we consider former C utterances (including u_i itself) as candidates for parent node of u_i, the input of a PrLM is in the form of `[CLS]` u_{i-j} `[SEP]` U_i `[SEP]`, where $0 \leq j \leq C - 1$. The output is denoted as $H_0 \in \mathbb{R}^{C \times L \times D}$, where C denotes the window length in which former utterances are considered as candidates of the parent, L denotes the input sequence length in tokens, D denotes the dimension of hidden states of the PrLM. Note that there is a situation where the golden parent utterance is beyond the range of $[u_{i-(C-1)}, u_i]$. We label a self-loop for u_i in this case, which means being too far from the parent making u_i a beginning of a new dialogue thread. It makes sense in the real world, because when users join in a chat (*e.g.* entering a chatting room), they intend to check a limited number of recent messages and make replies, instead of scanning the entire chatting record.

Utterance Aggregation H_0 is pairwise contextualized representations of each pair of token sequences (u_{i-j}, u_i), thus need to be aggregated to context-level representation for further modeling. Since special token `[CLS]` makes more sense on classification tasks (Devlin et al., 2019), we simply reserve the representations of `[CLS]`. The

Figure 2: Overview of the model and data flow. A dialogue is encoded to context-level in the encoder module. Then speaker-aware and reference-aware features are enhanced in the structural modeling layer. And context-aware prediction model makes the final prediction.

concatenated pairwise context-level representations from all candidates is denoted as $H_1 \in \mathbb{R}^{C \times D}$, where C denotes the window length and D denotes the dimension of hidden states of the PrLM.

3.2.2 Structural Modeling

For our structural modeling, a simple but effective method is preferred. Hence, for speaker property, we applied the idea of masked MHSA method (Liu et al., 2021c) for better effectiveness and conciseness (Ma et al., 2021). In dependency modeling, we only built one relation type, i.e., reference, where a vanilla r-GCN (Schlichtkrull et al., 2018) is an appropriate baseline method.

Speaker Property Modeling We use the term *Speaker Property* to denote the user identity from whom an utterance is, in formulation, s_i. Modeling speaker property could be worthwhile because sometimes a participant may focus on conversations with specific speakers. Following the idea of masking attention (Liu et al., 2021c), we build a Multi-Head Self-Attention (MHSA) mechanism to emphasize correlations between utterances from the same speaker. The mask-based MHSA is formulated as follows:

$$\begin{aligned} &A(Q, K, V, M) = \text{softmax}(\frac{QK^T}{\sqrt{d_k}} + M)V, \\ &head_t = A(HW_t^Q, HW_t^K, HW_t^V, M), \\ &MHSA(H, M) = [head_1, , \ldots, head_N]W^O, \end{aligned} \tag{1}$$

where A, $head_t$, Q, K, V, M, N denote the attention, head, query, key, value, mask, and the number of heads, respectively. H denotes the input matrix, and W_t^Q, W_t^K, W_t^V, W^O are parameters. Operator $[\cdot, \cdot]$ denotes concatenation. At this stage, the input of MHSA is the aggregated representation H_1 with a speaker-aware mask matrix M. The element at the i-th row, j-th column of M depend on speaker properties of u_i and u_j:

$$M[i, j] = \begin{cases} 0, & s_i = s_j \\ -\infty, & \text{otherwise} \end{cases} \tag{2}$$

$$H_2 = MHSA(H_1, M),$$

The output of MHSA, H_{MHSA}, has the same dimension with $H_1 \in \mathbb{R}^{C \times D}$. We concatenate H_1 and H_{MHSA} and adjust to the same size using a linear layer, resulting in an output of this module denoted as $H_2 \in \mathbb{R}^{C \times D}$.

Reference Dependency Modeling As discussed above, the relation of references between speakers is the most important and straightforward dependency among utterances. Because references indicate interactions between users, it is the internal motivation of the development of a dialogue. To this end, we build a matrix to label the references, which is regarded as an adjacency matrix of a graph representation. In the graph of references, a vertice denotes an utterance and an edge for reference dependence. For example, u_{1012} in Figure 1 mentions and reply to *regum*, forming dependence to utterances from *regum*, i.e., u_{1009}, u_{1010}, and u_{1014}. Thus there are edges from v_{1012} to v_{1009}, v_{1010}, and v_{1014}. Impressed by the significant influence of graph convolutional network (GCN) (Kipf and Welling, 2017), we borrow the relation-modeling of relational graph convolutional network (r-GCN) (Schlichtkrull et al., 2018; Shi and Huang, 2019) in order to enhance the reference dependencies, which can be denoted

as follows:

$$h_i^{(l+1)} = \sigma(\sum_{r\in\mathcal{B}} \sum_{j\in N_i^r} \frac{1}{c_{i,r}} W_r^{(l)} h_j^{(l)} + W_0^{(l)} h_i^{(l)}),$$

where $\mathcal{B}$ is the set of relationships, which in our module is only reference dependencies. N_i^r denotes the set of neighbours of vertice v_i, which are connected to v_i through relationship r, and $c_{i,r}$ is constant for normalization. $W_r^{(l)}$ and $W_0^{(l)}$ are parameter matrix of layer l. σ is activated function, which in our implementation is ReLU (Glorot et al., 2011; Agarap, 2018). H_2 is fed into this module and derives $H_3 \in \mathbb{R}^{C\times D}$ through r-GCN.

3.2.3 Context-aware Prediction

The structure-aware representation H_3 needs to be combined with the original representation of `[CLS]` H_0 for enhancement. An LSTM-like layer (Hochreiter and Schmidhuber, 1997; Li et al., 2020b) can be utilized for compensating contextualized information of the whole candidate window.

Motivated by the two points above, we employ a Syn-LSTM module (Xu et al., 2021), which was originally proposed for named entity recognition (NER). A Syn-LSTM is distinguished from an additional input gate for an extra input source, whose parameters are trainable, achieving a better fusion of two input sources. Thus, a layer of Syn-LSTM models the contextual information while the reference dependency is highlighted, enriching relations among parent candidates. In a Syn-LSTM cell, the cell state is derived from the two input and former state as well:

$$\begin{aligned}
c_{1_t} &= \tanh(\mathrm{W}^{(k)}\mathrm{x}_{1_t} + \mathrm{U}^{(k)}\mathrm{h}_{t-1} + \mathrm{b}_k),\\
c_{2_t} &= \tanh(\mathrm{W}^{(p)}\mathrm{x}_{2_t} + \mathrm{U}^{(p)}\mathrm{h}_{t-1} + \mathrm{b}_p),\\
c_t &= f_t \odot c_{t-1} + i_{1_t} \odot c_{1_t} + i_{2_t} \odot c_{2_t},\\
h_t &= o_t \odot \tanh(\mathrm{c}_t),
\end{aligned}$$

where $f_t, o_t, i_{1_t}, i_{2_t}$ are forget gate, output gate and two input gates. c_{t-1}, c_t denote former and current cell states. h_{t-1} is former hidden state. And W, U, b are learnable parameters. We use the Syn-LSTM in a bi-directional way, and the output is denoted as $H_4 \in \mathbb{R}^{C\times 2D_r}$, where D_r is the hidden size of the Syn-LSTM.

At this stage, H_4 is the structural feature-enchanced representation of each pair of the utterance U_i and a candidate parent utterance u_{i-j}. To measure the correlations of these pairs, we follow previous work (Li et al., 2020b) to consider the Siamese architecture between each $[u_i, u_{i-j}]$ pair ($1 \leq j \leq C-1$) and $[u_i, u_i]$ pair:

$$\mathrm{H}_5[j] = [\mathrm{p}_{ii}, \mathrm{p}_{ij}, \mathrm{p}_{ii} \odot p_{ij}, \mathrm{p}_{ii} - \mathrm{p}_{ij}],$$

where p_{ij} is the representation for the pair of $[U_i, U_{i-j}]$ from H_4, and we got $H_4 \in \mathbb{R}^{C \times 8D_r}$. H_5 is then fed into a classifier to predict the most correlated pair and predict the parent. Cross-entropy loss is used as the model training objective.

4 Experiments

Our proposed model is evaluated on a large-scale multi-party dialogue log dataset Ubuntu IRC (Kummerfeld et al., 2019), which is also used as a dataset of DSTC-8 Track2 Task4. The results show that our model surpasses the baseline significantly and achieves a new state-of-the-art.

4.1 Dataset

Ubuntu IRC (Internet Relay Chat) (Kummerfeld et al., 2019) is the first available dataset and also the largest and most influential benchmark corpus for dialogue disentanglement, which promotes related research heavily. It is collected from `#Ubuntu` and `#Linux` IRC channels in the form of chatting logs. The usernames of dialogue participants are reserved, and reply-to relations are manually annotated in the form of `(parent utterance, son utterance)`. Table 2 shows statics of Ubuntu IRC.

	Passages	Utterances	Links	Avg. users
Train	153	22,0463	69,395	130.3
Dev	10	12,500	2,607	128.1
Test	10	15,000	5,187	156.9

Table 2: Statistics of Ubuntu IRC (Kummerfeld et al., 2019).

4.2 Metrics

Reply-to relations We calculate the accuracy for the prediction of parent utterance, indicating the inference ability for reply-to relations.

Disentanglement For the goal of dialogue disentanglement, threads of a conversation are formed by clustering all related utterances bridged by reply-to relations, in other words, a connected subgraph. At this stage, we use metrics to evaluate following DSTC-8, which are scaled-Variation of Information (VI) (Kummerfeld et al., 2019), Adjusted rand index (ARI) (Hubert and Arabie, 1985), One-to-One Overlap (1-1) (Elsner and Charniak, 2010), precision (P), recall (R), and F1 score of clustering. Note that in the table of results, we present 1-VI instead of VI (Kummerfeld et al., 2019), thus for all metrics, we expect larger numerical values that mean stronger performance.

Model	**VI**	**ARI**	**1-1**	**F1**	**P**	**R**

Layers of Syn-LSTM						
w/ 1 layer	**94.4**	**81.8**	**86.1**	**52.6**	51.0	**54.3**
w/ 2 layers	94.0	78.2	84.6	50.4	50.9	50.0
w/ 3 layers	94.3	79.6	85.3	52.2	**51.9**	52.6

Table 3: Results of architecture optimizing experiments.

4.3 Setup

Our implementations are based on *Pytorch* and *Transformers* Library (Wolf et al., 2020). We fine-tune the model employing AdamW (Loshchilov and Hutter, 2019) as the optimizer. The learning rate begins with 4e-6. In addition, due to the trade-off for computing resources, the input sequence length is set to 128, which our inputs are truncated or padded to, and the window width of considered candidates is set to 50.

4.4 Experimental Results

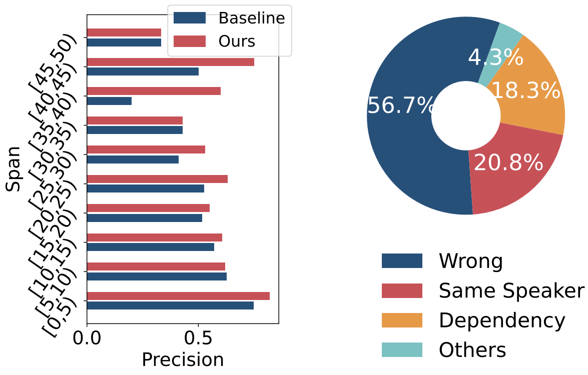
As is presented in Table 1, the experimental results show that our model outperforms all baselines by a large margin as the annotated difference values. It is also shown that our model achieves superior performance on most metrics compared to previously proposed models as highlighted in the table, making a new state-of-the-art (SOTA).

5 Analysis

5.1 Architecture Optimizing

5.1.1 Ablation Study

We study the effect of speaker property and reference dependency respectively to verify their specific contribution. We ablate either of the characters and train the model. Results in Table 3 show that both speaker property and reference dependency are non-trivial.



(a) (b)

Figure 3: Analysis on (a) Precision on different span lengths. (b) Bad case study.

5.1.2 Methods of Aggregation

At the stage of aggregation heading for context-level representations, we consider the influence of different methods of aggregation, i.e., max-pooling and extraction of `[CLS]` tokens, the models are trained with the same hyper-parameters. Results in Table 3 show `[CLS]` tokens is a better representation.

5.1.3 Layers of LSTM

To determine the optimal depth of the Bi-Syn-LSTM, we do experiments on the number of layers of a Syn-LSTM, also with the same hyper-parameters. According to the results, as shown in Table 3, we put a one-layer Bi-Syn-LSTM for better performance.

5.2 Prediction Analysis

To intuitively show and discuss the advantages of the proposed approach, we analyze predictions made by our model and the baseline model (i.e., BERT) in the following aspects.

1) We categorize reply-to relationships based on the length of their golden spans (in utterances), and compute the precision of the baseline model and ours. Figure 3a shows that our model outperforms baseline by larger margins on links with longer spans (longer than 20 utterances), indicating that our model is more robust on the longer passages.

2) We select bad cases of the baseline model to find out how the structure-aware modeling benefits dialogue disentanglement. We study predictions from our model on these bad cases. As depicted in Figure 3b, the model well solves 43.3% bad cases. Our model is observed to correct 20.8% bad cases whose utterance pairs are from the same speakers, and 18.3% bad cases whose utterance pairs have a reference. As the illustration shows, our model effectively captures the structural features caused by speaker property and reference dependency, thus gaining improvement. 56.7% predictions are still wrong. It may suggest deeper inner relationships remain to be studied.

5.3 Metrics

The used metrics are explained and analyzed briefly for a better understanding of model performance in Appendix A.1.

6 Applications

Empirically, it is consistent with our intuition that clarifying the structure of a passage helps with reading comprehension. This section studies the potential of dialogue disentanglement by conducting experiments on different tasks and domains.

6.1 Response Selection

The dataset of DSTC7 subtask1 (Gunasekara et al., 2019) is a benchmark of response selection tasks, derived from Ubuntu chatting logs, which is challenging because of its massive scale. As shown in Table 4, it contains hundreds of thousand dialogue passages, and each dialogue has speaker-annotated messages and 100 response candidates.

In the implementation, pre-processed context passages are firstly fed into the trained model for disentanglement to obtain predicted partitions of context utterances. Then when dealing with the response selection task, we add a self-attention layer to draw attention between utterances within a common cluster in the hope of labels of clusters leading to better contributions to performance.

6.2 Dialogue MRC

We also make efforts to apply disentanglement on span extraction tasks of question answering datasets, where we consider multi-party dialogue dataset Molweni (Li et al., 2020a), a set of speaker-annotated dialogues with some questions whose answers can be extracted from contexts, which is also collected from Ubuntu chatting logs 4. Because passages in Molweni are brief compared to other datasets we used, utterances tend to belong to the same conversation session through criss-crossed relations. Thus we alternatively leverage labels of reply-to relations from our model, and build graphs among utterances.

6.3 Open-domain QA

As the former two datasets are both extracted Ubuntu IRC chatting logs, we additionally consider an open-domain dataset, FriendsQA (Yang and Choi, 2019). It contains daily spoken languages from the TV show *Friends* 4. FriendsQA gives QA questions and is handled in the same way as the Molweni dataset.

	DSTC-7	**Molweni**	**FriendsQA**
Train (dial. / Q)	100,000/–	8,771 / 24,682	973 / 9,791
Dev (dial. / Q)	5000/–	883 / 2,513	113 / 1,189
Test (dial. / Q)	1000/–	100 / 2,871	136 / 1,172
Utterances	3-75	14	173
Responses	100	-	-
Open-domain	N	N	Y

Table 4: Statistics of datasets for applications.

Model	**DSTC-7**		**Molweni**		**FriendsQA**	
	R@1	MRR	EM	F1	EM	F1
Public Baseline	-	-	45.3	58.0	45.2	–
BERT$_{base}$	51.2	60.9	45.7	58.8	45.2	59.6
w/ label	51.4	61.5	46.1	61.7	45.2	60.9

Table 5: Results of application experiments.

Results of the above experiments are presented in Table 5. It is shown that the disentanglement model brings consistent profits to downstream tasks. Yet, gains on FriendsQA are less impressive, indicating domain limitations to some extent. Here we only consider naive baselines and straightforward methods for simplicity and fair comparison, which suggests there is still latent room for performance improvement in future work.

7 Conclusion

In this paper, we study disentanglement on long multi-party dialogue records and propose a new model by paying close attention to the characteristics of dialogue structure, i.e., the speaker property and reference dependency. Our model is evaluated on the largest and latest benchmark dataset Ubuntu IRC, where experimental results show a new SOTA performance and advancement compared to previous work. In addition, we analyze the contribution of each structure-related feature by ablation study and the effect of the different model architecture. Our work discloses that speaker and dependency-aware structural characters are significant and deserve studies in multi-turn dialogue modeling.

A Appendix

A.1 Metrics

The metrics for evaluating the performance of disentanglement are described as follows.

1) scaled-Variation of Information. For the two partition X and Y of set S, $VI(X;Y) = H(X,Y) - I(X,Y)$, where $H(X,Y)$ is the joint entropy of X and Y and $I(X,Y)$ is the mutual information between X and Y, both can be easily calculated from the contingency table. Following previous work(Kummerfeld et al., 2019), VI is scaled to be positive and between 0 and 1. i.e., $1 - VI/log_2(n)$, where n is the number of elements in the set S. Thus a bigger number means the two partitions are more similar.

2) Adjusted Rand Index. The adjusted Rand index is the corrected-for-chance version of the Rand index (Hubert and Arabie, 1985). ARI measures the links between elements under two partitions and indicates how many links lie in the i-th part of the predicted partition X and the j-th part of the ground truth partition Y. Given a contingency table, ARI can be formulated as:

$$\frac{\sum_{ij} C_{n_{ij}}^2 - [\sum_i C_{a_i}^2 \sum_j C_{b_j}^2]/C_{n_{ij}}^2}{\frac{1}{2}[\sum_i C_{a_i}^2 + \sum_j C_{b_j}^2] - [\sum_i C_{a_i}^2 \sum_j C_{b_j}^2]/C_{n_{ij}}^2}$$

, where a_i is the summation if row i and b_j is the summation of column j. C denotes combinatorial number.

3) One-to-One Overlap. One-to-one overlap, also called one-to-one accuracy, is calculated as the percentage overlap by pairing up clusters from two partitions to maximize overlap using the methods of max-flow algorithm (Elsner and Charniak, 2008), indicating how well a whole conversation can be extracted intact.

4-6) Exact Match. Precise, Recall, and F1 score are metrics to measure the exact matching of clusters, where single utterances (clusters only consist of one utterance) are discarded, following previous work.

Recently study made efforts to analyze measures (Jiang et al., 2021), where human satisfaction measures are applied on metrics: Normalized Mutual Information (NMI), Adjusted Rand Index (ARI), Shen-F, and F1. Results show that F1 is the most similar to human satisfaction scores, while ARI, NMI, and Shen-F tend to overrate disentanglement results but F1 underrates. Here we present a scatterplot 4 based on our experimental results.

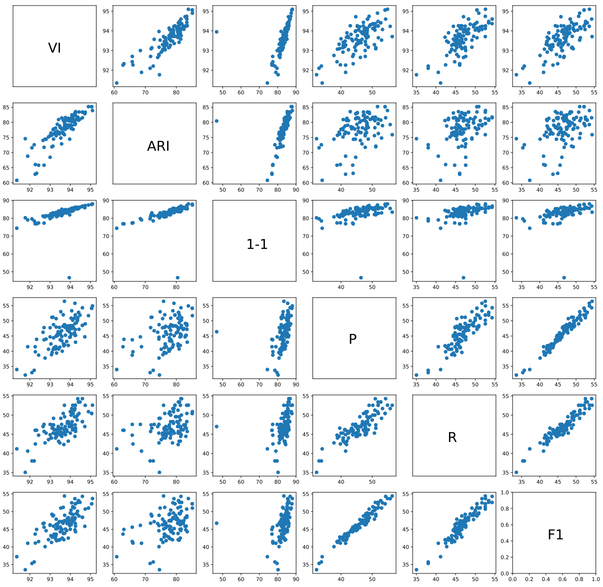

Figure 4: Scatter plots matrix for metrics.

A.2 Syn-LSTM

As space is limited, we present a complete mathematical representation of Syn-LSTM (Xu et al., 2021) here.

$$\begin{aligned}
f_t &= \sigma(\mathrm{W}^{(f)}\mathrm{x}_{1_t} + \mathrm{U}^{(f)}\mathrm{h}_{t-1} + \mathrm{Q}^{(f)}\mathrm{x}_{2_t} + \mathrm{b}_f),\\
o_t &= \sigma(\mathrm{W}^{(o)}\mathrm{x}_{1_t} + \mathrm{U}^{(o)}\mathrm{h}_{t-1} + \mathrm{Q}^{(o)}\mathrm{x}_{2_t} + \mathrm{b}_o),\\
i_{1_t} &= \sigma(\mathrm{W}^{(i_1)}\mathrm{x}_{1_t} + \mathrm{U}^{(i_1)}\mathrm{h}_{t-1} + \mathrm{b}_{i_1}),\\
i_{2_t} &= \sigma(\mathrm{W}^{(i_2)}\mathrm{x}_{2_t} + \mathrm{U}^{(i_2)}\mathrm{h}_{t-1} + \mathrm{b}_{i_2}),\\
c_{1_t} &= \tanh(\mathrm{W}^{(k)}\mathrm{x}_{1_t} + \mathrm{U}^{(k)}\mathrm{h}_{t-1} + \mathrm{b}_k),\\
c_{2_t} &= \tanh(\mathrm{W}^{(p)}\mathrm{x}_{2_t} + \mathrm{U}^{(p)}\mathrm{h}_{t-1} + \mathrm{b}_p),\\
c_t &= f_t \odot c_{t-1} + i_{1_t} \odot c_{1_t} + i_{2_t} \odot c_{2_t},\\
h_t &= o_t \odot \tanh(\mathrm{c}_t),
\end{aligned}$$

where x_{1_t} and x_{2_t} are inputs.c_{t-1}, c_t denote former and current cell states. h_{t-1} is former hidden state. W, U, b are learnable parameters. $f_t, o_t, i_{1_t}, i_{2_t}$ are forget gate, output gate and two input gates. And σ denotes sigmoid function.

Multi-Party Empathetic Dialogue Generation: A New Task for Dialog Systems

Abstract

Empathetic dialogue assembles emotion understanding, feeling projection, and appropriate response generation. Existing work for empathetic dialogue generation concentrates on the two-party conversation scenario. Multi-party dialogues, however, are pervasive in reality. Furthermore, emotion and sensibility are typically confused; a refined empathy analysis is needed for comprehending fragile and nuanced human feelings. We address these issues by proposing a novel task called Multi-Party Empathetic Dialogue Generation in this study. Additionally, a Static-Dynamic model for Multi-Party Empathetic Dialogue Generation, SDMPED, is introduced as a baseline by exploring the static sensibility and dynamic emotion for the multi-party empathetic dialogue learning, the aspects that help SDMPED achieve the state-of-the-art performance.

1 Introduction

Empathetic conversation studies have been coming to the forefront in recent years owing to the increasing interest in dialogue systems. Empathetic dialogues not only provide dialogue partners with highly relevant contents but also project their feelings and convey a special emotion, that is, empathy. As revealed by previous studies (Fraser et al., 2018; Zhou et al., 2020), empathy can enhance conversation quality and transmit appropriate emotional responses to partners. Accordingly, most, if not all, existing work focuses on taking an emotional perspective in dialogue studies (Levinson et al., 2000; Kim et al., 2004; Bertero et al., 2016; Fraser et al., 2018; Rashkin et al., 2019).

Although the empathetic conversation has received extensive attention, its exploration is still limited to the scenario with only two parties. In fact, multi-party chatting scenes are common in seminar discussions, conferences, and group chats.

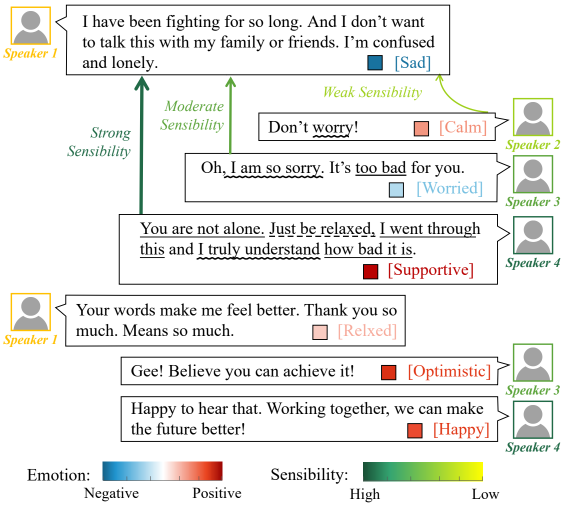

Figure 1: An empathetic dialogue example of multi-party. When people with different sensibilities respond to the same requests for help, their emotions and empathy differ. Different shades of red and blue denote the degree of positive and negative emotions, and different shades of green denote the degree of sensibilities. The texts use three kinds of underlines: straight, wavy, and dotted, which depict appropriate Emotional Reactions, Interpretations, and Explorations (three criteria to assess empathy), respectively.

Multi-party conversations also rely on aid from empathy analysis. For instance, people with a similar experience can smoothly communicate with each other and easily feel understood, encouraged, and supported. These observations encourage us to present a novel natural language processing task called Multi-Party Empathetic Dialogue Generation.

Generating multi-party empathetic dialogues faces two challenges. One challenge is the way to model multi-party dialogues. First, existing two-party dialogue models follow a seq2seq structure, whereas most multi-party dialogues are non-sequential. As shown in Figure 1, in response to *Speaker 1*, the third and fourth utterances both express empathy for his/her stress and struggle. Sec-

---

Volume 1: Long Papers, pages 298 - 307
May 22-27, 2022

ond, in addition to the target participant, other participants also have implicit influence and interaction, and should be considered of generating utterances at each step. For instance, as an example of how to successfully resolve the situation, *Speaker 4* inspires *Speaker 1* as well as relieves *Speaker 3* of his/her worry.

Another challenge is the way to model the fragile and nuanced feelings of dialogue participants. We first clarify the relations of sensibility, emotion, and empathy in this study. Previous empathy studies recognized the emotion of one party and generated dialogues coupled with the same emotion (Rashkin et al., 2019; Shin et al., 2020). However, empathy is also determined by sensibility, which is a perspective-taking ability to experience other partners' emotions and make an appropriate response with his/her own view. According to the response "I went through this" in Figure 1, we can find that *Speaker 4* has a similar experience to *Speaker 1*, while *Speaker 2* can only provide superficial comfort to *Speaker 1* due to his/her weak sensibility. We observe that sensibility arises from personality and experience, and remains static throughout a conversation. On the other hand, emotion may dynamically change. For example, *Speakers 2, 3*, and *4* possess different sensibilities to *Speaker 1*, and these personal background-related attributes are persistent in the conversation. By contrast, the emotion of *Speaker 1* gets reversed after receiving positive replies, as well as the main tone of this dialogue.

To comprehensively cope with the aforementioned challenges in this study, we present a **S**tatic-**D**ynamic model for **M**ulti-**P**arty **E**mpathetic **D**ialogue Generation called SDMPED. SDMPED models multi-party dialogues by constructing a dynamic graph network with temporal information and explores participants' dynamic emotions and static sensibilities by fusing speaker information.

The contributions of our work are as follows:

- We propose a new task called Multi-party Empathetic Dialogue Generation, which attempts to resolve the emotional changes and empathy generation of multiple participants in a conversation.
- We propose an effective baseline model SDMPED for this new task, which combines dynamic emotions and static sensibilities from multiple parties.
- We demonstrate that our approach leads to performance exceeding the state of the art when trained and evaluated on multi-party empathetic data.

2 Related Work

2.1 Empathy Analysis

Considering empathy in modeled conversations has been proposed as early as 20 years ago (Levinson et al., 2000). However, this idea has not been widely studied in NLP field due to the limitations of the available data. Recently, Rashkin et al. (2019) re-introduced the concept of empathetic dialogue and constructed the first empathetic dialogue dataset, EMPATHETICDIALOGUES (ED), which contains 32 emotions in 25K dialogues. Another dataset, PEC (Zhong et al., 2020), provides assurance that most of the data are in line with the characteristics of empathy, yet it lacks emotion-related annotations. Another limitation is that data in PEC come from only two forums on Reddit (i.e., happy5 and offmychest). The data in BlendedSkillTalk dataset (Smith et al., 2020) are collected from the ED, ConvAI2 (Dinan et al., 2020), and Persona-Chat (Zhang et al., 2018) datasets. However, only a small portion of these data are characterized by empathy. Notably, none of the aforementioned datasets have multiple (>2) persons participating in the same conversation, neither they include empathy degree labels.

Shin et al. (2020) formulated a reinforcement learning problem to maximize the user's emotional perception of the generated responses. Li et al. (2020b) utilized the coarse-grained dialogue-level and the fine-grained token-level emotions, which helped better capture the nuances of user emotions. In Caire (Lin et al., 2020), the empathy generation tasks are reinforced with an auxiliary objective for emotion classification by using a transfer learning model. Nevertheless, current empathetic dialogue models are conducted in the context of two participants; they do not explore the implicit interactions among multiple speaking persons and do not consider the differences in their sensibilities.

2.2 Multi-Party Dialogue

There have been quite a few studies on multi-party conversations before (Strauss and Minker, 2010), but they all focused on speech rather than conversational text. A recent multi-party study (Meng et al., 2018) has tended to focus on the Address and

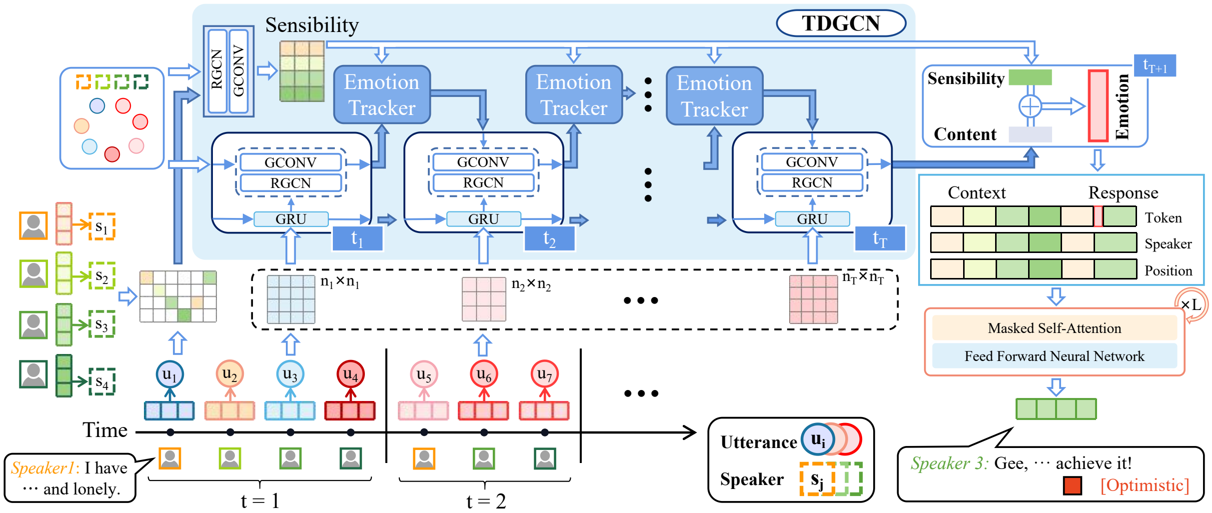

Figure 2: The overall architecture of SDMPED. Feature extraction provides the utterance and speaker sensibility nodes u_j and s_i, which will be input into TDGCN. By considering the utterance nodes and a segmented edge matrix E_t at time step t, we are able to compute the emotion-related content features. We combine static sensibilities with the current content information to get dynamic emotional information and input into the next moment. Finally, we use prompt tuning to generate final dialogue responses based on the dynamic emotions at $t+1$.

Response Selection (ARS) task and ignore the influence of emotions, which is a significant departure from our empathetic dialogue task.

Over the last years, researchers have gradually shifted from studying simple emotions in two-party dialogues (Busso et al., 2008; Li et al., 2017) to conducting more complex emotion analysis of multiple participants. STAC (Asher et al., 2016) and ARS (Ouchi and Tsuboi, 2016) are the multi-party dialogue datasets without emotion labels. MELD (Poria et al., 2019) and MESID (Firdaus et al., 2020) create the multi-modal multi-party emotional dialogue datasets from the TV series *Friends*. However, these two datasets contain the emotion-related data derived from short and colloquial chats from TV series, and consequently, their dialogue quality cannot be guaranteed. Additionally, these datasets can only be utilized for simple upstream tasks, such as emotion recognition. Most of the dialogues in current datasets are daily conversations on trivial topics, while those modeling empathy dialogues are lacking.

Majumder et al. (2019) proposed a conversational emotion recognition model based on RNN to dynamically model the states of multiple speakers. Later, Ghosal et al. (2019) and Li et al. (2020a) also studied context and speaker sensitivity based on the approach of Majumder et al. (2019). A common problem of these models is that they only focus on the accuracy of emotion recognition while ignoring the dynamic changes of emotions.

3 Model

In this section, we introduce a static-dynamic model called SDMPED as shown in Figure 2. We begin by describing the construction of the Temporal Dynamic Graph Network (TDGCN), including speaker sensibility nodes, emotion-related utterance nodes, and various types of edges between them. Thereafter, we use TDGCN to obtain dynamic emotions and static speaker sensibilities by integrating nodes and edges. Finally, we use prompt tuning to generate final dialogue responses based on emotion and sensibility information.

3.1 Problem Definition

We regard an empathetic post and its meaningful replies as a dialogue and ensure that each dialogue has more than three participating speakers. A post contains replies from multiple people, along with associated emotion and empathy degree labels. The empathy degree label of each utterance will be used in conjunction with the emotional content in our future model to learn the sensibility of each person.

We propose a concept called dialogue emotional turn, which is different from the traditional dialogue turn. Specifically, a dialogue is assumed to have multiple sentences in one emotional turn but with the same emotional tone. When a person utters a second sentence, the emotion may already differ from the previous one. Other people's subsequent utterances and emotions will be centered around this sentence. Therefore, we divide the dialogues to study the emotion variations over time, according to the principle that the same speaker can make at most one utterance during each emotional turn.

Then, we introduce key symbols and concepts used in our study. A T emotional turns dialogue with N utterances between M $(M > 2)$ speakers can be expressed as $U = \{u_{ik} | 1 \leq i \leq N$ and $1 \leq k \leq M\}$, where u_{ik} represents the ith sentence from jth speaker. To better study emotion variations, we specify that a speaker can at most utter one sentence in each emotional turn. Thus, U can be divided into $U = \{U_t | 1 \leq t \leq T\}$, where each part U_t has n_t nodes. Further, the sensibilities of speakers can be expressed as $S = \{s_1, s_2, ..., s_M\}$. Our model aims to generate an empathy response of length L.

3.2 Graph Construction

SDMPED captures the sensibility information and emotional variations of multiple parties owing to a novel graph network.

First, we train the multi-scale TextCNN (Zhang and Wallace, 2015) according to the empathy degrees of our dataset, and we extract the d-dimensional utterance-level features containing sensibility information. In each turn, we use the emotion of the first speaker as the main emotional tone, and extract the emotional content features based on those emotion labels in the same way.

Using these sensibility-related features as nodes and speaker-utterance relationships as an adjacency matrix, we construct a two-step static graph network to determine the static sensibility information $H_S = \{(H_x)_S | 1 \leq x \leq M\}$ of speakers. Thereafter, we represent the dialogue as a directed graph $G = (V, E, R, W)$ to obtain additional emotional information. The graph is constructed as follows:

Nodes V: The node set $V = \{v_{ik} | 1 \leq i \leq N$ and $1 \leq k \leq M\}$ incorporates emotion-related utterances. Among them, each node v_{ik} (abbreviated as v_i) is initialized with the extracted feature u_i spoken by the speaker s_k.

Adjacency Matrix E: E represents the adjacency matrix between emotion-related utterances. $e_{ij} \in E$ represents the edge from the utterance node v_i to v_j.

Edge Relations R: The relationship r_{ij} of edge e_{ij} is set mainly depending upon two things (Ghosal et al., 2019; Yang et al., 2021): the relative occurrence positions of u_i and u_j in the conversation (with three types of relations, namely, *Before*, *Current*, and *After*) and both speakers of the constituting utterance nodes, as shown in Figure 3.

Edge Weights W:Based on our assumptions, the edge weights are based on similarity-based attention, and the edge weights $\alpha_{ij} \in W$ are calculated as follows:

$$\begin{aligned} &\alpha_{ij} = \text{softmax}(u_i^T W[u_{i-p}, ..., u_{i+f}]), \\ &\text{for} \quad j = i - p, ..., i + f. \end{aligned} \tag{1}$$

And the relationship between the utterance and its speakers α_{ki} in static graph network can also be represented as $\frac{c}{Freq}$. Speaking frequency of the speakers $Freq$ denotes the utterance number of a speaker in the whole conversations. c is a speaking coefficient to avoid over-fitting.

Time Division Before feeding it into TDGCN, we need to divide E into T steps: $E = \{E_t | 1 \leq t \leq T\}$. At time step t, the divided matrix E_t includes only edges corresponding to the utterance in the emotional turn t.

As shown in Figure 1, four speakers participate in the dialogue with 7 utterances. This dialogue has two emotional turns: u_1 to u_4 and u_5 to u_7. The nodes and edges are constructed in Figure 3. We take node u_3 as an example. The edge e_{13} represents that u_1 spoken by s_1 appears before u_3 spoken by s_3 and the influence between them; the self-loop e_{33} represents the influence of current node u_3 on itself.

Two-Step Graph Update: The graph update mechanism has been implemented in two steps in order to better track conversation information and dynamic emotions. The update mechanism is calculated as follows:

$$\begin{aligned} h_i^{(1)} &= \sigma(\sum_{r \in R} \sum_{j \in N_i^r} \frac{\alpha_{ij}}{c_{i,r}} W_r^{(1)} u_j + \alpha_{ii} W_0^{(1)} u_i), \\ h_i^{(2)} &= \sigma(\sum_{j \in N_i^r} W^{(2)} h_j^{(1)} + W_0^{(2)} h_i^{(1)}), \end{aligned} \tag{1}$$

where α_{ij} and α_{ii} are the edge weights and N_i^r denotes the neighboring indices of node v_i under relation $r \in R$. $c_{i,r}$ can be set in advance, such as $c_{i,r} = |N_i^r|$. σ is the activation function ReLU, while $W_r^{(1)}$, $W_0^{(1)}$, $W^{(2)}$, and $W_0^{(2)}$ are learnable parameters.

Utilizing the Two-Step Graph Update mechanism, we can effectively normalize the local neighborhood through neighborhood connections and enable self-dependent feature transformation through

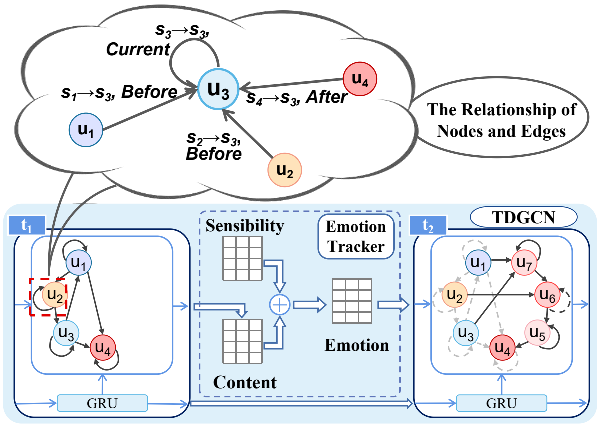

Figure 3: Transformation of dynamic emotions from t_1 to t_2, as well as various types of edges between different nodes (e.g., Node u_3).

self-connections, thereby extracting further information (Ghosal et al., 2019): We can call these two steps RGCONV and GCONV respectively in Figure 2.

3.3 TDGCN

Previous dynamic graphs were mostly used in spatio-temporal traffic networks with separated spatial and time features (Guo et al., 2019; Zhao et al., 2020). However, given that the utterance node is time-related and changes frequently, we implement the dynamic graph by updating a weight matrix through GRU and updating the hidden layer through the two-step graph:

$$\begin{aligned} M_t^{(l)} &= \mathrm{GRU}(H_{t-1}^{(l)}, M_{t-1}^{(l)}), \\ H_t^{(l)} &= \mathrm{GCONV}(\mathrm{RGCONV}(E_t, H_{t-1}^{(l)}, M_t^{(l)})), \end{aligned} \quad (2)$$

where $t \in [1, T]$ and $l \in [1, L]$ (L generally equals 2) denote the time and layer index, respectively. $M_{t-1}^{(l)}$ represents the weight matrix updated by GRU. $H_t^{(0)}$ is equal to the node features V. The hidden state $H_t^{(l)}$ of the lth layer at time step t can be divided into n_t parts: $H_t^{(l)} = \{(h_x)_t^{(l)}\}$, where x represents the speaker index. By concatenating person's sensibility with corresponding emotion-related content $(h_x)_t^{(l)}$, we obtain dynamic emotion embedding:

$$(e_x)_t^{(l)} = \left[(H_x)_S; (h_x)_t^{(l)}\right]. \quad (3)$$

Then, the emotion embedding set $e_t = \{(e_x)_t^{(l)}\}$ is sent to a fully connected layer and regarded as H_t at $t+1$ time step. We can also obtain a cross-entropy loss function at $t+1$:

$$\begin{aligned} P_e &= softmax(W_l e_{t+1}), \\ L_{emo} &= -\log\left(P_e[e]\right). \end{aligned} \quad (4)$$

3.4 Decoder and Loss

We adopt prompt tuning (Lester et al., 2021) to generate responses, which is a lightweight alternative to fine-tuning the generation task and keeps language model parameters unchanged while optimizing the prompt. The prompt adjustment achieves comparable performance in the full data setting by learning only parameters with a small proportion.

The representation e_{t+1} is first transformed by a linear transformation into prompt. We can obtain the input of the empathy decoder $Z = [X; \mathrm{prompt}; Y]$, where X and Y represent the context and target response, respectively. We use the standard maximum likelihood estimate to optimize the response prediction, and we obtain another loss function through the decoder:

$$L_{res} = -\log\big(p(Y|R_{generate})\big). \quad (5)$$

Finally, all the parameters are jointly trained end-to-end to optimize the listener selection and response generation by minimizing the sum of two losses:

$$L = L_{emo} + L_{res}. \quad (6)$$

4 Experiments

4.1 Dataset

Data Pre-Processing The MPED data is obtained from an online peer-to-peer support platform, where users can express their emotions by chatting with others who have similar experiences. Generally, we permit the words of each utterance to range between 3 and 100, excluding emojis, which are stored separately[1]. We discard artificially repeated characters, correct spelling errors, and standardize network language. Developing a dialogue model requires more ethical considerations. Therefore, we focus our analysis on help-seeking or emotional comfort-seeking conversations. As a result, the conversations with sensitive contents are filtered out. In the end, we further ensure that no private information is included.

---

[1] Emotional utterances have been incorporated in MPED yet not in our proposed baseline since we focus on unimodal text in this study.

It is quite beneficial that emotional category labels are available, which saves a lot of manual work. We have confirmed their accuracy and constructed the MPED dataset with kinds of emotions. We further classify these emotions for simplicity into 10 types, that is, *happy*, *sad*, *calm*, *angry*, *excited*, *exhausted*, *supportive*, *bored*, *nervous*, and *thankful*. MPED includes single-turn and multi-turn dialogue data, called MPED-S and MPED-M. We randomly split them into 80% training set, 10% validation set, and 10% testing set, respectively.

Empathetic Pre-Processing Given that empathy is a complex feeling, gathering empathetic data is challenging. We first remove the conversations that do not contain empathetic posts, such as games, and so forth. Then, we design a three-point scale (0 to 2) and evaluate empathy, where three criteria are used: Emotional Reactions (expressing warmth and compassion), Interpretation (articulating understanding of feelings and experiences), and Exploration (exploring feelings and experiences not stated in the post). Considering manually screening dialogues is infeasible on large-size data, we filter out simple replies and label single-turn dialogues. In the end, three degrees of empathy are included in MPED, that is, *weak*, *moderate*, and *strong*.

4.2 Experimental Setting

The hyper-parameters in our approach are set as follows. The input embeddings are 300-dimensional pre-trained 840B GloVe vectors. The speaking coefficient c is 5. The learning rate is 0.003 and batch size is 16. The dropout rate is 0.6, while the loss weight is $5e^{-4}$.

4.3 Evaluation Criteria

Automatic Evaluation Criteria We calculate the AVG BLEU (average of BLEU-1,-2,-3,-4) (Papineni et al., 2002) and ROUGE-L (Lin, 2004) scores as evaluations of model response generation, which have been often used to compare the system-generated response against the human-gold response in generation tasks.

Human Evaluation Criteria We randomly collect 100 dialogue samples and their corresponding generations from each model. Then, we assign human annotators to rate each response between 1 and 5 on three distinct attributes:

- *Empathy*: assesses whether the speaker of the response understands the feelings of others and fully manifests it;
- *Relevance*: evaluates whether the generated response is relevant with the dialogue context and consistent with the expressed information or background knowledge;
- *Fluency*: measures whether the response is smooth and grammatically correct.

4.4 Baselines and Models

MReCoSa: A context-sensitive model with multi-head self-attention (Zhang et al., 2019).

Multi-Trans: This multi-task model learns emotion classification and dialogue generation at the same time (Rashkin et al., 2018).

MoEL: This model (Lin et al., 2019) combines the response representations from multiple emotion-specific decoders.

EmpGD: This method (Li et al., 2020b) exploits coarse-grained and fine-grained emotions by an adversarial learning framework.

Caire: This method (Lin et al., 2020) fine-tunes a large-scale pre-trained language model with multiple objectives: response language modeling, response prediction, and dialogue emotion detection.

Random Prompt: We built a network with random values for prompt according to Lester et al. (2021).

We describe the variants of our model below:

Graph-Based: This simple model uses a graph-based model to build the empathetic dialogue graph of multi-party.

Two-Step Graph: This model adopts a graph network with two-step graph update.

SDMPED without Sensibility (SDMPED w/o S): This model ignores the sensibilities of speakers but maintains a TDGCN structure.

SDMPED: Our final model combines dynamic emotions with static sensibilities to produce empathy responses.

4.5 Experimental Results

Automatic Evaluation Results According to the experimental results shown in Table 1, our model SDMPED achieves the highest scores under most metrics compared with other baselines. The noticeable improvement indicates the effectiveness of SDMPED on empathetic expressions of multi-party. Since multi-party dialogues are not time-sequential

Model	MPED-M					MPED-S				
Metrics	ROUGE-L	AVG BLEU	Emp.	Rel.	Flu.	ROUGE-L	AVG BLEU	Emp.	Rel.	Flu.

Table 2: Ablation study on MPED-M and MPED-S.

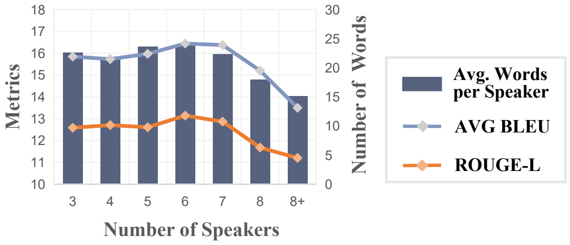

Figure 4: The effect of different numbers of speakers. The orange and blue lines represent BLEU-1 and ROUGE-L, and histograms in dark blue show the average number of words spoken by each person in multi-turn dialogues.

and multi-turn dialogues need to consider the impact of each turn, SDMPED performs better than the models MoEL, EmpDG, and Caire that are designed solely for two-party dialogue. Compared with the Random prompt model, our model has been greatly improved, which demonstrates that our emotional prompt design plays an important role. Given that persons have different sensibilities, adding the characteristics of different people to explore their conversations helps improve the performance. Thus, SDMPED obtains a performance improvement on the basis of SDMPED without Sensibility.

Human Evaluation Results Table 1 shows that SDMPED has achieved good performance in *Empathy*, *Relevance*, and *Fluency*. Our model is effective in capturing different emotional changes between multiple speakers and generating appropriate responses. MoEL and EmpDG are more inclined towards the characteristics of two-party dialogues, and thus cannot fully adapt to the new situation of multi-party. Random prompt and Caire are basically as good as our model in *Fluency*, however their *Empathy* and *Relevance* are inferior. These two models are pre-trained transfer learning models, and the generated responses are fluent and grammatical while being simple and general.

4.6 Ablation Study

We perform an ablation study to better understand the contributions of the main parts of our model. As shown in Table 2, the performance becomes noticeably worse, especially in the multi-turn dialogue data, after we remove the sensibility component. The degree of empathy for empathetic dialogues depends on the emotional tone at that time and the speakers' own abilities of perspective-taking, so studying sensibilities can help better investigate the responses generated by different people. According to the comparison of SDMPED without Sensibility and Two-Step Graph, emotions of people change at every moment, and updating the graph structure at each emotional turn is particularly necessary.

After removing the two-step graph update mechanism, we find that the results of Graph-Based have further declined, which indicates that the two-step graph convolution process can better extract empathetic and dialogue features.

4.7 Analysis of Speakers and Tokens

We investigate the effects of different numbers of speakers and tokens. When 3–7 speakers are available, as shown in Figure 4, the model maintains fairly stable results, indicating that it can handle multiple-party empathetic dialogues effectively. However, the results decline as the speaker number continues to increase. The reason for the drop is

	Speaker	**Sensibility**	**Utterance**
Context	*Speaker 1*	-	I am alone and have no friends now. I need a single hug. (Sad)
Response	*Speaker 2*	Weak	A virtual, because it could be possible. (Calm)
	Speaker 3	Moderate	**You are welcome to talk with me**. (Worried)
	Speaker 4	**Strong**	**I am sorry to hear that.** I believe **you can get through this** and **focus on what you love to do at the moment.** (Optimistic)
	Speaker 5	**Strong**	**Don't be miserable! Sending you sunshine to brighten your day**. (Supportive)

Table 3: An example of different responses by different speakers. Shades of blue represent the attention weights of *Speaker 1*. Below the text are three kinds of lines: straight, wavy, and dotted, which depict appropriate Emotional Reactions, Interpretations, and Explorations (three criteria to assess empathy).

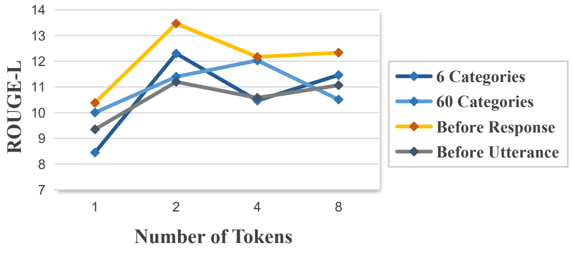

Figure 5: The effect of different numbers of tokens. The first three lines of this legend compare the effects when the emotion categories are 6, 10, and 60. **Before Utterance** and **Before Response** compare the effects of using different prompt embedding positions when dividing emotions into 10 categories.

that our conversations are typically concentrated between 3 to 5 people, and those with more than 7 people contain little content per speaker.

In Figure 5, we compare our model with two prompt embedding methods and different numbers of emotion classification categories. The comparison between the orange and blue curves shows that dividing emotions into 10 categories gives better results than the 6 and 60 categories (6 and 60 categories are similar to the number of categories in MELD and ED datasets). Clearly, dividing emotions into 10 categories and placing a prompt matrix with 2 tokens before the response can yield promising performance.

4.8 Case Study

We apply different speakers' sensibilities to the empathy decoder in the same multi-turn conversation context and obtain results based on MPED in Table 3. When presented with *Speaker 1*'s loneliness and depression, the following four speakers are willing to provide support, but they come up with different responses due to their different sensibilities. *Speaker 2* is relatively unable to appreciate the emotions of *Speaker 1* and jokes that he/she can find a virtual friend to hug; *Speaker 3* expresses warmth and *Speaker 4* and *Speaker 5* comfort *Speaker 1* and express their understanding. They also look forward to the future by suggesting that *Speaker 1* can do something that helps distract himself/herself.

5 Conclusions and Future Work

We have introduced a novel task called Multi-Party Empathetic Dialogue Generation.We have proposed a model called SDMPED suitable for the characteristics of the task. Our experiments have demonstrated that SDMPED is superior to other approaches on MPED. Future work can explore related issues such as integrating empathy into the dialogues, combining emojis and responses, guiding the active development of conversation.

Ethical Considerations

Data Collection. We collected publicly available data and removed all personal information (phone, email, postcode, location, and any other privacy information). Any potentially sensitive dialogues were completely removed from our data. No treatment recommendations or diagnostic claims were given in this study.

This research is approved and monitored by the University's Institutional Review Board and performed in accordance with the principle of GDPR (General Data Protection Regulation[2]) as follows: data processing shall be lawful if it is necessary for the performance of a task carried out in the public interest. Additionally, this study is explored not for any commercial use while merely for scientific

---

[2] https://gdpr-info.eu/.

purpose and public interest, which are safeguarded by the Art. 89 GDPR.

Annotator Compensation. We resorted to the Amazon Mechanical Turk crowdsourcing platform to evaluate three artificial indicators (i.e., Empathy, Relevance, and Fluency). The crowdworkers were assessed with 20 random sentences, which averagely took 5-6 minutes to accomplish, and compensated with \$0.8 per HIT (Human Intelligence Task). The compensation was determined based on the US minimum wage of \$7.12 per hour.

Potential Misuse. Our model is less likely to contribute to depression of users or generate non-empathic expressions (e.g., discrimination, criticism, and antagonism), since the model is based on the assumption that everyone has varying degrees of sensibility and empathy. Additionally, this model removes any sensitive information of users, and it is basically impossible to infer their personalities, preferences, interests, or other private information from the generated dialogues.

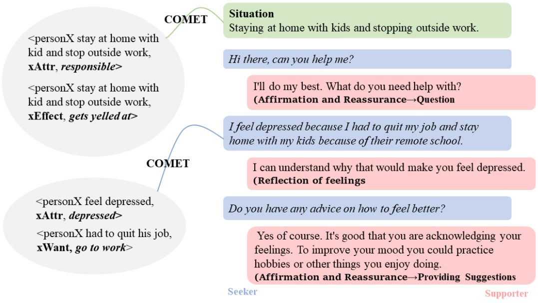
Abstract

Applying existing methods to emotional support conversation—which provides valuable assistance to people who are in need—has two major limitations: (a) they generally employ a conversation-level emotion label, which is too coarse-grained to capture user's instant mental state; (b) most of them focus on expressing empathy in the response(s) rather than gradually reducing user's distress. To address the problems, we propose a novel model **MISC**, which firstly infers the user's fine-grained emotional status, and then responds skillfully using a mixture of strategy. Experimental results on the benchmark dataset demonstrate the effectiveness of our method and reveal the benefits of fine-grained emotion understanding as well as mixed-up strategy modeling. Our code and data could be found in `https://github.com/morecry/MISC`.

1 Introduction

Empathy is the ability to perceive what others feel, think in their places and respond properly. It has a broad application scenarios to endow machines with the ability of empathy, including automatic psycho-therapist, intelligent customer service, empathetic conversational agents, and etc (Fitzpatrick et al., 2017; Shin et al., 2019; Ma et al., 2020).

In this work, we focus on a special kind of human-computer empathetic conversation, i.e., emotional support conversation (Liu et al., 2021). Distinguishedly, emotional support conversation happens between a seeker and supporter, where the supporter aims to gradually reduce seeker's distress as the conversation goes. This makes existing approaches unsuitable for our setting for at least two reasons. Firstly, existing work on emotional chatting learns to predict user emotion using a conversation-level emotion label, which is *coarse-grained* and *static* to the conversation context (Rashkin et al., 2019; Lin et al., 2019c; Li et al., 2020a). However, emotion is complex and user emotion intensity will *change* during the developing of the conversation (Liu et al., 2021). It is thus a necessity to tell seeker's *fine-grained* mental state at each utterance. Secondly, most of empathetic chatbots are trained to respond emotionally in accordance with the predicted coarse-grained emotion class, without consideration on how to address the seeker's emotional problem (De Graaf et al., 2012; Majumder et al., 2020; Xie and Park, 2021). Hence, they are deficient to apply for emotional support conversation whose goal is to help others work through the challenges they face.



Situation
Staying at home with kids and stopping outside work.

Hi there, can you help me?

I'll do my best. What do you need help with?
(Affirmation and Reassurance→Question

I feel depressed because I had to quit my job and stay home with my kids because of their remote school.

I can understand why that would make you feel depressed.
(Reflection of feelings

Do you have any advice on how to feel better?

Yes of course. It's good that you are acknowledging your feelings. To improve your mood you could practice hobbies or other things you enjoy doing.
(Affirmation and Reassurance→Providing Suggestions

Figure 1: An Emotional Support Conversation Example.

To tackle these issues, we propose a novel approach **MISC**, a.k.a. **MI**xed **S**rategy-aware model integrating **C**OMET for emotional support conversation. As to the first issue, we introduce COMET, a pre-trained generative commonsense reasoning model (Bosselut et al., 2019a), and devise an attention mechanism to selectively adopt the COMET knowledge tuples for fine-grained emotion understanding. As shown in Figure 1, this allows us to capture seeker's instantaneous mental state using different COMET tuples. In addition, we propose to also consider response strategy when generating empathetic responses for the second issue. Instead of modeling response strategy as a one-hot indi-

May 22-27, 2022

cator, we formulate it as a probability distribution over a strategy codebook, and guide the response generation using a mixture of strategies. At last, our MISC produces supportive responses based on both COMET-enhanced mental information and distributed strategy representation. The unique design of mixed strategy not only helps to increase the expressed empathy, but also facilitates to learn the gradual transition in the long response, as the last utterance in Figure 1, which will in turn make the conversation more smooth.

To evaluate our model, we conduct extensive experiments on ESConv benchmark (Liu et al., 2021) and compare with 5 state-of-the-art empathetic chatbots. Based on both automatic metrics and manual judgments, we demonstrate that the responses generated by our model MISC are more relevant and empathetic. Besides, additional experimental analysis reveal the importance of response strategy modeling, and sheds light on how to learn a proper response strategy as well as how response strategy could influence the empathy of the chatbot.

In brief, our contributions are as follows: (1) We present a Seq2Seq model MISC, which incorporates commonsense knowledge and mixed response strategy into emotional support conversation; (2) We conduct experiments on ESConv dataset, and demonstrate the effectiveness of the proposed MISC by comparing with other SOTA methods. (3) We implement different ways of strategy modeling and give some hints on strategy-aware emotional support conversation.

2 Related Work

2.1 Emotion-aware Response Generation

As suggested in Liu et al. (2021), emotion-aware dialogue systems can be categorized into three classes: emotional chatting, empathetic responding and emotional support conversation. Early work target at emotional chatting and rely on emotional signals (Li et al., 2017; Zhou et al., 2018a; Wei et al., 2019; Zhou and Wang, 2018; Song et al., 2019). Later, some researchers shift focus towards eliciting user's specific emotion (Lubis et al., 2018; Li et al., 2020b). Recent work begin to incorporate extra information for deeper emotion understanding and empathetic responding (Lin et al., 2020; Li et al., 2020a; Roller et al., 2021). Li et al. (2021a) and Zhong et al. (2021) exploit ConceptNet to enhance emotion reasoning for response generation. Different from them, our work exploits a generative commonsense model COMET (Bosselut et al., 2019b), which enables us to capture seeker's mental states and facilitates strategy prediction in emotional support conversation.

2.2 Commonsense Knowledge for NLP

Recently, there is a large body of literature injecting commonsense knowledge into various NLP tasks, including classification (Chen et al., 2019; Paul and Frank, 2019), question answering (Mihaylov and Frank, 2018; Bauer et al., 2018; Lin et al., 2019a), story and language generation (Guan et al., 2019; Ji et al., 2020), and also dialogue systems (Zhou et al., 2018b; Zhang et al., 2020; Li et al., 2021a; Zhong et al., 2021). These dialogue systems often utilize ConceptNet (Speer et al., 2017), aiming to complement conversation utterances with physical knowledge. Distinguished from ConceptNet, ATOMIC (Sap et al., 2019) covers social knowledge including event-centered causes and effects as well as person-related mental states. To this end, ATOMIC is expected beneficial for emotion understanding and contributing to response empathy. In this work, we leverage COMET (Bosselut et al., 2019b), a commonsense reasoning model trained over ATOMIC for emotional support conversation.

2.3 Strategy-aware Conversation Modeling

Conversation strategy can be defined using different notions from different perspectives. A majority of research works is conducted under the notion of dialog acts, where a plethora of dialog act schemes have been created (Mezza et al., 2018; Paul et al., 2019; Yu and Yu, 2021). Dialog acts are empirically validated beneficial in both task-oriented dialogue systems and open-domain social chatbots (Zhao et al., 2017; Xu et al., 2018; Peng et al., 2020; Li et al., 2020c). As to empathetic dialogues, conversation strategy is often defined using the notion of response intention or communication strategy, which is inspired from the theories of empathy in psychology and neuroscience (Lubis et al., 2019; Li et al., 2021b). Whereas Welivita and Pu (2020) define a taxonomy of 15 response intentions through which humans empathize with others, Liu et al. (2021) define a set of 8 support strategies that humans utilize to reduce other's emotional distress. This partially reveals that response strategy is complex, which motivates us to condition on a mixture of strategy when generating supportive responses.

3 Preliminaries

3.1 ESConv Dataset

In this paper, we use the **E**motional **S**upport **Conv**ersation dataset, **ESConv** (Liu et al., 2021). Before conversations start, seekers should determine their emotion types, and tell the situation they are dealing with to supporters. Besides, the strategy of every supporter's utterance is marked, which is the most important to our work. In total, there are 8 kinds of strategies, and they are almost evenly distributed. More details are given in Appendix.

3.2 Problem Formulation

For general dialogue response generation, the target is to estimate the probability distribution $p(\boldsymbol{r}|\boldsymbol{c})$ of the dataset $\mathcal{D} = \{\boldsymbol{c}^{(i)}, \boldsymbol{r}^{(i)}\}_{i=1}^{N}$, where $\boldsymbol{c}^{(i)} = (\boldsymbol{u}_1^{(i)}, \boldsymbol{u}_2^{(i)}, ..., \boldsymbol{u}_{n_i}^{(i)})$ consists of a sequence of n_i utterances in the dialogue history, and $\boldsymbol{r}^{(i)}$ is the target response. For the sake of brevity, we omit the superscript (i) when denoting a single example in the remaining part.

In the setting of emotional support conversation, the seeker's situation $\boldsymbol{s}$ is considered as an extra input, which describes the seeker's problem in free-form text. We also denote the seeker's last post (utterance) as $\boldsymbol{x}$. Consequently, the target becomes to estimate the probability distribution $p(\boldsymbol{r}|\boldsymbol{c}, \boldsymbol{s}, \boldsymbol{x})$.

4 Model: MISC

The overview of our approach is shown in Figure 2. Based on blenderbot-small (Roller et al., 2021), our model MISC consists three main components: (1) a mental state-enhanced encoder (Bosselut et al., 2019a); (2) a mixed strategy learning module; and (3) a multi-factor-aware decoder.

4.1 Mental State-Enhanced Encoder

Following common practice, we firstly represent the context using the encoder $\mathtt{E}$:

$$\boldsymbol{C} = \mathtt{E}(\mathtt{CLS}, \boldsymbol{u}_1, \mathtt{EOS}, \boldsymbol{u}_2, ..., \boldsymbol{u}_{n_i}) \tag{1}$$

where `CLS` is the start-token and `EOS` is the separation-token between two utterances.

To better understand the seeker's situation, we exploit COMET (Bosselut et al., 2019a), a commonsense knowledge generator to supply mental state information related to the conversation. Concretely, we treat the situation $\boldsymbol{s}$ as an event, and feed it with different relations into COMET:

$$\boldsymbol{B}^s = \bigcup_{j=1}^{N_r} \mathtt{COMET}(rel_j, \boldsymbol{s}) \tag{2}$$

where N_r is the number of pre-defined relations in COMET, and rel_j stands for the j-th specific relation, such as `xAttr` and `xReact`.[1] Note that given a certain event-relation pair, COMET is able to generate multiple "tails" of free-form mental state information, $\boldsymbol{B}^s$ is a set of N_s mental state blocks, i.e., $\boldsymbol{B}^s = \{\boldsymbol{b}_j^s\}_{j=1}^{N_s}$. Similarly, we can obtain the set of mental state blocks $\boldsymbol{B}^x$ using the seeker's last post $\boldsymbol{x}$.

Then, all of the free-form blocks will be transformed into dense vectors using our encoder $\mathtt{E}$:

$$\begin{aligned} \hat{\boldsymbol{H}}^s &= [\boldsymbol{h}_{1,1}^s, \boldsymbol{h}_{2,1}^s, ..., \boldsymbol{h}_{N_{st},1}^s] \\ \boldsymbol{h}_j^s &= \mathtt{E}(\boldsymbol{b}_j^s) \end{aligned} \tag{3}$$

and the hidden state of each block's first token will be used to represent the corresponding block. Later, due to the noisy of COMET blocks, a lot of them are irrelevant to the context. We creatively take attention method to refine the strongly relevant blocks. That operation could be expressed as

$$\begin{aligned} \boldsymbol{Z} &= \mathtt{softmax}(\hat{\boldsymbol{H}}^s \cdot \boldsymbol{C}^{\mathrm{T}}) \cdot \boldsymbol{C} \\ \boldsymbol{H}^s &= \mathtt{LN}(\hat{\boldsymbol{H}}^s + \boldsymbol{Z}) \end{aligned} \tag{4}$$

where `LN` is the LayerNorm module (Ba et al., 2016). Similarly, we could transform $\boldsymbol{x}$ to $\boldsymbol{H}^x$ following the same method as $\boldsymbol{s}$ to $\boldsymbol{H}^s$. At last, we get the conversation-level and utterance-level representation of seeker's mental state $\boldsymbol{H}^s$ and $\boldsymbol{H}^x$, which are enhanced with commonsense information.

4.2 Mixed Strategy Learning Module

One straightforward way to predict the response strategy is to train a classifier upon the CLS states of the context representation $\boldsymbol{C}$ from Eq. (1):

$$\boldsymbol{p}^g = \mathtt{MLP}(\boldsymbol{C}_1) \tag{5}$$

where `MLP` is a multi-layer perceptron, and $\boldsymbol{p}^g$ records the probabilities of each strategy to be used.

To model the complexity of response strategy as discussed before, we propose to employ the distribution $\boldsymbol{p}^g$ and model a mixture of strategies for

---

[1] Please refer to the appendix file for the definitions of all the relations as well as a brief introduction of COMET.

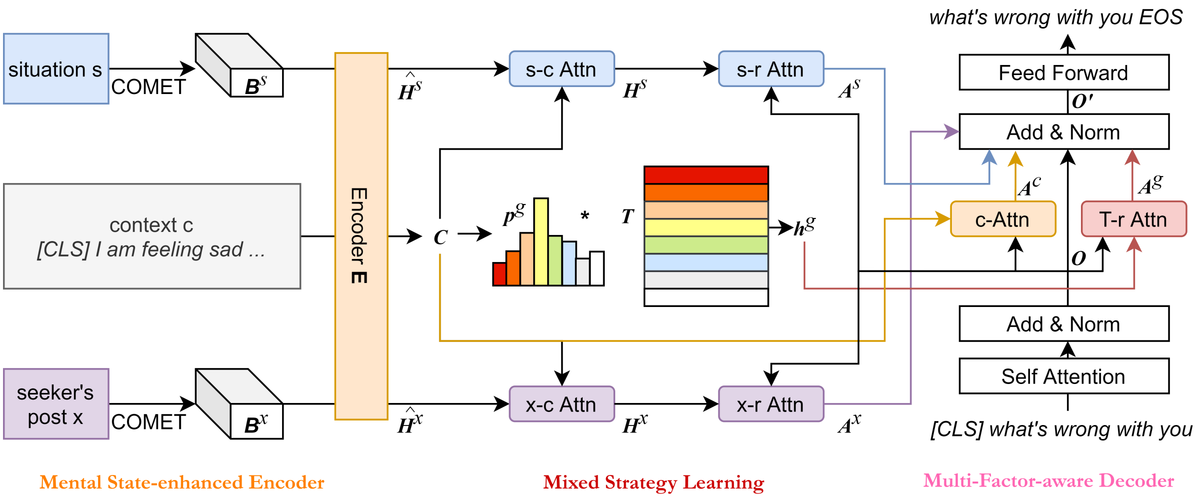

Figure 2: The overview of the proposed MISC which consists of a mental state-enhanced encoder, a mixed strategy learning module, and a multi-factor-aware decoder.

response generation. Here, we masterly learn from the idea of VQ-VAE's codebook to represent strategy(Oord et al., 2017). The strategy codebook $\boldsymbol{T} \in \mathbb{R}^{m \times d}$ represent m strategy latent vectors (here m = 8) with the dimension size d. By weighting $\boldsymbol{T}$ using $\boldsymbol{p}^g$, we are able to obtain a comprehensive strategy representation $\boldsymbol{h}^g$

$$\boldsymbol{h}^g = \boldsymbol{p}^g \cdot \boldsymbol{T} \tag{6}$$

Our codebook-based method has two benefits: (1) It is beneficial when long responses are needed to skillfully reduce the seeker's distress, which is common in emotional support conversation. (2) It is flexible to learn. Intuitively, if a strategy has a higher probability in $\boldsymbol{p}^g$, it should take greater effect in guiding the support conversation. In the extreme case where we have a sharp distribution, one single strategy will take over the control.

4.3 Multi-Factor-Aware Decoder

The remaining is to properly utilize the inferred mental states and the strategy representation. To notify the decoder of these information, we modify the backbone's cross attention module as:

$$\begin{aligned}
\boldsymbol{A}^c &= \texttt{CROSS-ATT}(\boldsymbol{O}, \boldsymbol{H}) \\
\boldsymbol{A}^s &= \texttt{CROSS-ATT}(\boldsymbol{O}, \boldsymbol{H}^s) \\
\boldsymbol{A}^x &= \texttt{CROSS-ATT}(\boldsymbol{O}, \boldsymbol{H}^x) \\
\boldsymbol{A}^g &= \texttt{CROSS-ATT}(\boldsymbol{O}, \boldsymbol{h}^g) \\
\boldsymbol{O}' &= \texttt{LN}(\boldsymbol{A}^c + \boldsymbol{A}^s + \boldsymbol{A}^x + \boldsymbol{A}^g + \boldsymbol{O})
\end{aligned} \tag{7}$$

where `CROSS-ATT` stands for the backbone's cross attention module, and $\boldsymbol{O}$ is the hidden states of the decoder, which produces the final response by interacting with multi-factors.

Based on blenderbor-small (Roller et al., 2021), we jointly train the model to predict the strategy and produce the response:

$$\begin{aligned}
\mathcal{L}_r &= -\sum_{t=1}^{n_r} \texttt{log}(p(r_t | \boldsymbol{r}_{j<t}, \boldsymbol{c}, \boldsymbol{s}, \boldsymbol{x})) \\
\mathcal{L}_g &= -\texttt{log}(p(g | \boldsymbol{c}, \boldsymbol{s}, \boldsymbol{x})) \\
\mathcal{L} &= \mathcal{L}_r + \mathcal{L}_g
\end{aligned} \tag{8}$$

where n_r is the length of response, g is the true strategy label, $\mathcal{L}_g$ is the loss of predicting strategy, $\mathcal{L}_r$ is the loss of predicting response, and $\mathcal{L}$ is combined objective to minimize.

5 Experiments

5.1 Experimental Setups

We evaluate our and the compared approaches on the dataset ESConv (Liu et al., 2021). For preprocessing, we truncate the conversation examples every 10 utterances, and randomly spilt the dataset into train, valid, test with the ratio of 8:1:1. The statistics is given in Table 1.

Category	**Train**	**Dev**	**Test**
# dialogues	14117	1764	1764
Avg. # words per utterance	17.25	17.09	17.11
Avg. # turns per dialogue	7.61	7.58	7.49
Avg. # words per dialogue	148.46	146.66	145.17

Table 1: The statistics of processed ESConv dataset.

5.2 Evaluation Metrics

We adopt a set of automatic and human evaluation metrics to assess the model performances:

Automatic Metrics. (1) We take the strategy prediction accuracy **ACC.** as an essential metric. A higher ACC. indicates that the model has a better capability to choose the response strategy. (2) We then acquire the conventional **PPL** (perplexity), **B-2** (BLEU-2), **B-4** (BLEU-4) (Papineni et al., 2002), **R-L** (ROUGE-L) (Lin, 2004) and **M** (Meteor) (Denkowski and Lavie, 2014) metrics to evaluate the lexical and semantic aspects of the generated responses. (3) For response diversity, we report **D-1** (Distinct-1) and **D-2** (Distinct-2) numbers, which assesses the ratios of the unique n-grams in the generated responses (Li et al., 2016).

Human Judgments. Following See et al. (2019), we also recruit 3 professional annotators with linguistic and psychologist background and ask them to rate the generated responses according to Fluency, Knowledge and Empathy aspects with level of {0,1,2}. For fair comparison, the expert annotators do not know which model the response is from. Note that these 3 writers are paid and the results are proof-checked by 1 additional person.

5.3 Compared Models

Transformer is a vanilla Seq2Seq model trained based on the MLE loss (Vaswani et al., 2017).

MT Transformer is the **M**ulti-**T**ask transformer which considers emotion prediction as an extra learning task (Rashkin et al., 2018). In specific, we use the conversation-level emotion label provided in ESConv to learn emotion prediction.

MoEL softly combines the output states from multiple listeners (decoders) to enhance the response empathy for different emotions (Lin et al., 2019b).

MIME considers the polarity-based emotion clusters and emotional mimicry for empathetic response generation (Majumder et al., 2020).

BlenderBot-Joint is the SOTA model on ESConv dataset, which prepends a special strategy token before the response utterances (Liu et al., 2021).

5.4 Implementation Details

We implement our approach based on blenderbot-small (Roller et al., 2021) using the default sizes of vocabulary and the hidden states. For the last post x and the situation s, we set the maximum number of the retrieved COMET blocks as 30 and 20 respectively. The inferred COMET blocks will be sent to the encoder with a maximum of 10 words.

To be comparable with the SOTA model in Liu et al. (2021), we fine-tune MISC based on the blenderbot-small with the size of 90M parameters by a Tesla-V100 GPU. The batch size of training and evaluating is 20 and 50, respectively. We initialize the learning rate as 2e-5 and change it during training using a linear warmup with 120 warmup steps. We use AdamW as optimizer (Loshchilov and Hutter, 2018) with β_1=0.9, β_2=0.999 and ϵ=1e-8. After training 8 epochs, the checkpoint with the lowest perplexity on the validation set is selected for testing. Following (Liu et al., 2021), we also adopt the decoding algorithms of Top-p and Top-k sampling with p=0.3, k=30, temperature τ=0.7 and the repetition penalty 1.03. We will release the source code to facilitate future work.

5.5 Experimental Results

As shown in Table 2, the vanilla Transformer performs the worst according to its relatively low PPL, BLEU-n and distinct-n scores. This is not suprising because it does not have any other specific optimization objective to learn the ability of empathy, and it is observed to be deficient for capturing long context as that in the ESConv dataset.

The performances of MT Transformer, MoEL and MIME, are also disappointing. Even though they three are equipped with empathetic objectives such as emotion prediction and ensembling listener, they are based on the conversation-level static emotion label, which is not adequate for fine-grained emotion understanding. More importantly, these three empathetic models lack of the ability of strategically consoling the seekers in the setting of emotional support conversation.

By comparing with the SOTA model BlenderBot-Joint, we can see that our model MISC is more effective especially in predicting more accurate response strategy. Whereas BlenderBot-Joint predicts one single strategy at the first decoding step, our method MISC models mixed response strategies using a strategy codebook and allows the decoder to learn the smooth transition and exhibit empathy more naturally. The comparison result suggests that it is beneficial to predict the response strategy as an extra task and to take into consideration the strategy complex for emotional support conversation.

The human evaluation results in Table 3 are consistent with the automatic results. Thanks to the pre-

trained LM blenderbot-small (Rashkin et al., 2018), BlenderBot-Joint and our MISC significantly outperform other models on the Fluency aspect. Notably, our MISC yields the highest Knowledge score, which indicates that the responses produced by our approach contain much more specific information related to the context. We conjecture that our multi-factor-aware decoder successfully learns utilize the mental state knowledge from COMET with the mixture of the predicted strategies.

Overall speaking, MISC performs the best on almost every metric. It strongly demonstrates the effectiveness of our approach, and highlights the importance of fine-grained mental state modeling and mixed response strategy incorporation.

6 Analysis

Our method MISC has two novel designs: considering the fine-grained mental states and incorporating a mixture of response strategy. To investigate more, we conduct extra experiments, and the analysis results give us hints of how to develop better emotional support conversational agents.

6.1 Ablation Study

In order to verify the improvement brought by each added part (g, s, x), we drop these three parts from the MISC and check the performance changes. As shown in Table 4, the scores on all the metrics decrease dramatically when the g is albated. Consequently, we suppose the strategy attention is vital for guiding the semantics of the response. In addition, the scores also decline when we remove the the situation s and the seeker's last query x. According to the above experiments, each main part of the MISC is proven effective.

Model	**D-1↑**	**B-2↑**	**R-L↑**	**M(%)↑**
MISC	**4.41**	**7.31**	**17.91**	**11.05**
w/o g	3.85	7.09	16.75	9.85
w/o s	4.39	6.35	17.05	10.06
w/o x	4.27	6.49	17.03	10.09

Table 4: Evaluation Results of Ablation Study.

6.2 Case Study

In Table 5, an example is present to compare the response generated by the MISC and the other models. Various problems appear in the compared models, such as inconsistency, repetition, contradiction, etc. Intuitively, our model achieves the best performance in contrast. Besides, we present a visualization in Figure 4 to interpret how the MISC organizes the response under the combined effect of the COMET blocks and the mixture of strategies.

6.3 Fine-grained Emotion Understanding

As discussed before, one limitation of previous approaches is that they solely rely on a conversation-level emotion label, which is too coarse to guide the chatbot respond strategically and help the emotional conversation progress healthily. To remedy this issue, we exploit the commonsense knowledge generator COMET to supplement fine-grained information of seeker's mental state.

In order to fairly examine the effects of different emotional information, we discard the COMET blocks and implement a variant of our method MISE, a.k.a. **MI**xed-**S**rategy-aware model integrating **E**motion, where an extra emotion classification objective is added to the main architecture, as in Rashkin et al. (2018). Table 6 summarizes the comparison results between our full model MISC and its variant MISE. Obviously, all the metrics

Situation	
Seeker	My boyfriend and I recently broke up due to long-distance relationship and the impact COVID-19...
Context	
Seeker	Hi, I'm hoping you can help me get through this difficult time.
Supporter	Hi, can you please explain the difficult time you are having?
Seeker	My boyfriend broke up with me and I've been upset. We live in different parts of the country and...
	......
Seeker	Have you ever gone through a break up?
Response	
Transformer	I am so sorry that you are not able to get your friends and family. (*Inconsistency*)
MT Transformer	I have had a similar situation and I understand. It was the only way I was in similar situation, I have found that way to get out of my life. I have ... and i was in a similar situation. (*Repetition*)
MIME	I know it is hard, but it is always good to do things out for yourself. (*Poor Empathy*)
MoEL	I am so sorry that you are feeling better. I had a relationship with your boyfriend! (*Aggressiveness*)
BlenderBot-Joint	I have not but i have been through a lot of breakups... (*Contradiction*)
MISC	I have been through a breakup and I can tell you that it was very painful. I have had to move on from a relationship because of it. (*Strong Empathy*)
Ground-Truth	It sounds like you are really stressed over the breakup and you want to know how to move forward.

Table 5: Responses generated from MISC and other compared models. Some words are omitted due to space limit.

Component	D-1↑	B-2↑	R-L↑	M(%)↑
MISC	**4.41**	**7.31**	**17.91**	**11.05**
MISE	3.94	7.09	16.93	10.53

Table 6: Results of MISC with Different Emotions.

drop when replacing the fine-grained mental information with coarse-grained emotion label.

To depict the advantage of fine-grained mental state information, we visualize the attended COMET blocks of the example in Table 5. As shown in Figure 4, our chatbot MISC pays much attention of those inferred knowledge that are beneficial for fine-grained emotion understanding and strategy-aware empathetic responding.

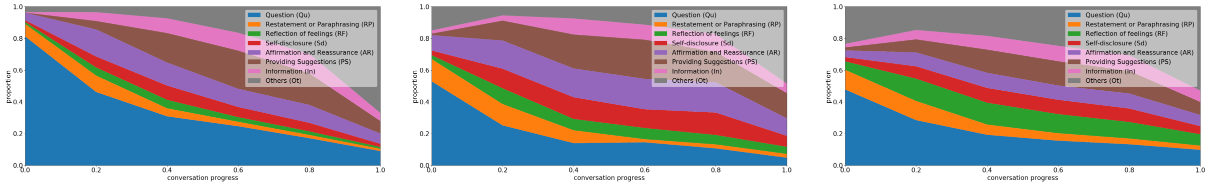
More specifically, the attended COMET blocks (`xReact`, *hurt*) and (`xAttr`, *sad*) permit our chatbot MISC to utter the words "*it was painful*" which reflects its understanding of the seeker's feeling. Besides, note that the COMET blocks with white background are retrieved using the situation information s, and the grey ones are collected using the seeker's last post x. Despite of some overlapping, the white and grey attended blocks do contain distinct and crucial mental state knowledge. This partially validates that s and x is complementary to each other, and they two are useful information for emotional support conversation.

6.4 Mixed-Strategy-Aware Empathetic Responding

Meanwhile, the mixture of response strategy also plays a vital role for emotional support conversation. By analyzing the aforementioned case in depth, we find some hints on why our way to model conversation strategy is more preferred in the setting of emotional support conversation.

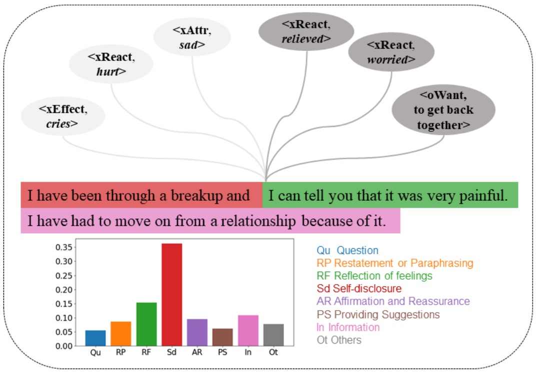
Hint 1: Mixed strategy is beneficial for Smooth Emotional Support. In Figure 4, we visualize the predicted strategy representation and the generated support response in Table 5. After understanding the seeker's situation of break-up and feelings of sadness, our MISC reasons that it might be proper to employ the strategies of *Self-disclosure*, *Reflection of feelings* to emotionally reply and effectively console the seeker's. Then, MISC organizes the response by firstly reveals that "it" has similar experiences and knows the feelings like. Moreover, the chatbot also supplements detailed information of *move on from a relationship* to suggest that the life will go on. These added-up words could be regarded as using the strategy of *Information* or *Others*, which is useful to transit the conversation to the next step smoothly. This case vividly shows how response generation is guided by the mixed strategies, and how skillful of our chatbot MISC is.

Hint 2: Mixed strategy is more effective than single strategy. In addition to the case study, we also attempt to quantitatively assess the benefit of the mixed strategy modeling. To do so, we implement another variant of our chatbot **Single** where the mixed representation is replaced with an one-hot representation. Typically, we pick up the strategy dimension with the largest probability value as the one-hot output. The comparison results are given in Table 7. Although yielding a slightly better distinct-n scores, the single-strategy variant lags far behind according to the lexical and semantic scores.



(a) predicted by the MISC. (b) from the test set. (c) predicted by the BlenderBot-Joint.

Figure 3: The strategy distribution in the different stage of conversation.



I have been through a breakup and I can tell you that it was very painful. I have had to move on from a relationship because of it.

Figure 4: The visualization of how the MISC organizes the response under the effect of multiple factors.

Recall that the SOTA model BlenderBot-Joint (Liu et al., 2021) can also be regarded as a single-strategy model where a special strategy token is firstly decoded at the beginning of the response generation. We then compare their way of strategy modeling with our mixed strategy representation. As shown in Figure 5, the top-k strategy prediction accuracy of our MISC always surpasses that of BlenderBot-Joint, and the top-5 accuracy of our model reaches over 80%. This again proves the success of our strategy modeling.

Strategy	**D-1**↑	**B-2**↑	**R-L**↑	**M(%)**↑
Mixture	4.41	**7.31**	**17.91**	**11.05**
Single	**4.79**	6.30	17.01	10.22

Table 7: Comparison of different strategy modeling.

Hint 3: Mixed strategy is suitable for ESC Framework. The emotional support conversations in the dataset ESConv are guided by the ESC Framework, which suggests that emotional support generally follows a certain order of strategy flow. Similar to (Liu et al., 2021), here we also visualize the strategy distributions learned from different models, and compare them with the "ground-truth" strategy distribution in the original dataset. As shown in Figure 3, we can find: (1) Comparing our model with the SOTA model BlenderBot-Joint, we can find that our MISC better mimics the skill of strategy adoption in emotional support conversation. (2) At almost all stages of the conversation, our model is less likely to predict the strategy of *Others* (the grey part), as compared to BlenderBot-Joint. This indicates that the strategy acquired by our model is more discriminative than those by BlenderBot-Joint. (3) Overall speaking, the strategy distribution from our model share very similar patterns as compared to the ground-truth distribution. This implies that our way to model the strategy learning is suitable for the ESC framework.

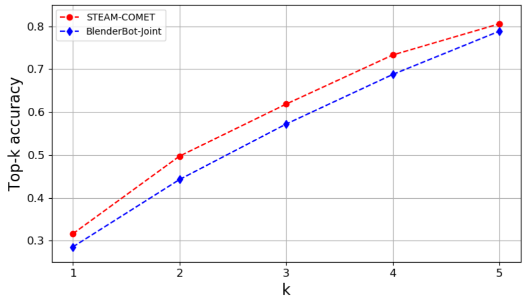


Figure 5: The Top-k Strategy Prediction Accuracy.

7 Conclusions

In this paper, we propose MISC, a novel framework for emotional support conversation, which introduces COMET to capture user's instant mental state, and devises a mixed strategy-aware decoder to generate supportive response. Through extensive experiments, we prove the superiority and rationality of our model. In the future, we plan to learn the mixed response strategy in a dynamic way.

8 Ethical Considerations

At last, we discuss the potential ethic impacts of this work: (1) The ESConv dataset is a publicly-available, well-established benchmark for emotional support conversation; (2) **Privacy**: The original providers have filtered the sensitive information such as personally identifiable information (Liu et al., 2021); (3) Nevertheless, due to the limitation of filtering coverage, the conversations might still remain some languages that are emotionally triggering. Note that our work focuses on building emotional support conversational agents. For risky situations such as self-harm-related conversations, we do not claim any treatments or diagnosis.

A Distribution of Strategies

As show in Figure 6, we can see that the proportion of each strategy is relatively balanced.

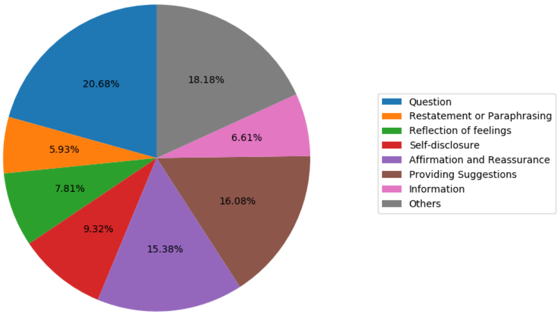

Figure 6: The strategy distribution in the original ESConv dataset.

B Definition of Strategies

Here, we directly adopted from (Liu et al., 2021) to help readers to learn about the specific meaning of each strategy more conveniently.

Question Asking for information related to the problem to help the help-seeker articulate the issues that they face. Open-ended questions are best, and closed questions can be used to get specific information.

Restatement or Paraphrasing A simple, more concise rephrasing of the help-seeker's statements that could help them see their situation more clearly.

Reflection of Feelings Articulate and describe the help-seeker's feelings.

Self-disclosure Divulge similar experiences that you have had or emotions that you share with the help-seeker to express your empathy.

Affirmation and Reassurance Affirm the help-seeker's strengths, motivation, and capabilities and provide reassurance and encouragement.

Providing Suggestions Provide suggestions about how to change, but be careful to not overstep and tell them what to do.

Information Provide useful information to the help-seeker, for example with data, facts, opinions, resources, or by answering questions.

Others Exchange pleasantries and use other support strategies that do not fall into the above categories.

C Description of COMET Relations

In the section, we also adopted the description from (Bosselut et al., 2019a), so as reader needn't to find it in original text.

`oEffect` The effect the event has on others besides Person X.

`oReact` The reaction of others besides Person X to the event.

`oWant` What others besides Person X may want to do after the event.

`xAttr` How Person X might be described given their part in the event.

`xEffect` The effect that the event would have on Person X.

`xIntent` The reason why X would cause the event.

`xNeed` What Person X might need to do before the event.

`xReact` The reaction that Person X would have to the event.

`xWant` What Person X may want to do after the event.

GLM: General Language Model Pretraining with Autoregressive Blank Infilling

Abstract

There have been various types of pretraining architectures including autoencoding models (e.g., BERT), autoregressive models (e.g., GPT), and encoder-decoder models (e.g., T5). However, none of the pretraining frameworks performs the best for all tasks of three main categories including natural language understanding (NLU), unconditional generation, and conditional generation. We propose a General Language Model (GLM) based on autoregressive blank infilling to address this challenge. GLM improves blank filling pretraining by adding 2D positional encodings and allowing an arbitrary order to predict spans, which results in performance gains over BERT and T5 on NLU tasks. Meanwhile, GLM can be pretrained for different types of tasks by varying the number and lengths of blanks. On a wide range of tasks across NLU, conditional and unconditional generation, GLM outperforms BERT, T5, and GPT given the same model sizes and data, and achieves the best performance from a single pretrained model with 1.25× parameters of $\text{BERT}_{\text{Large}}$, demonstrating its generalizability to different downstream tasks.[1]

1 Introduction

Language models pretrained on unlabeled texts have substantially advanced the state of the art in various NLP tasks, ranging from natural language understanding (NLU) to text generation (Radford et al., 2018a; Devlin et al., 2019; Yang et al., 2019; Radford et al., 2018b; Raffel et al., 2020; Lewis et al., 2019; Brown et al., 2020). Downstream task performance as well as the scale of the parameters have also constantly increased in the past few years.

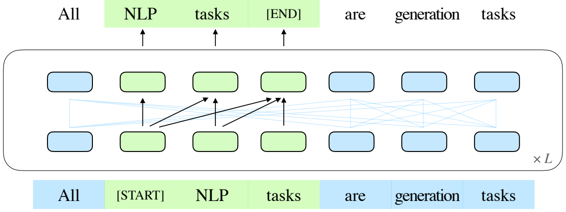

Figure 1: Illustration of GLM. We blank out text spans (green part) and generate them autoregressively. (Some attention edges are omitted; cf. Figure 2.)

In general, existing pretraining frameworks can be categorized into three families: *autoregressive*, *autoencoding*, and *encoder-decoder* models. Autoregressive models, such as GPT (Radford et al., 2018a), learn left-to-right language models. While they succeed in long-text generation and show few-shot learning ability when scaled to billions of parameters (Radford et al., 2018b; Brown et al., 2020), the inherent disadvantage is the unidirectional attention mechanism, which cannot fully capture the dependencies between the context words in NLU tasks. Autoencoding models, such as BERT (Devlin et al., 2019), learn bidirectional context encoders via denoising objectives, e.g. Masked Language Model (MLM). The encoders produce contextualized representations that suit natural language understanding tasks, but could not be directly applied for text generation. Encoder-decoder models adopt bidirectional attention for the encoder, unidirectional attention for the decoder, and cross attention between them (Song et al., 2019; Bi et al., 2020; Lewis et al., 2019). They are typically deployed in conditional generation tasks, such as text summarization and response generation. [2]. T5 (Raffel et al., 2020) unifies NLU and conditional generation via encoder-decoder models but requires more parameters to match the performance

of BRET-based models such as RoBERTa (Liu et al., 2019) and DeBERTa (He et al., 2021).

None of these pretraining frameworks is flexible enough to perform competitively across all NLP tasks. Previous works have tried to unify different frameworks by combining their objectives via multi-task learning (Dong et al., 2019; Bao et al., 2020). However, since the autoencoding and autoregressive objectives differ by nature, a simple unification cannot fully inherit the advantages of both frameworks.

In this paper, we propose a pretraining framework named GLM (General Language Model), based on autoregressive blank infilling. We randomly blank out continuous spans of tokens from the input text, following the idea of autoencoding, and train the model to sequentially reconstruct the spans, following the idea of autoregressive pretraining (see Figure 1). While blanking filling has been used in T5 (Raffel et al., 2020) for text-to-text pretraining, we propose two improvements, namely span shuffling and 2D positional encoding. Empirically, we show that with the same amount of parameters and computational cost, GLM significantly outperforms BERT on the SuperGLUE benchmark by a large margin of 4.6% – 5.0% and outperforms RoBERTa and BART when pretrained on a corpus of similar size (158GB). GLM also significantly outperforms T5 on NLU and generation tasks with fewer parameters and data.

Inspired by Pattern-Exploiting Training (PET) (Schick and Schütze, 2020a), we reformulate NLU tasks as manually-crafted cloze questions that mimic human language. Different from the BERT-based models used by PET, GLM can naturally handle multi-token answers to the cloze question via autoregressive blank filling.

Furthermore, we show that by varying the number and lengths of missing spans, the autoregressive blank filling objective can pretrain language models for conditional and unconditional generation. Through multi-task learning of different pretraining objectives, a single GLM can excel in both NLU and (conditional and unconditional) text generation. Empirically, compared with standalone baselines, GLM with multi-task pretraining achieves improvements in NLU, conditional text generation, and language modeling tasks altogether by sharing the parameters.

2 GLM Pretraining Framework

We propose a general pretraining framework GLM based on a novel autoregressive blank infilling objective. GLM formulates NLU tasks as cloze questions that contain task descriptions, which can be answered by autoregressive generation.

2.1 Pretraining Objective

2.1.1 Autoregressive Blank Infilling

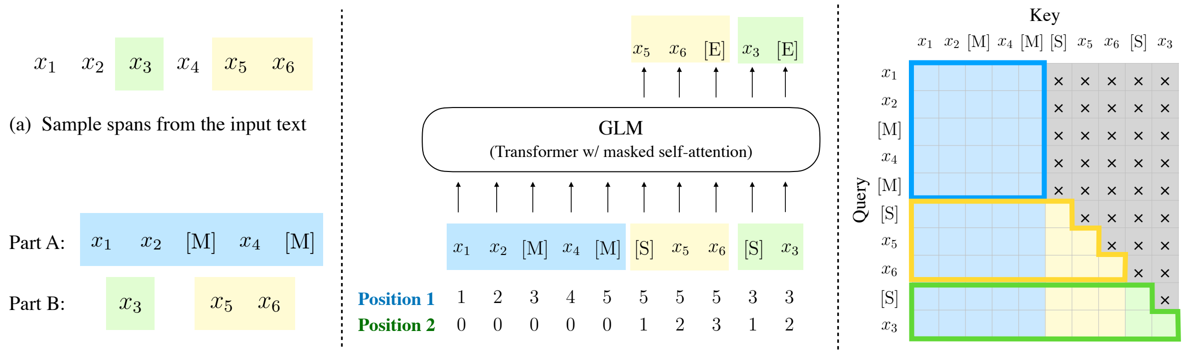
GLM is trained by optimizing an *autoregressive blank infilling* objective. Given an input text $\boldsymbol{x} = [x_1, \cdots, x_n]$, multiple text spans $\{\boldsymbol{s}_1, \cdots, \boldsymbol{s}_m\}$ are sampled, where each span $\boldsymbol{s}_i$ corresponds to a series of consecutive tokens $[s_{i,1}, \cdots, s_{i,l_i}]$ in $\boldsymbol{x}$. Each span is replaced with a single [MASK] token, forming a corrupted text $\boldsymbol{x}_{\text{corrupt}}$. The model predicts the missing tokens in the spans from the corrupted text in an autoregressive manner, which means when predicting the missing tokens in a span, the model has access to the corrupted text *and* the previously predicted spans. To fully capture the interdependencies between different spans, we randomly permute the order of the spans, similar to the permutation language model (Yang et al., 2019). Formally, let Z_m be the set of all possible permutations of the length-m index sequence $[1, 2, \cdots, m]$, and $\boldsymbol{s}_{\boldsymbol{z}_{<i}}$ be $[\boldsymbol{s}_{z_1}, \cdots, \boldsymbol{s}_{z_{i-1}}]$, we define the pretraining objective as

$$\max_{\theta} \mathbb{E}_{\boldsymbol{z} \sim Z_m} \left[\sum_{i=1}^{m} \log p_\theta(\boldsymbol{s}_{z_i} | \boldsymbol{x}_{\text{corrupt}}, \boldsymbol{s}_{\boldsymbol{z}_{<i}}) \right] \quad (1)$$

We always generate the tokens in each blank following a left-to-right order, i.e. the probability of generating the span $\boldsymbol{s}_i$ is factorized as:

$$\begin{aligned} & p_\theta(\boldsymbol{s}_i | \boldsymbol{x}_{\text{corrupt}}, \boldsymbol{s}_{\boldsymbol{z}_{<i}}) \\ = & \prod_{j=1}^{l_i} p(s_{i,j} | \boldsymbol{x}_{\text{corrupt}}, \boldsymbol{s}_{\boldsymbol{z}_{<i}}, \boldsymbol{s}_{i,<j}) \end{aligned} \quad (2)$$

We implement the autoregressive blank infilling objective with the following techniques. The input $\boldsymbol{x}$ is divided into two parts: Part A is the corrupted text $\boldsymbol{x}_{\text{corrupt}}$, and Part B consists of the masked spans. Part A tokens can attend to each other, but cannot attend to any tokens in B. Part B tokens can attend to Part A and antecedents in B, but cannot attend to any subsequent tokens in B. To enable autoregressive generation, each span is padded with special tokens [START] and [END], for input and



(a) Sample spans from the input text

(b) Divide the input into Part A / Part B

(c) Generate the Part B spans autoregressively

(d) Self-attention mask

Figure 2: GLM pretraining. (a) The original text is $[x_1, x_2, x_3, x_4, x_5, x_6]$. Two spans $[x_3]$ and $[x_5, x_6]$ are sampled. (b) Replace the sampled spans with [M] in Part A, and shuffle the spans in Part B. (c) GLM autoregressively generates Part B. Each span is prepended with [S] as input and appended with [E] as output. 2D positional encoding represents inter- and intra-span positions. (d) Self-attention mask. Grey areas are masked out. Part A tokens can attend to themselves (blue frame) but not B. Part B tokens can attend to A and their antecedents in B (yellow and green frames correspond to the two spans). [M] := [MASK], [S] := [START], and [E] := [END].

output respectively. In this way, our model automatically learns a bidirectional encoder (for Part A) and a unidirectional decoder (for Part B) in a unified model. The implementation of GLM is illustrated in Figure 2.

We randomly sample spans of length drawn from a Poisson distribution with $\lambda = 3$. We repeatedly sample new spans until at least 15% of the original tokens are masked. Empirically, we have found that the 15% ratio is critical for good performance on downstream NLU tasks.

2.1.2 Multi-Task Pretraining

In the previous section, GLM masks short spans and is suited for NLU tasks. However, we are interested in pretraining a single model that can handle both NLU and text generation. We then study a *multi-task pretraining* setup, in which a second objective of generating longer text is jointly optimized with the blank infilling objective. We consider the following two objectives:

- Document-level. We sample a single span whose length is sampled from a uniform distribution over 50%–100% of the original length. The objective aims for long text generation.
- Sentence-level. We restrict that the masked spans must be full sentences. Multiple spans (sentences) are sampled to cover 15% of the original tokens. This objective aims for seq2seq tasks whose predictions are often complete sentences or paragraphs.

Both new objectives are defined in the same way as the original objective, i.e. Eq. 1. The only difference is the number of spans and the span lengths.

2.2 Model Architecture

GLM uses a single Transformer with several modifications to the architecture: (1) we rearrange the order of layer normalization and the residual connection, which has been shown critical for large-scale language models to avoid numerical errors (Shoeybi et al., 2019); (2) we use a single linear layer for the output token prediction; (3) we replace ReLU activation functions with GeLUs (Hendrycks and Gimpel, 2016).

2.2.1 2D Positional Encoding

One of the challenges of the autoregressive blank infilling task is how to encode the positional information. Transformers rely on positional encodings to inject the absolute and relative positions of the tokens. We propose 2D positional encodings to address the challenge. Specifically, each token is encoded with two positional ids. The first positional id represents the position in the corrupted text $\boldsymbol{x}_{\text{corrupt}}$. For the masked spans, it is the position of the corresponding [MASK] token. The second positional id represents the intra-span position. For tokens in Part A, their second positional ids are 0. For tokens in Part B, they range from 1 to the length of the span. The two positional ids are projected into two vectors via learnable embedding tables, which are both added to the input token embeddings.

Our encoding method ensures that the model is not aware of the length of the masked span when

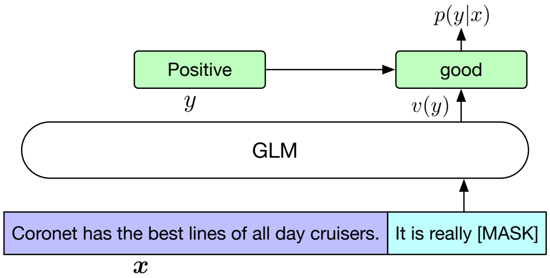


Figure 3: Formulation of the sentiment classification task as blank infilling with GLM.

reconstructing them. It is an important difference as compared to other models. For example, XLNet (Yang et al., 2019) encodes the original position so that it can perceive the number of missing tokens, and SpanBERT (Joshi et al., 2020) replaces the span with multiple [MASK] tokens and keeps the length unchanged. Our design fits downstream tasks as usually the length of the generated text is unknown beforehand.

2.3 Finetuning GLM

Typically, for downstream NLU tasks, a linear classifier takes the representations of sequences or tokens produced by pretrained models as input and predicts the correct labels. The practices are different from the generative pretraining task, leading to inconsistency between pretraining and finetuning.

Instead, we reformulate NLU classification tasks as generation tasks of blank infilling, following PET (Schick and Schütze, 2020a). Specifically, given a labeled example $(\boldsymbol{x}, y)$, we convert the input text $\boldsymbol{x}$ to a cloze question $c(\boldsymbol{x})$ via a pattern containing a single mask token. The pattern is written in natural language to represent the semantics of the task. For example, a sentiment classification task can be formulated as "{SENTENCE}. It's really [MASK]". The candidate labels $y \in \mathcal{Y}$ are also mapped to answers to the cloze, called verbalizer $v(y)$. In sentiment classification, the labels "positive" and "negative" are mapped to the words "good" and "bad". The conditional probability of predicting y given $\boldsymbol{x}$ is

$$p(y|\boldsymbol{x}) = \frac{p(v(y)|c(\boldsymbol{x}))}{\sum_{y' \in \mathcal{Y}} p(v(y')|c(\boldsymbol{x}))} \quad (3)$$

where $\mathcal{Y}$ is the label set. Therefore the probability of the sentence being positive or negative is proportional to predicting "good" or "bad" in the blank. Then we finetune GLM with a cross-entropy loss (see Figure 3).

For text generation tasks, the given context constitutes the Part A of the input, with a mask token appended at the end. The model generates the text of Part B autoregressively. We can directly apply the pretrained GLM for unconditional generation, or finetune it on downstream conditional generation tasks.

2.4 Discussion and Analysis

In this section, we discuss the differences between GLM and other pretraining models. We are mainly concerned with how they can be adapted to downstream blank infilling tasks.

Comparison with BERT (Devlin et al., 2019). As pointed out by (Yang et al., 2019), BERT fails to capture the interdependencies of masked tokens due to the independence assumption of MLM. Another disadvantage of BERT is that it cannot fill in the blanks of multiple tokens properly. To infer the probability of an answer of length l, BERT needs to perform l consecutive predictions. If the length l is unknown, we may need to enumerate all possible lengths, since BERT needs to change the number of [MASK] tokens according to the length.

Comparison with XLNet (Yang et al., 2019). Both GLM and XLNet are pretrained with autoregressive objectives, but there are two differences between them. First, XLNet uses the original position encodings before corruption. During inference, we need to either know or enumerate the length of the answer, the same problem as BERT. Second, XLNet uses a two-stream self-attention mechanism, instead of the right-shift, to avoid the information leak within Transformer. It doubles the time cost of pretraining.

Comparison with T5 (Raffel et al., 2020). T5 proposes a similar blank infilling objective to pretrain an encoder-decoder Transformer. T5 uses independent positional encodings for the encoder and decoder, and relies on multiple sentinel tokens to differentiate the masked spans. In downstream tasks, only one of the sentinel tokens is used, leading to a waste of model capacity and inconsistency between pretraining and finetuning. Moreover, T5 always predicts spans in a fixed left-to-right order. As a result, GLM can significantly outperform T5 on NLU and seq2seq tasks with fewer parameters and data, as stated in Sections 3.2 and 3.3.

Comparison with UniLM (Dong et al., 2019). UniLM combines different pretraining objectives under the autoencoding framework by changing the attention mask among bidirectional, unidirectional, and cross attention. However, UniLM always replaces masked spans with [MASK] tokens, which limits its ability to model the dependencies between the masked spans and their context. GLM feeds in the previous token and autoregressively generates the next token. Finetuning UniLM on downstream generation tasks also relies on masked language modeling, which is less efficient. UniLMv2 (Bao et al., 2020) adopts partially autoregressive modeling for generation tasks, along with the autoencoding objective for NLU tasks. Instead, GLM unifies NLU and generation tasks with autoregressive pretraining.

3 Experiments

We now describe our pretraining setup and the evaluation of downstream tasks.

3.1 Pretraining Setup

For a fair comparison with BERT (Devlin et al., 2019), we use BooksCorpus (Zhu et al., 2015) and English Wikipedia as our pretraining data. We use the uncased wordpiece tokenizer of BERT with 30k vocabulary. We train GLM_{Base} and $\text{GLM}_{\text{Large}}$ with the same architectures as $\text{BERT}_{\text{Base}}$ and $\text{BERT}_{\text{Large}}$, containing 110M and 340M parameters respectively.

For multi-task pretraining, we train two Large-sized models with a mixture of the blank infilling objective and the document-level or sentence-level objective, denoted as GLM_{Doc} and GLM_{Sent}. Additionally, we train two larger GLM models of 410M (30 layers, hidden size 1024, and 16 attention heads) and 515M (30 layers, hidden size 1152, and 18 attention heads) parameters with document-level multi-task pretraining, denoted as GLM_{410M} and GLM_{515M}.

To compare with SOTA models, we also train a Large-sized model with the same data, tokenization, and hyperparameters as RoBERTa (Liu et al., 2019), denoted as $\text{GLM}_{\text{RoBERTa}}$. Due to resource limitations, we only pretrain the model for 250,000 steps, which are half of RoBERTa and BART's training steps and close to T5 in the number of trained tokens. More experiment details can be found in Appendix A.

3.2 SuperGLUE

To evaluate our pretrained GLM models, we conduct experiments on the SuperGLUE benchmark (Wang et al., 2019) and report the standard metrics. SuperGLUE consists of 8 challenging NLU tasks. We reformulate the classification tasks as blank infilling with human-crafted cloze questions, following PET (Schick and Schütze, 2020b). Then we finetune the pretrained GLM models on each task as described in Section 2.3. The cloze questions and other details can be found in Appendix B.1.

For a fair comparison with GLM_{Base} and $\text{GLM}_{\text{Large}}$, we choose $\text{BERT}_{\text{Base}}$ and $\text{BERT}_{\text{Large}}$ as our baselines, which are pretrained on the same corpus and for a similar amount of time. We report the performance of standard finetuning (i.e. classification on the [CLS] token representation). The performance of BERT with cloze questions is reported in Section 3.4. To compare with $\text{GLM}_{\text{RoBERTa}}$, we choose T5, $\text{BART}_{\text{Large}}$, and $\text{RoBERTa}_{\text{Large}}$ as our baselines. T5 has no direct match in the number of parameters for $\text{BERT}_{\text{Large}}$, so we present the results of both T5_{Base} (220M parameters) and T5_{Large} (770M parameters). All the other baselines are of similar size to $\text{BERT}_{\text{Large}}$.

Table 1 shows the results. With the same amount of training data, GLM consistently outperforms BERT on most tasks with either base or large architecture. The only exception is WiC (word sense disambiguation). On average, GLM_{Base} scores 4.6% higher than $\text{BERT}_{\text{Base}}$, and $\text{GLM}_{\text{Large}}$ scores 5.0% higher than $\text{BERT}_{\text{Large}}$. It clearly demonstrates the advantage of our method in NLU tasks. In the setting of $\text{RoBERTa}_{\text{Large}}$, $\text{GLM}_{\text{RoBERTa}}$ can still achieve improvements over the baselines, but with a smaller margin. Specifically, $\text{GLM}_{\text{RoBERTa}}$ outperforms T5_{Large} but is only half its size. We also find that BART does not perform well on the challenging SuperGLUE benchmark. We conjecture this can be attributed to the low parameter efficiency of the encoder-decoder architecture and the denoising sequence-to-sequence objective.

3.3 Multi-Task Pretraining

Then we evaluate the GLM's performance in a multi-task setting (Section 2.1). Within one training batch, we sample short spans and longer spans (document-level or sentence-level) with equal chances. We evaluate the multi-task model for NLU, seq2seq, blank infilling, and zero-shot language modeling.

SuperGLUE. For NLU tasks, we evaluate models on the SuperGLUE benchmark. The results

Table 2: Results of abstractive summarization on the CNN/DailyMail and XSum test sets.

Model	CNN/DailyMail			XSum		
	RG-1	RG-2	RG-L	RG-1	RG-2	RG-L
BERTSumAbs (Liu and Lapata, 2019)	41.7	19.4	38.8	38.8	16.3	31.2
UniLMv2$_{\text{Base}}$ (Bao et al., 2020)	43.2	20.4	40.1	44.0	21.1	36.1
T5$_{\text{Large}}$ (Raffel et al., 2020)	42.5	20.7	39.8	40.9	17.3	33.0
BART$_{\text{Large}}$ (Lewis et al., 2019)	**44.2**	**21.3**	**40.9**	45.1	22.3	**37.3**
GLM$_{\text{RoBERTa}}$	43.8	21.0	40.5	**45.5**	**23.5**	**37.3**

are also shown in Table 1. We observe that with multi-task pretraining, GLM$_{\text{Doc}}$ and GLM$_{\text{Sent}}$ perform slightly worse than GLM$_{\text{Large}}$, but still outperform BERT$_{\text{Large}}$ and UniLM$_{\text{Large}}$. Among multi-task models, GLM$_{\text{Sent}}$ outperforms GLM$_{\text{Doc}}$ by 1.1% on average. Increasing GLM$_{\text{Doc}}$'s parameters to 410M (1.25×BERT$_{\text{Large}}$) leads to better performance than GLM$_{\text{Large}}$. GLM with 515M parameters (1.5×BERT$_{\text{Large}}$) can perform even better.

Sequence-to-Sequence. Considering the available baseline results, we use the Gigaword dataset (Rush et al., 2015) for abstractive summarization and the SQuAD 1.1 dataset (Rajpurkar et al., 2016) for question generation (Du et al., 2017) as the benchmarks for models pretrained on BookCorpus and Wikipedia. Additionally, we use the CNN/DailyMail (See et al., 2017) and XSum (Narayan et al., 2018) datasets for abstractive summarization as the benchmarks for models pretrained on larger corpora.

The results for models trained on BookCorpus and Wikipedia are shown in Tables 3 and 4. We observe that GLM$_{\text{Large}}$ can achieve performance matching the other pretraining models on the two generation tasks. GLM$_{\text{Sent}}$ can perform better than GLM$_{\text{Large}}$, while GLM$_{\text{Doc}}$ performs slightly worse than GLM$_{\text{Large}}$. This indicates that the document-level objective, which teaches the model to extend the given contexts, is less helpful to conditional generation, which aims to extract useful information from the context. Increasing GLM$_{\text{Doc}}$'s parameters to 410M leads to the best performance on both tasks. The results for models trained on larger corpora are shown in Table 2. GLM$_{\text{RoBERTa}}$ can achieve performance matching the seq2seq BART model, and outperform T5 and UniLMv2.

Text Infilling. Text infilling is the task of predicting missing spans of text which are consistent

Table 3: Results on Gigaword summarization.

GLM$_{\text{410M}}$	**22.9**	**25.6**	50.5

Table 5: BLEU scores on Yahoo text infilling. † indicates the results from (Shen et al., 2020).

Mask ratio	10%	20%	30%	40%	50%
BERT†	82.8	66.3	50.3	37.4	26.2
BLM†	86.5	73.2	59.6	46.8	34.8
GLM$_{\text{Large}}$	**87.8**	**76.7**	**64.2**	**48.9**	**38.7**
GLM$_{\text{Doc}}$	87.5	76.0	63.2	47.9	37.6

with the surrounding context (Zhu et al., 2019; Donahue et al., 2020; Shen et al., 2020). GLM is trained with an autoregressive blank infilling objective, thus can straightforwardly solve this task. We evaluate GLM on the Yahoo Answers dataset (Yang et al., 2017) and compare it with Blank Language Model (BLM) (Shen et al., 2020), which is a specifically designed model for text infilling. From the results in Table 5, GLM outperforms previous methods by large margins (1.3 to 3.9 BLEU) and achieves the state-of-the-art result on this dataset. We notice that GLM$_{\text{Doc}}$ slightly underperforms GLM$_{\text{Large}}$, which is consistent with our observations in the seq2seq experiments.

Language Modeling. Most language modeling datasets such as WikiText103 are constructed from Wikipedia documents, which our pretraining dataset already contains. Therefore, we evaluate the language modeling perplexity on a held-out test set of our pretraining dataset, which contains about 20M tokens, denoted as BookWiki. We also evaluate GLM on the LAMBADA dataset (Paperno et al., 2016), which tests the ability of systems to model long-range dependencies in text. The task is to predict the final word of a passage. As the baseline, we train a GPT$_{\text{Large}}$ model (Radford et al., 2018b; Brown et al., 2020) with the same data and tokenization as GLM$_{\text{Large}}$.

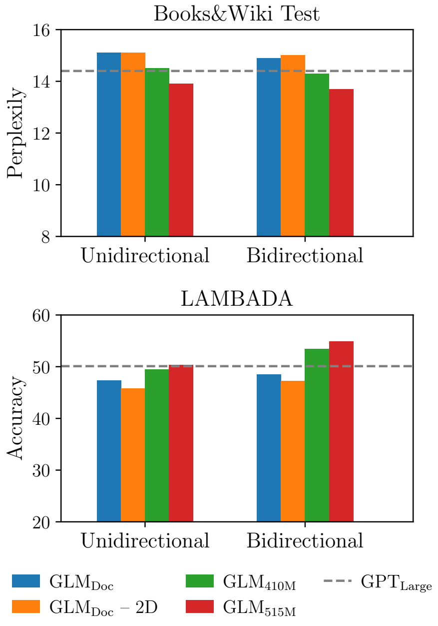

Figure 4: Zero-shot language modeling results.

The results are shown in Figure 4. All the models are evaluated in the zero-shot setting. Since GLM learns the bidirectional attention, we also evaluate GLM under the setting in which the contexts are encoded with bidirectional attention. Without generative objective during pretraining, GLM$_{\text{Large}}$ cannot complete the language modeling tasks, with perplexity larger than 100. With the same amount of parameters, GLM$_{\text{Doc}}$ performs worse than GPT$_{\text{Large}}$. This is expected since GLM$_{\text{Doc}}$ also optimizes the blank infilling objective. Increasing the model's parameters to 410M (1.25× of GPT$_{\text{Large}}$) leads to a performance close to GPT$_{\text{Large}}$. GLM$_{\text{515M}}$ (1.5× of GPT$_{\text{Large}}$) can further outperform GPT$_{\text{Large}}$. With the same amount of parameters, encoding the context with bidirectional attention can improve the performance of language modeling. Under this setting, GLM$_{\text{410M}}$ outperforms GPT$_{\text{Large}}$. This is the advantage of GLM over unidirectional GPT. We also study the contribution of 2D positional encoding to long text generation. We find that removing the 2D positional encoding leads to lower accuracy and higher perplexity in language modeling.

Table 6: Ablation study on the SuperGLUE dev set. (T5 ≈ GLM – shuffle spans + sentinel tokens.)

Model	ReCoRD F1/Acc.	COPA Acc.	WSC Acc.	RTE Acc.	BoolQ Acc.	WiC Acc.	CB F1/Acc.	MultiRC F1a/EM	Avg

– shuffle spans	82.0 / 81.4	61.0	79.8	54.5	65.8	56.3	90.5 / 92.9	76.7 / 37.6	68.5
+ sentinel tokens	81.8 / 81.3	69.0	78.8	**77.3**	81.2	68.0	93.7 / 94.6	**77.5 / 37.7**	76.0

Summary. Above all, we conclude that GLM effectively shares model parameters across natural language understanding and generation tasks, achieving better performance than a standalone BERT, encoder-decoder, or GPT model.

3.4 Ablation Study

Table 6 shows our ablation analysis for GLM. First, to provide an apple-to-apple comparison with BERT, we train a BERT$_{\text{Large}}$ model with our implementation, data, and hyperparameters (row 2). The performance is slightly worse than the official BERT$_{\text{Large}}$ and significantly worse than GLM$_{\text{Large}}$. It confirms the superiority of GLM over Masked LM pretraining on NLU tasks. Second, we show the SuperGLUE performance of GLM finetuned as sequence classifiers (row 5) and BERT with cloze-style finetuning (row 3). Compared to BERT with cloze-style finetuning, GLM benefits from the autoregressive pretraining. Especially on ReCoRD and WSC, where the verbalizer consists of multiple tokens, GLM consistently outperforms BERT. This demonstrates GLM's advantage in handling variable-length blank. Another observation is that the cloze formulation is critical for GLM's performance on NLU tasks. For the large model, cloze-style finetuning can improve the performance by 7 points. Finally, we compare GLM variants with different pretraining designs to understand their importance. Row 6 shows that removing the span shuffling (always predicting the masked spans from left to right) leads to a severe performance drop on SuperGLUE. Row 7 uses different sentinel tokens instead of a single [MASK] token to represent different masked spans. The model performs worse than the standard GLM. We hypothesize that it wastes some modeling capacity to learn the different sentinel tokens which are not used in downstream tasks with only one blank. In Figure 4, we show that removing the second dimension of 2D positional encoding hurts the performance of long text generation.

We note that T5 is pretrained with a similar blank infilling objective. GLM differs in three aspects: (1) GLM consists of a single encoder, (2) GLM shuffles the masked spans, and (3) GLM uses a single [MASK] instead of multiple sentinel tokens. While we cannot directly compare GLM with T5 due to the differences in training data and the number of parameters, the results in Tables 1 and 6 have demonstrated the advantage of GLM.

4 Related Work

Pretrained Language Models. Pretraining large-scale language models significantly improves the performance of downstream tasks. There are three types of pretrained models. First, autoencoding models learn a bidirectional contextualized encoder for natural language understanding via denoising objectives (Devlin et al., 2019; Joshi et al., 2020; Yang et al., 2019; Liu et al., 2019; Lan et al., 2020; Clark et al., 2020). Second, autoregressive models are trained with a left-to-right language modeling objective (Radford et al., 2018a,b; Brown et al., 2020). Third, encoder-decoder models are pretrained for sequence-to-sequence tasks (Song et al., 2019; Lewis et al., 2019; Bi et al., 2020; Zhang et al., 2020).

Among encoder-decoder models, BART (Lewis et al., 2019) conducts NLU tasks by feeding the same input into the encoder and decoder, and taking the final hidden states of the decoder. Instead, T5 (Raffel et al., 2020) formulates most language tasks in the text-to-text framework. However, both models require more parameters to outperform autoencoding models such as RoBERTa (Liu et al., 2019). UniLM (Dong et al., 2019; Bao et al., 2020) unifies three pretraining models under the masked language modeling objective with different attention masks.

NLU as Generation. Previously, pretrained language models complete classification tasks for

NLU with linear classifiers on the learned representations. GPT-2 (Radford et al., 2018b) and GPT-3 (Brown et al., 2020) show that generative language models can complete NLU tasks such as question answering by directly predicting the correct answers without finetuning, given task instructions or a few labeled examples. However, generative models require much more parameters to work due to the limit of unidirectional attention. Recently, PET (Schick and Schütze, 2020a,b) proposes to reformulate input examples as cloze questions with patterns similar to the pretraining corpus in the few-shot setting. It has been shown that combined with gradient-based finetuning, PET can achieve better performance in the few-shot setting than GPT-3 while requiring only 0.1% of its parameters. Similarly, Athiwaratkun et al. (2020) and Paolini et al. (2020) convert structured prediction tasks, such as sequence tagging and relation extraction, to sequence generation tasks.

Blank Language Modeling. Donahue et al. (2020) and Shen et al. (2020) also study blanking infilling models. Different from their work, we pre-train language models with blank infilling objectives and evaluate their performance in downstream NLU and generation tasks.

5 Conclusions

GLM is a general pretraining framework for natural language understanding and generation. We show that the NLU tasks can be formulated as conditional generation tasks, and therefore solvable by autoregressive models. GLM unifies the pretraining objectives for different tasks as autoregressive blank infilling, with mixed attention masks and the novel 2D position encodings. Empirically we show that GLM outperforms previous methods for NLU tasks and can effectively share parameters for different tasks.

A Pretraining Setting

A.1 Datasets

To train GLM$_{\text{Base}}$ and GLM$_{\text{Large}}$, we use BookCorpus (Zhu et al., 2015) and Wikipedia used by BERT (Devlin et al., 2019).

To train GLM$_{\text{RoBERTa}}$, we follow the pretraining datasets of RoBERTa (Liu et al., 2019), which consist of BookCorups (Zhu et al., 2015),Wikipedia (16GB), CC-News (the English portion of the CommonCrawl News dataset[3] 76GB), OpenWebText (web content extracted from URLs shared on Reddit with at least three upvotes(Gokaslan and Cohen, 2019), 38GB) and Stories (subset of CommonCrawl data filtered to match the story-like style of Winograd schemas (Trinh and Le, 2019), 31GB). The Stories dataset is no longer publicly available[4]. Therefore, we remove the Stories dataset and replace OpenWebText with OpenWebText2[5] (66GB). The CC-News dataset is not publicly available and we use the CC-News-en published by (Mackenzie et al., 2020). All the datasets used total 158GB of uncompressed texts, close in size to RoBERTa's 160GB datasets.

A.2 Hyperparameters

The hyperparameters for GLM$_{\text{Base}}$ and GLM$_{\text{Large}}$ are similar to those used by BERT. For trade-off of training speed and fair comparison with BERT (batch size 256 and 1,000,000 training steps), we use batch size of 1024 and 200,000 training steps for GLM$_{\text{Large}}$. Since GLM$_{\text{Base}}$ is smaller, we reduce the number of training steps to 120,000 to speed up pre-training. The hyperparameters for GLM$_{\text{Doc}}$ and GLM$_{\text{Sent}}$ are the same as those of GLM$_{\text{Large}}$. The hyperparameters except Transformer architecture for GLM$_{\text{410M}}$ and GLM$_{\text{515M}}$ are the same as those of GLM$_{\text{Large}}$. The models are trained on 64 V100 GPUs for 200K steps with batch size of 1024 and maximum sequence length of 512, which takes about 2.5 days for GLM$_{\text{Large}}$.

To train GLM$_{\text{RoBERTa}}$, we follow most of the hyperparameters of RoBERTa. The main difference

[5] `https://openwebtext2.readthedocs.io/en/latest`

Table 7: Hyperparameters for pretraining

Hyperparameters	GLM $_{\text{Base}}$	GLM $_{\text{Large}}$	GLM $_{\text{RoBERTa}}$
Number of Layers	12	24	24
Hidden size	768	1024	1024
FFN inner hidden size	3072	4096	4096
Attention heads	12	16	16
Attention head size	64	64	64
Dropout	0.1	0.1	0.1
Attention Dropout	0.1	0.1	0.1
Warmup Steps	6k	8k	30K
Peak Learning Rate	4e-4	2e-4	4e-4
Batch Size	1024	1024	8192
Weight Decay	0.1	0.1	0.01
Max Steps	120k	200k	250k
Learning Rate Decay	Cosine	Cosine	Cosine
Adam ϵ	1e-6	1e-6	1e-6
Adam β_1	0.9	0.9	0.9
Adam β_2	0.98	0.98	0.98
Gradient Clipping	1.0	1.0	1.0

includes: (1) Due to resource limit, we only pretrain GLM $_{\text{RoBERTa}}$ for 250,000 steps, which are half of RoBERTa and BART's training steps, and close to T5 in number of trained tokens. (2) We use cosine decay instead of linear decay for learning rate scheduling (3) We additionally apply gradient clipping with value 1.0.

The hyperparameters for all the pre-training settings are summarized in Table 7.

A.3 Implementation

Our pretraining implementation is based on Megatron-LM (Shoeybi et al., 2019) and DeepSpeed (Rasley et al., 2020). We include our code in the supplementary material. Due to the size limit of supplementary material, we cannot include the pretrained models, but will make them public available in the future.

B Downstream Tasks

B.1 SuperGLUE

The SuperGLUE benchmark consists of 8 NLU tasks. We formulate them as blank infilling tasks, following (Schick and Schütze, 2020b). Table 8 shows the cloze questions and verbalizers we used in our experiments. For 3 tasks (ReCoRD, COPA, and WSC), the answer may consist of multiple tokens, and for the other 5 tasks, the answer is always a single token.

When finetuning GLM on the SuperGLUE tasks, we construct the input using the cloze questions in Table 8 and replace the blank with a [MASK] token. Then we compute the score of generating each answer candidate. For the 5 single-token tasks, the score is defined to be the logit of the verbalizer token. For the 3 multi-token tasks, we use the sum of the log-probabilities of the verbalizer tokens. Thanks to the autoregressive blank infilling mechanism we proposed, we can obtain all the log-probabilities in one pass. Then we compute the cross entropy loss using the groundtruth label and update the model parameters.

For the baseline classifiers, we follow the standard practice to concatenate the input parts of each task (such as the premise and hypothesis for textual entailment, or the passage, question and answer for ReCORD and MultiRC) and add a classification layer on top of the [CLS] token representation. We also implemented cloze-style finetuning for the other pre-trained models, but the performance was usually similar to the standard classifier, as we shown in the ablation study. Models with blank-infilling objectives, such as T5 and our GLM, benefits more from converting the NLU tasks into cloze questions. Thus for T5 and GLM, we report the performance after such conversion in our main results.

Table 8: Cloze questions and verbalizers for the 8 SuperGLUE tasks used in our experiments. * denotes the answer contains multiple tokens.

Dataset	Task	Cloze Question	Verbalizers
ReCoRD*	Question answering	[passage p] [cloze question q]	Answer candidates
COPA*	Causal reasoning	"[choice c_1]" or "[choice c_2]"? [premise p], so ___.	c_1 / c_2
WSC*	Coreference resolution	[sentence s] The pronoun '$*p*$' refers to ___.	Noun n
RTE	Textual entailment	"[hypothesis h]"? | ___, "[premise p]"	"yes" (entailment), "no" (not entailment)
BoolQ	Question answering	[passage p]. Question: q? Answer: ___.	"yes" / "no"
WiC	Word sense disambiguation	"[sentence s_1]" / "[sentence s_2]" Similar sense of [word w]? ___.	"yes" / "no"
CB	Textual entailment	"[hypothesis h]"? | ___, "[premise p]"	"yes" (entailment), "no" (contradiction), "maybe" (neutral)
MultiRC	Question answering	[passage p]. Question: q? Is it [answer a]? ___.	"yes" / "no"

B.2 Sequence-to-Sequence

Fot the text summarization task, we use the dataset Gigaword (Rush et al., 2015) for model fine-tuning and evaluation. We finetune GLM$_{\text{LARGE}}$ on the training set for 4 epochs with AdamW optimizer. The learning rate has a peak value of 3e-5, warm-up over the 6% training steps and a linear decay. We also use label smoothing with rate 0.1 (Pereyra et al., 2017). The maximum document length is 192 and the maximum summary length is 32. During decoding, we use beam search with beam size of 5 and remove repeated trigrams. We tweak the value of length penalty on the development set. The evaluation metrics are the F1 scores of Rouge-1, Rouge-2, and Rouge-L (Lin, 2004) on the test set.

For the question generation task, we use the SQuAD 1.1 dataset (Rajpurkar et al., 2016) and follow the dataset split of (Du et al., 2017). The optimizer hyperparameters are the same as those of abstractive summarization. The maximum passage length is 464 and the maximum question length is 48. During decoding, we use beam search with beam size 5 and tweak the value of length penalty on the development set. The evaluation metrics are the scores of BLEU-1, BLEU-2, BLEU-3, BLEU-4 (Papineni et al., 2002), METEOR (Denkowski and Lavie, 2014) and Rouge-L (Lin, 2004).

Results of T5$_{\text{Large}}$ on XSum are obtained by running the summarization script provided by Huggingface transformers[6]. All the other results of baselines on seq2seq tasks are obtained from the corresponding papers.

B.3 Text Infilling

We follow (Shen et al., 2020) and evaluate text infilling performance on the Yahoo Answers dataset (Yang et al., 2017), which contains 100K/10K/10K documents for train/valid/test respectively. The average document length is 78 words. To construct the text infilling task, we randomly mask a given ratio $r \in \{10\% \cdots 50\%\}$ of each document's tokens and the contiguous masked tokens are collapsed into a single blank. We finetune GLM$_{\text{Large}}$ on the training set for 5 epochs with dynamic masking, i.e. the blanks are randomly generated at training time. Similar to the sequence-to-sequence experiments, we use an AdamW optimizer with a peak learning rate 1e-5 and 6% warm-up linear scheduler.

For comparison with previous work, we use the same test set constructed by (Shen et al., 2020). The evaluation metric is the BLEU score of the infilled text against the original document. We compare with two baselines: (1) BERT, which learns a left-to-right language model to generate the masked tokens on top of the blank representation, and (2) BLM proposed by (Shen et al., 2020), which can fill in the blank with arbitrary trajectories.

B.4 Language Modeling

We evaluate the model's ability of language modeling with perplexity on BookWiki and accuracy on the LAMBDA dataset (Paperno et al., 2016).

Perplexity is an evaluation criterion that has been

---

[6] `https://github.com/huggingface/transformers/tree/master/examples/pytorch/summarization`

well studied for language modeling. Perplexity is the exponentiation of the average cross entropy of a corpus.

$$\mathrm{PPL} = \exp(-\frac{1}{T}\sum_{t=1}^{T} p(x_t|\boldsymbol{x}_{<t})) \tag{4}$$

where $\boldsymbol{x}_{<t} = [x_0, \cdots, x_{t-1}]$. Since transformers can only operate on a window of fixed input size w, we cannot fully calculate $p(x_t|\boldsymbol{x}_{<t})$ and can only calculate $p(x_t|\boldsymbol{x}_{t-w:t-1})$. Even calculating this value for each token is prohibitively expensive, since we need to conduct T evaluations of w-size contexts. To improve evaluation efficiency, we adopt *overlapping evaluation*, where we advance the sliding windows by some overlap o each time and only compute the cross entropy loss for the last o tokens of the window. In our experiments we set $o = 256$ for all the models.

LAMBDA is a cloze-style dataset to test the ability of long-range dependency modeling. Each example is a passage consisting of 4-5 sentences with the last word missing and the model is required to predict the last word of the passage. Since we use WordPiece tokenization, a word can be split into several subword units. We use teacher forcing and consider the prediction correct only when all the predicted tokens are correct.

C Results on Other NLU Benchmarks

GLUE (Wang et al., 2018) is another widely-used NLU benchmark, including single sentence tasks (e.g. sentiment analysis (Socher et al., 2013)) and sentence pair tasks (e.g. text similarity (Cer et al., 2017) and natural language inference (Williams et al., 2018; Dagan et al., 2005)). The benchmark is usually considered as less challenging than SuperGLUE. SQuAD (Rajpurkar et al., 2016, 2018) is an extractive question answering benchmark. We further compare GLM with BERT on the two benchmarks.

The results on GLUE and SQuAD are shown in Tables 9 and 10. On the two benchmarks, GLM can still outperform BERT with the same amount of parameters, but with a smaller margin.

D Text Generation Samples

We show texts generated by $\mathrm{GLM}_{\mathrm{Doc}}$ given unseen contexts randomly sampled from the test set. We use top-k random sampling with $k = 40$ for generation and set maximum sequence length to 512. Some of the texts are cut short.

Example D.1. The Wyoming State Legislature is the legislative branch of the U.S. State of Wyoming.

GLM: It consists of a state senate and a house of representatives. As of 2019, state senators are Steve Kish, Joe L. Williams, and Linda S. Bollens. Members of the Wyoming State Legislature are elected from single-member districts representing the majority of the state. The current state senate members are: In recent years, there have been four changes to the senate. The most recent is the creation of a six-seat district that includes all or part of the following: In the 2009 elections, the state senate members were elected to six-year terms. The current state house members are: The Wyoming Constitution assigns certain powers to the governor. Most notably, the governor is president of the senate and governor. However, if the governor desires to appoint a member to the Wyoming state senate, a law authorizes the governor to do so. The governor of Wyoming holds no legislative power but has the power to veto lawmakers, which is not limited to the veto of laws. Under the wyoming state constitution, the governor can veto the actions of the other members of the wyoming house of representatives. The governor can also appoint members of the wyoming senate. In addition, the governor can appoint members of the Wyoming house of representatives. Wyoming's constitution provides that the governor can appoint a member of the wyoming state senate to the wyoming supreme court, and the chairman of the wyoming senate.

Example D.2. Jonathan Terry is a television and film actor.

GLM: He was a voice actor for the “X-Men" cartoon series. He was also a voice actor for “the Simpsons" as well as “the marvelous misadventures of superman. He also has voiced characters in “the legend of korra" He has appeared on several television series, including “the simpsons", “the x-files", “heroes" and “the simpsons movie" as the character captain billy higgledy-pig, and the web series “krusty mysteries" as the character Colonel Trungus. He wrote for “the Guardian" newspaper. Jonathan Terry was born in London. Terry grew up in Surrey, England and attended the University of Sussex in the United Kingdom, graduating with a degree in english literature. He was a guest lecturer at King's College London, and then took two years of acting courses at the brit school of acting to prepare for his future career in the entertainment industry. Terry first appeared in the TV series “the

Table 9: Results on the GLUE dev set.

Model	MNLI	QNLI	QQP	RTE	SST-2	MRPC	CoLA	STS-B	Avg
$\text{BERT}_{\text{Large}}$	86.6	92.3	91.3	73.6	93.2	88.0	60.6	90.0	84.4
$\text{GLM}_{\text{Large}}$	**86.7**	**92.8**	**91.5**	**74.0**	**93.5**	**90.0**	**61.4**	**90.7**	**85.1**

Model	SQuAD v1.1 EM/F1	SQuAD v2.0 EM/F1
$\text{BERT}_{\text{Base}}$	80.8 / 88.5	73.7 / 76.3
GLM_{Base}	**81.5 / 88.6**	**74.7 / 77.8**
$\text{BERT}_{\text{Large}}$	84.1 / 90.9	79.0 / 81.8
$\text{GLM}_{\text{Large}}$	**85.4 / 91.6**	**80.3 / 83.3**

Simpsons" as the character captain Billy Higgledy-pig, but his character was only a one-time recurring character in the series' first six seasons. He later appeared as a regular for the show's final six seasons, and has been a frequent guest in the show since. He appeared in the first few episodes of “" as the character major Jack Ryan. He has also appeared as part of the supporting cast of several episodes of “the secret life of pets". He has also worked on “the simpsons" TV show since “the simpsons movie", most notably playing the roles of Captain Skeletor and the ghost of the same name. He plays characters in several films, including “", “", “" and “". He has appeared in music videos for the killers in 1993, the pretenders in 1995, and in the TV shows “the royal" and “the bill".

Example D.3. Corona was a station along the port Washington branch of the long island rail road in the Corona section of queens, New York City. It was one of two stations built by the flushing railroad in Corona, this one having been at Grand Avenue (later called National Avenue, now National Street) and 45th Avenue.

GLM: It had a brick entrance building next to the tracks, and one platform with 2 side platforms. The station burned down and was rebuilt in 1908. The station closed on september 15, 1927, with the train service transferred from Grand Avenue to 45th Avenue. There were plans to build a subway extension to Corona, but it was never built. In the 1980s, two stations were constructed on the line, Corona Road and Corona Park. The new Corona station opened in 1988, and the original Corona station was demolished.

Example D.4. Robert Lee Smith (born July 5, 1938) is a former American football cornerback in the national football league. He played for the Los Angeles Rams (1962–1965) and the Detroit Lions (1965–1966). He was also a kick and punt returner.

GLM: In his four-year NFL career, he played in 33 games and started 14, registering 62 career interceptions. He completed his NFL career with five interceptions. Smith was born in La Canada Flintridge, Michigan, in 1938. He attended Bishop O' Dowd high school in Flintridge. Smith' s father was a pharmacist. He graduated from Michigan State University in 1958 with a degree in business administration. Smith played for the Michigan Wolverines football team from 1959 to 1963. In his two years as a reserve cornerback, he led the conference in interceptions with five. In 1962, he set the Wolverines' all-time interception record with 13, and was second overall in the 1962 season's Heisman Trophy voting. Smith also won the Dick Butkus award as the nation's outstanding linebacker. In 1961, the “Los Angeles Times" wrote that Smith “is an outstanding pass rusher, with an average of almost 100 yards per punt return." Smith was inducted into the university of Michigan athletic hall of honor in 1989 and the national football foundation hall of fame in 1991. He was elected to the Michigan sports hall of fame in 1995. Smith earned the honor because of his accomplishments prior to his NFL career. He was one of four Michigan players honored as first-overall selections in the 1964 NFL draft. The others were Joe Namath, Bill Nelsen, and Jerry Kramer. In 1966, the NFL gave players $300,000 a season to play football. After his rookie season, he was not selected to play in the 1966 pro bowl. On January 13, 1966, the Rams traded smith to the Detroit Lions for Paul Hornung, and later that year he was traded to the Lions for Ray “the Lion" Jones in exchange for Linebacker Jim “the Hawk" Johnson. On September 10, 1968, he was traded back to Los Angeles for a second round pick in the 1970 draft. He was also traded to the St. Louis Cardinals for a second round pick in the 1970 draft. On June 2, 1970 he was cut by the Cardinals. On November 15, 1970, the Los Angeles Rams acquired Smith from the Lions in exchange for Linebacker Tony Harris. The Rams waived Smith during the September 1, 1972 offseason. Smith's number at Michigan State was # 7 in 1969.

QuoteR: A Benchmark of Quote Recommendation for Writing

Abstract

It is very common to use quotations (quotes) to make our writings more elegant or convincing. To help people find appropriate quotes efficiently, the task of quote recommendation is presented, aiming to recommend quotes that fit the current context of writing. There have been various quote recommendation approaches, but they are evaluated on different unpublished datasets. To facilitate the research on this task, we build a large and fully open quote recommendation dataset called QuoteR, which comprises three parts including English, standard Chinese and classical Chinese. Any part of it is larger than previous unpublished counterparts. We conduct an extensive evaluation of existing quote recommendation methods on QuoteR. Furthermore, we propose a new quote recommendation model that significantly outperforms previous methods on all three parts of QuoteR. All the code and data of this paper can be obtained at `https://github.com/thunlp/QuoteR`.

1 Introduction

A quotation, or quote for short, is a sequence of words that someone else has said or written. Quotes, especially the famous quotes including proverbs, maxims and other famous sayings, are quite useful in writing — they can not only help illuminate and emphasize the meaning we want to convey, but also endow our writing with elegance and credibility (Cole, 2008). As a result, the use of quotes is very common and, moreover, universal among all languages.

> "There's an old Bible verse my dad used to say all the time that says **sufficient unto the day is the evil thereof**," Pyron said. "In other words — today has its own set of problems, we can't do anything about yesterday, and I don't want to jump too far into tomorrow."

Figure 1: An example of usage of quotes.

However, it is not an easy job for ordinary people to promptly come up with appropriate quotes that fit the current context of writing, due to the huge number of quotes. Search engines can provide some help in finding quotes by keyword matching, but it is often not enough. Quotes generally express their meanings implicitly by rhetorical devices like metaphor and have different word usages from modern and everyday writing, as illustrated in Figure 1, for which quote search based on keyword matching is ineffective. In addition, some quote repository websites organize quotes by topic. However, even after filtering by topic, there are still too many candidate quotes, and selecting a suitable one remains time-consuming.

To tackle these challenges, Tan et al. (2015) introduce the task of quote recommendation, aiming to automatically recommend suitable quotes given the context of writing.[1] Afterward, a series of studies propose various approaches to this task (Ahn et al., 2016; Tan et al., 2016, 2018). However, these studies use different evaluation datasets, and none of them are publicly available. The lack of a standard and open dataset is undoubtedly a serious obstacle to the quote recommendation research.

In this paper, to solve this problem, we build a large quote recommendation dataset that is publicly available. This dataset is named QuoteR (abbreviated from **Quote R**ecommendataion) and composed of three parts: (1) the English part that comprises 6,108 English quotes with 126,713 contexts; (2) the standard Chinese (Mandarin) part, which contains 3,004 standard Chinese quotes with 40,842 contexts; and (3) the classical Chinese (Wenyan) part, which comprises 4,438 classical Chinese quotes (including classical poems) and 116,537 contexts. Any part of this dataset is abso-

lutely larger than, or even doubles, previous closed-source counterparts.

We conduct a fair and extensive evaluation of existing quote recommendation methods on QuoteR with a thorough set of metrics. By analyzing these methods and their evaluation results, we find two weaknesses of these methods and propose a new method by making corresponding improvements, which we believe would serve as a strong baseline for quote recommendation.

First, most existing methods encode contexts and quotes into vectors for quote-context matching, using LSTM (Hochreiter and Schmidhuber, 1997) or CNN (Kim, 2014) as the encoders. These encoders have proven inferior to the pre-trained language models like BERT (Devlin et al., 2019), which limits the final quote recommendation performance. Therefore, we try to utilize a pre-trained language model, specifically BERT, as the sentence encoders to learn representations of quotes and contexts. Considering the huge compute resulting from the large scale of the dataset and the BERT model, it is nontrivial to train the context and quote encoders simultaneously. We design an ingenious training strategy to address this issue.

Second, it is harder to learn good representations for quotes compared with contexts, because most quotes are quite pithy, and their words usually carry rich semantics, as shown in Figure 1. Existing methods, however, do not address this challenge well. To handle this challenge, we incorporate a kind of general lexical knowledge, namely *sememes*, into the quote encoder, aiming to improve the representations of quotes. A sememe is defined as the minimum semantic unit in linguistics (Bloomfield, 1926), and the sememes of a word atomically interpret the meaning of the word. Incorporating sememes can bring more semantic information for quote representation learning and conduce to a better quote vector.

In experiments, we demonstrate that both the utilization of BERT and the incorporation of sememes substantially improve quote recommendation performance. And the sememe-incorporated BERT-based model significantly outperforms all previous methods on QuoteR. Moroever, ablation and case studies as well as human evaluation further prove its effectiveness.

To conclude, our contributions are threefold: (1) building a large and the first open quote recommendation dataset; (2) conducting an extensive and fair evaluation of existing quote recommendation methods; (3) proposing a quote recommendation model that outperforms all previous methods and can serve as a strong baseline for future research.

2 Related Work

2.1 Quote Recommendation

The task of quote recommendation is originally presented in Tan et al. (2015). They propose a learning-to-rank framework for this task, which integrates 16 hand-crafted features. Tan et al. (2016) and Tan et al. (2018) introduce neural networks to the quote recommendation task. They use LSTMs to learn distributed vector representations of contexts and quotes and conduct sentence matching with these vectors. Ahn et al. (2016) combine four different quote recommendation approaches including matching granularity adjustment (a statistical context-quote relevance prediction method), random forest, CNN and LSTM.

In addition quote recommendation for writing, some studies focus on recommending quotes in dialog. Lee et al. (2016) propose an LSTM-CNN combination model to recommend quotes according to Twitter dialog threads, i.e., sequences of linked tweets. Wang et al. (2020) utilize an encoder-decoder framework to generate quotes as response, based on the separate modeling of the dialog history and current query. Wang et al. (2021) adopt a semantic matching fashion, which encodes the multi-turn dialog history with Transformer (Vaswani et al., 2017) and GRU (Cho et al., 2014) and encodes the quote with Transformer.

In terms of the datasets of quote recommendation for writing, Tan et al. (2015) construct an English dataset comprising 3,158 quotes and 64,323 contexts extracted from e-books in Project Gutenberg.[2] Ahn et al. (2016) build a similar English dataset that contains 400 most frequent quotes with contexts from e-books in Project Gutenberg and blogs. Tan et al. (2018) build a classical Chinese poetry quotation dataset that comprises over 9,000 poem sentences with 56,949 contexts extracted from Chinese e-books on the Internet. Unfortunately, all these datasets are not publicly available.

2.2 Content-based Recommendation

Quote recommendation is essentially a kind of content-based recommendation task (Pazzani and Billsus, 2007), which is aimed at recommending

---

[2] `https://www.gutenberg.org/`

products to users according to product descriptions and users' profiles.

A closely related and widely studied task is content-based citation recommendation (Strohman et al., 2007), especially local citation recommendation that recommends related papers given a particular context of academic writing (He et al., 2010; Huang et al., 2012, 2015). Compared with quote recommendation, this task is targeted at structured documents (papers), which are much longer and possess abundant information such as title, abstract and citation relations that are useful for recommendation. Quotes are shorter and usually have no available information except the text, which renders quote recommendation more challenging.

Another highly related but niche task is idiom recommendation (Liu et al., 2018, 2019), which aims to recommend appropriate idioms for a given context. Existing idiom recommendation methods are essentially covered by the quote recommendation methods described in §2.1. Liu et al. (2018) recommend idioms by learning representations of the contexts and idioms, similar to the context-quote relevance-based quote recommendation methods (Ahn et al., 2016; Tan et al., 2018). The difference lies in the use of word embeddings of idioms rather than a sentence encoder. Liu et al. (2019) regard idiom recommendation as a context-to-idiom machine translation problem and use an LSTM-based encoder-decoder framework, which is similar to Wang et al. (2020).

2.3 Other Quote-related Tasks

In addition to quote recommendation, there are some other quote-related tasks. For example, quote detection (or recognition) that is aimed at locating spans of quotes in text (Pouliquen et al., 2007; Scheible et al., 2016; Pareti et al., 2013; Papay and Padó, 2019), and quote attribution that intends to automatically attribute quotes to speakers in the text (Elson and McKeown, 2010; O'Keefe et al., 2012; Almeida et al., 2014; Muzny et al., 2017). Different from quote recommendation that focuses on famous quotes, these tasks mainly deal with the general quotes of utterance.

3 Task Formulation

Before describing our dataset and model, we first formulate the task of quote recommendation for writing and introduce several basic concepts, most of which follow previous work (Tan et al., 2015).

For a piece of text containing a quote q, the text segment occurring before the quote is named *left context* c_l while the text segment occurring after the quote is named *right context* c_r. The concatenation of left and right contexts form the *quote context* $c = [c_l; c_r]$. Suppose there is a *quote set* that comprises all the known candidate quotes $Q = \{q_1, \cdots, q_{|Q|}\}$, where $|\cdot|$ denotes the cardinality of a set.

In the task of quote recommendation for writing, a *query context* $c = [c_l; c_r]$ is given, and the *gold quote* q_c is wanted, where the query context is the context provided by the user and the gold quote is the quote in the quote set that fits the query context best. Theoretically, a query context may have more than one gold quote because there are some quotes that convey almost the same meaning. Following previous work (Tan et al., 2015; Ahn et al., 2016), for simplicity, we only regard the quote that actually appears together with the query context in corpora as the gold quote.

For a quote recommendation model, given the quote set Q, its input is a query context $c = [c_l; c_r]$, and it is supposed to calculate a rank score for each candidate quote in Q and output a quote list according to the descending rank scores.

4 Dataset Construction

In this section, we present the building process and details of the QuoteR dataset.

4.1 The English Part

We begin with the English part. We choose the popular and free quote repository website Wikiquote[3] as the source of English quotes. We download its official dump and extract over 60,000 English quotes in total to form the quote set. We notice that previous work (Tan et al., 2015; Ahn et al., 2016) collects quotes from another website named Library of Quotes, but this website has closed down.

To obtain real contexts of quotes, we use three corpora. The first is the Project Gutenberg corpus that previous studies use, which comprises over 50,000 e-books. The second corpus is BookCorpus containing about 11,000 e-books (Zhu et al., 2015). In addition to the two book corpora, we use the OpenWebText corpus (Gokaslan and Cohen, 2019) which is composed of text from web pages and has different text styles from books. The total size of the raw text of the three corpora reaches 48.8 GB.

Part	Train	Validation	Test	Total
English	101,171/6,008	12,771/6,108	12,771/6,108	126,713/6,108
sChinese	32,472/2,904	4,185/3,004	4,185/3,004	40,842/3,004
cChinese	93,031/4,338	11,753/4,438	11,753/4,438	116,537/4,438

Table 1: Statistics of the three parts of QuoteR. sChinese and cChinese refer to standard and classical Chinese, respectively. Each item like m/n means m context-quote pairs involving n quotes. Appendix A gives more detailed statistics.

We search all the corpora for the occurrences of quotes in the quote set. Some quotes are composed of multiple sentences, and only part of them are cited in some cases. To cope with this situation, we split each quote into sentences using Stanza (Qi et al., 2020) and then search for each constituent sentence in the corpora. If multiple constituent sentences of a quote appear sequentially, we combine them into an occurrence of the quote. Compared with previous work that searches for quotes as a whole (Tan et al., 2015; Ahn et al., 2016), we can find more quote occurrences.

For each quote occurrence, we take the 40 words preceding and following it as its left and right contexts, respectively. The concatenation of the left and right contexts forms a context, and a context and the corresponding quote form a context-quote pair. We remove the repeated context-quote pairs and filter out the quotes appearing less than 5 times in the corpora. To avoid dataset imbalance, we randomly select 200 context-quote pairs for a quote appearing more than 200 times and discard its other context-quote pairs. Finally, we obtain 126,713 context-quote pairs involving 6,108 different quotes, which form the English part of QuoteR.

We split all the context-quote pairs into training, validation and test sets roughly in the ratio 8:1:1, making sure that all the quotes appear in the validation and test sets while 100 quotes do not appear in the training set. We split the dataset in this way in order to observe how quote recommendation models perform in the zero-shot situation, where the model has never seen the gold quote of some validation/test contexts during training. The statistics of the final split dataset are listed in Table 1.

4.2 The Standard Chinese Part

We gather standard Chinese quotes from a large quote collection website named Juzimi[4]. More than 32,000 standard Chinese quotes are collected altogether. To obtain quote contexts, we use two corpora including a corpus composed of answer text from a Chinese QA website[5] and a large-scale book corpus that we specifically build and comprises over 8,000 free Chinese e-books. The total size of the two corpora is about 32 GB.

Then we use the same method in building the English part to extract quote occurrences from the corpora. Since Chinese is not naturally word-segmented, we take the 50 characters (rather than words) before and after a quote occurrence as the left and right contexts. In addition, since there are fewer quotes and contexts for the standard Chinese part, we reduce the minimum number of occurrences for a selected quote to 3, and the maximum number of retained contexts per quote to 150. After deduplication and filtering, we obtain the standard Chinese part of QuoteR, which has 40,842 context-quote pairs involving 3,004 quotes.

We split the standard Chinese part in the same way as the English part, and the statistics are also shown in Table 1.

4.3 The Classical Chinese Part

Classical Chinese quotes, including classical poems and proverbs, are often cited in standard Chinese writing. Considering that classical Chinese is very different from standard Chinese, we separate classical Chinese quotes from standard Chinese ones. We collect over 17,000 classical Chinese quotes from Gushiwenwang,[6] a classical Chinese poetry and literature repository website, and aforementioned Juzimi.[7]

Then we adopt the same way as standard Chinese to extract context-quote pairs from the two Chinese corpora and conduct deduplication and filtering. Finally, we obtain the classical Chinese part of QuoteR that comprises 116,537 context-quote pairs of 4,438 quotes. The statistics of this part after splitting are also in Table 1.

4.4 Quality Assessment by Human

After the construction of QuoteR, we assess its quality by human. For each part, we randomly sample 100 context-quote pairs, and ask three annotators to independently determine whether each quote fits the corresponding context. The final results are

---

[4] `https://www.juzimi.com/`

[5] `https://github.com/brightmart/nlp_chinese_corpus`

[6] `https://www.gushiwen.org/`

[7] Juzimi provides the dates when the quotes appear so that we can distinguish classical and standard Chinese quotes.

obtained by voting. Finally, 99/98/94 context-quote pairs are regard as suitable for the three parts, respectively. The results verify the quality of QuoteR, which is expected because the data are extracted from high-quality corpora like books.

5 Methodology

In this section, we elaborate on our proposed quote recommendation model. This model is based on the representative pre-trained language model BERT (Devlin et al., 2019), but can be readily adapted to other pre-trained language models.

5.1 Basic Framework

Similar to most previous methods (Tan et al., 2016; Ahn et al., 2016), we use BERT as the text encoder to learn vector representations of contexts and quotes, and then calculate the similarity between the representations of the query context and a candidate quote as the rank score of the quote.

Learning Representations of Quotes

We first obtain the representations of quotes. Formally, for a candidate quote comprising m tokens $q = \{x_1, \cdots, x_m\} \in Q$, we feed it into BERT and obtain a series of hidden states:

$$\mathbf{h}^q_{\texttt{[C]}}, \mathbf{h}^q_1, \cdots, \mathbf{h}^q_m = \mathrm{BERT}^q(\texttt{[C]}, x_1, \cdots, x_m), \quad (1)$$

where `[C]` denotes the special `[CLS]` token in BERT that is added to the front of a sequence. Following Devlin et al. (2019), we use the hidden state of `[C]` as the representation of the quote: $\mathbf{q} = \mathbf{h}^q_{\texttt{[C]}}$. The representations of all quotes form the quote representation matrix $\mathbf{Q} = [\mathbf{q}_1, \cdots, \mathbf{q}_{|Q|}]$.

Learning Representations of Contexts

We can use another BERT as the context encoder to obtain the representation of the query context $c = [c_l; c_r]$. Considering the context is composed of left and right contexts that are not naturally joined, we can insert an additional separator token between them before feeding them into BERT:

$$\mathbf{h}^c_{\texttt{[C]}}, \cdots = \mathrm{BERT}^c(\texttt{[C]}, c_l, \texttt{[S]}, c_r), \quad (2)$$

where `[S]` is the sentence separator token `[SEP]` in BERT. We can also use the hidden state of `[C]` as the representation of the context: $\mathbf{c} = \mathbf{h}^c_{\texttt{[C]}}$.

However, it is actually inconsistent with the general use of BERT. Whether in pre-training or fine-tuning, when the input to BERT is two text segments connected by the separator token, the hidden state of `[CLS]` is only used to classify the relation between the two segments, e.g., to predict whether the second segment is the actual next sentence of the first segment in the next sentence prediction (NSP) pre-training task (Devlin et al., 2019).

We turn to another pre-training task of BERT, masked language modeling (MLM), which is a cloze task (Taylor, 1953) aimed at predicting masked tokens. Specifically, some tokens in a text sequence are randomly substituted by the special `[MASK]` tokens and the hidden states of the `[MASK]` tokens are fed into a classifier to predict the original tokens. Quote recommendation given context can be regarded as a special cloze task whose object of prediction is quotes rather than tokens. Inspired by the MLM pre-training task, we propose another way to learn the context representation by inserting an additional `[MASK]` token:

$$\mathbf{h}^c_{\texttt{[C]}}, \cdots, \mathbf{h}^c_{\texttt{[M]}}, \cdots = \mathrm{BERT}^c(\texttt{[C]}, c_l, \texttt{[M]}, c_r), \quad (3)$$

where `[M]` is the `[MASK]` token. We use the hidden state of `[M]` as the representation of the query context: $\mathbf{c} = \mathbf{h}^c_{\texttt{[M]}}$.[8]

Calculating Rank Scores of Candidate Quotes

After obtaining the representations of all candidate quotes and the query context, the rank score of a candidate quote can be calculated by softmax:

$$\mathbf{p} = \mathrm{softmax}(\mathbf{Q}^\top \mathbf{c}), \quad (4)$$

where $\mathbf{p}$ is a normalized probability vector whose i-th element is the rank score of the i-th quote.

5.2 Training Strategy

As in previous work (Tan et al., 2016), we can simply use the cross-entropy loss to train the quote and context encoders simultaneously. However, there are two problems. (1) For each context in the training set, the quote encoder needs to be updated for every quote in the quote set. In other words, the BERT-based quote encoder would be fine-tuned thousands of times per training instance, which requires formidably big GPU memory and long training time.[9] (2) The huge imbalance between positive and negative samples (one vs. several thousands) would weaken the capacity of the

---

[8] The hidden state of `[M]` can also be regarded as the representation of the *required* quote for the query context. In this view, the rank score in Eq. (4) is actually calculated by the similarity between a candidate quote and the required quote.

[9] We find that four 16-GB GPUs would be out of memory during training even though we set the batch size to 1.

quote encoder and, in turn, impair the final quote recommendation performance.

A simple solution is to freeze the quote encoder during training, i.e., use the raw pre-trained BERT as the quote encoder, and train the context encoder only. But the untrained quote encoder would decrease final quote recommendation performance, as demonstrated in later experiments. To address these issues, inspired by the study on noise contrastive estimation (NCE) (Gutmann and Hyvärinen, 2012), we adopt the negative sampling strategy in training. For each context-quote pair, we select some non-gold quotes as negative samples, and calculate a pseudo-rank score of the gold quote among the selected quotes. Formally, for a context-quote pair (c, q), the pseudo-rank score of q is

$$p^* = \frac{e^{\mathbf{q}\cdot\mathbf{c}}}{e^{\mathbf{q}\cdot\mathbf{c}} + \sum_{q^*\in\mathbb{N}(q)} e^{\mathbf{q}^*\cdot\mathbf{c}}}, \quad (5)$$

where $\mathbb{N}(q)$ is the set of quotes selected as negative samples. Then the training loss is the cross-entropy based on the pseudo-rank score: $\mathcal{L} = -\log(p^*)$.

The problem about quote encoder training has been largely solved, but the context encoder may be under-trained. The context encoder needs to process lots of contexts and thus requires more training than the quote encoder. Therefore, we adopt a two-stage training strategy. After the simultaneous training of quote and context encoders in the first stage, we continue to train the context encoder while freezing the quote encoder in the second stage. The training loss of the second stage is the cross-entropy loss among all quotes.

5.3 Incorporation of Sememes

Most quotes are quite pithy, and thus it is usually hard to learn their representations well. To obtain better quote representations, previous work tries incorporating external information, including the topic and author information of quotes, in the quote encoder (Tan et al., 2016, 2018). Although helpful, this external information is not always available or accurate — quite a few quotes are anonymous, and the topics attributed to quotes are usually from crowdsourcing and uninspected.

We propose to incorporate sememe knowledge into quote representation learning, which is more general (every word can be annotated with sememes) and credible (the sememe annotations of words are given by experts). A sememe is the minimum semantic unit of human languages (Bloomfield, 1926), and it is believed that meanings of all words can be represented by a limited set of sememes. Sememe knowledge bases like HowNet (Dong and Dong, 2006) use a set of predefined sememes to annotate words, so that the meaning of a word can be precisely expressed by its sememes. With the help of such sememe knowledge bases, sememes have been successfully utilized in various NLP tasks (Qi et al., 2021a), including semantic composition (Qi et al., 2019), word sense disambiguation (Hou et al., 2020), reverse dictionary (Zhang et al., 2020a), adversarial attacks (Zang et al., 2020), backdoor learning (Qi et al., 2021b), etc.

Inspired by the studies on incorporating sememes into recurrent neural networks (Qin et al., 2020) and transformers (Zhang et al., 2020b) to improve their representation learning ability, we adopt a similar way to incorporate sememes into the quote encoder. We simply add the average embedding of a word's sememes to every token embedding of the word in BERT. Formally, for a word in a quote that is divided into n tokens after tokenization $w = x_1, \cdots, x_n$, the embedding of its each token $\mathbf{x}_i$ is transformed into

$$\mathbf{x}_i \rightarrow \mathbf{x}_i + \frac{\alpha}{|\mathbb{S}(w)|} \sum_{s_j\in\mathbb{S}(w)} \mathbf{s}_j, \ \forall i = 1, \cdots, n \quad (6)$$

where $\mathbb{S}(w)$ is the sememe set of the word w, and α is a hyper-parameter controlling the weight of sememe embeddings. Following previous work (Qin et al., 2020), the sememe embeddings are randomly initialized and updated during training.

6 Experiments

In this section, we evaluate our model and previous quote recommendation methods on QuoteR.

6.1 Approaches for Comparison

We have three groups of approaches for comparison. The first group consists of two methods that widely serve as baselines in previous studies. (1.1) **CRM**, namely context-aware relevance model (He et al., 2010) that recommends the quote whose known contexts are most similar to the query context. (1.2) **LSTM**, which uses two LSTM encoders to learn representations of quotes and contexts.

The second group includes representative approaches proposed in previous studies. (2.1) **top-k RM**, namely top-k rank multiplication (Ahn et al., 2016), which is a rank aggregation method based

Table 2: Quote recommendation results on the three parts of QuoteR. Recall@1/10/10 is percentage. The **boldfaced** results exhibit statistically significant improvement over the other results with p<0.1 given by paired *t*-tests, and the underlined results mean no significant difference. The same is true for the following Tables.

on the ensemble of a statistical method, random forest, CNN and LSTM. (2.2) **NNQR** (Tan et al., 2016), which reforms LSTM by incorporating additional quote information (topic and author) into the quote encoder and perturbing the word embeddings of quotes. (2.3) **N-QRM** (Tan et al., 2018), which further improves NNQR mostly by adjusting the training loss to prevent overfitting. (2.4) **Transform** (Wang et al., 2021), which uses Transformer+GRU to encode contexts and transforms context embeddings into the space of quote embeddings learned from another Transformer.[10]

The third group comprises two BERT-based approaches that are frequently utilized in sentence matching and sentence pair classification. (3.1) **BERT-Sim**, which is the vanilla BERT-based model discussed in §5.1. It directly uses the hidden states of the `[CLS]` tokens as the representations of both quotes and contexts, and freezes the quote encoder during training, as explained in §5.2. (3.2) **BERT-Cls**, which conducts a binary classification for the concatenation of the query context and a candidate quote.

6.2 Evaluation Metrics

Following previous work (Ahn et al., 2016; Tan et al., 2018), we use three evaluation metrics: (1) Mean reciprocal rank (**MRR**), the average reciprocal values of the ranks of the gold quotes; (2) Normalized discounted cumulative gain (**NDCG@K**) (Järvelin and Kekäläinen, 2002), a widely used measure of ranking quality and is computed by

$$\text{NDCG@K} = Z_K \sum_{i=1}^{K} \frac{2^{r(i)} - 1}{\log_2(i+1)}, \qquad (7)$$

where $r(i) = 1$ if the i-th quote is the gold quote, otherwise $r(i) = 0$, $Z_K = 1$ is a normalization constant. We report the average of NDCG@5 scores of all the evaluated query contexts. (3) **Recall@K**, the proportion of query contexts whose gold quotes are ranked in respective top K candidate quotes, $K = \{1, 10, 100\}$.

Besides, we use another three evaluation metrics: (4) **Median Rank** ($\tilde{R}$), (5) **Mean Rank** ($\bar{R}$) and (6) **Rank Variance** (σ_R), the median, average and standard deviation of the ranks of gold quotes.

The higher MRR, NDCG@K and Recall@K and the lower $\tilde{R}$, $\bar{R}$ and σ_R are, the better a model is.

6.3 Implementation Details

We use $\text{BERT}_{\text{BASE}}$ for both English and Chinese from Transformers (Wolf et al., 2020). We use the AdamW optimizer (Loshchilov and Hutter, 2018) with an initial learning rate 5e-5 that gradually declines to train our model. We randomly select N negative samples, and N is tuned in {4,9,$\underline{19}$,29,39} on the validation set. The weight of sememe embeddings α is tuned in {0.1, 0.2, $\underline{0.5}$, 1.0, 2.0}. The underlined numbers are final picks. For the previous methods, we use their original hyperparameters and experimental settings given in the papers.

6.4 Main Results

Table 2 lists the evaluation results of different methods on the three parts of QuoteR. We observe that (1) our method achieves the best overall results and displays its superiority to other methods; (2) the two BERT-based models, especially BERT-Sim, yield quite high performance, which reflects the importance of a powerful sentence encoder to quote recommendation; (3) among the three parts, almost all methods perform worse on Classical Chinese,

---

[10] It is originally designed to recommend quotes in dialog, and we adapt it to the writing situation. It is also the only adaptable method of other content-based recommend tasks.

Table 3: Quote recommendation results on the three parts of QuoteR, **given the left context only**.

which is presumably because Chinese BERT is pre-trained on standard Chinese corpora and not suitable to encode the classical Chinese quotes.

Ablation Study

We conduct ablation studies to investigate the effectiveness of our training strategy and the incorporation of sememes. We first remove the incorporation of sememes (-Sememe), then further do not separately train the context encoder after the simultaneous training of the context and quote encoders (-ReTrain), and finally discard the simultaneous training of the two encoders and train the context encoder only (-SimTrain). -SimTrain differs BERT-Sim only in the choice of context representation (`[MASK]` vs. `[CLS]`).

The results of ablation studies are given in the last three rows of Table 2. We have the following observations: (1) -Sememe causes consistent performance decline as compared to Ours, which demonstrates the role of sememes in improving quote encoding, thereby benefiting quote recommendation; (2) the performance of -ReTrain is pretty poor, which reflects the necessity of separate training for the context encoder after simultaneous training; (3) -SimTrain is inferior to -Sememe, which displays the usefulness of simultaneously training the two encoders; (4) -SimTrain outperforms BERT-Sim, proving the superiority of choosing `[MASK]` to represent contexts in our method.

6.5 Quote Recommendation with Left Context Only

Following previous work (Tan et al., 2015; Ahn et al., 2016; Tan et al., 2018), the evaluation experiments are mainly conducted in the setting where both the left and right contexts are given. However, in practical terms, quote recommendation given the left context only might be more useful. Therefore, we also conduct experiments in the setting where only the left context is given. Table 3 shows the results. We can see that our method is still the best one on all three parts. In addition, the performance of all methods decreases substantially, which indicates that both the left and right contexts provide important information for quote recommendation.

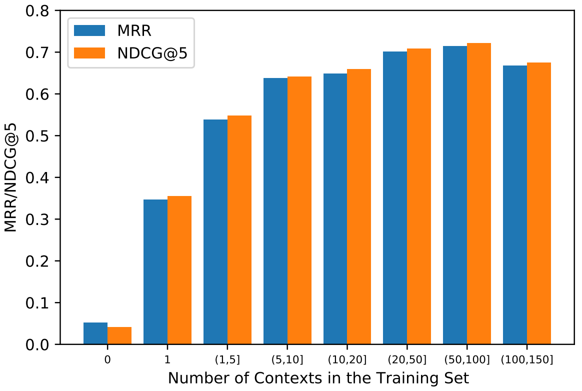

Figure 2: Recommendation performance for quotes within different occurrence frequency ranges. The quote numbers in the ranges are 100, 843, 985, 437, 283, 225, 74 and 47, respectively.

6.6 Effect of Occurrence Frequency

In this subsection, we investigate the effect of the gold quote's occurrence frequency on recommendation performance. Figure 2 shows MRR and NDCG@5 results for quotes that have different numbers of contexts in the training set of the standard Chinese part.

We observe that the occurrence frequency has great impact on quote recommendation performance. Basically, increasing occurrences of quotes in the training set can increase recommendation performance, because we can learn better representations for the quotes with more adequate training. But the most frequent quotes does not have the best performance, possibly because these quotes carry very rich semantics and can be cited in various contexts , which makes it very hard to correctly recommend them. In addition, the performance for the unseen quotes is very limited. It reflects the

#NS	MRR	NDCG	$\tilde{R}$ / $\bar{R}$ / σ_R	Recall@1/10/100
4	0.533	0.540	2 / 161 / 412	47.48 / 63.23 / 77.68
9	0.534	0.541	2 / 148 / 381	47.50 / 63.97 / 78.83
19	0.541	0.548	2 / 139 / 370	**47.91** / 64.97 / 79.35
29	**0.545**	**0.552**	2 / 174 / 434	47.06 / 63.58 / 76.92
39	0.535	0.543	2 / 132 / **357**	47.17 / 64.97 / 79.43

Table 4: Quote recommendation results with different negative sample numbers (#NS).

weakness of our model in the zero-shot situation, whose solution is left for future work.

6.7 Effect of Negative Sample Number

In this subsection, we investigate the effect of the negative sample number (#NS), a hyper-parameter of our method, on quote recommendation performance. Table 4 gives the results of different negative sample numbers on the validation set of the standard Chinese part of QuoteR.

We can see that increasing negative samples (from 4 to 19) can increase quote recommendation performance, which is because the quote encoder can be trained more sufficiently. However, when the negative samples continue increasing, the performance fluctuates or even decreases. That is possibly because of the imbalance of positive and negative samples (there is only one positive sample, namely the gold quote), as explained in §5.2. Therefore, taking both performance and computation efficiency into consideration, we choose 19 as the final negative sample number.

6.8 Human Evaluation

As mentioned in §3, there may be other quotes that are suitable for a query context besides the gold quote. Hence, we conduct a human evaluation on the recommendation results of our method. We randomly select 50 contexts from the validation set of the standard Chinese part and list the top 10 quotes recommended by our method for each context. Then we ask annotators to make a binary suitability decision for the quotes. Each quote is annotated by 3 native speakers and the final decision is made by voting. For each context, we regard the suitable quote with the highest ranking as the gold quote, and re-evaluate the recommendation performance: NDCG@5=0.661, Recall@1/10=0.50/0.92.[11] In contrast, the original evaluation results among the 50 contexts are NDCG@5=0.439 , Recall@1/10=0.36/0.64. By comparison, we can conclude that the real performance of our method is substantially underestimated. We also count the average number of suitable quotes among the top 10 quotes, which is 1.76.

Rank	Quote	Score
1	sufficient for the day is its own trouble	0.723
2	**sufficient unto the day is the evil thereof**	0.124
3	you can never plan the future by the past	0.060
4	tomorrow will be a new day	0.025
5	the darkest hour is just before the dawn	0.008

Table 5: Top 5 results for the context in Figure 1.

6.9 Case Study

We feed the context in Figure 1 into our model, and print the top 5 recommended quotes and their rank scores in Table 5. We find that the gold quote is ranked second, but the first one is actually another statement version of the gold quote and has exactly the same meaning. In addition, the third and fourth quotes are also related to the context. This case, together with more cases in Appendix B, can demonstrate the practical effectiveness and usefulness of our model.

7 Conclusion and Future Work

In this paper, we build a large and the first open dataset of quote recommendation for writing named QuoteR and conduct an extensive evaluation of existing quote recommendation methods on it. We also propose a new model that achieves absolute outperformance over previous methods, and its effectiveness is proved by ablation studies. In the future, we will try to improve our model in handling classical Chinese quotes by using a special classical Chinese pre-trained model to encode them. We will also consider boosting the performance of our model in the few-shot and zero-shot situations.

[11] Since we only annotate the top 10 results, there are no other available metrics than NDCG@5 and Recall@1/10.

Ethical Statements

In this section, we discuss the ethical considerations of this paper from four perspectives.

Dataset and Human Evaluation In terms of our QuoteR dataset, all the quotes are collected from free and open quote repository websites. Besides, all the contexts are extracted from open corpora, including free public domain e-books and other open corpora. Therefore, there is no intellectual property problem for the dataset. In addition, we conduct the human evaluation by a reputable data annotation company. The annotators are fairly compensated by the company, based on the previous annotation tasks. Further, we do not directly communicate with the annotators, so that their privacy is well preserved. Finally, the dataset and the human evaluation are not sensitive and thus do not need to be approved by the institutional review board (IRB).

Application Quote recommendation is a practical task and our model can be put into service. In actual use cases, users just need to input a query context and our model should output a list of candidate quotes that fit the given context. All people may benefit from our model during writing. If our model fails, some inappropriate quotes that cannot fit the query context would be output, but no one would be harmed. There are indeed biases in the dataset we build. Some quotes are very frequent while the others are not, as illustrated in §6.6. The infrequent quotes are less recommended and may cause the failure of our model in some cases. In terms of misuse, to the best of our knowledge, such a quote recommendation model is hardly misused. After the deployment of our model, the system would not collect data from users. It does not have any potential harm to vulnerable populations, either.

Energy Saving To save energy, we use the base version of BERT rather than larger pre-trained language models, although the larger ones would probably yield better performance. Besides, as discussed in §5.2, we find that the simultaneous training of the context and quote encoders requires very big memory and computation resources, and thus we adopt the strategy of negative sampling in training.

Use of Identity Characteristics In this work, we do not use any demographic or identity characteristics information.

A More Statistics of QuoteR

We count the numbers of quotes within different ranges of context-quote pair numbers, and the results are shown in Table 6. We can see the long tail, i.e., most quotes occur a few times while a small amount of quotes appear very frequently, which demonstrates the necessity of restricting the maximum number of contexts for a quote during the construction of QuoteR.

English					
#Context	[5,10]	(10,20]	(20,50]	(50,100]	(100,200]
#Quote	2,994	1,456	1,233	257	168
Standard Chinese					
#Context	[5,10]	(10,20]	(20,50]	(50,100]	(100,150]
#Quote	2,207	371	272	79	75
Classical Chinese					
#Context	[3,10]	(10,20]	(20,50]	(50,100]	(100,150]
#Quote	1,995	1,074	761	316	292

Table 6: The distribution of quotes within different occurrence frequency (the number of context-quote pairs) ranges of the three parts of QuoteR.

B More Case Studies

Table 7-9 show three quote recommendation cases for English, standard and classical Chinese, respectively.

- For the standard Chinese case in Table 7, the gold quote is also ranked first properly. Moreover, the 2nd and 5th recommendations, which convey the meaning of "change is the only constant thing in the world", also fit the given context.
- For the English case in Table 8, the gold quote is correctly ranked first. And the 2nd and 5th recommended quotes have the same meaning as the gold one, and thus suitable for the context as well.
- For the classical Chinese case in Table 9, the gold quote receives the highest rank score once again. And the 2nd recommended quote actually suits the context too. In addition, the 4th quote is also semantically related to the meaning of the context.

The three cases can demonstrate the effectiveness and practicability of our quote recommendation model.

C Reproducibility

In this section, we report more experimental details to ensure the reproducibility of this paper.

All the experiments are conducted on a server that has 32 Intel(R) Xeon(R) Platinum 8163 @2.50GHz CPUs and 4 16-GB Nvidia Tesla V100 GPUs. The operation system is Ubuntu 18.04. We use Python v3.6.9 and PyTorch (Paszke et al., 2019) v1.7.1 to implement our model. More details about the implementation, e.g., dependency libraries, can be found in the README file of the Software in the supplementary materials.

In addition, our models for English, standard Chinese and classical Chinese have about 308M, 308M and 329M parameters, respectively. And the average training time is 7.5h, 26h and 29h, respectively.

Rank	Quote	Score
1	人不能两次踏进同一条河流 **No man ever steps in the same river twice**	0.995
2	世界上唯一不变的就是变化 The only constant in life is change	0.002
3	萧瑟秋风今又是，换了人间 The autumn wind still sighs, but the world has changed	0.001
4	前途是光明的，道路是曲折的 The road is tortuous, but the future is bright	0.001
5	只有变化是永恒的 Change is the only constant	0.001

Table 7: A standard Chinese quote recommendation case. Top 5 recommended quotes (the gold quote is in boldface) are listed for the context: 从盘面上看，股票价格会呈现某种带漂移的无规则行走，涨跌无常，难以捉摸。[Quote]，这话放在投资领域也同样受用。事物是在不断变化的，历史数据只能起一定程度的参考作用。投资者想凭借历史数据准确预测未来几乎是不可能的。(*The stock price shows some kind of irregular walk with drift, up and down unpredictably. The saying that [Quote] is also applicable to investment. Things are constantly changing, and historical data have limited reference value. It is almost impossible for investors to accurately predict the future based on historical data.*)

Rank	Quote	Score
1	**Truth is always strange**	0.984
2	Truth is always stranger than fiction	0.005
3	Truth is dangerous	0.002
4	Truth is subjectivity	0.001
5	Fact is stranger than fiction	0.001

Table 8: An English quote recommendation case. Top 5 recommended quotes (the gold quote is in boldface) are listed for the context: *We've talked about some of the prophecies that have already come true in our cities from science fiction. What are some prophecies that have yet to come true? In a way, while sci-fi is fascinating, [Quote]. The transformation around surveillance is already mimicking a lot of the predictions in, say, minority report, which was very much emphasizing how surveillance and marketing were becoming completely tailored to the individual.*

Rank	Quote	Score
1	道不同，不相为谋 **Persons walking different paths cannot work together**	0.412
2	话不投机半句多 One word is too much for someone uncongenial	0.270
3	惺惺惜惺惺 The wise appreciate one another	0.111
4	白头如新，倾盖如故 You may know a little about old acquaintances and make close friends with a stranger soon	0.033
5	近朱者赤，近墨者黑 One takes the behavior of one's company	0.024

Table 9: A classical Chinese quote recommendation case. Top 5 recommended quotes (the gold quote is in boldface) are listed for the context: 我是少数群体中的一员，谈不上饱受社会不文明的欺压，却也受到主流文化对边缘群体的排斥。你不认可我，所谓[Quote]，我哪里还能跟你热情。相反，认可我的人就会享受我的回应，真诚也好，善良也好，温柔也好，我会把我好的一面展示给他们。(*I am a member of a minority group, not suffering from the oppression of uncivilized people in society, but being ostracized by mainstream culture. If you don't approve of me, as the saying goes, [Quote], I can't be enthusiastic about you. In contrast, the persons who approve of me will enjoy my good side, including sincerity, goodness and gentleness.*)

Towards Comprehensive Patent Approval Predictions: Beyond Traditional Document Classification

Abstract

Predicting the approval odds of a patent application is a challenging problem involving multiple factors. The most important factor is arguably the novelty — *35 U.S. Code § 102* rejects applications that are not sufficiently differentiated from prior art. Novelty evaluation distinguishes the patent approval prediction from conventional document classification — too-similar newer submissions are considered as not novel and would receive the opposite label, thus confusing standard document classifiers (e.g., BERT). To address this issue, we propose a novel framework AISeer that unifies the document classifier with handcrafted features, particularly time-dependent novelty scores. Specifically, we formulate the novelty scores by comparing each application with millions of prior art using a hybrid of efficient filters and a neural bi-encoder. Moreover, we impose a new regularization term into the classification objective to enforce the monotonic change of approval prediction w.r.t. novelty scores, From extensive experiments on a large-scale USPTO dataset, we find that standard BERT fine-tuning can partially learn the correct relationship between novelty and approvals from inconsistent data. However, our time-dependent novelty feature and other handcrafted features offer a significant boost on top of it. Also, our monotonic regularization, while shrinking the search space, can drive the optimizer to better local optima, yielding a further small performance gain.

1 Introduction

Intellectual property (IP) is an important and integral to the economy. IP-intensive industries directly accounted for 27.9 million jobs in the U.S. (USPTO, 2016) Theoretical and empirical evidence shows that patents are effective in fostering technological progress. (Gallini, 2002; Hu and Png, 2013; Hall and Harhoff, 2012) Securing patent approvals offers a major shot in the arm to inventors and innovators, increasing the chances of obtaining angel and venture capital investments. However, the process of getting a patent approved can cost applicants tens of thousands of dollars in payments to law firms who claim to be helpful in understanding what gets approved and improving the odds of success of a patent application. Thus, algorithmic approaches to aid in the patent evaluation process can potentially save precious time and resources for applicants during the patent application phase, as well as benefit patent examiners in government patent offices around the world, accelerating and improving the review process (Ebrahim, 2018).

The approval of a *patent application*, according to U.S. patent laws, is determined necessarily and sufficiently by the approval of *application claims*. Patent laws define individual claims as the subject matter of *inventions* (*35 U.S. Code* §112), on which "patentability" is defined (*35 U.S. Code §* 101, 102, and 103) (refer to Appendix B). No overall assessment of a patent application is provisioned.

In practice, application claims demarcate the scope of legal protection that an applicant is seeking and are the eventual objects for investigation under legal disputes or transfer of commercial rights. Patent examiners from the U.S. Patent and Trademark Office (USPTO) make decisions on each application claim individually and independently with other sections as supporting materials. Therefore we focus on claim texts and use the term "*patent approval*" informally and interchangeably referring to "*claims approval*." In particular, we primarily consider *35 U.S. Code § 102*, assessing the *novelty* of application claims.

To the best of our knowledge, we are the first to try to predict patent (claim) approval, which is as an extremely challenging problem for multiple reasons. First, patent documents comprise of technically nuanced and challenging to parse language (intricate legalese). Patent texts are usually legal and technical descriptions of objects or pro-

Volume 1: Long Papers, pages 349 - 372
May 22-27, 2022

cesses, which tend to be complex in vocabulary and grammatical structures (Singer and Smith, 1967). Claims are examined not only literally, but also for their legal implications. Appendix A provides a few example application claims.

Second, the patent examination process tends to suffer from subjectivity and inconsistencies (O'Neill, 2018a), exemplified by variance across offices and groups, (O'Neill, 2018b) and across human examiners. In FY17, only 66% of primary examiners are within a 12.5% delta off the average allowance rate (USPTO, 2017).

Third, at the core of patent examination, evaluation of novelty is time-dependent. Rejections of claims by *35 U.S. Code § 102* require examiners to *cite* prior approved patent claims, *prior art*, as evidence. More details about the examination process can be found in USPTO (2020). The United States Patent and Trademark Office (USPTO) receives thousands of applications a week; thus a novel application at one time may be dramatically different in the assessment of novelty after a short time period. This means that a classifier can pick up a positive label from an earlier approved application but receive a negative label from an application sometime later with similar technical content, which is deemed no longer novel. Such conflicting information can confuse the classifier and undermine its performance. In other words, the data labels are intrinsically noisy and inconsistent due to the nature of the domain problem.

Although AI/ML approaches are often discussed in the patent domain (Aristodemou and Tietze, 2018) such as in the area of information retrieval (Kang et al., 2007; Fujii, 2007; Shalaby and Zadrozny, 2019), applications of deep NLP methods are mostly concerned with classifying the content domains of patents (Verberne et al., 2010; D'hondt et al., 2013; Hu et al., 2016; Lee and Hsiang, 2019). In addition, the extant literature usually explores approved patents rather than applications (Balsmeier et al., 2018). Even to simply classify the topics of approved patents, state-of-the-art document classifiers can only achieve an accuracy of about 69.3% - only 2.2% over RoBerta (Zaheer et al., 2020). Due to these issues, patent approval prediction task is much more challenging than topic classification for document classifiers.

To mitigate the issues, we first develop several handcrafted features based on domain knowledge for use alongside the language model for context and control. The time-dependent nature of the novelty also makes traditional document classifiers not suitable here, because they typically assume that similar instances belong to the same label. To address this challenge, we propose a novel framework AISeer as shown in Figure 1. We formulate a time-dependent novelty score for each patent claim with its semantic similarity against prior approved claims from *patent grants*, which are final versions of *approved* patents. Specifically, inside a comprehensive pool comprising millions of grants, we consider those approved before the filing date of the focal application and then measure the maximum semantic similarity score of the focal patent claim matched with all approved claims in the time-dependent sub-pool. To improve computing efficiency, we apply document-level filters to narrow the sub-pool for each claim. Integrating such similarity scores with handcrafted features and BERT, we conduct experiments on the large-scale USPTO dataset and find significant performance gains over fine-tuning a standard BERT alone.

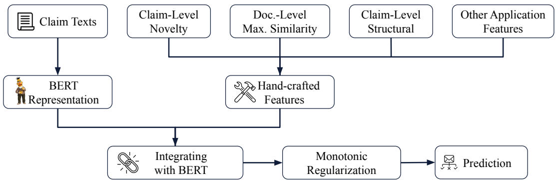

Figure 1: An overview of our proposed AISeer.

All else equal, a patent claim with a higher similarity score, i.e., semantically more similar to prior approved claims, should be less likely to be approved. Hence we propose to impose monotonic regularization on the novelty score so that the loss function has an additional term of the hinge loss to further penalize non-decreasing predictions in the similarity. This effectively restricts the search space for the optimizer to prediction mechanisms that are reasonably consistent with the novelty measure. From our experiments, this regularization significantly impacts the model outputs. Although performance improvements are limited, it can help the optimizer steer away from unfavorable local optima and further improve AUROC. We further discuss the experimental findings in depth to illustrate how BERT and handcrafted features contribute in overcoming the unconventional data issues.

In summary, our contributions are as follows.

- We collect patent application data from several data sections of USPTO and integrate full texts,

Table 1: Dataset Statistics. The approval ratio is calculated based on *35 U.S. Code § 102* labels.

	Train	**Validation**	**Test**
Applications M	216,101	175,597	153,632
Claims N	3.90M	3.07M	2.58M
Approval %	80.65	80.16	81.68
Time range	04/16-02/17	03/17-10/17	11/17-06/19

metadata, office actions, rejections and citations data into a massive dataset;

- We develop a series of handcrafted features to aid the prediction of *35 U.S. Code § 102* approval decisions. In particular, we design and analyze a time-dependent feature that measures the novelty of patent applications at the time of filing;
- We incorporate the handcrafted features and impose monotonic regularization on the novelty features to shed light on how the intrinsic data inconsistency issues in the domain problem can be mitigated.

Reproducibility. We will release the benchmark dataset and our code on GitHub: `https://github.com/acl-2022-towards-comprehensive/acl-2022-camera-ready`.

2 Problem Formulation and Benchmark

In this section, we formally formulate the novelty-based patent approval problem. We describe the experiment setup, the dataset, and baseline results with common document classifiers.

2.1 Problem Definition and Formulation

We follow legal definitions under *35 U.S. Code § 102*. Despite the popular notions of patent approval or issues, what is actually being approved/rejected are individual claims.

Each patent applications A_k, $k \in \{1 \cdots M\}$, sorted by filing dates, comprises of a number of application claims. Given text representation $\mathbf{X}_i$, $i \in \{1 \cdots N\}$, of each application claim, there exist $\{i_k\}$, $k \in \{0 \cdots M\}$ such that claim representations $\{\mathbf{X}_{i_{k-1}} \cdots \mathbf{X}_{i_k}\}$ belong to patent application A_k. Binary labels y_i indicate approval decisions derived from patent rejections and office actions data where $y_i = 1$ indicates claim approvals. We would like to classify application claims according to approval labels.

2.2 Benchmark Dataset Preparation

Dataset Collection. USPTO provides public data arranged in separate sources, including application and grant full texts, application metadata, citations, office actions, and rejections (USPTO, d,e). Patent grants are final versions of approved patent applications. Later we will utilize grants for constructing the application novelty feature. To extract labels and create handcrafted features, we utilize both the legacy data system for office actions, rejections and citations made between 2008 and mid-2017 (Lu et al., 2017), and newer v2 APIs that cover mid-2018 onward. For application metadata, we obtain bulk data from PEDS (Patent Examination Data System) (USPTO, b). In order to match all the available labels, we obtain weekly bulk releases for of both utility patent applications and utility patent grants in XML format ranging between 2005 and 2019. In total, we extract 8.8 million patent applications and 3.7 million patent grants during the same time period whose texts are around 730 GB.

Dataset Processing. According to patent laws, only one version among possibly a number of revisions is published and available as full-text data. Meanwhile, for a considerate amount of applications, the entire history of office action data and rejection data are available, where allowances or rejections for each individual claim under each legal clause are formally made. Hence we ought to identify the labels associated with the published version among patent examination rejection data and office action data.

We take a "snapshot" approach. Given the available publication version of each application as snapshots, the examination decisions of each claim particularly with respect to the snapshot version are processed and attached as classification labels. Therefore, with the huge number of snapshots, regardless of the subsequent actions of the applicant, e.g. abandonment, the model can be kept agnostic of the status in the application pipeline. This way, we allow the model to predict for any version of a patent application so that the attorneys and applicants can evaluate their chances for decision making. Technical preparations for publication of an application generally begin 4 months prior to the projected date of publication. Hence we match the closest office action dates with publication dates minus 4 months which is supposed to be the benchmark date for the available version, so that correct labels can be obtained. Please refer to the essential publication regulations in Appendix D.

Data are merged by the application number and ingested into a DBMS. We find out around 900K applications under which all corresponding sections of data are available. Because of the data size and to control for computation times, we choose the most recent, around 500K applications and effectively around 9.5 million claims for experiments.

Dataset Splits. We split the data into training, validation, and testing sets by their filing dates. The more recent ones are chosen for testing. The size for final experimental data, including the abstract, claim texts, labels, and handcrafted features, is around 15 GB. The dataset is highly imbalanced towards positive labels (see Table 1 Approval %).

2.3 Common Document Classifier Benchmark

Common Document Classifiers. We mainly evaluate the following common document classifiers.

- **Log. Reg.** refers to logistics regression using TF-TDF features.
- **Text-CNN** (Kim, 2014) with GloVe (Pennington et al., 2014) embeddings as the input. Adam optimizer with learning rate 0.001. 10 epochs' run; batch size as 1024;
- **LSTM** (Hochreiter and Schmidhuber, 1997) with GloVe embeddings as the input. AdamW optimizer with learning rate 0.005 and 10 epochs' run; batch size as 1024;
- **BERT** (Devlin et al., 2018) fine-tuning. AdamW optimizer with learning rate 5e-5 as the optimizer. The number of fine-tuning epochs as 5; batch size as 256. This is the the same model as in the state-of-the-art model, **PatentBERT**, in patent content classification (Lee and Hsiang, 2019) with a different set of hyper-parameters and balanced class weights. The original PatentBERT model is designed for a different task, and the experimental setting is not suitable for predicting patent approvals, hence we make the tweaks.

In all of the models, we impose class weights in the loss functions inversely proportional to the number of class instances, such that two classes are treated equally by the optimizer. For the details, please refer to Section 3.1. The neural models are trained with text inputs processed at a maximum length of 128 tokens per claim and on a single GPU.

Evaluation Metrics. Given the imbalanced nature of our dataset, we adopt both the Area Under the Curve for the ROC plot (Fawcett, 2004) (AUROC) and macro F1 score as our evaluation metrics. With AUROC, the predicting performance of the minority class could be taken into consideration with a similar weight as for the majority class (in our case, positive class). Moreover, the probability-based metric can provide more detailed insights into model performances. Therefore, we choose **AUROC** as our **main metric**. The **macro F1** score is a direct average of F1 scores of both the positive class and the negative class and provides an alternative balanced view of both classes' performances. We treat it as a **secondary metric**. We compute the maximum macro F1 score (Lipton et al., 2014) by varying the decision threshold for each model. Other traditional measures focused on the positive class performance such as accuracy and recall have little practical implications due to data imbalance.

Table 2: Benchmarking Common Document Classifiers.

	AUROC %	Macro F1 %
Random Guess	50.00	50.00
Predicting All "1"	50.00	44.96
Log. Reg. (Tf-Idf)	58.94	54.54
TextCNN (GloVe)	59.70	55.58
LSTM (GloVe)	61.68	**56.95**
BERT (PatentBERT)	**61.79**	56.51

Benchmark Results. Table 2 shows common document classifiers' performance with some naive predictions as references. Results of neural models are reported with the median metrics among several runs with different optimizer random states. Figure 4 in Appendix F further visualizes more details of the ROC curves of these models. One can find that BERT and LSTM are arguably the most effective ones. Therefore, we will focus on BERT and LSTM for further comparisons.

3 The AISeer Framework

Our AISeer framework unifies the document classifier, handcrafted features and monotonic regularization, as shown in Figure 1. It is compatible with almost all document classifiers. In this paper, we choose BERT as the base document classifier to demonstrate the effects as it is widely adopted and also performs well in our benchmark evaluations. After each application claim text is run through the BERT model, the output representation is concatenated with the corresponding handcrafted features. Our handcrafted features include a time-dependent claim-level novelty score, claim-level structural features, document-level similarity scores, and other application metadata features. We further impose a monotonic regularization on the impact of the claim-level novelty score so that the loss function has an additional term of the hinge loss.

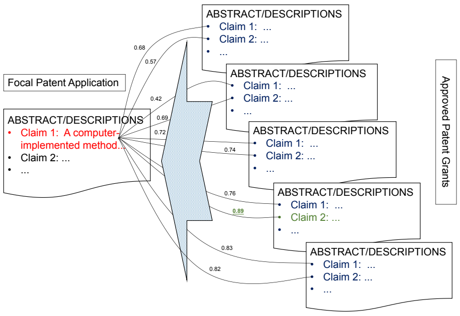

Figure 2: Illustration of Novelty Feature Construction.

3.1 Base Document Classifier

For self-containedess, we briefly introduce how we use BERT in AISeer. We first utilize BERT to transform the i-th application claim to a text representation $\mathbf{X_i}$ in batches of a size N_b, which is then passed to a linear layer to obtain the prediction through a softmax layer.

Approvals (i.e., $y_i = 1$) are much more popular than rejections (refer to Table 1), so the vanilla training will bias the model towards approvals. Therefore, we adopt a weighted loss for training: $\mathcal{L} = \sum_i -w_{y_i} \left(y_i \log \hat{y}_i + (1 - y_i) \log(1 - \hat{y}_i) \right)$ where w_{y_i} denotes the fixed weights of the two classes, which is inversely proportional to the number of instances from the corresponding class, balancing the training weights of the two classes.

3.2 Claim-Level Novelty Feature $\mathbf{N_{s,claim}}$

The backbone of the novelty feature is the *time-dependent* claim-level maximum similarity score.

We first index all patent grants with ElasticSearch (NV). Given a patent application and a claim under it, we first take advantage of its fast BM25-based document-level fuzzy matches to obtain the 5 most similar grant documents to the focal application document as a first-stage pre-filter. To account for time-dependence, each focal application is matched against a sub-pool of patent grants which are time-stamped to be approved strictly before the filing date of the focal application. In application level matching, all document sections are considered, including the abstract, summary of invention, and details of invention of all claims.

Among all claims under the top-5 matched grants, we then find the most similar one to the focal claim using sentence-transformer (Reimers and Gurevych, 2019) with `stsb-roberta-large` pre-trained bi-encoder model. Base cross-encoder transformers such as BERT can lack in performance for pure semantic similarity tasks. Although certain cross-encoders have excellent semantic similarity performance, it can be computationally too demanding for our purpose since the scale of the claims in all patent grants is more than 100 million, and since each grant claim can be required to be paired many times with a focal application claim. The Elasticsearch-based pre-filter process also helps manage the computational need.

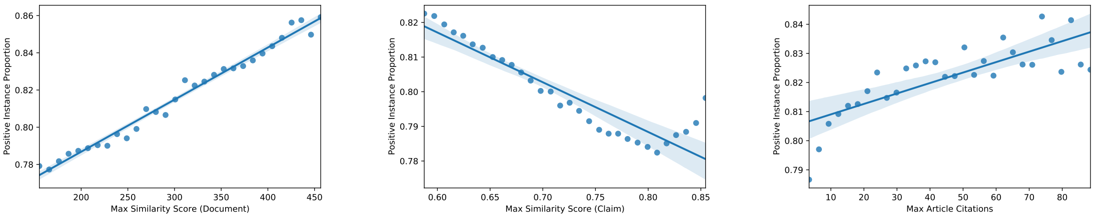
Figure 2 demonstrates how the time-dependent novelty feature is generated — the application that the red-highlighted focal claim belongs to is first matched with 5 patent grants on the application level; then the focal claim is matched against every claim under the 5 matched grants to compute the semantic similarity score, before the most similar grant claim is identified. Our experiments confirm that the claim-level maximum similarity score, as expected, is negatively correlated with *35 U.S. Code § 102* labels, as shown in Figure 3.

3.3 Application-Level Handcrafted Features

Application-Level Similarity. We consider the application-level maximum similarity score, denoted as $N_{s,doc}$, and mean similarity score generated by ElasticSearch (NV) as handcrafted features. These document-level scores measure how similar overall are the applications to the approved grants. The document-level similarity scores are positively correlated with *35 U.S. Code § 102* labels. We believe that they primarily capture the overall writing quality and the common language patterns of approvable applications.

Features from Metadata. The USPTO dataset offers a rich collection of metadata about each patent application. We use the following two of them:

- *Patent Classification*: the USPC class designated for the applications. USPC (USPTO, a) is a system of classifying the subject matter of each patent application for recording, publication, and assignment purposes. Different classes of patents tend to have varying approval rates (see Table 6 in Appendix C).
- *Number of Applicant Cited References*: the number of citations of other patents or articles initiated by the applicant herself. In the patent domain, most *citations* are initiated by the examiners as "prior arts" to reject application claims. However, they can also be made by the applicant to demonstrate understanding of related work and claim contributions. The number of applicant-initiated citations is a signal of the effort and



(a) $N_{s,doc}$ (b) $N_{s,claim}$ (c) Max Article Citation

Figure 3: Handcrafted Features vs. Proportions of Positive 102-Labels. Features are grouped into bins for 10-90 percentile against mean positive label proportions.

research the applicant puts in the application.

Other Application-Level Features are also considered for utility and writing as follows.

- *Max Citation*: based on ElasticSearch pre-filter, the maximum number of total citations among the top 5 most similar patent grant documents to the focal patent application.
- *Max Article Citation* refers to the maximum number of citations which are research articles (not other patents) in top matched grants.
- *Lexical Diversity*: the richness in the vocabulary of the abstract of the patent application.

3.4 Claim-Level Structural Features

We consider two indicators for each claim.

Component refers to indicator on whether the application claim is describing the components of a system (e.g., a machine, a process, a compound). Other claims may describe the properties or utility of particular components. This is identifiable by the transitional phrases used in the claim.

Transitional Phrase refers to indicator on whether a component claim is *open*, *closed*, or *half-open*, which is determined by which transitional phrase is used. Openness or closedness regulates the scope of legal IP protection the applicant enjoys once the patent is approved. Often it is a strategic choice by the applicant and the attorney. If a claim is *open*, indicated by transitional phrases “comprising” and legal synonyms, any additional components later added to the system are also protected, in contrast to closed claims . Open claims are more difficult to be approved. Other examples of transitional phrases include "consisting essentially of" and "consisting of". These particular language phenomena are well-known in the IP communities and sometimes referred to as “patentese” (Singer and Smith, 1967). The patent examination manual explicitly discusses these phrases with case law (USPTO, c; Silverman and Stacey, 1996).

3.5 Integrating with BERT

Now let $\mathbf{H_i}$ denote other handcrafted features in addition to $N_{s,claim}$ and $N_{s,doc}$. Figure 3 demonstrates the correlations between some representative handcrafted features and the positive label. Let $\mathbf{Z}_i = \mathbf{X_i} \cup \mathbf{H_i} \cup N_{s,claim} \cup N_{s,doc} \cup \{1\}$, $\forall i \in \{1, ..., N_b\}$. Note that X_i is the representation for the claim and that the document or application-level handcrafted features will be augmented to each claim. The concatenated Z_i will pass through the linear and the softmax layer.

3.6 Monotonic Regularization

Mathematically, we restrict the search space upon $N_{s,claim}$, regularizing predictions to be decreasing in it. The optimizer will potentially be able to find alternative paths to avoid undesirable local minima. Let $\tilde{\mathbf{Z}}_\mathbf{i}$ denote all other inputs except $N_{s,claim}$.

We manipulate the input such that inconsistency with the monotonicity in $N_{s,claim}$ is represented. The novelty scores need to be manipulated and multiplied by For a positive constant $C (0 < C < 1)$ let $N'_{s,claim} = CN_{s,claim}$, let $\mathbf{Z'_i} = \tilde{\mathbf{Z}}_\mathbf{i} \cup N'_{s,claim}$. Applying such a manual constraint on the input novelty representation completes such a monotonically decreasing relationship between input $N_{i,k}$ and output Given log-likelihood with respect to $\mathbf{Z_i}$,

$$F(\mathbf{Z_i}) = y_i \log \hat{y}_i(\mathbf{Z_i}) + (1 - y_i) \log(1 - \hat{y}_i(\mathbf{Z_i})),$$

we shall constrain $F(\mathbf{Z_i}) < F(\mathbf{Z'_i})$. To implement it, we shall impose a hinge loss penalty whenever $F(\mathbf{Z_i}) > F(\mathbf{Z'_i})$ and return 0 when otherwise.

Therefore, the final objective function becomes:

$$\mathcal{O} = \mathcal{L} + \lambda \sum_i \max \left\{0, F(\mathbf{Z_i}) > F(\mathbf{Z'_i})\right\},$$

where λ determines the regularization strength.

4 Experiments

In the experiments, we seek to answer a number of questions. To begin with, we evaluate how hand-

Table 3: Evaluation Results of AISeer, Compared Methods, and Ablations.

	AUROC%	Macro F1%
LSTM (GloVe)	61.68	56.95
BERT (patentBERT)	61.79	56.51
AISeer	**64.14**	**57.92**
Log. Reg. Feat. Only	60.45	55.47
AISeer w/o Regu.	63.71	57.73

crafted features can help the deep language model, i.e. BERT, adapt to a complex domain that differs from typical NLP use cases. In particular we focus on the novelty feature critical to patent approvals. We are interested in the extent to which a standard BERT application can learn from highly noisy labels and inconsistent data and find out the novelty pattern, i.e. the significance of novelty in determining patent approval outcomes. In addition, we study if the combination of BERT and handcrafted features serves to be adequate in capturing the novelty pattern. We also examine if monotonic regularization boosts the learning process to further overcome the intrinsic data inconsistencies.

We mainly compare **AISeer** with two baseline models, **BERT** and **LSTM**, as they are the best common document classifiers from our benchmark results. For ablation study purpose, we also compare with **Log. Reg. Feat. Only**, a logistics regression model with handcrafted features only, and **AISeer w/o Regu.**, which is a BERT model integrated with our handcrafted features but not regularized by our monotonic constraints. AISeer is trained with the same set of hyper-parameters as BERT: maximum token length as 128, fine-tuning for 5 epochs; batch size as 256; AdamW with learning rate being 5e-5 as the optimizer. The monotonic regularization parameter C is $\frac{1}{2}$ and λ is 5e-4. The models are trained on a single Nvidia Quadro RTX 8000 GPU.

The results are shown below in Table 3. The reported numbers are median results from 3 runs under the same hyperparameter setup.

4.1 Overall AISeer Results

The baseline BERT model gives decent AUC (ROC) and macro F1. The full-fledged AISeer, combining handcrafted novelty feature along with other computed ones and motonic regularization, helps with both the metric dimensions: AISeer boosts AUROC by around 2.5% percent and macro F1 by around 1% compared to the best common document classifiers. Figure 5 in Appendix F shows the AUROC improvement originates consistently from the entire spectrum of prediction scores.

Aforementioned in the introduction, when simply classifying the topics of approved patents, state-of-the-art document classifiers can only achieve an accuracy of about 69.3% (only 2.2% over RoBerta) (Zaheer et al., 2020). Given the difficulty level and subjective nature of the patent approval task, the performance improvement is nontrivial and practically impactful. Standard BERT fine-tuning realizes an AUROC increase of only 11.79% over completely random or naive predictions, which also exemplifies the problem's difficulty. Our approach achieves an additional performance of 2.35%, which is equivalent to 20% of the total benefits of the original BERT model. Given that BERT remains one of the most effective models in varieties of NLP tasks, and especially that handcrafted features have relatively low dimensionality compared to BERT, we believe that the performance gain equivalent to 20% of the performance gain of BERT is substantial for this completely new application domain.

The lower half of Table 3 shows the result of Log. Reg. Feat. Only, indicating the necessity of a language model. Neither a language model only nor handcrafted features only can yield satisfactory performance.

4.2 Evaluating Handcrafted Features

Comparing AISeer w/o Regu. result, also in the lower half of Table 3, and the standard BERT and LSTM results, it is shown that handcrafted features improve on best common document classifiers by about 2%. We believe that the handcrafted features combined, in particular, the novelty feature, helps in resolving label contradictions and data inconsistency.

We believe the novelty feature should be only considered under contexts and will not perform well on its own. First, novelty can be a subjective concept and may vary according to different types of claims, openness of claims, the department (category), etc. Second, novelty as practically measured by dis-similarity, can be easily achieved by poorly written random content, thus structural or overall similarity is also important. However, the observations indicate that there are potential conflicts between the novelty feature and other handcrafted features. While the latter helps with prediction performance on their own and provide contexts for the novelty feature thus imperative, it will also attenuate the effects of the regularized novelty feature. We leave this challenge for future work.

One may also ask whether the handcrafted features have contributed significantly given the moderate improvement. Granted, application full texts may also contain signals for the patent class and applicant efforts that may partially reflect handcrafted features and the document classifier such as BERT may pick them up.

To shed light on how AISeer learns from handcrafted features, we run linear regressions for the model prediction scores on handcrafted features for interpretable insights and present statistical results, as shown in Table 4. In the table, even prediction scores under BERT are significant in all handcrafted features, showing that BERT does learn knowledge overlapping with the handcrafted features to some extent.Overall, low R^2's indicate that knowledge from the deep neural model and knowledge from handcrafted features are quite distinct.

Comparing BERT and AISeer w/o. Regu., the significant R^2 increase from 0.085 to 0.125 shows that AISeer captures handcrafted features much more effectively than BERT. The prediction scores of AISeer w/o. Regu. have an additional about 4% increase in explanability by the handcrafted features.

4.3 Evaluating BERT Learning and Monotonic Regularization

In Table 3, comparing AISeer and AISeer w/o Regu., the median run result indicates that adding monotonic regularization produces a small magnitude of improvement. Table 4 also provides insights with respect to the monotonic regularization. According to Table 4, our claim-level novelty feature $N_{s,claim}$ has the most significant impact, i.e. the coefficients are much larger in every column. The use of monotonic regularization alone boosts the R^2 significantly, indicating that the approach also helps the model learn from handcrafted features overall.

About 19% of the knowledge of AISeer corresponds to handcrafted features, a 10% increase over BERT. Also, AISeer corrects incorrect coefficient signs from BERT. Intuitively, the approval chance shall increase with the number of applicant cited references. However, BERT prediction scores are negatively correlated with it statistically significantly. Under AISeer, this direction is reversed to match intuitions.

We also evaluate the Spearman correlation coefficients of the probability prediction scores produced by the models with the claim-level novelty feature Pearson correlations with the document-level similarity score. Spearman correlations measure the strength and direction of monotonic association between two variables. According to Table 5, first we can confirm that applying monotonic regularization significantly pushes the prediction scores to be more monotonically decreasing in the core novelty feature – the Spearman correlation shifts from -0.0230 to -0.103. However, compared to the BERT, the regularization effect is less prominent. Observe that adding handcrafted features will actually steer the monotonicity into the opposite direction. Our regularized AISeer model manages to both benefit from the novelty feature and incorporate knowledge from other handcrafted features.

While Table 4 illustrates the significant effects of applying the monotonic regularization on the prediction scores, we acknowledge that the observed main performance improvement is not very significant. In fact, although monotonic regularization raise the performance on average, it does not always yield desirable improvements depending on the random seed and the hyperparameter setup.

The BERT model may already have a decent learning power to mine the novelty measurement despite the noisy data. We observe that in Table 4, the BERT prediction scores, learned from texts only, are significant in the novelty feature and are in the correct direction. The relatively small performance gain of using monotonic regularization may also be attributed to the compromised precision of the novelty feature due to the use of the ElasticSearch pre-filter for the sake of computational costs.

5 Related Work

To our knowledge, our work is the first in predicting patent approvals according to the examination procedures at the government patent office. Few extant researches attempt to predict decisions in office. Winer (2017) studies PTAB (Patent Trial and Appeal Board) hearing decisions at USPTO. Other related work addresses patent quality in a general and broad sense (Wu et al., 2016). More broadly in the IP/patent domain, although AI/ML applications have been often advocated (Ebrahim, 2018), studied (for a review see (Aristodemou and

Tietze, 2018)) or implemented in practice (Lu et al., 2017), most work focus on determining patent content classes to save manpower or concern only with patent grants rather than applications (Verberne et al., 2010; D'hondt et al., 2013; Hu et al., 2016; Balsmeier et al., 2018; Lee and Hsiang, 2019). Recent studies (Hsu et al., 2020) emerge aiming at predicting patent transfers and the economic value.

Other streams of related work include those exploring patent similarity. Our approach of constructing the novelty feature with a state-of-the-art neural bi-encoder (Reimers and Gurevych, 2019) is significantly more advanced than relatively rudimentary approaches in the extant literature, such as text matching and frequency-based methods (Younge and Kuhn, 2016; Arts et al., 2018; Shahmirzadi et al., 2019). Studies on semantic analysis and representation of technology (Kim et al., 2016; Strumsky and Lobo, 2015) based on patent data are also related.

6 Conclusions and Future Work

In this paper, we tackle the challenging problem of predicting patent approval decisions as per *35 U.S. Code § 102*, namely the novelty-based decisions. We have prepared a large-scale benchmark dataset by consolidating different data sources from USPTO. From the evaluations of the popular document classifiers, BERT and LSTM are arguably the most effective ones. We identify the time-dependent challenge of the novelty judgement, and therefore propose AISeer, a novel framework going beyond the traditional document classifiers. Specifically, we construct a claim-level core novelty feature along with several other handcrafted features and apply them on top of the pre-trained BERT model. We further propose to add the monotonic regularization on the core novelty feature to resolve the potential label conflicts caused by the mechanism of the patent examination process. Experimental results have verified the superiority of AISeer and also the effectiveness of introducing novelty features and monotonic regularization.

We believe that our work is beneficial to various parties, including patent applicants, attorneys, examiners and regulators. While the advantages of our regularization methodology are significant, there is still room for potential metric improvements, thus further developing the work will yield opportunities for promising future research and greater contributions to the communities. In future, it is important to extend the scope from claims to the other sections in the patent applications. Relationships among components and entities described in claims and relations among claims are also critical to investigate.

Acknowledgments

We want to thank the anonymous reviewers for their insightful comments. The research was sponsored in part by National Science Foundation Convergence Accelerator under award OIA-2040727 as well as generous gifts from Google, Adobe, and Teradata. Ethical Consideration

This paper focuses on the patent approval prediction. The data is publicly available from USPTO and we collected it to form a large-scale dataset. Our architecture is built upon open-source models and all the datasets are available online. Therefore, we do not anticipate any major ethical concerns.

A Example Patent Claims

Example 1: *A computer-implemented method for managing deep-learning, the method comprising: deploying a first and a second scoring endpoint with payload logging for a deep-learning model; receiving, at the second scoring endpoint, native data and a user-generated score for the native data; pre-processing, at the second scoring endpoint, the native data into readable data for the deep-learning model; outputting, from the second scoring endpoint to the first scoring endpoint, the user-generated score for the native data and the readable data, wherein the first scoring endpoint is associated directly with the deep-learning model; outputting, from the second scoring endpoint to a payload store, a raw payload, wherein the raw payload includes the native data; processing, at the first scoring endpoint and using the deep-learning model, the readable data and the user-generated score to output a transformed payload and a prediction, respectively, to the payload store; matching, at the payload store, the raw payload with the transformed payload and the prediction to produce a comprehensive data set; evaluating the comprehensive data set to describe a set of transformation parameters; and retraining the deep-learning model to account for the set of transformation parameters.*

Example 2: *A system for use in allowing a user to conduct one or more transactions at one or more touchpoints in a business facility, the system comprising: an authentication component configured to authenticate the user as a person allowed to conduct the one or more transactions; a tracking component configured to track the user's location within the facility as the user moves through the facility; and a control component configured to: receive authentication information from the authentication component; receive location information from the tracking component; use the location information to recognize that the user has moved into position to engage one of the touchpoints; and deliver a message to the touchpoint authorizing the touchpoint to engage in one or more transactions with the user.*

Example 3: *A hybrid nano-filament composition for use in a lithium battery cathode, said composition comprising: a) An aggregate of nanometer-scaled, electrically conductive filaments that are substantially interconnected, intersected, or percolated to form a porous, electrically conductive filament network, wherein said filaments have a length and a diameter or thickness with said diameter or thickness being less than 500 nm; and b) Micron- or nanometer-scaled coating that is deposited on a surface of said filaments, wherein said coating comprises a cathode active material capable of absorbing and desorbing lithium ions and said coating has a thickness less than 10 μm.*

Example 4: *A method for automatically surfacing tagged content adjunct to a vertical application, the method comprising: receiving and parsing text from content in an end user application; comparing the parsed text to social bookmarks and associated metadata from a social bookmarking system and matching portions of the content to respective ones of the social bookmarks and associated metadata based upon the comparison; and, directing a visual emphasis of the matched portions of the content in the end user application, whereby the end user application is unmodified to perform the receiving, comparing and directing steps.*

Example 5: *A storable foamable emulsion composition adapted for delivery of an active pharmaceutical ingredient (API) to a delivery site in a subject, the composition comprising: a) at least one organic carrier selected from the group consisting of a hydrophobic organic carrier, an organic polar solvent, an emollient and mixtures thereof, at a concentration of about 2% to about 50% by weight; b) at least one surface-active agent at a concentration of about 0.01% to about 5% by weight; c) at least one polymeric agent selected from the group consisting of a bioadhesive agent, a gelling agent, a film forming agent and a phase change agent, each in a concentration of about 0.01% to about 5% by weight; d) water; e) an effective amount of at least one API selected from the group consisting of a steroid, a steroid derivative, and combinations thereof; f) optionally, a further active agent; and g) a propellant at a concentration of about 3% to about 25% by weight of the total foamable composition, wherein, at ambient temperature, the storable foamable emulsion composition is shakable, is resistant to centrifugation at about 3000 rpm for about 10 min, is substantially devoid of crystals, is resistant to at least one freeze-thaw cycle and does not phase separate within at least about one month; wherein the at least one API remains chemically stable for at least about one month; and wherein the composition is stored in an aerosol container and upon release expands to form a breakable foam* *having an average bubble size range of about 30 to about 250 micron.*

B Essential Legal Codes for Patent Examination

The followings are referred to in the paper that provision *patentability*:

B.1 35 U.S.C. 101 Inventions patentable.

Whoever invents or discovers any new and useful process, machine, manufacture, or composition of matter, or any new and useful improvement thereof, may obtain a patent therefor, subject to the conditions and requirements of this title.

B.2 35 U.S.C. 102 (a) Conditions for patentability; novelty.

(a) NOVELTY; PRIOR ART.—A person shall be entitled to a patent unless— (1) the claimed invention was patented, described in a printed publication, or in public use, on sale, or otherwise available to the public before the effective filing date of the claimed invention; or (2) the claimed invention was described in a patent issued under section 151 , or in an application for patent published or deemed published under section 122(b) , in which the patent or application, as the case may be, names another inventor and was effectively filed before the effective filing date of the claimed invention.

B.3 35 U.S.C. 103 Conditions for patentability; non-obvious subject matter.

A patent for a claimed invention may not be obtained, notwithstanding that the claimed invention is not identically disclosed as set forth in section 102 , if the differences between the claimed invention and the prior art are such that the claimed invention as a whole would have been obvious before the effective filing date of the claimed invention to a person having ordinary skill in the art to which the claimed invention pertains. Patentability shall not be negated by the manner in which the invention was made.

B.4 35 U.S.C. 112 (a) (b) Specification.

(a) IN GENERAL.—The specification shall contain a written description of the invention, and of the manner and process of making and using it, in such full, clear, concise, and exact terms as to enable any person skilled in the art to which it pertains, or with which it is most nearly connected, to make and use the same, and shall set forth the best mode contemplated by the inventor or joint inventor of carrying out the invention. (b) CONCLUSION.—The specification shall conclude with one or more claims particularly pointing out and distinctly claiming the subject matter which the inventor or a joint inventor regards as the invention.

C Example Approval Rates across Common Patent Classes

Table 6 demonstrates the variations of approval rates in different patent classess, ranging from 63.1% to 93.2%, indicating the inclusion of patent class feature is critical.

D 37 CFR 1.215 Patent Application Publication

(a) The publication of an application under 35 U.S.C. 122(b) shall include a patent application publication. The date of publication shall be indicated on the patent application publication. The patent application publication will be based upon the specification and drawings deposited on the filing date of the application, as well as the application data sheet and/or the inventor's oath or declaration. The patent application publication may also be based upon amendments to the specification (other than the abstract or the claims) that are reflected in a substitute specification under § 1.125(b), amendments to the abstract under § 1.121(b), amendments to the claims that are reflected in a complete claim listing under § 1.121(c), and amendments to the drawings under § 1.121(d), provided that such substitute specification or amendment is submitted in sufficient time to be entered into the Office file wrapper of the application before technical preparations for publication of the application have begun. Technical preparations for publication of an application generally begin four months prior to the projected date of publication. The patent application publication of an application that has entered the national stage under 35 U.S.C. 371 may also include amendments made during the international stage. See paragraph (c) of this section for publication of an application based upon a copy of the application submitted via the Office electronic filing system. (b) The patent application publication will include the name of the assignee, person to whom the inventor is under an obligation to assign the invention, or person who otherwise shows sufficient

Table 6: Example Approval Rates across Common Classes.

USPC Code	Application Counts	Approval Rate	Description
716	4425	63.10%	COMPUTER-AIDED DESIGN AND ANALYSIS OF CIRCUITS AND SEMICONDUCTOR MASKS
362	28054	75.59%	ILLUMINATION
257	151435	80.43%	ACTIVE SOLID-STATE DEVICES (E.G.,TRANSISTORS, SOLID-STATE DIODES)
375	44245	89.10%	PULSE OR DIGITAL COMMUNICATIONS
718	6848	93.17%	ELECTRICAL COMPUTERS AND DIGITAL PROCESSING SYSTEMS: VIRTUAL MACHINE TASK OR PROCESS MANAGEMENT OR TASK MANAGEMENT/CONTROL

proprietary interest in the matter if that information is provided in the application data sheet in an application filed under § 1.46. Assignee information may be included on the patent application publication in other applications if the assignee information is provided in an application data sheet submitted in sufficient time to be entered into the Office file wrapper of the application before technical preparations for publication of the application have begun. Providing assignee information in the application data sheet does not substitute for compliance with any requirement of part 3 of this chapter to have an assignment recorded by the Office. (c) At applicant's option, the patent application publication will be based upon the copy of the application (specification, drawings, and the application data sheet and/or the inventor's oath or declaration) as amended, provided that applicant supplies such a copy in compliance with the Office electronic filing system requirements within one month of the mailing date of the first Office communication that includes a confirmation number for the application, or fourteen months of the earliest filing date for which a benefit is sought under title 35, United States Code, whichever is later. (d) If the copy of the application submitted pursuant to paragraph (c) of this section does not comply with the Office electronic filing system requirements, the Office will publish the application as provided in paragraph (a) of this section. If, however, the Office has not started the publication process, the Office may use an untimely filed copy of the application supplied by the applicant under paragraph (c) of this section in creating the patent application publication.

E Example Rejections Data

The following excerpt entries (entry 0 to entry 6) are an example for office actions one application receives. These entries are part of the processed data ingested into a document-based DBMS. Office actions are where allowance and rejection decisions are formally made and sent to the applicant. The key `"submissionDate"` indicate the date when the office action is made. In the following 7 entries, 3 office action are involved, dated at 2017-11-2 (entries 0, 1, 4) 2018-06-28 (entries 3, 5), and 2018-12-27 (entries 2, 6.) Keys `"hasRej101"`, `"hasRej102"`, `"hasRej103"`, `"hasRej112"` indicate which are the legal sections raised and involved in the office action. Key `"legalSectionCode"` indicates which part of the rejections are covered in the office action with this entry. For example, for the office action made on 2017-11-29, legal sections *35 U.S. Code 102, 103, 112* are involved which shall spawn 3 entries. Entry 0 covers legal section code *112*. Entry 1 covers legal section code *103*. Entry 4 covers legal section code *102*. Then entry 4 describes that claim numbers 30,64,66,67, as indicated by key `"claimNumberArrayDocument"` are rejected due to *35 U.S. Code 102* on 2017-11-29. We utilize the merged data and inferred date to extract classification labels.

Abstract

Knowledge-based visual question answering (QA) aims to answer a question which requires visually-grounded external knowledge beyond image content itself. Answering complex questions that require multi-hop reasoning under weak supervision is considered as a challenging problem since i) no supervision is given to the reasoning process and ii) high-order semantics of multi-hop knowledge facts need to be captured. In this paper, we introduce a concept of hypergraph to encode high-level semantics of a question and a knowledge base, and to learn high-order associations between them. The proposed model, Hypergraph Transformer, constructs a question hypergraph and a query-aware knowledge hypergraph, and infers an answer by encoding inter-associations between two hypergraphs and intra-associations in both hypergraph itself. Extensive experiments on two knowledge-based visual QA and two knowledge-based textual QA demonstrate the effectiveness of our method, especially for multi-hop reasoning problem. Our source code is available at `https://github.com/yujungheo/kbvqa-public`.

1 Introduction

Visual question answering (VQA) is a semantic reasoning task that aims to answer questions about visual content depicted in images (Antol et al., 2015; Zhu et al., 2016; Hudson and Manning, 2019), and has become one of the most active areas of research with advances in natural language processing and computer vision. Recently, researches for VQA have advanced, from inferring visual properties on entities in a given image, to inferring commonsense or world knowledge about those entities (Wang et al., 2017, 2018; Marino et al., 2019; Shah et al., 2019; Zellers et al., 2019).

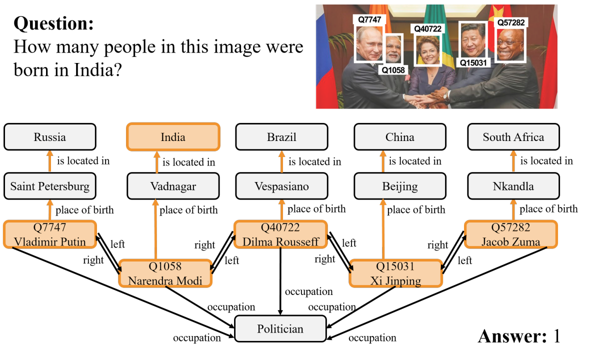

Figure 1: An example of knowledge-based visual question answering. The rectangles and arrows between the rectangles represent the entities and relations from KB. To answer the given question, the multiple reasoning evidences (marked as orange) are required.

In this paper, we focus on the task which is called knowledge-based visual question answering, where a massive number of knowledge facts from a general knowledge base (KB) is given with an image-question pair. To answer the given question as shown in Figure 1, a model should understand the semantics of the given question, link visual entities appearing in the given image to the KB, extract a number of evidences from the KB and predict an answer by aggregating semantics of both the question and the extracted evidences. Following these, there are two fundamental challenges in this task. i) To answer a complex question, multi-hop reasoning over multiple knowledge evidences is necessary. ii) Learning a complex reasoning process is difficult especially in a condition where only QA is provided without extra supervision on how to capture any evidence from the KB and infer based on them. That is, the model should learn which knowledge facts to be attended to and how to combine them to infer the correct answer on its own. Following the previous work (Zhou et al., 2018), we call this setting *under weak supervision*.

Under weak supervision, previous studies proposed memory-based methods (Narasimhan and Schwing, 2018; Shah et al., 2019) and graph-based

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 373 - 390

methods (Narasimhan et al., 2018; Zhu et al., 2020) to learn to selectively focus on necessary pieces of knowledge. The memory-based methods represent knowledge facts in a form of memory and calculate soft attention scores of each memory with respect to a question. Then, it infers an answer by attending to knowledge evidence with high attention scores. On the other hand, to explicitly consider relational structure between knowledge facts, graph-based methods construct a query-aware knowledge graph by retrieving facts from KB and perform graph reasoning for a question. These methods mainly adopt an iterative message passing process to propagate information between adjacent nodes in the graph. However, it is difficult to capture multi-hop relationships containing long-distance nodes from the graph due to the well-known over-smoothing problem, where repetitive message passing process to propagate information across long distance makes features of connected nodes too similar and undiscriminating (Li et al., 2018; Wang et al., 2020).

To address the above limitation, we propose a novel method, Hypergraph Transformer, which exploits hypergraph structure to encode multi-hop relationships and transformer-based attention mechanism to learn to pay attention to important knowledge evidences for a question. We construct a question hypergraph and a knowledge hypergraph to explicitly encode high-order semantics present in the question and each knowledge fact, and capture multi-hop relational knowledge facts effectively. Then, we perform hyperedge matching between the two hypergraphs by leveraging transformer-based attention mechanism. We argue that introducing the concept of hypergraph is powerful for multi-hop reasoning problem in that it can encode high-order semantics without the constraint of length and learn cross-modal high-order associations.

The main contributions of this paper can be summarized as follows. i) We propose Hypergraph Transformer which enhances multi-hop reasoning ability by encoding high-order semantics in the form of a hypergraph and learning inter- and intra-high-order associations in hypergraphs using the attention mechanism. ii) We conduct extensive experiments on two knowledge-based VQA datasets (KVQA and FVQA) and two knowledge-based textual QA datasets (PQ and PQL) and show superior performances on all datasets, especially multi-hop reasoning problem. iii) We qualitatively observe that Hypergraph Transformer performs robust inference by focusing on correct reasoning evidences under weak supervision.

2 Related Work

Knowledge-based visual question answering (Wang et al., 2017, 2018; Shah et al., 2019; Marino et al., 2019; Sampat et al., 2020) proposed benchmark datasets for knowledge-based visual question answering that requires reasoning about an image on the basis of facts from a large-scale knowledge base (KB) such as Freebase (Bollacker et al., 2008) or DBPedia (Auer et al., 2007). To solve the task, two pioneering studies (Wang et al., 2017, 2018) suggested logical parsing-based methods which convert a question to a KB logic query using predefined query templates and execute the generated query on KB for searching an answer. Since then information retrieval-based methods which retrieve knowledge facts associated with a question and conduct semantic matching between the facts and the question are introduced. (Narasimhan and Schwing, 2018; Shah et al., 2019) proposed memory-based methods that represent knowledge facts in the form of memory and calculate soft attention scores of the memory with a question. (Narasimhan et al., 2018; Zhu et al., 2020) represented the retrieved facts as a graph and performed graph reasoning through message passing scheme utilizing graph convolution. However, these methods are complicated to encode inherent high-order semantics and multi-hop relationships present in the knowledge graph. Therefore, we introduce a concept of hypergraph and propose transformer-based attention mechanism over hypergraphs.

Multi-hop knowledge graph reasoning is a process of sequential reasoning based on multiple evidences of a knowledge graph, and has been broadly used in various downstream tasks such as question answering (Lin et al., 2019; Saxena et al., 2020; Han et al., 2020b,a; Yadati et al., 2021), or knowledge-enhanced text generation (Liu et al., 2019; Moon et al., 2019; Ji et al., 2020). Recent researches have introduced the concept of hypergraph for multi-hop graph reasoning (Kim et al., 2020; Han et al., 2020b,a; Yadati et al., 2019, 2021; Sun et al., 2020). These models have a similar motivation to the Hypergraph Transformer proposed in this paper, but core operations are vastly different. These models mainly update node representations in the hypergraph through a message passing process using graph convolution operation. On the

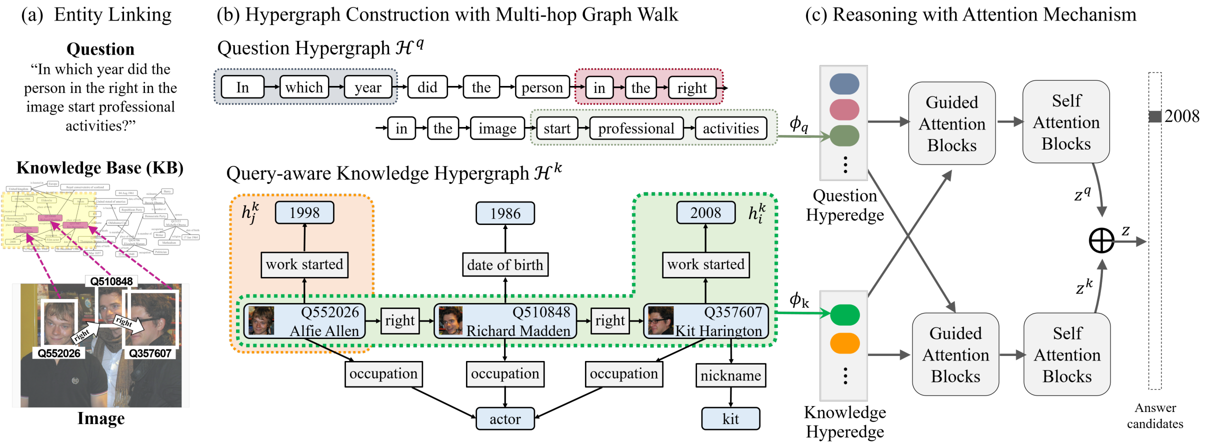

Figure 2: The overview of Hypergraph Transformer. (a) Entity linking module links concepts from query (a given image and a question) to KB. (b) Query-aware knowledge hypergraph $\mathcal{H}^k$ and question hypergraph $\mathcal{H}^q$ are constructed by multi-hop graph walk. (c) Two hyperedge sets are fed into the guided-attention and self-attention blocks to learn inter- and intra-association in them. The joint representation is used to predict an answer.

contrary, our method update node representations via hyperedge matching of hypergraphs instead of message passing scheme. We argue that this update process effectively learns the high-order semantics inherent in each hypergraph and the high-order associations between two hypergraphs.

3 Method

3.1 Notation

To capture high-order semantics inherent in the knowledge sources, we adopt the concept of hypergraph. Formally, directed hypergraph $\mathcal{H} = \{\mathcal{V}, \mathcal{E}\}$ is defined by a set of nodes $\mathcal{V} = \{v_1, ..., v_{|\mathcal{V}|}\}$ and a set of hyperedges $\mathcal{E} = \{h_1, ..., h_{|\mathcal{E}|}\}$. Each node is represented as a w-dimensional embedding vector, i.e., $v_i \in \mathbb{R}^w$. Each hyperedge connects an arbitrary number of nodes and has partial order itself, i.e., $h_i = \{v'_1 \preceq ... \preceq v'_l\}$ where $\mathcal{V}' = \{v'_1, ..., v'_l\}$ is a subset of $\mathcal{V}$ and $\preceq$ is a binary relation which denotes an element (v'_i) precedes the other (v'_j) in the ordering when $v'_i \preceq v'_j$. A hyperedge is flexible to encode different kinds of semantics in the underlying graph without the constraint of length.

3.2 Entity linking

As shown in Figure 2(a), entity linking module first links concepts from query (a given image-question pair) to knowledge base. We detect visual concepts (e.g., objects, attributes, person names) in a given image and named entities in a given question. The semantic labels of visual concepts or named entities are then linked with knowledge entities in the knowledge base using exact keyword matching.

3.3 Hypergraph construction

Query-aware knowledge hypergraph A knowledge base (KB), a vast amount of general knowledge facts, contains not only knowledge facts required to answer a given question but also unnecessary knowledge facts. Thus, we construct a query-aware knowledge hypergraph $\mathcal{H}^k = \{\mathcal{V}^k, \mathcal{E}^k\}$ to extract related information for answering a given question. It consists of a node set $\mathcal{V}^k$ and hyperedge set $\mathcal{E}^k$, which represent a set of entities in knowledge facts and a set of hyperedges, respectively. Each hyperedge connects the subset of vertices $\mathcal{V}'^k \subset \mathcal{V}^k$.

We consider a huge number of knowledge facts in the KB as a huge knowledge graph, and construct a hypergraph by traversing the knowledge graph. Such traversal, called graph walk, starts from the node linked from the previous module (see section 3.2) and considers all entity nodes associated with the start node. We define a triplet as a basic unit of graph walk to preserve high-order semantics inherent in knowledge graph, i.e., every single graph walk contains three nodes *{head, predicate, tail}*, rather than having only one of these three nodes. In addition to the triplet-based graph walks, a multi-hop graph walk is proposed to encode multiple relational facts that are interconnected. Multi-hop graph walk connects multiple facts by setting the arrival node (*tail*) of the preceding walk as the starting (*head*) node of the next walk, thus, n-hop graph walk combines n facts as a hyperedge.

Question hypergraph We transform a question sentence into a question hypergraph $\mathcal{H}^q$ consisting of a node set $\mathcal{V}^q$ and a hyperedge set $\mathcal{E}^q$. We assume that each word unit (a word or named entity) of the question is defined as a node, and has edges to adjacent nodes. For question hypergraph, each word unit is used as a start node of a graph walk. The multi-hop graph walk is conducted in the same manner as the knowledge hypergraph. A n-gram phrase is considered as a hyperedge in the question hypergraph (see Figure 2(b)).

3.4 Reasoning with attention mechanism

To consider high-order associations between knowledge and question, we devise structural semantic matching between the query-aware knowledge hypergraph and the question hypergraph. We introduce an attention mechanism over two hypergraphs based on guided-attention (Tsai et al., 2019) and self-attention (Vaswani et al., 2017). As shown in Figure 2(c), the guided-attention blocks are introduced to learn correlations between knowledge hyperedges and question hyperedges by inter-attention mechanism, and then intra-relationships of in knowledge or question hyperedges are trained with the following self-attention blocks. The details of two modules, guided-attention blocks and self-attention blocks, are described as below. Note that we use Q, K, and V for query, key, value, and q, k as subscripts to represent question and knowledge, respectively.

Guided-attention To learn inter-association between two hypergraphs, we first embed a knowledge hyperedge and a question hyperedge as follows: $e^k = \phi_k \circ f_k(h^k) \in \mathbb{R}^d, e^q = \phi_q \circ f_q(h^q) \in \mathbb{R}^d$ where $h^{[\cdot]}$ is a hyperedge in $\mathcal{E}^{[\cdot]}$. Here, $f_{[\cdot]}$ is a hyperedge embedding function and $\phi_{[\cdot]}$ is a linear projection function. The design and implementation of $f_{[\cdot]}$ are not constrained (e.g., any pooling operation or any learnable neural networks), but we use a simple concatenation operation of node representations in a hyperedge as $f_{[\cdot]}$. The representations of hyperedges in the same hypergraph (e.g., e^k, e^q) are packed together into a matrix E^k and E^q.

We define the knowledge hyperedges E^k and the question hyperedges E^q as a query and key-value pairs, respectively. We set a query $Q_k = E^k W_{Q_k}$, a key $K_q = E^q W_{K_q}$, and a value $V_q = E^q W_{V_q}$, where all projection matrices $W_{[\cdot]} \in \mathbb{R}^{d \times d_v}$ are learnable parameters. Then, scaled dot product attention using the query, key, and value is calculated as $\mathrm{Attention}(Q_k, K_q, V_q) = \mathrm{softmax}(\frac{Q_k K_q^T}{\sqrt{d_v}})V_q$ where d_v is the dimension of the query and the key vector. In addition, the guided-attention which uses the question hyperedges as query and the knowledge hyperedges as key-value pairs is performed in a similar manner: $\mathrm{Attention}(Q_q, K_k, V_k)$.

Self-attention The only difference between guided-attention and self-attention is that the same input is used for both query and key-value within self-attention. For example, we set query, key, and value based on the knowledge hyperedges E_k, and the self-attention for knowledge hyperedges is conducted by $\mathrm{Attention}(Q_k, K_k, V_k)$. For question hyperedges E_q, self-attention is performed in a similar manner: $\mathrm{Attention}(Q_q, K_q, V_q)$.

Following the standard structure of the transformer, we build up guided-attention block and self-attention block where each block consists of each attention operation with layer normalization, residual connection, and a single feed-forward layer. By passing the guided-attention blocks and self-attention blocks sequentially, representations of knowledge hyperedges and question hyperedges are updated and finally aggregated to single vector representation as $z_k \in \mathbb{R}^{d_v}$ and $z_q \in \mathbb{R}^{d_v}$, respectively.

3.5 Answer predictor

To predict an answer, we first concatenate the representation z_k and z_q obtained from the attention blocks and feed into a single feed-forward layer (i.e., $\mathbb{R}^{2d_v} \mapsto \mathbb{R}^w$) to make a joint representation z. We then consider two types of answer predictor: multi-layer perceptron and similarity-based answer predictor. Multi-layer perceptron as an answer classifier $p = \psi(z)$ is a prevalent for visual question answering problems. For similarity-based answer, we calculate a dot product similarity $p = zC^T$ between z and answer candidate set $C \in \mathbb{R}^{|\mathcal{A}| \times w}$ where $|\mathcal{A}|$ is a number of candidate answers and w is a dimension of representation for each answer. The most similar answer to the joint representation is selected as an answer among the answer candidates. For training, we use only supervision from QA pairs without annotations for ground-truth reasoning paths. To this end, cross-entropy between prediction p and ground-truth t is utilized as a loss function.

Model	Original (ORG)			Paraphrased (PRP)			Mean
	1-hop	2-hop	3-hop	1-hop	2-hop	3-hop	
BLSTM	-	-	-	-	-	-	51.0
MemNN (Sukhbaatar et al., 2015)	-	-	-	-	-	-	59.2
GCN (Kipf and Welling, 2017)	65.7	67.4	66.9	65.8	67.5	67.0	66.7
GGNN (Li et al., 2016)	72.9	74.5	74.0	72.9	74.6	74.1	73.8
MemNN† (Sukhbaatar et al., 2015)	78.1	77.8	76.1	78.0	78.1	76.0	77.3
HAN (Kim et al., 2020)	77.5	77.5	77.2	77.1	77.4	76.9	77.3

Ours	**88.1**	**90.2**	**91.0**	**87.8**	**90.5**	**90.7**	**89.7**

Table 1: QA accuracy on oracle setting in KVQA under weak supervision. ORG and PRP are a type of question and 1-hop, 2-hop, and 3-hop are the number of graph walks to construct a knowledge hypergraph. The performance of BLSTM and MemNN is reported in (Shah et al., 2019) and we re-implemented MemNN† for a fair comparison.

4 Experimental Settings

4.1 Datasets

In this paper, we evaluate our model across various benchmark datasets: Knowledge-aware VQA (KVQA) (Shah et al., 2019), Fact-based VQA (FVQA) (Wang et al., 2018), PathQuestion (PQ) and PathQuestion-Large (PQL) (Zhou et al., 2018). KVQA, a large-scale benchmark dataset for complex VQA, contains 183,007 pairs for 24,602 images from Wikipedia and corresponding captions, and provides 174,006 knowledge facts for 39,414 unique named entities based on Wikidata (Vrandečić and Krötzsch, 2014) since it requires world knowledge beyond visual content. KVQA consists of two types of questions: original (ORG) and paraphrased (PRP) question generated from the original question via the online paraphrasing tool. FVQA, a representative dataset for commonsense-enabled VQA, considers external knowledge about common nouns depicted in a given image, and contains 5,826 QA pairs for 2,190 images and 4,216 unique knowledge facts from DBPedia (Auer et al., 2007), ConceptNet (Liu and Singh, 2004), and WebChild (Tandon et al., 2014). The last two datasets, PQ and PQL, focus on evaluating multi-hop reasoning ability in the knowledge-based textual QA task. PQ and PQL contain 7,106 and 2,625 QA pairs on 4,050 and 9,844 knowledge facts from the subset of Freebase (Bollacker et al., 2008), respectively. The detailed statistics of the datasets are shown in Appendix A.

4.2 Implementation details

Each node in the knowledge hypergraph and the question hypergraph is represented as a 300-dimensional vector (i.e., $w = 300$) initialized using GloVe (Pennington et al., 2014). Random initialization is applied when a word for a node does not exist in the vocabulary of GloVe. Mean pooling is applied when a node consists of multiple words. For entity linking for KVQA, we apply the well-known pre-trained models for face identification: RetinaFace (Deng et al., 2020) for face detection and ArcFace (Deng et al., 2019) for face feature extraction. For all datasets, we follow the experimental settings as in previous works. We use the similarity-based answer predictor for KVQA, and MLP for the others. We adopt Adam (Kingma and Ba, 2015) to optimize all learnable parameters in the model. We describe details of the experimental settings and the tuned hyperparameters for each dataset in Appendix D.

5 Quantitative Results

5.1 Knowledge-aware visual question answering

We compare the proposed model, Hypergraph Transformer, with other comparative state-of-the-art methods. We report performances on original (ORG) and paraphrased (PRP) questions according to the number of graph walk. For comparative models, three kinds of methods are considered, which are graph-based, memory-based and attention-based networks. The detailed description about the comparative models is described in Appendix E. To evaluate a pure reasoning ability of the models regardless of the performance of entity linking, we first conduct experiments in the oracle setting which ground-truth named entities in an image are given.

As shown in Table 1, our model outperforms comparative models with a large margin across

	PathQuestion			PathQuestion-Large		
	PQ-2H	PQ-3H	PQ-M	PQL-2H	PQL-3H	PQL-M
Seq2Seq (Sutskever et al., 2014)	89.9	77.0	-	71.9	64.7	-
MemNN (Sukhbaatar et al., 2015)	89.5	79.2	86.8	61.2	53.6	55.8
KV-MemNN (Miller et al., 2016)	91.5	79.4	85.2	70.5	63.4	68.6
IRN (Zhou et al., 2018)	96.0	87.7	-	72.5	71.0	-
Embed (Bordes et al., 2014b)	78.7	48.3	-	42.5	22.5	-
Subgraph (Bordes et al., 2014a)	74.4	50.6	-	50.0	21.3	-
MINERVA (Das et al., 2018)	75.9	71.2	73.1	71.8	65.7	66.9
IRN-weak (Zhou et al., 2018)	91.9	83.3	85.8	63.0	61.8	62.4
SRN (Qiu et al., 2020)	96.3	89.2	89.3	78.6	77.5	78.3
Ours	**96.4**	**90.3**	**89.5**	**90.5**	**77.9**(*)	**94.5**

(*) For PQL-3H-More data (2x QA pairs on the same KB as PQL-3H), our model shows 95.4% accuracy.

Table 2: Accuracy on PathQuestion (PQ) and PathQuestion-Large (PQL). 2H and 3H represent the number of multi-hops in ground-truth reasoning paths to answer given questions, and M represents the mixture of 2H and 3H. The models in the first block employ a ground-truth reasoning path as extra supervision (i.e., fully-supervised), and the models in the second block including our model are under weak supervision.

all settings. From the results, we find that the attention mechanism between question and knowledge is crucial for complex QA. Since GCN (Kipf and Welling, 2017) and GGNN (Li et al., 2016) encode question and knowledge graph separately, they do not learn interactions between question and knowledge. Thus, GCN and GGNN show quite low performance under 74% mean accuracy. On the other hand, MemNN† (Weston et al., 2015), HAN (Kim et al., 2020), and BAN (Kim et al., 2018) achieve comparatively high performance because MemNN† adopts question-guided soft attention over knowledge memories. HAN and BAN utilize multi-head co-attention between question and knowledge.

Entity linking setting We also present the experimental results on the entity linking setting where the named entities are not provided as the oracle setting, but detected by the module as described in Section 3.2. As shown in Table 7 of Appendix E, our model shows the best performances for both original and paraphrased questions. For all comparative models, we use the same knowledge hypergraph extracted by the 3-hop graph walk. In entity linking setting, the constructed knowledge hypergraph can be incomplete and quite noisy due to the undetected entities or misclassified entity labels. However, Hypergraph Transformer shows robust reasoning capacity over the noisy inputs. Here, we remark that the upper bound of QA performance is 72.8% due to the error rate of entity linking module. We expect that the performance will be improved when the entity linking module is enhanced.

5.2 Fact-based visual question answering

We conduct experiments on Fact-based Visual Question Answering (FVQA) as an additional benchmark dataset for knowledge-based VQA. Different from KVQA focusing on world knowledge for named entities, FVQA considers commonsense knowledge about common nouns in a given image. Here, we assume that the performance of entity linking is perfect, and evaluate the pure reasoning ability of our model. As shown in Table 8 of Appendix D, Hypergraph Transformer shows comparable performance in both top-1 and top-3 accuracy in comparison with the state-of-the-art methods. We confirm that our model works effectively as a general reasoning framework without considering characteristics of different knowledge sources (i.e., Wikidata for KVQA, DBpedia, ConceptNet, WebChild for FVQA).

5.3 PathQuestion and PathQuestion-Large

To verify multi-hop reasoning ability of our model, we conduct experiments on PathQuestion (PQ) and PathQuestion-Large (PQL). PQ and PQL datasets have annotations of a ground-truth reasoning path to answer a given question. Specifically, {PQ, PQL}-{2H, 3H} denotes a split of PQ and PQL with respect to the number of hops in ground-truth reasoning paths (i.e., 2-hop or 3-hop). {PQ, PQL}-M is a mixture of the 2-hop and 3-hop questions in both dataset, and used to evaluate the more general scenario where the number of reasoning path

Model	Inputs		Original (ORG)			Paraphrased (PRP)			Mean
	Knowledge	Question	1-hop	2-hop	3-hop	1-hop	2-hop	3-hop	
(a) SA	Word	Word	79.4	79.6	77.6	77.1	77.7	77.7	78.2
(b) SA+GA	Word	Word	80.9	82.3	81.5	80.7	82.2	81.8	81.6
(c) SA+GA	Word	Hyperedge	82.1	84.2	82.8	81.1	83.5	82.3	82.7
(d) SA+GA	Hyperedge	Word	87.0	89.9	88.9	87.3	89.7	89.2	88.7
(e) SA+GA **(Ours)**	Hyperedge	Hyperedge	**88.1**	**90.2**	**91.0**	**87.8**	**90.5**	**90.7**	**89.7**
(f) **Ours**-SA	Hyperedge	Hyperedge	85.2	88.8	88.3	85.0	88.3	88.4	87.1
(g) **Ours**-GA	Hyperedge	Hyperedge	82.6	83.6	85.0	82.7	83.6	84.9	83.7

Table 3: (a-e) Validation for the effectiveness of using hypergraph. Here, we compare the results with respect to the different types of the input format (i.e., Single Word or Hyperedge) used to represent knowledge and question which are fed into the attention mechanism. (e-g) Ablation study for attention blocks of Hypergraph Transformer. GA and SA are abbreviations of guided-attention and self-attention, respectively.

required to answer a given question is unknown.

The experimental results on diverse split of PQ and PQL datasets are provided in Table 2. The first section in the table includes fully-supervised models which require a ground-truth path annotation as an additional supervision. The second section contains weakly-supervised models learning to infer the multi-hop reasoning paths without the ground-truth path annotation. Hypergraph Transformer is involved in the weakly-supervised models because it only exploits an answer as a supervision.

Our model shows comparable performances on PQ-{2H, 3H, M} to the state-of-the-art weakly-supervised model, SRN. Especially, Hypergraph Transformer shows significant performance improvement (78.6% → 90.5% for PQL-2H, 78.3% → 94.5% for PQL-M) on PQL. We highlight that PQL is more challenging dataset than PQ in that PQL not only covers more knowledge facts but also has fewer QA instances. We observe that the accuracy on PQL-3H is relatively lower than the other splits. This is due to the insufficient number of training QA pairs in PQL-3H. When we use PQL-3H-More which has twice more QA pairs (1031 → 2062) on the same knowledge base as PQL-3H, our model achieves 95.4% accuracy.

6 Validation for Hypergraph Transformer

We verify the effectiveness of each module in Hypergraph Transformer. To analyze the performances of the variants in our model, we use KVQA which is a representative and large-scale dataset for knowledge-based VQA. Here, we mainly focus on two aspects: i) effect of hypergraph and ii) effect of attention mechanism. To evaluate a pure reasoning ability of the models, we conduct experiments in the oracle setting.

6.1 Effect of hypergraph

To analyze the effectiveness of hypergraph-based input representation, we conduct comparative experiments on the different types of input formats for Transformer architecture. Here, we consider the two types of input format, which are single-word-unit and hyperedge-based representations. Compared to hyperedge-based inputs considering multiple relational facts as a input token, single-word-unit takes every entity and relation tokens as separate input tokens. We note that using single-word-unit-based input format for both knowledge and question is the standard settings for the Transformer network and using hyperedge-based input format for both is the proposed model, Hypergraph Transformer. We set the Transformer (SA+GA) as a backbone model, and present the results in Table 3(b-e). When hypergraph-based representations are used for both knowledge and question, the results show the best performance across all settings over question types (ORG and PRP) and a number of graph walk (1-hop, 2-hop, and 3-hop). As shown in Table 3, the mean accuracy of QA achieves 89.7% when both are encoded using hyperedges, while using single-word-unit-based representation causes performance to drop to 81.6%. Especially, when we convert the one of both hyperedge-level representation to single-word-unit-based representation, the mean accuracy of QA is 82.7% and 88.7%, respectively. These results validate that it is meaningful to consider not only knowledge but also question as hypergraphs.

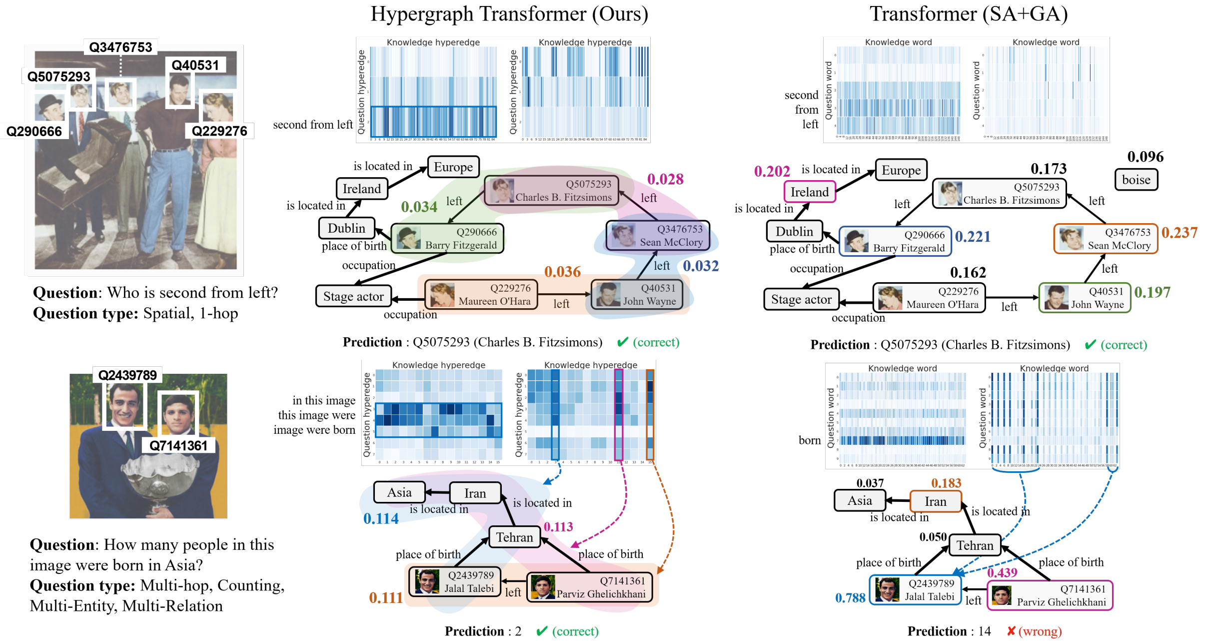

Figure 3: Qualitative analysis on effectiveness of using hypergraph as input format to Transformer architecture. Here, we visualize attention maps for Hypergraph Transformer and the Transformer (SA+GA). All attention scores are averaged over multi-heads and multi-layers. Each x and y axis represent indices of question and knowledge hyperedges in Hypergraph Transformer, and indices of question and knowledge word in Transformer (SA+GA). In the attention maps, the dark colors represent high values. The hyperedges with high attention scores are visualized.

Effect of multi-hop graph walk We compare the performances with different number of graph walks used to construct a knowledge hypergraph (i.e., 1-hop, 2-hop, and 3-hop). All models except ours show slightly lower performance on the 3-hop graph than on the 2-hop graph. We observe that the number of extracted knowledge facts increases when the number of graph walk increases, and unnecessary facts for answering a given question are usually included. Nonetheless, our model shows robust reasoning performance when a large and noisy knowledge facts are given.

6.2 Effect of attention mechanism

To investigate the impacts of each attention block (i.e., GA and SA), ablation studies are shown in Table 3(e-g). The scores across all settings drop when GA or SA is removed. Particularly, the mean accuracy of QA is decreased by 6.0% (89.7% → 83.7%), 2.6% (89.7% → 87.1%) for cutting out the GA and the SA block, respectively. Based on the two experiments, we identify that not only the guided-attention which captures inter-relationships between question and knowledge but also the self-attention which learns intra-relationship in them are crucial to the complex QA. To sum up, Hypergraph Transformer takes graph-level inputs, i.e., hyperedge, and conducts semantic matching between hyperedges by the attention mechanism. Due to the two characteristics, the model shows better reasoning performance focusing on the evidences necessary for reasoning under weak supervision.

7 Qualitative Analysis

Figure 3 provides the qualitative analysis on effectiveness of using a hypergraph as an input format to Transformer architecture. We present the attention map from the guided-attention block, and visualize top-k attended knowledge facts or entities with the attention scores. In the first example, both model, Hypergraph Transformer and Transformer (SA+GA), infer the correct answer, *Q5075293*. Our model responds by focusing on $\{second \preceq from \preceq left\}$ phrase of the question and four facts having a *left* relation among 86 knowledge hyperedges. In comparison, Transformer (SA+GA) strongly attends to the knowledge entities which appear repetitive in the knowledge facts. Especially, the model attends to *Q3476753*, *Q290666* and *Ireland* with the high attention score 0.237, 0.221, and 0.202. In the second example, our model attends to the correct knowledge hyperedges considering the multi-hop facts about *place of birth* of the people shown in the given image, and infers the correct answer. On the other hand, Transformer (SA+GA) strongly attends to the knowledge entity of person (*Q2439789*) presented in the image with undesired attention score 0.788. The second and third attended knowledge entities are the other person (*Q7141361*) and *Iran*. Transformer (SA+GA) fails to focus on the multi-hop facts required to answer the given question and predicts the answer with the wrong number at the end.

8 Discussion and Conclusion

In this paper, we proposed Hypergraph Transformer for multi-hop reasoning over knowledge graph under weak supervision. Hypergraph Transformer adopts hypergraph-based representation to encode high-order semantics of knowledge and questions and considers associations between a knowledge hypergraph and a question hypergraph. Here, each node representation in the hypergraphs is updated by inter- and intra-attention mechanisms in two hypergraphs, rather than by iterative message passing scheme. Thus, Hypergraph Transformer can mitigate the well-known over-smoothing problem in the previous graph-based methods exploiting the message passing scheme. Extensive experiments on various datasets, KVQA, FVQA, PQ, and PQL validated that Hypergraph Transformer conducts accurate inference by focusing on knowledge evidences necessary for question from a large knowledge graph. Although not covered in this paper, an interesting future work is to construct heterogeneous knowledge graph that includes more diverse knowledge sources (e.g. documents on web).

Appendix. This supplementary material provides additional information not described in the main text due to the page limit. The contents of this appendix are as follows: In Section A, we show the detailed statistics for the diverse splits of four benchmark datasets, i.e., KVQA, FVQA, PQ and PQL. In Section B and C, we present the additional quantitative and qualitative analyses on KVQA and PQ datasets, respectively. In Section D, we describe the experimental details for each dataset. In Section E, we depict the implementation details of comparative models for KVQA.

A Data Statistics

The diverse split statistics for four benchmark datasets, KVQA (Shah et al., 2019), FVQA (Wang et al., 2018), PQ and PQL (Zhou et al., 2018), are shown in Table 4. Here, we highlight four aspects as follows: 1) KVQA dataset covers the large number of entities (at least 5 times more) and knowledge facts (at least 17 times more) than FVQA, PQ and PQL. 2) PQ and PQL datasets have annotations of a ground-truth reasoning path to answer a given question. 2H and 3H denote the number of hops (i.e., 2-hop and 3-hop) in ground-truth reasoning paths. Also, M denotes a mixture of the 2H and 3H questions. 3) PQL covers more knowledge facts including a large number of entities and relations than PQ, but has fewer QA pairs. 4) PQL-3H has a quite limited number of QA pairs (1,031). PQL-3H-More has twice more QA pairs (2,062) with the same number of entities, relations, knowledge facts and answers as PQL-3H.

B Additional Analysis on KVQA

Here, we analyze more in-depth on KVQA dataset concerning i) categories of question, and ii) types of answer selector. All models are under the same setting of ORG+3-hop reported in Table 1.

B.1 Analysis on question categories

We analyze QA performances over different question categories in Table 5. Hypergraph Transformer achieves the best accuracy in all categories except Multi-hop (slightly low at second-best). Our model shows notable strengths especially on complex problems such as Comparison, Multi-entity or Subtraction. To draw inferences for these question categories, the model needs to attend to multiple knowledge facts related to a given question, and conducts multi-hop reasoning based on the facts. Also, our model shows significant improvement in spatial question compared to other models. Whereas spatial question is quite simple, it is required to understand a correct spatial relationship between multiple entities in a given image. Examples of QA on diverse question categories are depicted in Figure 4. Answers, inferred by five comparative models and the proposed model, are presented with corresponding image and question. The qualitative results indicate that our model draws reasonable inferences across diverse question categories.

B.2 Effect of similarity-based answer selector

To validate the impact of similarity-based answer selector, we replace the similarity-based answer selector (SIM) with a multi-layer perceptron (MLP). We first note that KVQA dataset includes a large number of unique answers (19,360), and contains a lot of zero-shot and few-shot answers in test phase. As shown in Table 6, the MLP fails to infer zero-shot answers which are not appeared in the training phase at all. Besides, the performance difference between SIM and MLP in one-shot answer (appeared in the only one time in training phase) is more than 18%. The MLP uses 17% more parameters than SIM because KVQA has a large number of answer candidates (19,360). When the number of candidate answers increases, the MLP needs more parameters, but SIM does not. To sum up, the similarity-based answer selector (SIM) contributes to infer few-shot and zero-shot answers in parameter-efficient manner.

C Qualitative Analysis on PathQuestion

Figure 5 shows the qualitative analysis of Hypergraph Transformer and Transformer (SA+GA) on PathQuestion. In Figure 5(a), Hypergraph Transformer attends to the second question hyperedge $\{the \preceq ethnicity \preceq of\}$ and the fourth knowledge hyperedge $\{Alice\ Betty\ Stern \preceq children \preceq Otto\ Frank \preceq ethnicity \preceq Germans\}$ to reason based on the multi-hop evidence about ethnicity. On the other hand, Transformer (SA+GA) focuses on the third question word *ethnicity* correctly, but attends to *Otto Frank*, *Jew*, *Male* with the high attention score 0.461, 0.242, and 0.204, not the exact knowledge entity, *Germans*. In Figure 5(b), both model, Hypergraph Transformer and Transformer (SA+GA), fail to infer the correct answer. The predicted answer of Hypergraph Transformer

	KVQA	FVQA	PQ-2H	PQ-3H	PQ-M	PQL-2H	PQL-3H	PQL-M
# Entities	39,414	3,391	1,057	1,837	2,257	5,035	6,506	6,506
# Relations	18	13	14	14	14	364	412	412
# Knowledge facts	174,006	4,216	1,211	2,839	4,050	4,247	5,597	9,844
# Words	63,164	6,663	1,180	1,929	2,407	5,505	7,001	7,034
# QA pairs	183,007	5,826	1,908	5,198	7,106	1,594	1,031	2,625
# Answers	19,360	500	305	1,009	1,107	380	292	438

(*) PQL-3H-More has twice more QA pairs (2,062) with the same number of entities, relations, knowledge facts and answers as PQL-3H.

Table 4: Statistics of four benchmark datasets: Knowledge-aware Visual Question Answering (KVQA), Fact-based Visual Question Answering (FVQA), PathQuestion (PQ) and PathQuestion-Large (PQL).

	Bool	Comp.	Multi entity	Multi hop	Multi relation	1-hop	1-hop subtract	Spatial	Subtract.
MemNN	75.1	50.5	43.5	53.2	45.2	61.0	-	48.1	40.5
GCN	86.8	87.7	87.7	96.7	77.7	61.4	53.7	29.4	37.7

Table 5: Analysis of QA accuracy over different question categories of original (ORG) questions in oracle setting. All models use 3-hop graph reported in Table 1. Comp. and Subtract. are abbreviations of Comparison and Subtraction. The best performance of each question type is highlighted in bold.

is wrong even though it attends correctly to the first knowledge hyperedge {*Wallace Reid* $\preceq$ *spouse* $\preceq$ *Dorothy Davenport* $\preceq$ *parents* $\preceq$ *Harry Davenport* $\preceq$ *cause of death* $\preceq$ *Myocardial Infarction*}. However, Transformer (SA+GA) attends to only the second and seventh word (*Dorothy Davenport*) and the fourth and ninth word (*Harry Davenport*) in knowledge with high attention score, not the answer entity, *Myocardial Infarction*. We consider that the reason why Hypergraph Transformer failed to infer the correct answer despite focusing on the exact knowledge fact is that the correct answer word (*Myocardial Infarction*) appears rarely in QA pairs.

D Experimental details

D.1 Knowledge-aware VQA

We follow the experimental settings suggested in (Shah et al., 2019). For entity linking, we apply well-known pre-trained models for face identification: RetinaFace (Deng et al., 2020) for face detection and ArcFace (Deng et al., 2019) for face feature extraction. We first assign a name of the detected faces with the label of the closest distance compared to all of the face embeddings of 18,880 named entities. In addition, we refine a list of detected named entities by matching the associated image caption (i.e., Wikipedia caption). By doing so, we obtain the result of entity linking with top-1 precision 65.0% and top-1 recall 72.8%. QA performances in the entity linking setting on KVQA are shown in Table 7. Here, we note that BLSTM and MemNN of the first section in the table are based on the different entity linking modules with top-1 precision 81.1% and top-1 recall 82.2%[1]. It is more accurate than ours around 9.4% in the recall metric.

D.2 Fact-based VQA

We follow the experimental settings suggested in (Wang et al., 2018). Following the paper, the dataset provides five splits of train and test data. We report the average accuracy of five repeated runs on different data split: 76.55 as top-1 accuracy (average of 76.93, 75.92, 76.24, 76.16, and 77.50) and 82.20 as top-3 accuracy (average of 82.90, 81.45, 81.70, 81.74 and 83.20). The experimental results are shown in Table 8.

---

[1] The code for the entity linking module has not been released publicly. As such, we implement the module based on the open-source: https://github.com/deepinsight/insightface. We use the pre-trained model named retinaface-mnet025-v2 and LResNet100E-IR,ArcFace@ms1m-refine-v2.

(a) Question: Who is in the right? ('1-hop', 'Spatial')

Answer (GCN) : Brian Orser ✗
Answer (GGNN) : Brian Orser ✗
Answer (MemNet†) : Brian Orser ✗
Answer (HAN) : Yuna Kim ✓

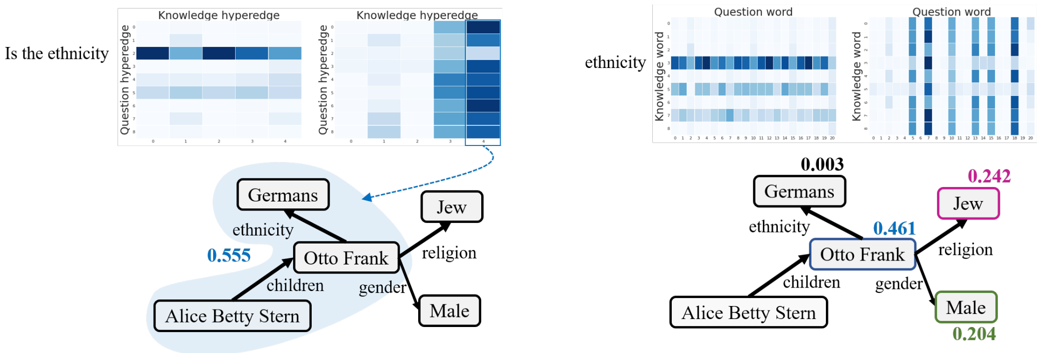
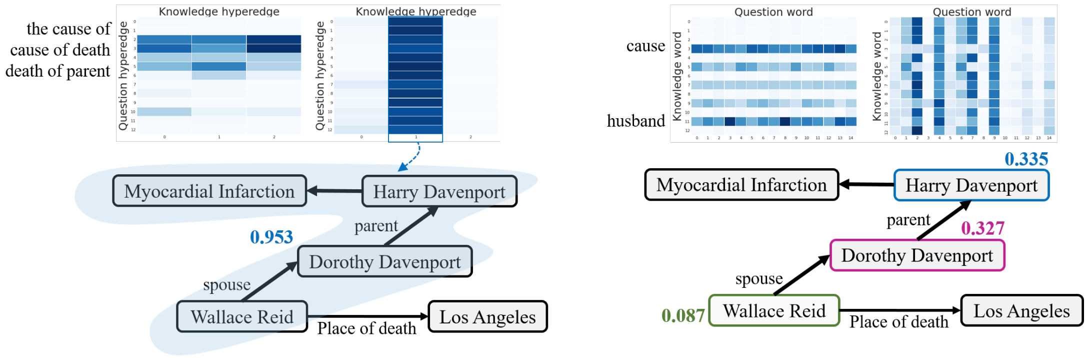
(a) Question: What is the ethnicity of heir of Alice Betty Stern?
Answer: Germans



Hypergraph Transformer (Ours): Germans ✓ **Transformer (SA+GA)**: Germans ✓

(b) Question: What is the cause of death of parent of Wallace Reid’s husband?
Answer: Myocardial Infarction



Hypergraph Transformer (Ours): Tuberculosis ✘ **Transformer (SA+GA)**: Dysentery ✘

Figure 5: Qualitative analysis on effectiveness of using hypergraph as input format to Transformer architecture. Here, we visualize attention maps ($\mathrm{Attention}(Q_k, K_q, V_q)$ and $\mathrm{Attention}(Q_q, K_k, V_k)$) for Hypergraph Transformer and the Transformer (SA+GA). All attention scores are averaged over multi-heads and multi-layers. Each x and y axis represent indices of question and knowledge hyperedges in Hypergraph Transformer, and indices of question and knowledge word in Transformer (SA+GA). In the attention maps, the dark colors represent high values. We also visualize the top-3 attended knowledge hyperedges in Hypergraph Transformer, and top-3 attended knowledge fact in Transformer (SA+GA) with the attention score.

D.3 PathQuestion and PathQuestion-Large

We follow the same experimental settings suggested in (Zhou et al., 2018). Following the paper, we split the dataset into train, validation, and test sets with a proportion of 8:1:1, and report the average accuracy of five repeated runs on different data split.

E Implementation Details of Comparative Models for KVQA

For comparative models for KVQA, three kinds of methods are considered, which are graph-based, memory-based and attention-based networks.

Graph-based networks. Graph convolutional networks (GCN) (Kipf and Welling, 2017) and gated graph neural networks (GGNN) (Li et al., 2016) are representative models of graph-based neural networks. Both learn node representations of a knowledge and question graph (not a hypergraph), propagating information between neighborhoods. After propagation, node representations in a graph are aggregated to encode a graph-level representation. Joint representation is obtained based on the two graph representations.

Memory-based networks. Memory network (MemNN) (Weston et al., 2015) is a de facto baseline for fact-based question answering. Each fact is embedded into a memory slot, and soft attention is calculated between memory slots and a given question. Joint representation is obtained based on the attention.

Attention-based networks. Bilinear attention networks (BAN) (Kim et al., 2018) and hypergraph attention networks (HAN) (Kim et al., 2020) consider interactions between knowledge and question based on co-attention mechanism. BAN calculates soft attention scores between knowledge entities and question words. Meanwhile, HAN employs stochastic graph walk in a knowledge and question graph to encode high-order semantics (e.g., knowledge facts and question phrases), and considers attention scores between knowledge facts and question phrases. Joint representation is obtained based on the attention as well. The more implementation details of the above comparative models is described as follows.

E.1 Graph convolutional networks

The knowledge and question graph are encoded separately by two graph convolutional networks (GCN) (Kipf and Welling, 2017). Each GCN model consists of two propagation layers and a sum pooling layer across the nodes in the graph. The operation of the propagation layer is as follows: $f(H^{(l)}, A) = \sigma(\hat{D}^{-\frac{1}{2}}\hat{A}\hat{D}^{-\frac{1}{2}}H^{(l)}W^{(l)})$ where $\hat{A} = A + I$, A is an adjacency matrix of the graph, I is an identity matrix, D is a degree matrix of A, $W^{(l)}$ is the model parameters of l-th layer, and $H^{(l)}$ is the representations of the graph in the l-th layer. Here, $H^{(0)}$ is the word embeddings of each entity in the knowledge and question graph. After propagation and aggregation phase, the knowledge and question graph representations are obtained. Then, the two graph representations are concatenated and fed into a single layer feed-forward layer to get joint representation.

E.2 Gated graph neural networks

As the same as graph convolutional networks, the knowledge and question graph are encoded separately by two gated graph neural networks (GGNN). Each GGNN model consists of three gated recurrent propagation layers and a graph-level aggregator. Motivated by Gated Recurrent Units (Cho et al., 2014), GGNN adopts a update gate and a reset gate to renew each node's hidden state. The detailed equation of gated recurrent propagation is as follows: $\mathbf{h}_v^{(1)} = [\mathbf{x}_v^T, \mathbf{0}]^T$ where $\mathbf{x}_v$ is the v-th word embedding of each entity in the knowledge and question graph, $\mathbf{a}_v^{(t)} = A_{v:}^T [\mathbf{h}_1^{(t-1)^T} \cdots \mathbf{h}_{|\mathcal{V}|}^{(t-1)^T}]^T + \mathbf{b}$ where the matrix A determines how nodes in the graph communicate each other and $\mathbf{b}$ is a bias vector. Then, the update gate and reset gate are computed as follows: $\mathbf{z}_v^t = \sigma(W^z\mathbf{a}_v^{(t)} + U^z\mathbf{h}_v^{(t-1)})$, $\mathbf{r}_v^t = \sigma(W^r\mathbf{a}_v^{(t)} + U^r\mathbf{h}_v^{(t-1)})$ where σ is a logistic sigmoid function, and $W^{[\cdot]}$ and $U^{[\cdot]}$ are learnable parameters. Finally, the hidden states of nodes in the given graph are updates as $\mathbf{h}_v^{(t)} = (1 - \mathbf{z}_v^t) \odot \mathbf{h}_v^{(t-1)} + \mathbf{z}_v^t \odot \tilde{\mathbf{h}}_v^{(t)}$ where $\tilde{\mathbf{h}}_v^{(t)} = \tanh(W^h\mathbf{a}_v^{(t)} + U^h(\mathbf{r}_v^t \odot \mathbf{h}_v^{(t-1)}))$. After the propagation phase, the nodes in the graph are aggregated to a graph-level representation as $\mathbf{h}_{\mathcal{G}} = \tanh(\sum_{v\in\mathcal{V}} \sigma(i(\mathbf{h}_v^{(T)}, \mathbf{x}_v)) \odot \tanh(j(\mathbf{h}_v^{(T)}, \mathbf{x}_v))$ where i and j are a single layer feed-forward layer, respectively. Then, the two aggregated graph representations are concatenated and fed into another single layer feed-forward layer to get joint representation of question and knowledge graph.

E.3 Memory networks

We reproduce end-to-end memory networks (Sukhbaatar et al., 2015) proposed as a baseline model in (Shah et al., 2019). First, we use Bag-of-words (BoW) representation for knowledge facts and a question. The soft attention over the knowledge facts and the given question is computed as follows: $p_{ij} = \mathrm{softmax}(q_{i-1}^T m_{ij})$ where m is the embeddings of knowledge facts, i is a number of layer and j is an index of knowledge facts. The output representation of i-th layer is $O_i = \sum_j p_{ij} o_{ij}$ where o is the another embeddings of knowledge facts different from m. The updated question representation is $q_{k+1} = O_{k+1} + q_k$, and based on the output representation and question representation, answer is predicted as follows: $\hat{a} = \mathrm{softmax}(f(O_K + q_{K-1}))$ where f is a single layer feed-forward layer. Here, we set up the model as three layers with adjacent and layer-wise weight tying.

E.4 Bilinear attention networks

Bilinear attention networks exploit a multi-head co-attention mechanism between knowledge and question. BAN calculates soft attention scores between knowledge entities and question words as follows: $\mathcal{A} = \mathrm{softmax}(W^h \circ (M^q W^q)(M^k W^k)^\top)$ where M^q, M^k are a row-wise concatenated question words and knowledge entities, $W^{[\cdot]}$ is learnable matrices, and $\circ$ is element-wise multiplication. Based on the attention map $\mathcal{A}$, the joint feature is obtained as follows: $z_i = (M^q W^q)_i{}^\top \mathcal{A}(M^k W^k)_i$ where the subscript i denotes the i-th index of column vectors in each matrix. For multi-head attention, the attended outputs with different heads are concatenated and fed into a single layer feed-forward layer to make a final representation. Here, we use four attention heads as multi-head.

E.5 Hypergraph attention networks

The model architecture and detailed operation of hypergraph attention networks are similar to that of BAN. The difference between BAN and HAN is the abstraction level of the input. For HAN, the hyperedges sampled by stochastic graph walk are fed into the co-attention mechanism. What HAN and our model have in common is introducing a hypergraph to consider high-order relationships in question graph and knowledge graph. Both models share the similar motivation, but the core operations are quite different. Especially, HAN employs stochastic graph walk to construct question and knowledge hypergraph. Due to the randomness of the stochasticity, misinformed or incomplete hyperedges can be extracted.

E.6 Transformer Variants

The model architectures of Transformer (SA) and Transformer (SA+GA) presented in this paper are the same as Hypergraph Transformer. The only difference is the abstraction level of input. The Transformer (SA) and Transformer (SA+GA) take single-word-unit as input tokens, and Hypergraph Transformer takes hyperedges as input tokens. Following (Vaswani et al., 2017; Tsai et al., 2019), we apply positional embeddings to the input sequence of both models. We stack two guided-attention blocks and three self-attention blocks, respectively. Each attention block has multi-head attention with four attention heads followed by layer normalization, residual connections and a single multi-layer perceptron. We set the dropout applied on the token embedding weights, query and key-value embedding weights, attention weights and residual connections from 0.05 to 0.2. We minimize negative log-likelihood using Adam optimizer (Kingma and Ba, 2015) with an initial learning rate from $1e-4$ to $1e-5$ with batch size from 128 to 256. All transformer variant models described in this paper have the same fixed-number of sequence length as follows: 300 for 1-hop, 1,000 for 2-hop and 1,800 for 3-hop graphs.

Cross-Utterance Conditioned VAE for Non-Autoregressive Text-to-Speech

Abstract

Modelling prosody variation is critical for synthesizing natural and expressive speech in end-to-end text-to-speech (TTS) systems. In this paper, a cross-utterance conditional VAE (CUC-VAE) is proposed to estimate a posterior probability distribution of the latent prosody features for each phoneme by conditioning on acoustic features, speaker information, and text features obtained from both past and future sentences. At inference time, instead of the standard Gaussian distribution used by VAE, CUC-VAE allows sampling from an utterance-specific prior distribution conditioned on cross-utterance information, which allows the prosody features generated by the TTS system to be related to the context and is more similar to how humans naturally produce prosody. The performance of CUC-VAE is evaluated via a qualitative listening test for naturalness, intelligibility and quantitative measurements, including word error rates and the standard deviation of prosody attributes. Experimental results on LJ-Speech and LibriTTS data show that the proposed CUC-VAE TTS system improves naturalness and prosody diversity with clear margins.

1 Introduction

Recently, abundant research have been performed on modelling variations other than the input text in synthesized speech such as background noise, speaker information, and prosody, as those directly influence the naturalness and expressiveness of the generated audio. Prosody, as the focus of this paper, collectively refers to the stress, intonation, and rhythm in speech, and has been an increasingly popular research aspect in end-to-end TTS systems (van den Oord et al., 2016; Wang et al., 2017; Stanton et al., 2018; Elias et al., 2021; Chen et al., 2021). Some previous work captured prosody features explicitly using either style tokens or variational autoencoders (VAEs) (Kingma and Welling, 2014; Hsu et al., 2019a) which encapsulate prosody information into latent representations. Recent work achieved fine-grained prosody modelling and control by extracting prosody features at phoneme or word-level (Lee and Kim, 2019; Sun et al., 2020a,b). However, the VAE-based TTS system lacks control over the latent space where the sampling is performed from a standard Gaussian prior during inference. Therefore, recent research (Dahmani et al., 2019; Karanasou et al., 2021) employed a conditional VAE (CVAE) (Sohn et al., 2015) to synthesize speech from a conditional prior. Meanwhile, pre-trained language model (LM) such as bidirectional encoder representation for Transformers (BERT) (Devlin et al., 2019) has also been applied to TTS systems (Hayashi et al., 2019; Kenter et al., 2020; Jia et al., 2021; Futamata et al., 2021; Cong et al., 2021) to estimate prosody attributes implicitly from pre-trained text representations within the utterance or the segment. Efforts have been devoted to include cross-utterance information in the input features to improve the prosody modelling of auto-regressive TTS (Xu et al., 2021).

To generate more expressive prosody, while maintaining high fidelity in synthesized speech, a cross-utterance conditional VAE (CUC-VAE) component is proposed, which is integrated into and jointly optimised with FastSpeech 2 (Ren et al., 2021), a commonly used non-autoregressive end-to-end TTS system. Specifically, the CUC-VAE TTS system consists of cross-utterance embedding (CU-embedding) and cross-utterance enhanced CVAE (CU-enhanced CVAE). The CU-embedding takes BERT sentence embeddings from surrounding utterances as inputs and generates phoneme-level CU-embedding using a multi-head attention (Vaswani et al., 2017) layer where attention weights are derived from the encoder output of each phoneme as well as the speaker information. The CU-enhanced

CVAE is proposed to improve prosody variation and to address the inconsistency between the standard Gaussian prior, which the VAE-based TTS system is sampled from, and the true prior of speech. Specifically, the CU-enhanced CVAE is a fine-grained VAE that estimates the posterior of latent prosody features for each phoneme based on acoustic features, cross-utterance embedding, and speaker information. It improves the encoder of standard VAE with an utterance-specific prior. To match the inference with training, the utterance-specific prior, jointly optimised with the system, is conditioned on the output of CU-embedding. Latent prosody features are sampled from the derived utterance-specific prior instead of a standard Gaussian prior during inference.

The proposed CUC-VAE TTS system was evaluated on the LJ-Speech read English data and the LibriTTS English audiobook data. In addition to the sample naturalness measured via subjective listening tests, the intelligibility is measured using word error rate (WER) from an automatic speech recognition (ASR) system, and diversity in prosody was measured by calculating standard deviations of prosody attributes among all generated audio samples of an utterance. Experimental results showed that the system with CUC-VAE achieved a much better prosody diversity while improving both the naturalness and intelligibility compared to the standard FastSpeech 2 baseline and two variants.

The rest of this paper is organised as follows. Section 2 introduces the background and related work. Section 3 illustrates the proposed CUC-VAE TTS system. Experimental setup and results are shown in Section 4 and Section 5, with conclusions in Section 6.

2 Background

Non-Autoregressive TTS. Promising progress has taken place in non-autoregressive TTS systems to synthesize audio with high efficiency and high fidelity thanks to the advancement in deep learning. A non-autoregressive TTS system maps the input text sequence into an acoustic feature or waveform sequence without using the autoregressive decomposition of output probabilities. FastSpeech (Ren et al., 2019) and ParaNet (Peng et al., 2019) requires distillation from an autoregressive model, while more recent non-autoregressive TTS systems, including FastPitch (La'ncucki, 2021), AlignTTS (Zeng et al., 2020) and FastSpeech 2 (Ren et al., 2021), do not rely on any form of knowledge distillation from a pre-trained TTS system. In this paper, the proposed CUC-VAE TTS system is based on FastSpeech 2. FastSpeech 2 replaces the knowledge distillation for the length regulator in FastSpeech with mean-squared error training based on duration labels, which are obtained from frame-to-phoneme alignment to simplify the training process. Additionally, FastSpeech 2 predicts pitch and energy from the encoder output, which is also supervised with pitch contours and L2-norm of signal amplitudes as labels respectively. The pitch and energy prediction injects additional prosody information, which improves the naturalness and expressiveness in the synthesized speech.

Pre-trained Representation in TTS. It is believed that prosody can also be inferred from language information in both current and surrounding utterances (Shen et al., 2018; Fang et al., 2019; Xu et al., 2021; Zhou et al., 2021). Such information is often entailed in vector representations from a pre-trained LM, such as BERT (Devlin et al., 2019). Some existing work incorporated BERT embeddings at word or subword-level into autoregressive TTS models (Shen et al., 2018; Fang et al., 2019). More recent work (Xu et al., 2021) used the chunked and paired sentence patterns from BERT. Besides, a relational gated graph network with pre-trained BERT embeddings as node inputs (Zhou et al., 2021) was used to extract word-level semantic representations, thus enhancing expressiveness.

VAEs in TTS. VAEs have been widely adopted in TTS systems to explicit model prosody variation. The training objective of VAE is to maximise $p_\theta(\boldsymbol{x})$, the data likelihood parameterised by θ, which can be regarded as the marginalisation w.r.t. the latent vector $\boldsymbol{z}$ as shown in Eq. (1).

$$p_\theta(\boldsymbol{x}) = \int p_\theta(\boldsymbol{x} \mid \boldsymbol{z}) p(\boldsymbol{z}) d\boldsymbol{z}. \quad (1)$$

To make this calculation tractable, the marginalisation is approximated using evidence lower bound (ELBO):

$$\begin{aligned} \mathcal{L}_{\text{ELBO}}(\boldsymbol{x}) = & \mathbb{E}_{q_\phi(\boldsymbol{z}|\boldsymbol{x})}[\log p_\theta(\boldsymbol{x}|\boldsymbol{z})] \\ & - \beta D_{\text{KL}}\left(q_\phi(\boldsymbol{z}|\boldsymbol{x}) \| p(\boldsymbol{z})\right), \quad (2) \end{aligned}$$

where $q_\phi(\boldsymbol{z}|\boldsymbol{x})$ is the posterior distribution of the latent vector parameterized by ϕ, β is a hyperparameter, and $D_{\text{KL}}(\cdot)$ is the Kullback-Leibler divergence. The first term measures the expected reconstruction performance of the data from the

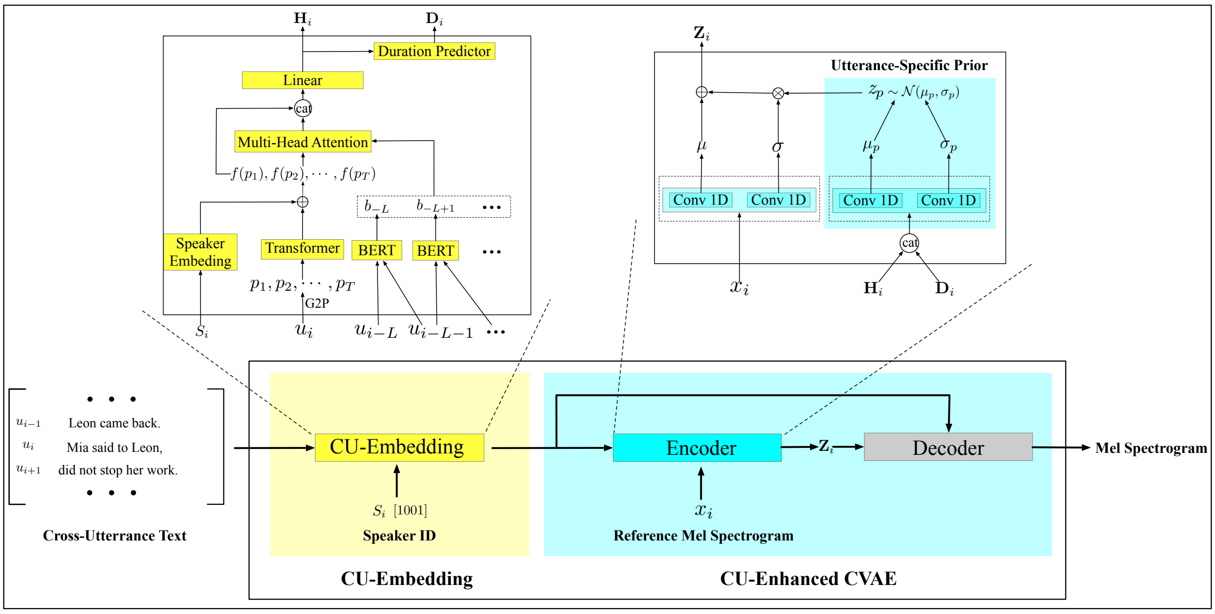

Figure 1: The CUC-VAE TTS system architecture consists of the cross-utterance embedding (CU-embedding) and the cross-utterance enhanced (CU-enhanced) CVAE, which are integrated into and jointly optimised with the FastSpeech 2 system.

latent vector and is approximated by Monte Carlo sampling of $\boldsymbol{z}$ according to the posterior distribution. The reparameterization trick is applied to make the sampling differentiable. The second term encourages the posterior distribution to approach the prior distribution which is sampled from during inference, and β weighs this term's contribution.

A large body of previous work on VAE-based TTS used VAEs to capture and disentangle data variations in different aspects in the latent space. Works by Akuzawa et al. (2018) leveraged VAE to model the speaking style of an utterance. Meanwhile, Hsu et al. (2019a,b) explored the disentanglement between prosody variation and speaker information using VAE together with adversarial training. Recently, fine-grained VAE (Sun et al., 2020a,b) was adopted to model prosody in the latent space for each phoneme or word. Moreover, vector-quantised VAE was also applied to discrete duration modelling by Yasuda et al. (2021).

CVAE is a variant of VAE when the data generation is conditioned on some other information $\boldsymbol{y}$. In CVAE, both prior and posterior distributions are conditioned on additional variables, and the data likelihood calculation is modified as shown below:

$$p_\theta(\boldsymbol{x} \mid \boldsymbol{y}) = \int p_\theta(\boldsymbol{x} \mid \boldsymbol{z}, \boldsymbol{y}) p_\phi(\boldsymbol{z} \mid \boldsymbol{y}) d\boldsymbol{z}. \quad (3)$$

Similar to VAE, this intractable calculation can be converted to the ELBO form as

$$\begin{aligned}\mathcal{L}_{\text{ELBO}}(\boldsymbol{x} \mid \boldsymbol{y}) &= \mathbb{E}_{q_\phi(\boldsymbol{z}\mid\boldsymbol{x},\boldsymbol{y})}[\log p_\theta(\boldsymbol{x} \mid \boldsymbol{z}, \boldsymbol{y})] \\ &\quad - \beta D_{\text{KL}}\left(q_\phi(\boldsymbol{z} \mid \boldsymbol{x}, \boldsymbol{y}) \| p(\boldsymbol{z} \mid \boldsymbol{y})\right).\end{aligned}$$

To model the conditional prior, a density network is usually used to predict the mean and variance based on the conditional input $\boldsymbol{y}$.

3 CUC-VAE TTS System

The proposed CUC-VAE TTS system, which is adapted from FastSpeech 2 as shown in Fig. 1, aims to synthesize speech with more expressive prosody. Fig. 1 describes the model architecture, which has two components: CU-embedding and CU-enhanced CVAE. The CUC-VAE TTS system takes as input $[\boldsymbol{u}_{i-L}, \cdots, \boldsymbol{u}_i, \cdots, \boldsymbol{u}_{i+L}]$, $\boldsymbol{s}_i$ and $\boldsymbol{x}_i$, where $[\boldsymbol{u}_{i-L}, \cdots, \boldsymbol{u}_i, \cdots, \boldsymbol{u}_{i+L}]$ is the cross-utterance set that includes the current utterance $\boldsymbol{u}_i$ and the L utterances before and after $\boldsymbol{u}_i$. Each $\boldsymbol{u}$ represents the text content of an utterance. Note that $\boldsymbol{s}_i$ is the speaker ID, and $\boldsymbol{x}_i$ is the reference mel-spectrogram of the current utterance $\boldsymbol{u}_i$. In this section, the two main components of the CUC-VAE TTS system will be introduced in detail.

3.1 Cross-Utterance Embedding

The CU-embedding encodes not only the phoneme sequence and speaker information but also cross-utterance information into a sequence of mixture encodings in place of a standard embedding. As shown in Fig. 1, the first L utterances and the last L utterances surrounding the current one, $\boldsymbol{u}_i$, are used as text input in addition to the current utterance and speaker information. Same as the standard embedding, an extra G2P conversion is first performed to convert the current utterance into phonemes $\boldsymbol{P}_i = [p_1, p_2, \cdots, p_T]$, where T is the number of phonemes. Then, a Transformer encoder is used to encode the phoneme sequence into a sequence of phoneme encodings. Besides, speaker information is encoded into a speaker embedding $\boldsymbol{s}_i$ which is directly added to each phoneme encoding to form the mixture encodings $\boldsymbol{F}_i$ of the phoneme sequence.

$$\boldsymbol{F}_i = [\boldsymbol{f}_i(p_1), \boldsymbol{f}_i(p_2), \cdots, \boldsymbol{f}_i(p_T)], \qquad (4)$$

where $\boldsymbol{f}$ represents resultant vector from the addition of each phoneme encoding and speaker embedding.

To supplement the text information from the current utterance to generate natural and expressive audio, cross-utterance BERT embeddings together with a multi-head attention layer are used to capture contextual information. To begin with, $2L$ cross-utterance pairs, denoted as $\boldsymbol{C}_i$, are derived from $2L+1$ neighboring utterances $[\boldsymbol{u}_{i-L}, \cdots, \boldsymbol{u}_i, \cdots, \boldsymbol{u}_{i+L}]$ as:

$$\boldsymbol{C}_i = [c(\boldsymbol{u}_{i-L}, \boldsymbol{u}_{i-L+1}), \cdots, c(\boldsymbol{u}_{i-1}, \boldsymbol{u}_i), \cdots, c(\boldsymbol{u}_{i+L-1}, \boldsymbol{u}_{i+L})], \qquad (5)$$

where $c(u_k, u_{k+1}) = \{[\text{CLS}], \boldsymbol{u}_k, [\text{SEP}], \boldsymbol{u}_{k+1}\}$, which adds a special token [CLS] at the beginning of each pair and inserts another special token [SEP] at the boundary of each sentence to keep track of BERT. Then, the $2L$ cross-utterance pairs are fed to the BERT to capture cross-utterance information, which yields $2L$ BERT embedding vectors by taking the output vector at the position of the [CLS] token and projecting each to a 768-dim vector for each cross-utterance pair, as shown below:

$$\boldsymbol{B}_i = [\boldsymbol{b}_{-L}, \boldsymbol{b}_{-L+1}, \cdots, \boldsymbol{b}_{L-1}],$$

where each vector $\boldsymbol{b}_k$ in $\boldsymbol{B}_i$ represents the BERT embedding of the cross-utterance pair $c(\boldsymbol{u}_k, \boldsymbol{u}_{k+1})$. Next, to extract CU-embedding vectors for each phoneme specifically, a multi-head attention layer is added to combine the $2L$ BERT embeddings into one vector as shown in Eq. (6).

$$\boldsymbol{G}_i = \text{MHA}(\boldsymbol{F_i}\boldsymbol{W}^{\text{Q}}, \boldsymbol{B}_i\boldsymbol{W}^{\text{K}}, \boldsymbol{B}_i\boldsymbol{W}^{\text{V}}), \qquad (6)$$

where $\text{MHA}(\cdot)$ denotes the multi-head attention layer, $\boldsymbol{W}^{\text{Q}}$, $\boldsymbol{W}^{\text{K}}$ and $\boldsymbol{W}^{\text{V}}$ are linear projection matrices, and $\boldsymbol{F}_i$ denotes the sequence of mixture encodings for the current utterance which acts as the query in the attention mechanism. For simplicity, we denote Eq. (6) as $\boldsymbol{G}_i = [\boldsymbol{g}_1, \boldsymbol{g}_2, \cdots, \boldsymbol{g}_T]$ from the multi-head attention being of length T and each of them is then concatenated with its corresponding mixture encoding. The concatenated vectors are projected by another linear layer to form the final output $\boldsymbol{H}_i$ of the CU-embedding, $\boldsymbol{H}_i = [\boldsymbol{h}_1, \boldsymbol{h}_2, \cdots, \boldsymbol{h}_T]$ of the current utterance, as shown in Eq. (7).

$$\boldsymbol{h}_t = [\boldsymbol{g}_t, \boldsymbol{f}(p_t)]\boldsymbol{W}, \qquad (7)$$

where $\boldsymbol{W}$ is a linear projection matrix. Moreover, an additional duration predictor takes $\boldsymbol{H}_i$ as inputs and predicts the duration $\boldsymbol{D}_i$ of each phoneme.

3.2 Cross-Utterance Enhanced CVAE

In addition to the CU-embedding, a CU-enhanced CVAE is proposed to conquer the lack of prosody variation of FastSpeech 2 and the inconsistency between the standard Gaussian prior distribution sampled by the VAE based TTS system and the true prior distribution of speech. Specifically, the CU-enhanced CVAE consists of an encoder module and a decoder module, as shown in Fig. 1. The utterance-specific prior in the encoder aims to learn the prior distribution $\boldsymbol{z}_p$ from the CU-embedding output $\boldsymbol{H}$ and predicts duration $\boldsymbol{D}$. For convenience, the subscript i is omitted in this subsection. Furthermore, the posterior module in the encoder takes as input reference mel-spectrogram $\boldsymbol{x}$, then model the approximate posterior $\boldsymbol{z}$ conditioned on utterance-specific conditional prior $\boldsymbol{z}_p$. Sampling is done from the estimated prior by the utterance-specific prior module and is reparameterized as:

$$\boldsymbol{z} = \boldsymbol{\mu} \oplus \boldsymbol{\sigma} \otimes \boldsymbol{z}_p, \qquad (8)$$

where $\boldsymbol{\mu}$ and $\boldsymbol{\sigma}$ are estimated from conditional posterior module to approximate posterior distribution $\mathcal{N}(\boldsymbol{\mu}, \boldsymbol{\sigma})$, $\boldsymbol{z}_p$ is sampled from the learned utterance-specific prior, and $\oplus, \otimes$ are elementwise addition and multiplication operation. Furthermore, the utterance-specific conditional prior module is conducted to learn utterance-specific prior with CU-embedding output $\boldsymbol{H}$ and $\boldsymbol{D}$. The reparameterization is as follows:

$$\boldsymbol{z}_p = \boldsymbol{\mu}_p \oplus \boldsymbol{\sigma}_p \otimes \boldsymbol{\epsilon}, \qquad (9)$$

where $\boldsymbol{\mu}_p, \boldsymbol{\sigma}_p$ are learned from the utterance-specific prior module, and $\boldsymbol{\epsilon}$ is sampled from the standard Gaussian $\mathcal{N}(0,1)$. By substituting Eq. (9) into Eq. (8), the following equation can be derived for the total sampling process:

$$\boldsymbol{z} = \boldsymbol{\mu} \oplus \boldsymbol{\sigma} \otimes \boldsymbol{\mu}_p \oplus \boldsymbol{\sigma} \otimes \boldsymbol{\sigma}_p \otimes \boldsymbol{\epsilon}. \tag{10}$$

During inference, sampling is done from the learned utterance-specific conditional prior distribution $\mathcal{N}(\boldsymbol{\mu}_p, \boldsymbol{\sigma}_p)$ from CU-embedding instead of a standard Gaussian distribution $\mathcal{N}(0,1)$. For simplicity, we can formulate the data likelihood calculation as follows, where the intermediate variable utterance-specific prior $\boldsymbol{z}_p$ from $\boldsymbol{D}, \boldsymbol{H}$ to obtain $\boldsymbol{z}$ is omitted:

$$p_\theta(\boldsymbol{x} \mid \boldsymbol{H}, \boldsymbol{D}) = \int p_\theta(\boldsymbol{x} \mid \boldsymbol{z}, \boldsymbol{H}, \boldsymbol{D}) p_\phi(\boldsymbol{z} \mid \boldsymbol{H}, \boldsymbol{D}) d\boldsymbol{z}, \tag{11}$$

In Eq. (11), ϕ, θ are the encoder and decoder module parameters of the CUC-VAE TTS system.

Moreover, the decoder in CU-enhanced CVAE is adapted from FastSpeech 2. An additional projection layer is firstly added to project $\boldsymbol{z}$ to a high dimensional space so that $\boldsymbol{z}$ could be added to $\boldsymbol{H}$. Next, a length regulator expands the length of input according to the predicted duration $\boldsymbol{D}$ of each phoneme. The rest of Decoder is same as the Decoder module in FastSpeech 2 to convert the hidden sequence into an mel-spectrogram sequence via parallelized calculation.

Therefore, the ELBO objective of the CUC-VAE can be expressed as,

$$\begin{aligned}\mathcal{L}(\boldsymbol{x} \mid \boldsymbol{H}, \boldsymbol{D}) = \; & \mathbb{E}_{q_\phi(\boldsymbol{z}|\boldsymbol{D},\boldsymbol{H})}[\log p_\theta(\boldsymbol{x} \mid \boldsymbol{z}, \boldsymbol{D}, \boldsymbol{H})] \\ & - \beta_1 \sum_{n=1}^{T} D_{\mathrm{KL}}\left(q_{\phi_1}\left(\boldsymbol{z}^n \mid \boldsymbol{z}_p^n, \boldsymbol{x}\right) \| q_{\phi_2}\left(\boldsymbol{z}_p^n \mid \boldsymbol{D}, \boldsymbol{H}\right)\right) \\ & - \beta_2 \sum_{n=1}^{T} D_{\mathrm{KL}}\left(q_{\phi_2}\left(\boldsymbol{z}_p^n \mid \boldsymbol{D}, \boldsymbol{H}\right) \| p(\boldsymbol{z}_p^n)\right),\end{aligned} \tag{12}$$

where ϕ_1, ϕ_2 are two parts of CUC-VAE encoder ϕ to obtain $\boldsymbol{z}$ from $\boldsymbol{z}_p, \boldsymbol{x}$ and $\boldsymbol{z}_p$ from $\boldsymbol{D}, \boldsymbol{H}$ respectively, β_1, β_2 are two balance constants, $p(\boldsymbol{z}_p^n)$ is chosen to be standard Gaussian $\mathcal{N}(0,1)$. Meanwhile, $\boldsymbol{z}^n$ and $\boldsymbol{z}_p^n$ correspond to the latent representation for the n-th phoneme, and T is the length of the phoneme sequence.

4 Experimental Setup

4.1 Dataset

To evaluate the proposed CUC-VAE TTS system, a series of experiments were conducted on a single speaker dataset and a multi-speaker dataset. For the single speaker setting, the LJ-Speech read English data (Ito and Johnson, 2017) was used which consists of 13,100 audio clips with a total duration of approximately 24 hours. A female native English speaker read all the audio clips, and the scripts were selected from 7 non-fiction books. For the multi-speaker setting, the train-clean-100 and train-clean-360 subsets of the LibriTTS English audiobook data (Zen et al., 2019) were used. These subsets used here consist of 1151 speakers (553 female speakers and 598 male speakers) and about 245 hours of audio. All audio clips were re-sampled at 22.05 kHz in experiments for consistency.

The proposed CU-embedding in our system learns the cross-utterance representation from surrounding utterances. However, unlike LJ-Speech, transcripts of LibriTTS utterances are not arranged as continuous chunks of text in their corresponding book. Therefore, transcripts of the LibriTTS dataset were pre-processed to find the location of each utterance in the book, so that the first L and last L utterances of the current one can be efficiently obtained during training and inference. The pre-processed scripts and our code are available [1].

4.2 System Specification

The proposed CUC-VAE TTS system was based on the framework of FastSpeech 2. The CU-embedding utilised a Transformer to learn the current utterance representation, where the dimension of phoneme embeddings and the size of the self-attention were set to 256. To explicitly extract speaker information, 256-dim speaker embeddings were also added to the Transformer output. Meanwhile, the pre-trained BERT model to extract cross-utterance information had 12 Transformer blocks and 12-head attention layers with 110 million parameters. The size of the derived embeddings of each cross-utterance pair was 768-dim. Note that the BERT model and corresponding embeddings were fixed when training the TTS system. Network in CU-enhanced CVAE consisted of four 1D-convolutional (1D-Conv) layers with kernel sizes of 1 to predict the mean and variance of 2-dim latent features. Then a linear layer was added to transform the sampled latent feature to a 256-dim vector. The duration predictor which consisted of two convolutional blocks and an extra linear layer

---

[1] `https://github.com/NeuroWave-ai/CUCVAE-TTS`

to predict the duration of each phoneme for the length regulator in FastSpeech 2 was adapted to take in CU-embedding outputs. Each convolutional block was comprised of a 1D-Conv network with ReLU activation followed by a layer normalization and dropout layer. The Decoder adopted four feed-forward Transformer blocks to convert hidden sequences into 80-dim mel-spectrogram sequence, similar to FastSpeech 2. Finally, HifiGAN (Kong et al., 2020) was used to synthesize waveform from the predicted mel-spectrogram.

4.3 Evaluation Metrics

In order to evaluate the performance of our proposed component, both subjective and objective tests were performed. First of all, a subjective listening test was performed over 11 synthesized audios with 23 volunteers asked to rate the naturalness of speech samples on a 5-scale mean opinion score (MOS) evaluation. The MOS results were reported with 95% confidence intervals. In addition, an AB test was conducted to compare the CU-enhanced CVAE with utterance-specific prior and normal CVAE with standard Gaussian prior. 23 volunteers were asked to choose the preference audio generated by different models in the AB test.

For the objective evaluation, F_0 frame error (FFE) (Chu and Alwan, 2009) and mel-cepstral distortion (MCD) (Kubichek, 1993) were used to measure the reconstruction performance of different VAEs. FFE combined the Gross Pitch Error (GPE) and the Voicing Decision Error (VDE) and was used to evaluate the reconstruction of the F_0 track. MCD evaluated the timbral distortion, which was computed from the first 13 MFCCs in our experiments. Moreover, word error rates (WER) from an ASR model trained on the real speech from the LibriTTS training set were reported. Complementary to naturalness, the WER metric showed both the intelligibility and the degree of inconsistency between synthetic speech and real speech. The ASR system used in this paper was an attention-based encoder-decoder model trained on Librispeech 960-hour data, with a WER of 4.4% on the test-clean set. Finally, the diversity of samples was evaluated by measuring the standard deviation of two prosody attributes of each phoneme: relative energy (E) and fundamental frequency (F_0), similar to Sun et al. (2020b). Relative energy was calculated as the ratio of the average signal amplitude within a phoneme to the average amplitude of the entire sentence, and fundamental frequency was measured using a pitch tracker. In this paper, the average standard deviation of E and F_0 of three phonemes in randomly selected 11 utterances was reported to evaluate the diversity of generated speech.

5 Results

This section presents the series of experiments for the proposed CUC-VAE TTS system. First, ablation studies were performed to progressively show the influence of different parts in the CUC-VAE TTS system based on MOS and WER. Next, the reconstruction performance of CUC-VAE was evaluated by FFE and MCD. Then, the naturalness and prosody diversity using CUC-VAE were compared to FastSpeech 2 and other VAE techniques. At last, a case study illustrated the prosody variations with different cross-utterance information as an example. The audio examples are available on the demo page [2].

5.1 Ablation Studies

Ablation studies in this section were conducted on the LJ-Speech data based on the subjective test and WER. First, to investigate the effect of the different number of neighbouring utterances, CUC-VAE TTS systems built with $L = 1, 3, 5$ were evaluated using MOS scores, as shown in Table 1.

Table 1: The MOS results of CUC-VAE TTS systems on LJ-Speech dataset. MOS was reported with 95% confident intervals. "$L = 1$","$L = 3$","$L = 5$" represented the number of past and future utterances.

Systems	Cross-utterance ($2L$)	**MOS**
CUC-VAE	$L = 1$	2.93 ± 0.12
CUC-VAE	$L = 3$	3.72 ± 0.09
CUC-VAE	$L = 5$	**3.95 ± 0.07**

The effect of the different number of neighbouring utterances on the naturalness of the synthesized speech can be observed by comparing MOS scores which is the higher the better. The CUC-VAE with $L = 5$ achieved highest score 3.95 compared to system with $L = 1$ and $L = 3$. Since only marginal MOS improvements were obtained using more than 5 neighbouring utterances, the rest of experiments were performed using $L = 5$.

Then we investigated the influence of each part of CUC-VAE on performance. The baseline was

---

[2] `http://bit.ly/cuc-vae-tts-demo`

our implementation of Fastspeech 2. For the system denoted as Baseline + fine-grained VAE which served as a stronger baseline, the pitch predictor and energy predictor of FastSpeech 2 were replaced with a fine-grained VAE with 2-dim latent space. Based on the fine-grained VAE baseline, the CVAE was added without the CU-embedding to the system, referred to as Baseline+CVAE to verify the function of CVAE on the system, which conditions on the current utterance. Again, MOS was compared among these systems as shown in Table 2.

Table 2: The MOS results of TTS systems with different modules on LJ-Speech dataset. MOS was reported with 95% confident intervals. Baseline + fine-grained VAE added a fine-grained VAE to baseline. Baseline+CVAE represents a CVAE TTS system without CU-embedding.

Systems	**MOS**
Ground Truth	4.31 ± 0.06
Baseline	3.85 ± 0.07
Baseline+Fine-grained VAE	3.55 ± 0.08
Baseline+CVAE	3.64 ± 0.08
CUC-VAE	**3.95 ± 0.07**

As shown in Table 2, MOS progressively increased when fine-grained VAE, CVAE, and CU-embedding were added in consecutively. The proposed CUC-VAE TTS system achieved the highest MOS 3.95 compared to baselines. The results indicated that CUC-VAE module played a crucial role in generating more natural audio.

To verify the importance of the utterance-specific prior to the synthesized audio, the same CUC-VAE system was used, and the only difference is whether to sample latent prosody features from the utterance-specific prior or from a standard Gaussian distribution. A subjective AB test was performed which required 23 volunteers to provide their preference between audios synthesized from the 2 approaches. Moreover, WER was also compared here to show the intelligibility of the synthesized audio. As shown in Table 3, the preference rate of using the utterance-specific prior is 0.52 higher than its counterpart, and a 4.9% absolute WER reduction was found, which confirmed the importance of the utterance-specific prior in our CUC-VAE TTS system.

5.2 Reconstruction Performance

FFE and MCD were used to measure the reconstruction performance of VAE systems. An utterance-level prosody modelling baseline which extract one latent prosody feature vector for an utterance was added for more comprehensive comparison, and is referred to as the Global VAE.

Table 3: The subjective listening preference rate between CUC-VAE with or without utterance-specific prior from the AB test. The CUC-VAE without utterance-specific prior was a simplified version of our proposed CUC-VAE where latent samples were drawn from a standard Gaussian distribution instead of utterance-specific prior. WER metric was also reported.

System	utterance-specific prior	**RATE**	**WER**
CUC-VAE	✗	0.24	14.8
CUC-VAE	✓	**0.76**	**9.9**

Table 4: Reconstruction preformance on LJ-Speech and LibriTTS dataset. + Global VAE and + fine-grained VAE represent that the baseline is added the global VAE and the fine-grained VAE, respectively.

Systems	**LJ-Speech**		**LibriTTS**	
	MCD	**FFE**	**MCD**	**FFE**
Baseline	6.70	0.58	6.32	0.58
Baseline+Global VAE	6.50	0.41	6.27	0.45
Baseline+Fine-grained VAE	6.34	0.26	6.28	0.35
CUC-VAE	**6.27**	**0.24**	**6.04**	**0.34**

Table. 4 shows the reconstruction performance on the LJ-Speech dataset and LibriTTS dataset, respectively. Baseline had the highest value of FFE and MCD on the LJ-Speech dataset and LibriTTS dataset. The value of FFE and MCD decreased when the global VAE was added and was further reduced when the fine-grained VAE was added to the baseline. Our proposed CUC-VAE TTS system achieved the lowest FFE and MCD across the table on both the LJ-Speech and LibriTTS datasets. This indicated that richer prosody-related information entailed in both cross-utterance and conditional inputs was captured by CUC-VAE.

5.3 Sample Naturalness and Diversity

Next, sample naturalness and intelligibility were measured using MOS and WER respectively on both LJ-Speech and LibriTTS datasets. Complementary to the naturalness, the diversity of generated speech from the conditional prior was evaluated by comparing the standard deviation of E and F_0 similar to (Sun et al., 2020b).

LJ-Speech experiments were shown in left part of Table. 5. Compared to the global VAE and fine-grained VAE, the proposed CUC-VAE received the highest MOS and achieved the lowest WER.

Table 5: Sample naturalness and diversity results on LJ-Speech and LibriTTS datasets. Three metrics are reported for each dataset, namely MOS, WER, and Prosody Std. The Prosody Std. includes standard deviations of relative energy (E) and fundamental frequency (F_0) in Hertz within each phonene.

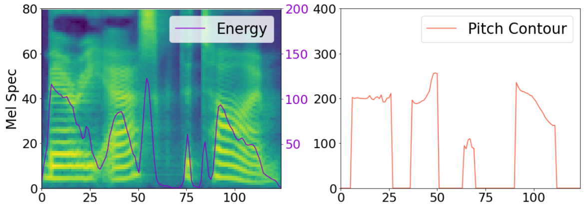
	LJ-Speech				**LibriTTS**			
	MOS	**WER**	**Prosody Std.**		**MOS**	**WER**	**Prosody Std.**	
			$\boldsymbol{F_0}$	$\boldsymbol{E}$			$\boldsymbol{F_0}$	$\boldsymbol{E}$
Ground Truth	4.31 ± 0.06	8.8	-	-	4.10 ± 0.07	5.0	-	-
Baseline	3.85 ± 0.07	10.8	1.86×10^{-13}	6.78×10^{-7}	3.53 ± 0.08	6.0	2.13×10^{-13}	7.22×10^{-7}
Baseline+Global VAE	3.82 ± 0.07	10.4	1.46	0.0004	3.59 ± 0.08	10.8	2.01	0.0054
Baseline+Fine-grained VAE	3.55 ± 0.08	12.8	49.60	0.0670	3.43 ± 0.08	5.6	63.64	0.0901
CUC-VAE	$\mathbf{3.95 \pm 0.07}$	**9.9**	26.35	0.0184	$\mathbf{3.63 \pm 0.08}$	**5.5**	30.28	0.0217

Although both F_0 and E of the CUC-VAE TTS system were lower than the baseline + fine-grained VAE, the proposed system achieved a clearly higher prosody diversity than the baseline and baseline + global VAE systems. The fine-grained VAE achieved the highest prosody variation as its latent prosody features were sampled from a standard Gaussian distribution, which lacks the constraint of language information from both the current and the neighbouring utterances. This caused extreme prosody variations to occur which impaired both the naturalness and the intelligibility of synthesized audios. As a result, the CUC-VAE TTS system was able to achieve high prosody diversity without hurting the naturalness of the generated speech. In fact, the adequate increase in prosody diversity improved the expressiveness of the synthesized audio, and hence increased the naturalness.

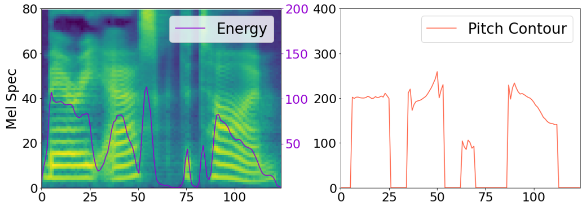
The right part of Table. 5 showed the results on LibriTTS dataset. Similar to the LJ-Speech experiments, the CUC-VAE TTS system achieved the best naturalness measured by MOS, the best intelligibility measured by WER, and the second-highest prosody diversity across the table. Overall, consistent improvements in both naturalness and prosody diversity were observed on both single-speaker and multi-speaker datasets.

5.4 A Case Study

To better illustrate how the utterance-specific prior influenced the naturalness of the synthesized speech under a given context, a case study was performed by synthesizing an example utterance, "Mary asked the time", with two different neighbouring utterances: "Who asked the time? Mary asked the time." and "Mary asked the time, and was told it was only five." Based on the linguistic knowledge, to answer the question in the first setting, an emphasis should be put on the word "Mary", while in the second setting, the focus of the sentence is "asked the time". The model trained on LJ-Speech dataset was used to synthesize the utterance and the results were shown in Fig. 2.



(a) Who asked the time? **Mary asked the time.**



(b) **Mary asked the time,** and was told it was only five.

Figure 2: Comparisons between the energy and pitch contour of same text "Mary asked the time" but different neighbouring utterances, generated by CUC-VAE TTS trained on LJ-Speech.

Fig. 2 showed the energy and pitch of the two utterance. Energy of the first word "Mary" in Fig. 2(a) changed significantly (energy of "Ma-" was much higher than "-ry"), which reflected an emphasis on the word "Mary", whereas in Fig. 2(b), energy of "Mary" had no obvious change, i.e., the word was not emphasized. On the other hand, the fundamental frequency of words "asked" and "time" stayed at a high level for a longer time in the second audio than the first one, reflecting another type of emphasis on those words which was also coherent with the given context. Therefore, the difference of energy and pitch between the two utterances demonstrated that the speech synthesized by our model is sufficiently contextualized.

6 Conclusion

In this paper, a non-autoregressive CUC-VAE TTS system was proposed to synthesize speech with better naturalness and more prosody diversity. CUC-VAE TTS system estimated the posterior distribution of latent prosody features for each phone based on cross-utterance information in addition to the acoustic features and speaker information. The generated audio was sampled from an utterance-specific prior distribution, approximated based on cross-utterance information. Experiments were conducted to evaluate the proposed CUC-VAE TTS system with metrics including MOS, preference rate, WER, and the standard deviation of prosody attributes. Experiment results showed that the proposed CUC-VAE TTS system improved both the naturalness and prosody diversity in the generated audio samples, which outperformed the baseline in all metrics with clear margins.

Abstract

Recent work on controlled text generation has either required attribute-based fine-tuning of the base language model (LM), or has restricted the parameterization of the attribute discriminator to be compatible with the base autoregressive LM. In this work, we propose Mix and Match LM, a global score-based alternative for controllable text generation that combines arbitrary pre-trained black-box models for achieving the desired attributes in the generated text without involving any fine-tuning or structural assumptions about the black-box models. We interpret the task of controllable generation as drawing samples from an energy-based model whose energy values are a linear combination of scores from black-box models that are separately responsible for fluency, the control attribute, and faithfulness to any conditioning context. We use a Metropolis-Hastings sampling scheme to sample from this energy-based model using bidirectional context and global attribute features. We validate the effectiveness of our approach on various controlled generation and style-based text revision tasks by outperforming recently proposed methods that involve extra training, fine-tuning, or restrictive assumptions over the form of models.

1 Introduction

While large transformer-based autoregressive language models trained on massive amounts of data found on the internet exhibit exceptional capabilities to generate natural language text, effective methods for generating text that satisfy global constraints and possess holistic desired attributes remains an active area of research. These mechanisms for controlling the generation of language have the potential to mitigate undesirable biases encoded by the large language models and prevent the generation of hate speech and toxic language (Xu et al.; Gehman et al., 2020; Sap et al., 2021; Baheti et al., 2021; Mireshghallah and Berg-Kirkpatrick, 2021). Much of the prior work has approached controlled generation via either training domain-conditioned neural language models (Prabhumoye et al., 2020; He et al., 2020; Lample et al., 2018; Shen et al., 2017; Krishna et al., 2020; Reif et al., 2021; Ficler and Goldberg, 2017; Khalifa et al., 2021) or finetuning/modifying an underlying large pre-trained base model for generation on domain-specific data for attribute sensitive generation (Ziegler et al., 2019; Keskar et al., 2019; Mai et al., 2020; Gururangan et al., 2020; Chronopoulou et al., 2021). Not only do these approaches involve computational overhead and estimation errors associated with the training of language models, but they are also dependent on access to a large amount of attribute-specific language data which can be impractical in many scenarios and exacerbate privacy concerns (Brown et al., 2022; Mireshghallah et al., 2021; Kandpal et al., 2022).

Our approach eschews training and focuses on generation-time control from pre-trained modules. Recent work in this space has used attribute discriminators (Dathathri et al., 2020; Krause et al., 2020; Yang and Klein, 2021; Holtzman et al., 2018) to steer the generation from a large autoregressive language model. These discriminators need to be separately trained on partial generations in order to be operationalized with step-wise autoregressive models. As a result, this approach also requires availability of data to train step-wise discriminators for attributes that are essentially global (at the sequence-level) in nature. Therefore, we focus on drawing samples from a test-time combination of *pretrained blackbox* experts that each score a desired property of output text – for example, fluency, attribute sensitivity, or faithfulness to the context. Specifically, we view the product of these black-box experts as a probabilistic energy model (Hinton, 2002) – i.e., a *non-autoregressive*, globally normalized language model – and then sample (without further training or fine-tuning) using a specialized Gibbs sampler with a Metropolis-Hastings correction step (Goyal et al., 2021).

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 401 - 415

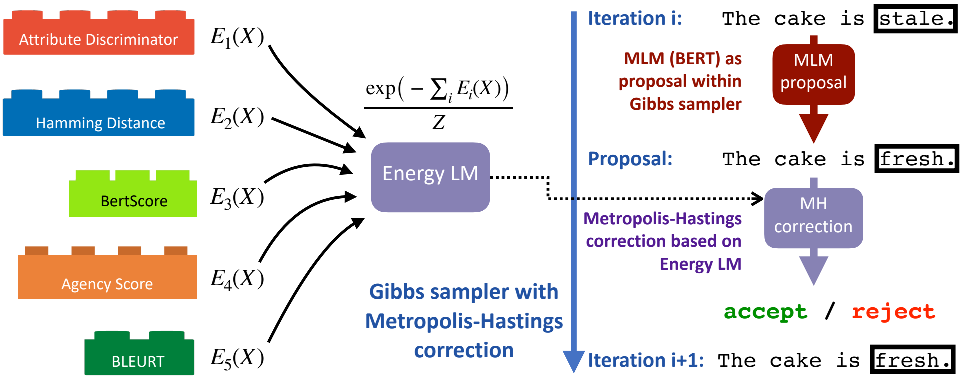

Figure 1: Overview of Mix and Match LM. The Lego pieces show different experts that can be used to form the energy LM and help control different features in the generated text. The right side shows the ith step in the the Gibbs sampling chain, where a proposal is made by the MLM, and then it is accepted/rejected based on the energy score.

Our full framework, which we entitle Mix and Match LM (depicted in Figure 1), enables the generation of high-quality attribute-controlled samples by mixing and matching black-box models like off-the-shelf pre-trained attribute-sensitive discriminators (e.g., sentiment classifiers), large bidirectional pre-trained language models like BERT (Devlin et al., 2019), and other modules specializing in capturing desirable features pertaining to faithfulness to any additional context, like hamming distance, or BertScore distance (Zhang et al., 2020) between the sample and the conditioning context. We generate samples from the energy language model assembled from these component experts by using the recently proposed Gibbs-Metropolis-Hastings scheme (Goyal et al., 2021) for sampling from energy models using a masked language model as a proposal distribution. In this scheme, an expressive bidirectional language model like BERT is used to make a proposal at each transition step in the Gibbs chain to jump to a sequence $\bar{\mathbf{x}}$ from the current sequence $\mathbf{x}$. This proposal's fitness is judged by the change in the energy language model's score, with the sampler accepting proposals with larger energy reductions at a higher rate. While the MCMC nature of our sampler negatively impacts the runtime during decoding compared to autoregressive approaches with ancestral sampling, we find our approach to still be practical and yield high-quality diverse samples that respect the distribution induced by the product of expert black-box models.

We demonstrate the flexibility of our approach by performing a variety of controlled generation tasks, such as aspect-based text revision, style transfer, and attribute grounded generation and compare it to recently proposed controlled generation approaches that are more resource/data intensive. We observe that our approach, which does not require any gradient optimization and is able to combine arbitrary heterogeneous black-box models, outperforms other approaches according to various automated metrics of fluency, quality, and control, as well as human evaluations. We have provided code, data, and sample generations in this GitHub repository: `https://github.com/mireshghallah/mixmatch` (see A.1 for details on reproducing the results).

2 Related Work

The approaches closest in spirit to our work involve steering generation from a base language model with external attribute-sensitive control mechanisms. Plug-and-Play LM (Dathathri et al., 2020) uses discriminators learned from an autoregressive LM's top-level hidden layer to modify the LM's states toward increasing the probability of the desired attribute via gradient ascent at each step. GeDi (Krause et al., 2020) and FUDGE (Yang and Klein, 2021) take a similar approach but train custom step-wise attribute-sensitive discriminators that decide whether the desired attribute is likely to be satisfied by the current generation path. GeDi trains class-conditional language models for these discriminators and hence additionally relies on access to attribute sensitive language data. Kumar et al. (2021) formulate the task of controlled generation as optimizing the base LM's likelihood subject to global differentiable attribute-based constraints by gradient descent over the position-wise simplexes over the vocabulary. DExperts (Liu et al., 2021) is another decoding-time controllable generation approach that modifies the step-wise softmax logits of an autoregressive pre-trained LM with softmax logits of separately trained domain-specific *expert* autoregressive language models. These approaches require training of custom modules and do not readily enjoy the benefits of incorporating global attribute-based features into the generation mechanism in a simple probabilistic manner. In contrast, our energy-based formulation is not only optimization-free but also fully modular and able to easily incorporate global features, allowing for heterogeneous black-box experts to be combined with each other.

3 Mix-and-match Language Models

In this section, we describe our approach and motivation behind our method. Specifically, we frame the problem of performing controlled generation as a problem of sampling from a specialized energy-based (or globally normalized) sequence model that defines a probability distribution that satisfies the desired constraints we wish to impose in the controlled generation setting. As described below, this energy-based model is composed of pre-trained components and does not require any further optimization. An energy-based sequence model defines the probability distribution over the space of possible sequences $\mathcal{X}$ as:[1] $p(X;\theta) = \frac{e^{-E(X;\theta)}}{\sum_{X' \in \mathcal{X}} e^{-E(X';\theta)}}$, where $E(X;\theta)$ refers to the scalar energy of a sequence X that is parametrized by θ. Lower energy corresponds to the higher likelihood of X. In contrast to the common autoregressive sequence models, exact likelihood computation and efficient sampling from these models is challenging. Despite these challenges, we focus on this paradigm of sequence modeling because energy-based models offer increased flexibility via sequence-level features and constraints. As we discuss next, this capability lets us easily define expressive functions for controlled generation of sequences which is not readily offered by the autoregressive modeling paradigm.

3.1 Product of Experts Energy-based Models and Controlled Generation

Our approach is motivated by the perspective that the task of controlled generation requires concentrating probability mass over a small subspace of sequences in $\mathcal{X}$ that satisfies various constraints pertaining to fluency, target attributes, and other control variables. Consider the task of generating positive sentiment sentences. This requires satisfaction of two major constraints: (1) The sequence X should be well-formed, (2) The sequence X should express positive sentiment. If we have access to two separate probability distributions over $\mathcal{X}$, one for modeling well-formedness ($p_1(X)$) and another for modeling positivity ($p_2(X)$), then a natural solution for controlled generation in this setting would be to draw samples from a probability distribution that is a product of these two distributions i.e. $p_{\texttt{desire}}(X) \propto p_1(X) \cdot p_2(X)$. In our approach, we further relax this requirement by assuming access to *expert black-boxes* that yield scalar non-probabilistic energy scores E_1 and E_2 indicating fitness of a sequence w.r.t. well-formedness and positivity respectively. Under the product of experts framework above the desired probability distribution would take the form: $\log p_{\texttt{desire}}(X) = -(E_1(X) + E_2(X)) - \log Z$. This expression shows that when working with scalar scores for the expert black-boxes, the product of expert models yields an energy model whose energy is simply the sum of the scalar energy values obtained from the expert models. Inspired by this, we propose a framework for controlled generation that involves linear combinations of various black-box experts in order to obtain a distribution whose samples satisfy the requirements of a desired controlled generation task: $E_{\texttt{M\&M}}(X) = \sum_{i=1}^{k} \alpha_i E_i(X)$, where our proposed *mix-and-match* energy is composed of k expert energy components, which are weighted by scalar hyperparameters α.

3.2 Expert Factors in Mix-and-Match LM

As shown in Fig. 1, we use the following black-box experts in our experiments as modules that we can add or remove to produce desired behavior:

$\mathbf{E}_{\texttt{mlm}}(\mathbf{X})$: Recent work has shown that large masked language models (MLM) like BERT can discriminate between well-formed and ill-formed sentences (Zhang et al., 2020) and induce an implicit energy function over the sequences (Goyal et al., 2021). Hence, we use BERT-base as a black-box to model the form and fluency of sentences. Specifically, we use an energy parametrization introduced in Goyal et al. (2021) which is negative of the sum of unnormalized logits iteratively computed at each position obtained via the forward pass of the MLM after masking the corresponding position.

$\mathbf{E}_{\texttt{disc}}(\mathbf{X})$: This particular expert module refers to the energy obtained via the discriminator for the attributes of interest. What this module returns is the raw logits of the discriminator, for the target attribute. For instance, if we have a sentiment classifier, and want to produce positive sentiment, then $E_{\texttt{disc}}(X) = -\log p(+|X)$.

---

[1] For simplicity, we are concerned with a finite set of sequences limited by some maximum length.

$\mathbf{E}_{\texttt{hamm}}(\mathbf{X};\mathbf{X}')$: For a given sequence X', this quantity refers to the hamming distance between the sequence X and X'. This penalizes token level deviation from X' which is useful if we are interested in only making minor edits to X' as described later.

$\mathbf{E}_{\texttt{fuzzy}}(\mathbf{X};\mathbf{X}')$: Similar to the hamming distance, this quantity refers to the BertScore (Zhang et al., 2020) computed between X and X' which can be viewed as a *fuzzy* hamming distance that takes semantic similarity into account.

3.3 Sampling scheme

To sample from the energy parametrizations described in the previous section, we follow the Metropolis-Hastings (Hastings, 1970) MCMC scheme for sampling from the masked language models introduced by Goyal et al. (2021). While the proposal distribution we use is the same as Goyal et al. (2021) i.e. masked language model's (BERT's) conditionals, the energy parametrizations we use are more suitably designed for controlled generation.

We briefly explain the sampling procedure, which involves forming long Markov chains of sequences starting with a random sequence, and following the MH scheme which uses a proposal distribution to propose a new sequence at each step in a chain which is either accepted or rejected based on its fitness to the energy function. The sequences at the end of these chains correspond to samples from the desired energy-based model. Operationally, at each MCMC step, we mask out a token at a random position in the current sequence X in the chain and propose a new sequence $\bar{X}$ to transition to by sampling a token from the MLM conditional softmax at the masked position. This proposed sequence is evaluated by its ability to reduce the energy from the current sequence in the chain and is accepted with the probability $p(\bar{X}; X) = \min\left(1, \frac{e^{-E_{\text{M\&M}}(\bar{X})}\, p_{\text{mlm}}(X_i|X_{\setminus i})}{e^{-E_{\text{M\&M}}(X)}\, p_{\text{mlm}}(\bar{X}_i|X_{\setminus i})}\right)$. $E_{M\&M}(X)$ refers to the product of experts energy, i refers to the position chosen for masking, p_{mlm} refers to the MLM's conditional distribution at the `[MASK]` position. Intuitively, this acceptance probability indicates that the proposed sequence $\bar{X}$ is more acceptable if it has lower energy than the current sequence X in the chain and is rare or less likely to be proposed by the proposal distribution again.

3.4 Controlled generation Tasks

We use the expert black-box factors and the sampling scheme described above in our framework to perform two kinds of controlled generation tasks.

Prompted generation: This task focuses on generating well-formed sentences that start with a specified prompt and also satisfy a target attribute for which we have access to a discriminator. An example task would be to generate positive sentiment sequences starting with `This movie`. The energy function takes the form:

$$E_{\texttt{gen}}(X) = E_{\texttt{mlm}}(X) + \alpha\, E_{\texttt{disc}}(X) \qquad (1)$$

α is a hyperparameter that controls the tradeoff between the MLM score and the discriminator's influence. For MH-based sampling for this task, we initialize the sequence with the starting prompt and the rest of the tokens masked out, which creates a seed text of shape `the movie [MASK] [MASK] ... [MASK]`, for the prompt example of `the movie`. The number of mask tokens depends on the target generation length, and we constrain the sampler to only produce proposals and revise non-prompt tokens, and mark the prompt tokens as "frozen".

Controlled text revision: This task involves editing a source sequence X' in order to satisfy the desired target attributes exhibited by the generated sequence X. The energy function for this task is:

$$E_{\texttt{rev}}(X) = E_{\texttt{gen}}(X) + \beta\, E_{\texttt{hamm}}(X,X') + \gamma\, E_{\texttt{fuzzy}}(X,X') \qquad (2)$$

This energy function in addition to valuing well-formedness and satisfying target attribute requirements also focuses on maintaining faithfulness to the source sequence X'. For sampling with this energy, we initialize the sequence with the sequence X' to be edited. This sets the length of the target sequence to be the same as the source. In this setup, the sampler can revise all tokens and is not constrained.

For both these tasks, we run a separate MCMC chain for each generated sentence for 8 to 15 epochs, depending on the task. An epoch refers to one masking cycle over all the non-frozen positions (selected randomly) of the sequence.

4 Experimental Setup

We provide full experimental details in appendix Section B, here we provide a brief overview of the tasks, datasets, baselines, and metrics used in the experiments.

4.1 Tasks and Datasets

Controllable debiasing (ROC story corpus): We use the subset of the ROC story corpus (Mostafazadeh et al., 2016) test-set that is used by PowerTransformer (Ma et al., 2020) for their evaluations. We use this data for controllable debiasing, a text revision task which aims to correct the implicit and potentially undesirable agency biases in character portrayals, by replacing verbs such as “wish" and “dream", with “pursue" and “achieve".

Sentiment transfer (Yelp): We use Yelp (Shen et al., 2017) dataset's test-set for the task of sentiment transfer. The test set comprises 1000 sentences, half with positive and half with negative sentiment. We also have a reference set of handwritten sentiment transferred sentences, provided by (He et al., 2020) that we use for reporting evaluation metrics.

Formality transfer (GYAFC): We use 1051 sentences from the entertainment and music domain subset of the GYAFC (Rao and Tetreault, 2018) dataset, which contains formal and informal sentences for the task of formality transfer (both directions of formal to informal and informal to formal).

Prompted generation: We evaluate our approach on two forms of prompted generation: 1) sentiment controlled generation and 2) topic controlled generation. For sentiment controlled generation, we set Mix and Match LM to generate text with positive or negative sentiment given prompts, by using a Yelp sentiment classifier as discriminator and compare against PPLM (Dathathri et al., 2020) which is a popular sentiment controlled generation method. For topic controlled generation, we compare against FUDGE (Yang and Klein, 2021), and follow their experimental setup consisting of 7 distinct topics and 20 prompts.

4.2 Expert Component Configurations

We use a Huggingface pre-trained `bert-base-uncased` model as our MLM for yielding $E_{\texttt{mlm}}$ and also providing the proposal distribution in our MH MCMC sampler. For obtaining $E_{\texttt{disc}}$, we train BERT-based classifiers on the training-set of our datasets to use as our attribute discriminators. We could have used any pre-trained attribute classifier from Huggingface for $E_{\texttt{disc}}$, but we keep those aside to use as external attribute classifiers for fair evaluation against baselines. For experiments in which we add the BertScore (Zhang et al., 2020) component to the energy, we use the pre-trained `roberta-large_L17` model. Finally, for agency score, we use the lexicon provided by (Sap et al., 2017) and check each generated sequence and count the number of target agency verbs that exist there. The count becomes the agency score.

4.3 Baselines

PowerTransformer. For the task of controllable debiasing (agency revision), we compare our work with PowerTransformer (Ma et al., 2020), an approach that uses paraphrasing and self-supervision based on a reconstruction loss, building on pre-trained language models, to re-write text and control agency level of sentences.

He et al. For style transfer on sentiment an formality, we compare with He et al. (2020), a generative style transfer framework which uses a variational autoencoder (VAE) built using a sequence-to-sequence LSTM-based model to do unsupervised style transfer. This framework needs to be trained from scratch for each style transfer task.

UNMT. As a second baseline for style transfer, we use UNMT (Lample et al., 2018), an unsupervised machine translation framework that demonstrates high performance for sentiment transfer.

PPLM. For the task of sentiment controlled generation, we compare to Plug-and-Play LM (PPLM) Dathathri et al. (2020), which does attribute controlled generation using the flow of gradients from discriminators trained on the last hidden layer representations of the generator, to guide generation.

FUDGE. This approach (Yang and Klein, 2021) trains step-wise discriminators on partial generations from GPT-2 to determine whether the constraints related to desired attributes will be satisfied by the future completion of the sequence or not. We compare against this on topic controlled generation as this approach was shown to be superior to PPLM on this task.

4.4 Evaluation Metrics

We use a variety of evaluation metrics to compare our approach's performance on two major facets: (1) Quality of generated text, and (2) success on matching the target attribute used for control.

4.4.1 Text Quality and Semantic Similarity

GPT-2 PPL. We feed our generated test sentences to a Huggingface (Radford et al., 2019) pre-trained GPT-2 xl model, and report its perplexity (PPL), as an automatic measure of fluency. Although this measure is not a perfect indicator of fluency, we find it to be a useful metric alongside human judgements. [2]

BLEU. For sentiment (Yelp) and formality (GYAFC) transfer where we have reference text, we

---

[2] Due to the high variance in the PPL scores generated across sentences by GPT-2, we report the median score for each system under comparison.

report the BLEU score. For controlled debiasing, we report BLEU between generated text and source and show it as BLEU (src).

BertScore. As a measure of meaning preservation, we use the F1 BertScore metric (Zhang et al., 2020) to compare the semantic similarity of the provided reference sentence with the generated output.

Hamming Distance. We also report the hamming distance between the source text and generated text, to measure the extent of the change.

4.4.2 Attribute Quality

Internal Classifier Accuracy. We report the accuracy of the internal classifier (the discriminator used for generation) on the generated text, assuming the target attribute is the correct label. The higher this accuracy is, the better.

External Classifier Accuracy. It is natural to get high accuracy on the internal classifier, since we are sampling from it. To have a fair comparison, we report accuracy using external classifiers from Huggingface (`textattack/bert-base-uncased-yelp-polarity` (Morris et al., 2020) for sentiment and `cointegrated/roberta-base-formality` for formality).

Agency Lexicon Accuracy. For controlled debiasing, we measure the accuracy of the change in agency by comparing the target agency level with that of the generated text, extracted using the connotation frames lexicon, and following the setup from Ma et al. (2020).

5 Results

5.1 Controllable Debiasing

Tables 1 and 2 show our results for the task of text revision for controlling agency bias which is introduced by PowerTransformer Ma et al. 2020, our Baseline for this task. PowerTransformer has a vanilla (no boost) variant and a variant with vocab boosting, which up-weights the logits of verbs that belong to the target agency lexicon so as to increase their probability and incentivize generation in that direction. We also measure our metrics on the original test-set, without revision, to provide a better sense of the changes made.

We offer different variants of our framework, to provide a fair comparison and to better ablate our proposed method. "Disc" denotes our framework where we add the discriminator expert ($E_{\texttt{disc}}$) which is trained to predict the agency level of a sentence, to the energy along with $E_{\texttt{mlm}}$, and $E_{\texttt{hamm}}$ (Eq. 2). Hamming distance is computed between the generated proposals and the source sentence. The "Agency Score" variant adds an alternative term to $E_{\text{M\&M}}$ instead of $E_{\texttt{disc}}$, which is the number of target agency verbs according to the connotation frames lexicon (Sap et al., 2017) in the sentence. The "Disc+Agency" variant has both energy components. We also apply our method in two ways: "Verb Replace" which allows the sampler to propose revisions for only one pre-determined verb (provided in the dataset). In this setup, all tokens remain frozen, except for the given verb. The conventional mode (M&M LM), however, proposes revisions for all tokens in the sentence and is not constrained.

Table 2 shows that in the conventional setup, Mix and Match LM (Disc only) has performance similar to that of PowerTransformer, without boosting. With the Agency Score component, our method outperforms PowerTransformer in terms of accuracy of revision as per the agency lexicon accuracy metric, with negligible loss in meaning (BertScore). The reason behind this better performance in terms of applying target agency accuracy is that our method's sampling is guided by the energy that is directly built on the metrics we care about, as opposed to trying to apply them through paraphrasing and proxies such as vocab boosting, which are employed in the PowerTransformer method.

Another important observation here is the difference between "Verb Replace" and conventional modes. This ablation shows that although our method makes few changes (the average Hamming distance between source and output sentences are between 1.37 and 2.45), it still outperforms a "static" method that has extra knowledge of the offending verb and focuses on changing only that verb, by a significant margin.

5.2 Style Transfer

In this section we experiment with sentiment and formality transfer, where Sentiment transfer needs fewer changes and formality transfer needs more structural change to the original sentence. We show sample sentences and transfers in Table 1 (we cannot show samples for formality as the dataset is not public).

5.2.1 Sentiment Transfer

For this task, we include two components in our energy model, the attribute discriminator ($E_{\texttt{disc}}$), to induce the target style, and the hamming distance ($E_{\texttt{hamm}}$), to maintain the meaning of the sentence.

Table 1: Original and style transferred sample sentences, using Mix & Match LM. Sentiment shows the task of sentiment transfer, from negative to positive and positive to negative, on Yelp. Agency shows the controllable agency de-biaisng task (Ma et al., 2020). In the examples, we are transferring negative agency to positive.

	Original	Transferred
Sentiment	the food 's ok , the service is among the worst i have encountered .	the food 's wonderful , the service is among the finest i have encountered .
	we will not be using this location again .	we will definitely be seeking this location again .
	good selection of parts and accessories and reasonable prices .	poor selection of parts and accessories and high prices .
	it is a cool place , with lots to see and try .	it is a stupid place , with nothing to see and try .
Agency	mary needed new shoes .	mary got new shoes .
	she followed the instructions as best as she could .	she executed the instructions as best as she could .
	pam wanted to have a special cake for her son 's birthday .	pam decides to have a special cake for her son 's birthday .
	whitney is going to fail her test .	whitney is set to get her test .

Table 2: Controllable debiasing/ sentence agency revision on ROC-story corpus. The *(src)* next to the metrics denotes measurement with respect to the source text. *Int. Clsf.* is the accuracy of the discriminator used in the energy. *Hamm.* shows the Hamming distance. *Agency Acc.* is the accuracy of agency revision based on the agency lexicon (Sec B.4.1).

	M&M LM (BertScore↑)	27.71	194.4	**0.93**	2.50	72.12	**94.26**	**19.01**

We don't include the more complex semantic similarity-related component like $E_{\texttt{fuzzy}}$, since sentiment transfer can normally be done by making only a few changes to the sentence. We report results with two different variants, one where the discriminator component has a higher coefficient in the energy (Discriminator↑) and one where the hamming distance has a higher coefficient (Hamming↑). In effect, these two show the trade-off between transfer quality and faithfulness to the source sentence.

We see in Table 3 that our method, with the hamming component up-weighted, outperforms both the generative baselines in terms of transfer accuracy (Ext. Clsf.) and semantic similarity (BertScore). We can also see Mix and Match LM has higher BLEU score, with respect to the provided hand-written reference sentences. We hypothesize that this superiority is due to the tendency of our model to make minimal revisions that satisfy the product of experts energy model. Therefore, our model can successfully change the style without changing the meaning of the sentence. The generative baselines, however, regenerate the sentence which imposes more change, as can be observed from the hamming distance column (Hamm.(src)) in Table 3.

5.2.2 Formality Transfer

For this task, we include the formality classifier ($E_{\texttt{disc}}$), Hamming distance ($E_{\texttt{hamm}}$), and BertScore ($E_{\texttt{fuzzy}}$) components in the energy formulation, to permit the transfer of style and also maintain the meaning of the sentence. $E_{\texttt{fuzzy}}$ helps with imposing semantic similarity between the source and generated sentences, since Hamming alone isn't sufficient for judging comparable formal and informal sentences. We show results for two setups of our framework, one where the discriminator coefficient is higher (Discriminator↑) and another where the BertScore coefficient is higher (BertScore↑).

In Table 4 we have broken down the external classifier accuracy for the different transfer directions of formal to informal (→ Inf.) and vice versa. We do this because the → Form. task is generally harder and therefore has lower accuracy. We observe that our method outperforms the baselines in terms of BertScore and BLEU, for similar levels of external classifier accuracy. However, we can see that the GPT-2 PPL of our method is higher than the baselines. The reason behind this is the format and noise in the data. The samples for this dataset are taken from the music and entertainment industry domain and contain some symbols and characters similar to emojis (e.g. ":)" and "***"). This is where the tendency of our approach toward minimal revisions is hurtful–our revisions of text, often do not get rid of all of these symbols, while the baselines' generative methods successfully remove all the superfluous characters because they rewrite sentences from scratch.

5.3 Prompted Controlled Generation

5.3.1 Sentiment Controlled Generation

We generate 560 sequences of different lengths (12, 20 and 50 tokens), given 14 prompts, 2 sentiments, and 20 sequences per sentiment, taken from Dathathri et al. (2020)'s experimental setup. The prompts and sample generations are in the appendix B.9 and A.2, and a full list of generations is in the supplementary material.

Table 6 shows our results for this experiment. Here, we have an additional metric, the MLM energy (lower is better), which, like GPT-2, indicates the quality of generated sentences (Salazar et al., 2020) according to BERT. We report this extra metric here since PPLM uses a GPT model for generation, and it is natural that it would measure better on this metric. The table shows that for all lengths of generated sentences, our method is much better at inducing the target sentiment. However, we observe that PPLM performs better in terms of GPT-2 while our method performs better on the MLM energy metric. This suggests the tendency of model-based fluency metrics to be biased toward the corresponding models as the PPLM uses GPT-2 for generation and M&M LM uses BERT. To enable a more conclusive comparison of the text quality, we report results with human evaluations. For these evaluations, we randomly select 10 generated outputs for each prompt, per sentiment (240 overall), and asked three Amazon Turkers per sample pair, which sample they find more fluent. We report the majority vote of the Turkers in the table. The results show that for sequences with lengths 12 and 20, they found our generations more fluent. However, for length 50, the preference rate for M&M drops to 46.7%, which shows that our method is superior to PPLM for short/medium length generation, however, PPLM does better at generating longer sequences.

5.3.2 Topic Controlled Generation

We follow FUDGE's (Yang and Klein, 2021) experimental setup which covers 7 topics, given 20 prompts and generate 7×20 sequences of length 20. To enforce topicality on our generations, we add a topic-based energy, $E_{\texttt{topic}}$. This energy is essentially the negative count of the number of topic-related words (using the list provided by FUDGE).

Table 7 shows the results of this experiment, generations are also provided in A.2. Topic-score (↑) is the usage rate of topic-related words that were used for training and evaluation of topic controlled generation by Yang and Klein in their paper. Grammaticality (↑) is the score of grammaticality given by a Roberta-based CoLA grammaticality model averaged over all outputs (Warstadt et al., 2019). The "Div" (↑) metrics show the diversity of generated text, over unigrams, bigrams and trigrams. Finally, the human evaluations show human preference, in terms of fluency of the sentences (B.10). As shown by the table, the fluency of our method is comparable to that of FUDGE, even better in terms

Diversity over Bigrams (↑)	0.86	0.89
Diversity over Trigrams (↑)	0.87	0.88
Human Preference(%) (↑)	36.5	63.5

of human preference and grammaticality judgment. FUDGE has a slightly higher topic score, which is expected since it trains a custom step-wise discriminator for each topic that is optimized for the task. But our approach shows competitive faithfulness to the topics especially considering the fact that prompted GPT-2 generations without the FUDGE discriminators only achieve a topic-score of 0.23.

5.4 Inference Speed

Given that our model's inference procedure involves MCMC sampling, it's reasonable to expect its run-time to be slower than more traditional baselines. For sequences of length 20, we find that our un-optimized implementation requires 8 seconds per generation and 3 seconds per revision – while, in contrast, baseline system PPLM requires 16 seconds and FUDGE requires 0.4 seconds per generation. This is a substantial slowdown compared to FUDGE, but not one that renders the proposed approach impractical in offline settings. Further, faster sampling schemes are beyond the scope of this paper but might be explored in future work to speed up models like M&M LM.

6 Conclusion

We present Mix and Match Language Models (M&M LM), a training-free framework for controlled text generation that can easily mix heterogeneous expert modules. We show that our framework outperforms prior methods on a suite of text revision and attribute-controlled generation tasks. Further, our results indicate that probabilistic energy language models, typically considered intractable, can be used for practical text generation tasks when combined with an appropriate sampling scheme.

Acknowledgments

The authors would like to thank the anonymous reviewers and meta-reviewers for their helpful feedback. We also thank our colleagues at the UCSD/CMU Berg Lab for their helpful comments and feedback.

Ethical Considerations

The proposed approach takes steps towards a novel paradigm that might partially mitigate the need for energy-intensive GPU training – potentially leading to positive environmental impact down the line. The approach may also have positive impacts on accessibility as strong computational resources are not required when setting up a new controlled text generation system. We do however acknowledge that strong controlled generation methods that rely on discriminators have the potential to regurgitate sensitive training data and produce harmful outputs and toxic language (Xu et al.; Gehman et al., 2020; Wallace et al., 2020). However, if used properly and for good, we anticipate a positive impact on debiasing and safe generation.

A Appendix

A.1 Code and Data Directory Structure

We have provided all our code, data and our generations in `https://github.com/mireshghallah/mixmatch`, and our checkpoints are uploaded anonymously here `https://zenodo.org/record/5855005`. There is a `readme` file in the repo, which has instructions on how to run generation and get evaluation metrics. We have not included the data files for the formality, since the GYAFC dataset requires permission for access, so we cannot release it.

A.2 Sample Generations

Due to page limitations in the body of the paper, we include more sample generations from our method in the form of tables here. We have no samples from the formality transfer task, however, since the data used (GYAFC) is protected and needs permissions for access, so we cannot publish it. However, we have provided code needed to reproduce our results, once access to the original data is gained. Table 8 shows FUDGE generations versus Mix and Match generations.

B Experimental Setup Details

B.1 Tasks and Datasets

Controllable debiasing (ROC story corpus): We use the subset of the ROC story corpus (Mostafazadeh et al., 2016) test-set that is used by PowerTransformer (Ma et al., 2020) for their evaluations. We use this data for controllable debiasing, a text revision task which aims to correct the implicit and potentially undesirable agency biases in character portrayals. This test-set consists of 549 sentences, where 224 sentences have low agency verbs (such as wish, dream, etc.) and the rest have high agency (like pursue, achieve, etc.). The task is to revise the sentences such that the meaning is preserved, but the agency of the sentence is changed in the target direction.

Sentiment transfer (Yelp): We use Yelp (Shen et al., 2017) dataset's test-set for the task of sentiment transfer. The test set comprises of 1000 sentences, half with positive and half with negative sentiment. We also have a reference set of hand written sentiment transferred sentences, provided by (He et al., 2020) that we use for reporting evaluation metrics.

Formality transfer (GYAFC): We use 1051 sentences from the test-set of the GYAFC (Rao and Tetreault, 2018) dataset, which contains formal and informal sentences for the task of formality transfer (both directions of formal to informal and informal to formal). Here we use the entertainment and music domain subset of this data, following the evaluation setup of (He et al., 2020). This dataset also contains parallel data between formal and informal sentences, which we use as reference for reporting evaluation metrics.

Prompted generation: We evaluate our approach on two forms of prompted generation: 1) sentiment controlled generation, and 2) topic controlled generation. on prompted generation. For sentiment controlled generation, we set Mix and Match LM to generate text with positive or negative sentiment given prompts (listed in Appendix B.9) by using a Yelp sentiment classifier as discriminator and compare against PPLM (Dathathri et al., 2020) which is a popular sentiment controlled generation method. For topic controlled generation, we compare against FUDGE (Yang and Klein, 2021), and follow their experimental setup consisting of 7 distinct topics and 20 prompts.

B.2 Expert Component Configurations

We use a Huggingface pre-trained `bert-base-uncased` model as our MLM for yielding $E_{\texttt{mlm}}$ and also providing the proposal distribution in our MH MCMC sampler. For obtaining $E_{\texttt{disc}}$, we train BERT-based classifiers on the training-set of our datasets to use as our attribute discriminators. Although we could have used any pre-trained attribute classifier from a model repository like Huggingface for $E_{\texttt{disc}}$, we train our own classifier for controlled empirical comparison. As described later, we do use pretrained Huggingface attribute classifiers as external attribute classifiers for fair evaluation against baselines. For experiments in which we add the BertScore (Zhang et al., 2020) component to the energy, we download the pre-trained `roberta-large_L17` models from Huggingface, respectively. We have provided implementation details and hyperparameter ablations of all the experiments in Appendix B.6, B.7, B.8 and B.9.

B.3 Baselines

PowerTransformer. For the task of controllable debiasing (agency revision), we compare our work with PowerTransformer (Ma et al., 2020), an approach that uses paraphrasing and self-supervision based on a reconstruction loss, building on pre-trained language models, to re-write text and control agency level of sentences.

et al., 2018), an unsupervised machine translation framework that demonstrates high performance for sentiment transfer.

PPLM. For the task of sentiment controlled generation, we compare our work to Plug-and-Play LM (PPLM) Dathathri et al. (2020), which does attribute controlled generation using the flow of gradients from discriminators trained on the last hidden layer representations of the generator, to guide generation.

FUDGE. This approach (Yang and Klein, 2021) trains step-wise discriminators on partial generations from GPT-2 to determine whether the constraints related to desired attributes will be satisfied by the future completion of the sequence or not. We compare against this on topic controlled generation as this approach was shown to be superior to PPLM on this task.

B.4 Evaluation Metrics

We use a variety of evaluation metrics to compare our approach's performance on two major facets: (1) Quality of generated text, and (2) success on matching the target attribute used for control.

B.4.1 Text Quality and Semantic Similarity

GPT-2 PPL. We feed our generated test sentences to a Huggingface (Radford et al., 2019) pre-trained GPT-2 xl model, and report its perplexity (PPL), as an automatic measure of fluency. Although this measure is not a perfect indicator of fluency, we find it to be a useful metric alongside human judgements. [3]

BLEU. For sentiment (Yelp) and formality (GYAFC) transfer experiments, since we have reference text, we report the BLEU score. For controlled debiasing, we report BLEU between generated text and source, and show it as BLEU (src).

BertScore. As a measure of meaning preservation, we use the F1 BertScore metric (Zhang et al., 2020) to compare the semantic similarity of the provided reference sentence with the generated output.

Hamming Distance. We also report the hamming distance between the source text and generated text, to measure the extent of the change induced by our framework.

B.4.2 Attribute Quality

Internal Classifier Accuracy. To evaluate the quality of applying target attributes, we report accuracy of the internal classifier (the discriminator used for generation) on the generated text, assuming the target attribute is the correct label. The higher this accuracy is, the better.

External Classifier Accuracy. Since the internal classifier is the one we are sampling from, it is natural that we would get high accuracy on it, compared to our baselines. To create a more fair comparison, we also report classification accuracy using external classifiers, downloaded from Huggingface. For sentiment classification we use `textattack/bert-base-uncased-yelp-polarity` (Morris et al., 2020), and for formality we use `cointegrated/roberta-base-formality`.

Agency Lexicon Accuracy. For the controlled debiasing experiment, we measure the accuracy of the change in agency by comparing the target agency level with that of the generated text, extracted using the connotation frames lexicon, and following the setup from Ma et al. (2020).

B.5 Hyper-parameter and Component Selection

Selection of components is based on the needs of the task and is straight forward. You add each component you need, to satisfy some condition. If you want to do sentiment controlled generation, you add a sentiment classifier. Finding the hyper-parameters for each component (the multiplier in energy) is also simple, since the trade-off between

---

[3] Due to the high variance in the PPL scores generated across sentences by GPT-2, we report the median score for each system under comparison.

the different components is clear. For instance, as shown in Table 9, increasing the discriminator score results in a more successful sentiment transfer, and increasing the Hamming score results in keeping the sentence the same.

B.6 Controllable Debiasing: Hyper parameters

For the results presented in Table 2, we ran the Gibbs chain for 8 epochs (8 iterations over all the tokens) for the conventional mode of our method, and 30 iterations for verb replacement. We used the parameters $\alpha = 100, \beta = 50, \theta = 100$, where θ is the coefficient assigned to the agency scorer, and α and β are defined in Equations 1 and 2.

B.7 Sentiment Transfer: Hyperparameters

In this section we discuss the hyperparameters used for sampling and see the effects of each one. For the results presented in Table 3, we ran the Gibbs chain for 8 epochs (8 iterations over all the tokens), and used the parameters $\alpha = 100, \beta = 25$ (for Discriminator ↑) and $\alpha = 100, \beta = 50$, for Hamming ↑. α and β are defined in Equations 1 and 2.

Table 9 shows six different scenarios, with six different coefficeints for the Disciriminator (α), BERT MLM (δ) and Hamming distance (β) components in the energy function, which helps understand the effect each expert has.

B.8 Formality Transfer: Hyperparameters

For the results presented in Table 4, we ran the Gibbs chain for 5 epochs (5 iterations over all the tokens), and used the parameters $\alpha = 140, \beta = 15, \gamma = 100$ (for Discriminator ↑) and $\alpha = 140, \beta = 50, \gamma = 300$, for BertScore ↑. α, β and γ are defined in Equations 1 and 2.

Table 10 shows four different scenarios, with four different coefficeints for the BLEURT and BertScore components in the energy function, which helps understand the effect each expert has. For BLEURT, we use pre-trained `Elron/bleurt-base-512` from Huggingface.

B.9 Prompts and Hyperparameters Used for Controlled Generation

We have listed the prompts that we used for controlled text generation (these prompts are taken from Dathathri et al. (2020)): the country, the lake, the chicken, the movie, the pizza, the painting, the year, the city, the book, the potato, the horse, the road, the president, once upon a time. We collect these prompts from PPLMs github repo, available at this url: `https://github.com/uber-research/PPLM/tree/master/human_annotation/pplm_labeled_csvs`.

PPLM has multiple knobs to tune for sampling, and after running a greed search we found that `gamma=1,num_iterations=10,step_size=0.1,kl_scale=0.01` and `gm_scale=0.95` yeild the best results (reported in Table 6). We generated samples by running the command `python run_pplm.py -D sentiment`, with the mentioned hyperparameters. For FUDGE, we tune the λ parameter, and we find that $\lambda = 10$ works best.

For our method, we ran the Gibbs chain for 15 epochs, and used hyperparameter $\alpha = 40$, from Eq. 1. We don't use any experts other than the yelp sentiment classifier, so we don't have any other hyperparamters.

B.10 Human Evaluations

We used Amazon Mechanical Turk for our evaluations, where each HIT was a two choice question of "which sentence is more fluent?" and the providers were paid $\$0.1$ per HIT. We selected Turkers from English speaking countries. We also had each each question answered 3 times (by 3 Turkers), to create redundancy and robustness.

B.11 GPU Hours and Infrastructure

One of the main purposes of this work is to introduce a paradigm in which we re-use existing models and do not retrain. As such, we did not need GPUs for training (we finetuned two classifier for demonstration purposes, which took less than two GPU hours).

However, we do use GPUs for inference (less computationally intensive), for generating samples. We used an in-house 4GPU server (NVIDIA RTX2080), and the samplings and hyperparameter tuning took an overall of around 10-14 full days on the 4 GPUs.

So Different Yet So Alike!
Constrained Unsupervised Text Style Transfer

Abstract

Automatic transfer of text between domains has become popular in recent times. One of its aims is to preserve the semantic content of text being translated from source to target domain. However, it does not explicitly maintain other attributes between the source and translated text, for e.g., text length and descriptiveness. Maintaining constraints in transfer has several downstream applications, including data augmentation and de-biasing. We introduce a method for such constrained unsupervised text style transfer by introducing two complementary losses to the generative adversarial network (GAN) family of models. Unlike the competing losses used in GANs, we introduce cooperative losses where the discriminator and the generator cooperate and reduce the same loss. The first is a *contrastive* loss and the second is a *classification* loss — aiming to regularize the latent space further and bring similar sentences across domains closer together. We demonstrate that such training retains lexical, syntactic, and domain-specific constraints between domains for multiple benchmark datasets, including ones where more than one attribute change. We show that the complementary cooperative losses improve text quality, according to both automated and human evaluation measures. [1]

1 Introduction

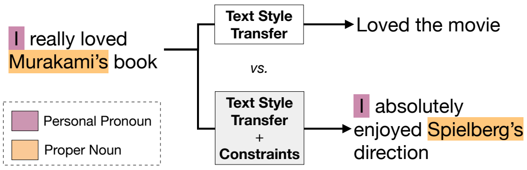

Figure 1: Illustrative example showing transfer of text from books to movies while maintaining constraints of identity.

Modern neural networks methods are capable of mapping data from one domain to another. Prominent examples include translation of text between languages (Vaswani et al., 2017; Artetxe et al., 2018; Lample et al., 2017), emoji creation from human faces (Taigman et al., 2017), and stylistic transfer of speech (Yuan et al., 2021). In Natural Language Processing (NLP), the umbrella term *attribute transfer* (Jin et al., 2020b) (or *domain transfer*) refers to similar methods[2]. The aim is to maximally preserve the semantics of the source sentence ("content") but change other properties ("attributes"), such as sentiment (Jin et al., 2020b), expertise (Cao et al., 2020), formality (Rao and Tetreault, 2018) or a combination of them (Subramanian et al., 2018).

Text style transfer, a popular form of attribute transfer, regards "style" as any attribute that changes between datasets (Jin et al., 2020a). Building on the progress of supervised transfer models, recent works have focused on *unsupervised style transfer* that avoids costly annotation of parallel sentences. However, models built using unsupervised methods perform poorly when compared to supervised (parallel) training (Artetxe et al., 2020). These methods, while capable of achieving the target domain characteristics, often fail to maintain the invariant content. Figure 1 illustrates one such example, where a sentence from the BOOKS domain is translated to the MOVIE domain. While the translated sentence "*Loved the movie*" has correctly transferred the attribute (style), it does not have the same length, does not retain the personal noun ("*I*"), nor use a domain-appropriate proper noun. Comparatively, the higher-fidelity transfer "*I absolutely enjoyed Spielberg's direction*", maintains such *constraints of identity*, in addition to being apt.

This problem setting is an important application

---

[1] `https://github.com/abhinavkashyap/dct`

[2] While the literature primary utilizes the term *style transfer*, we adopt the more general term *attribute* as suggested by Jin et al. (2020a).

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 416 - 431
May 22-27, 2022 ©2022 Association for Computational Linguistics

of text transfer, as enforcing constraints of identity can help maintain the brand identity when the product descriptions are mapped from one commercial product to another. They can also help in data augmentation for downstream domain adaptation NLP applications (§ 5). Constraints of identity are explored extensively in the computer vision task of cross-domain image generation. (Taigman et al., 2017), but these issues—to the best of our knowledge—are unexplored in NLP.

In this paper, we improve unsupervised attribute transfer by enforcing invariances via explicit constraints. Current methods in text attribute transfer lack mechanisms to explicitly enforce such constraints between the source and the transferred sentence. To this end, we build upon unsupervised text style transfer work by introducing an additional explicit regularization component in the latent space of a GAN-based *seq2seq* network through two complementary losses (§ 3). Unlike the adversarial losses in the GAN framework, our proposed losses cooperatively reduce the same objective. The first loss is a contrastive loss (Le-Khac et al., 2020) that brings sentences that have similar constraints closer and pushes sentences that are dissimilar farther away. The second loss is a classification loss that helps maintain the sentence identity via constraints from the latent vectors (Odena et al., 2017).

Our approach, while simple and aimed at maintaining constraints, improves the overall performance of the generation. We demonstrate these gains over three datasets: YELP (Zhao et al., 2018b), IMDB (Dai et al., 2019) and POLITICAL (Prabhumoye et al., 2018), generating six constraints including lexical, syntactic and domain-specific constraints. The introduced cooperative losses satisfy the constraints more effectively compared against strong baselines. Since multiple attributes can change between two domains (Subramanian et al., 2018), we test our method on one such dataset and show that the constraints of identity are maintained more effectively (§ 4.4.2). To the best of our knowledge, our approach is the first to introduce cooperative losses in a GAN-like setup for NLG.

2 Preliminaries

Task Setup: We consider two sets of sentences (or corpora) $\mathcal{S} = \{x^1_{src}, x^2_{src}, \ldots x^m_{src}\}$ and $\mathcal{T} = \{x^1_{trg}, x^2_{trg}, \ldots x^n_{trg}\}$, as the *source* and *target* domains, respectively. Each corpus — which we interpret as domains — contain discernable attributes, ranging from sentiment (e.g., positive vs. negative), topics, political slant (e.g., democratic vs. republican), or some combination (Li et al., 2018; Lample et al., 2019). The overall task is to rewrite a piece of text $s_i \in \mathcal{S}$ to $t_i \in \mathcal{T}$, such that the translation changes the attributes varying across the two domains but retains the remaining content. While content retention is not explicitly defined in the literature, we design this new task of constrained unsupervised attribute transfer that assigns explicit constraints $\mathcal{C} = \{c_1, c_2, \ldots, c_{|\mathcal{C}|}\}$, to be retained. These constraints can be defined at various levels of a sentence: lexical, syntactic and domain-specific.

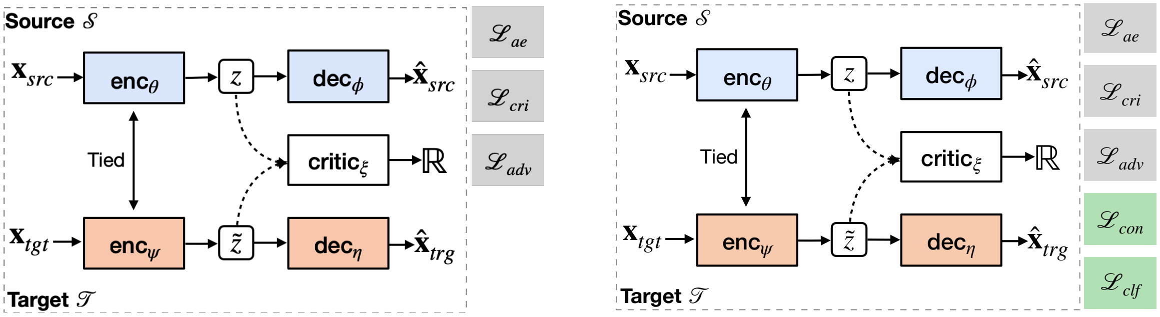
Adversarially Regularized Autoencoder (ARAE): To perform unsupervised attribute transfer, we consider *seq2seq* models that encode source sentences to a latent space and then decodes them to the target sentences. ARAEs (Zhao et al., 2018b) are the auto-encoder variants of the Generative Adversarial Network (GAN) (Goodfellow et al., 2014) framework. They learn smooth latent spaces (by imposing implicit priors) to ease the sampling of latent sentences. ARAEs have been widely adopted in tasks like unsupervised text generation (Huang et al., 2020), topic modeling (Hu et al., 2020), among others, and form the backbone of our proposed model.

ARAE consists of an auto-encoder with a deterministic encoder $enc_\theta : \mathcal{X} \rightarrow \mathcal{Z}$ that encodes sentences into a latent space; i.e., $\mathbf{z} = enc_\theta(\mathbf{x}) \sim P_z$, and a conditional decoder $p_\phi(\mathbf{x}|\mathbf{z})$ that generates a sentence given a latent code. ARAE regularizes this latent space utilizing a GAN-like setup that includes an implicit prior obtained from a parameterized generator network $enc_\psi : \mathcal{N}(0, I) \rightarrow \mathcal{Z}$. Here, enc_ψ maps a noise sample $s \sim \mathcal{N}(0, I)$ to the corresponding prior latent code $\bar{\mathbf{z}} = enc_\psi(s) \sim P_{\bar{z}}$.

A critic $crc_\xi : \mathcal{Z} \rightarrow \mathbb{R}$ then learns to distinguish between real and generated samples, whereas both enc_θ and enc_ψ are adversarially trained to fool the critic. This results in a minimax optimization which implicitly minimizes the JS-Divergence between the two distributions P_z and $P_{\bar{z}}$:

$$\min_\psi \max_\xi \underset{\mathbf{z} \sim P_z}{\mathbb{E}} [crc_\xi(\mathbf{z})] - \underset{\bar{\mathbf{z}} \sim P_{\bar{z}}}{\mathbb{E}} [crc_\xi(\bar{\mathbf{z}})] \quad (1)$$

The training involves three optimizations: i) reducing the auto-encoder loss $\mathcal{L}_{ae}$, which tries to reconstruct the input and encourages copying be-



(a)

(b)

Figure 2: (a) ARAE$_{seq2seq}$ – We replace the generator of ARAE with an encoder that encodes text from $\mathcal{T}$. (b) Adding our proposed cooperative losses to the model.

havior and maintain semantics similar to the original text (Eq. 2); ii) optimizing the critic's loss $\mathcal{L}_{cri}$ to distinguish between real and fake samples (Eq. 3) iii) training the encoder and generator $\mathcal{L}_{adv}$ to fool the critic (Eq. 4):

$$\mathcal{L}_{ae}(\theta, \phi) = \mathop{\mathbb{E}}_{\mathbf{z}\sim P_z}[-\log\, p_\phi(\mathbf{x}|\mathbf{z})] \quad (2)$$

$$\mathcal{L}_{crc}(\xi) = -\mathop{\mathbb{E}}_{\mathbf{z}\sim P_z}[crc_\xi(\mathbf{z})] + \mathop{\mathbb{E}}_{\bar{\mathbf{z}}\sim P_{\bar{z}}}[crc_\xi(\bar{\mathbf{z}})] \quad (3)$$

$$\mathcal{L}_{adv}(\theta, \psi) = \mathop{\mathbb{E}}_{\mathbf{z}\sim P_z}[crc_\xi(\mathbf{z})] - \mathop{\mathbb{E}}_{\bar{\mathbf{z}}\sim P_{\bar{z}}}[crc_\xi(\bar{\mathbf{z}})] \quad (4)$$

3 Proposed Method

3.1 Base Model (ARAE$_{seq2seq}$)

While ARAE is an auto-encoder that recreates input $\mathbf{x} \rightarrow \hat{\mathbf{x}}$, our requirement is to translate sentences from one domain to another. Given this, we modify the ARAE to a *seq2seq* variant such that we can translate input sentences between source and target domains; i.e., $\mathbf{x}_{src} \rightarrow \hat{\mathbf{x}}_{tgt}$ and $\mathbf{x}_{tgt} \rightarrow \hat{\mathbf{x}}_{src}$.

To achieve this, we utilize enc_θ to encode $\mathbf{x}_{src}$ and repurpose enc_ψ to encode $\mathbf{x}_{tgt}$. We obtain their latent codes $(\mathbf{z}, \bar{\mathbf{z}})$ which we name as $(\mathbf{z}^s, \mathbf{z}^t)$, i.e., $\mathbf{z}^s = enc_\theta(\mathbf{x}_{src})$ and $\mathbf{z}^t = enc_\psi(\mathbf{x}_{tgt})$.

Next, to generate sentences, we consider two decoders $\hat{\mathbf{x}}_{src} \sim p_\phi(\mathbf{x}|\mathbf{z})$ and $\hat{\mathbf{x}}_{tgt} \sim p_\eta(\mathbf{x}|\mathbf{z})$. Here, $\mathbf{z}$ can be either $\mathbf{z}^s$ or $\mathbf{z}^t$ based on whether we auto-encode (e.g., $p_\phi\,(\mathbf{x}|\mathbf{z}^s = enc_\theta(\mathbf{x}_{src}))$) or translate (e.g., $p_\phi\left(\mathbf{x}|\mathbf{z}^t = enc_\psi(\mathbf{x}_{tgt})\right)$). Unlike ARAE's single decoder, we incorporate two decoders to enable bi-directional translation.

In the above process, instead of sampling s from a noise distribution like $\mathcal{N}(0, I)$ and passing it through a generator enc_ψ, we feed it text from the target domain $\mathcal{T}$ and a decoder dec_η that decodes text in $\mathcal{T}$. This is inspired from Cycle-GAN (Zhu et al., 2017), where instead of matching the noise distribution $\mathcal{N}$, we match the distribution of $\mathcal{T}$.

In addition, we tie the weights of the encoders from both domains, so that the encoders learn to encode domain-agnostic information. Tying encoder weights has also been used by unsupervised machine translation (Artetxe et al., 2018; Lample et al., 2017) and multiple other works (Mai et al., 2020; Huang et al., 2020; Hu et al., 2020; Artetxe et al., 2018)[3].

3.2 Adding Constraints via Co-op Training

While the latent space in ARAE$_{seq2seq}$ learns to match $\mathcal{S}$ and $\mathcal{T}$ sentences, there is no guarantee on translations maintaining the "content". This issue is particularly pronounced in unsupervised attribute transfer due to lack of parallel sentences between $\mathcal{S}$ and $\mathcal{T}$.

To alleviate the issue, we propose to learn a structured latent space which embodies notions of our constraints in its embedded latent codes. This ensure that instances with similar constraints are closer in the latent space. In particular, we propose two types of optimization — self-supervised and discriminative — to maintain the constraints better.

3.2.1 Cooperative Contrastive Learning

We use contrastive representation learning to regularize the latent space, such that encoders bring two sentences sharing similar constraints closer together (positive pairs), and force dissimilar ones away (negative pairs). For example, sentences of similar lengths (irrespective of their domains) should be closer together.

Among many self-supervised metric losses such as Triplet Loss (Hoffer and Ailon, 2015) and NT-

---

[3] We tried with separate encoders and decoders, but encoders with tied weights work best

Algorithm 1: ARAE$_{seq2seq}$ + CLF + CONTRA

```
1  for each training iteration do
2      1) Train the Auto-encoders:
3          Sample $\mathbf{x}_{src} \sim \mathcal{S}$ , $\mathbf{x}_{trg} \sim \mathcal{T}$
4          $\mathbf{z}^s = enc_\theta(\mathbf{x}_{src}),\ \mathbf{z}^t = enc_\psi(\mathbf{x}_{trg})$
5          Backprop loss, $\mathcal{L}_{ae}(\theta, \phi)$, $\mathcal{L}_{ae}(\psi, \eta)$
6      2) Train the Critic:
7          Sample $\mathbf{x}_{src} \sim \mathcal{S}$ , $\mathbf{x}_{trg} \sim \mathcal{T}$
8          $\mathbf{z}^s = enc_\theta(\mathbf{x}_{src}),\ \mathbf{z}^t = enc_\psi(\mathbf{x}_{trg})$
9          $\mathbf{z}^s_{crc} = crc^{hid}_\xi(\mathbf{z}^s),\ \mathbf{z}^t_{crc} = crc^{hid}_\xi(\mathbf{z}^t)$
10         $l_{crc} \leftarrow \mathcal{L}_{crc}(\xi)$
11     2a) Critic Co-op Training:
12         Backprop loss, $l_{crc} + \lambda_1 \mathcal{L}_{con}(\xi) + \lambda_2 \mathcal{L}_{clf}(\xi,\ \delta)$
13     3) Adversarial Training:
14         Sample $\mathbf{x}_{src} \sim \mathcal{S}$ , $\mathbf{x}_{trg} \sim \mathcal{T}$
15         $\mathbf{z}^s = enc_\theta(\mathbf{x}_{src}),\ \mathbf{z}^t = enc_\psi(\mathbf{x}_{trg})$
16         Backprop loss, $\mathcal{L}_{adv}(\theta, \psi)$
17     3a) Encoder Co-op Training:
18         Backprop loss, $\lambda_1 \mathcal{L}_{con}(\theta,\ \phi) + \lambda_2 \mathcal{L}_{clf}(\theta,\ \phi,\ \delta)$
```

Xent loss (Chen et al., 2020), we use one that is amenable to multiple positive instances (Khosla et al., 2020). Given a sentence $s_i \in \mathcal{S}$ in a mini-batch of size B, we mine P positive sentences each from $\mathcal{S}$ and $\mathcal{T}$ that share the same constraints with s_i. This contrastive loss is given by:

$$\mathcal{L}_{con}(\theta, \psi, \xi) = -\frac{1}{|P|} \log \left(\sum_{j=1}^{P} \frac{e^{(\mathbf{z}_i \cdot \mathbf{z}_j)}}{\sum_{k=1}^{B \setminus \{i\}} e^{(\mathbf{z}_i \cdot \mathbf{z}_k)}} \right) \quad (5)$$

where $\mathbf{z}$'s are representations obtained from the encoders in $\mathcal{S}$, $\mathcal{T}$ or representations obtained from the last layer of critic crc_ξ. $\mathcal{C}_i$ are a set of constraints for a sentence. Recently, (Kang and Park, 2020) introduced the cooperative loss in the adversarial setup where contrastive losses are added to both the *critic* and *generator* for GANs. Unlike the normal opposing losses of the generator and the critic, both of them cooperatively reduce the contrastive loss. We follow a similar principle and add the loss to both the encoders and the critic (Lines 18).

3.2.2 Cooperative Classification

Contrastive learning might be sub-optimal if we do not mine good quality positive and negative samples (Tian et al., 2020). To address this, we propose another way to regularize the latent space. Similar to ACGAN (Odena et al., 2017), we encourage the encoders and the critic to cooperatively reduce a classification loss. We include a classifier $D_\delta : \mathcal{Z} \rightarrow \mathbb{R}^{|\mathcal{C}|}$ that predicts the different constraints $\mathcal{C}$ of the sentences and the binary cross entropy loss is reduced.

Dataset	Attributes	Train	Dev	Test	Avg len.	Vocab
YELP	Positive	266,041	25,278	50,278	8.9	10K
	Negative	177,218	38,205	76,392		
IMDB	Positive	178,869	2K	1K	18.5	30K
	Negative	187,597	2K	1K		
POLITICAL	Democratic	270,000	2K	28K	16	30K
	Republican	270,000	2K	28K		

Table 1: Dataset splits for YELP, IMDB and POLITICAL.

$$\mathcal{L}_{clf}(\theta, \phi, \xi, \delta) = -\sum_{c=1}^{|\mathcal{C}|} \log \left(\sigma\left(l_c\right)^{y_c} \left(1 - \sigma\left(l_c\right)\right)^{1-y_c} \right) \quad (6)$$

where $|\mathcal{C}|$ is the number of constraints per sentence, σ is the sigmoid function and l_c are the logits produced by the classifier for z_i. As in contrastive loss, the z_i can be produced by encoders of $\mathcal{S}$, $\mathcal{T}$ or from the hidden layers of the critic.

The overall training process is highlighted in Algorithm 1 where $\mathcal{L}_{con}$ and $\mathcal{L}_{clf}$ are weighted by λ_1 and λ_2. We choose $\lambda_1,\ \lambda_2 \in \{0, 1\}$.

4 Experiments

Datasets. We use three datasets with single attribute changes: $i)$ **Yelp Reviews**: business reviews listed on Yelp, labeled as either a positive or negative sentiment. $ii)$ **IMDb Movie Reviews**: consists of movie reviews (Dai et al., 2019) also labelled as positive or negative. $iii)$ **Political Slant**: consists of Facebook posts from the politicians of the United States Senate and the House of Representatives (Prabhumoye et al., 2018), labeled with either democratic/republican slant.

We provide a summary of the dataset statistics in Table 1. We include datasets of varied length and complexity. Apart from having different topics, the IMDB dataset is more formal compared to the more colloquial YELP. We fix the maximum vocabulary size for YELP, IMDB and POLITICAL at 30K which is also the default maximum vocab size used in (Zhao et al., 2018b).

Constraints: We constrain every sentence along *six* diverse dimensions that we desire to control

Model	Sampling	YELP				IMDB				POLITICAL			
		ACC	FL	SIM	AGG	ACC	FL	SIM	AGG	ACC	FL	SIM	AGG
DRG	greedy	67.4	54.5	**43.6**	16.7	56.5	44.3	**54.1**	14.4	61.3	35.7	38.7	8.8

Table 2: Evaluation of ARAE$_{seq2seq}$ with ACC (transfer accuracy), FL (fluency) and SIM (semantic similarity), AGG (aggregate metric). Cooperatively reducing the contrastive or the classification loss is better than ARAE. We report the mean of five runs for our experiments. The bolded measures are the best results

between the two domains: $i)$ **Lexical**: *Sentence length* – The transferred sentence should maintain a length similar to the original sentence (binarized to long sentences with 10 or or more words or short otherwise). $ii)$ **Syntactic**: Presence of personal pronouns (binarized to indicate the presence of a *personal pronoun*); number of adjectives (categorical up to 5); number of proper nouns (categorical up to 3); syntactic tree height (categorical up to 10). $iii)$ **Domain specific** – number of *domain-specific attributes* (Li et al., 2018) (categorical up to 5). Further, we label the sentence with a constraint-specific, catch-all label if the bounds are beyond what we mention above. Since the distribution of the labels may be different, we report the F1 score on our constraints.

4.1 Model Details

For the encoders, we use a one-layer LSTM network with 300 hidden dimensions for all the datasets. For the critics and classification loss, we use a two-layer multi-layer perceptron with 100 hidden units.

Training Hyper-parameters: For all our experiments we set the learning rate of the auto-encoder (lr_{ae}) to 1e-3 and (lr_{disc}) to 1e-4. The number of discriminator steps (n_{dis}) is set to 5. The Adam optimizer parameters β_1=0.5 and β_2=0.9, which ensures a more conservative optimization and is known to improve stability. We also add a gradient penalty to the loss function of the discriminator that stabilizes training. All the suggestions for stabilizing training are mostly obtained from (Arjovsky and Bottou, 2017).

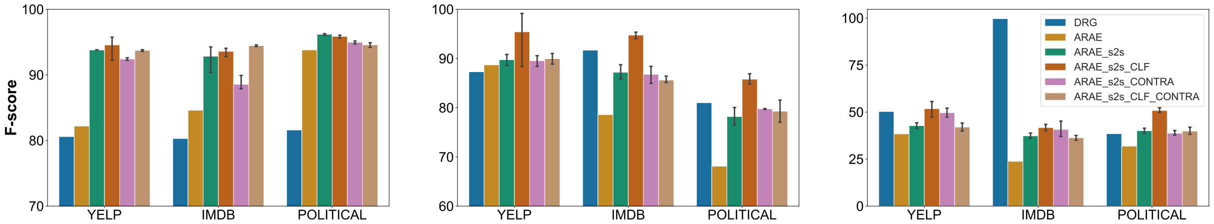
Inference Hyper-parameters: We used nucleus sampling with $p \in [0.6, 0.9]$. We tried different temperatures of scaling the softmax (Guo et al., 2017) - 0.4, 0.5, 0.6, 0.7 and chose the one that produced the best result on the dev set.

4.2 Evaluation Setup

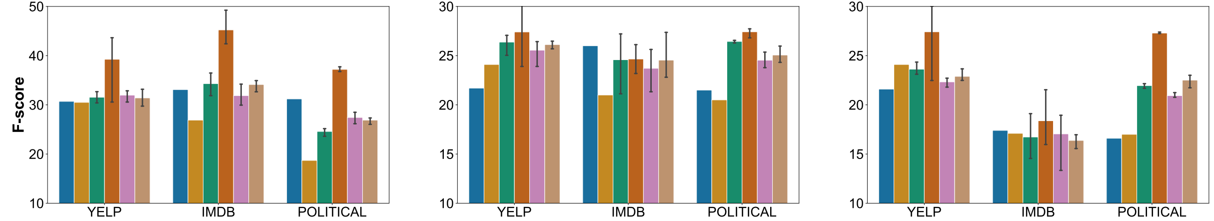
Automatic Evaluation: Our automatic evaluation considers the following three prominent criteria: $i)$ **Semantic Similarity (SIM):** Measured between source and translated target sentences using encoders (Wieting et al., 2019), instead of *n-gram* metrics like BLEU (Papineni et al., 2002) which have weak correlations with human judgments. $ii)$ **Transfer Accuracy (ACC):** The transferred sentence should belong to the target domain and a classifier is trained to distinguish between the source and the target sentence. We use *fastText* classifiers (Joulin et al., 2017) for every dataset. We achieve accuracy of 97.9 for YELP, 96.9 for IMDB and 97.1 for POLITICAL. $iii)$ **Fluency (FL):** A transferred sentence should be grammatically correct. We fine-tune a RoBERTa-large model on the COLA (Warstadt et al., 2018) dataset to indicate whether a sentence is linguistically acceptable. Finally, we combine the three scores into an aggregate, following the criteria suggested by Krishna et al. (2020):

$$AGG = \frac{1}{|S|} \sum_{s \in S} \text{ACC}\,(s) \cdot \text{SIM}\,(s) \cdot \text{FL}\,(s)$$

Human Evaluation: We also perform an indicative human evaluation where we randomly sample 100 samples from each of the three datasets and hire three researchers to rate every sentence for FL, SIM and ACC on a 3-point scale (Krishna et al., 2020).



(a) Length (b) Personal Pronouns (c) Proper Noun



(d) Descriptive (e) Tree Height (f) # Domain Attributes

Figure 3: F-scores of different constraints. Adding cooperative losses helps in better maintaining the constraints. The error bars show the variance of generating text using greedy decoding and nucleus sampling with $p = \{0.6, 0.9\}$.

4.3 Baselines

We compare ARAE$_{seq2seq}$ with the following baselines: **a) DRG**: The Delete, Retrieve, Generate method that deletes domain specific attributes, retrieves a template and generates the target domain text (Li et al., 2018). We use the stronger, entire system rather than the weaker DELETEONLY and RETRIEVEONLY baselines; **b) ARAE**: Adversarially regularized autoencoders our system is based on (Zhao et al., 2018b); **c) ARAE$_{seq2seq}$**: Our model without the contrastive learning or cooperative classifier; **d) ARAE$_{seq2seq}$ + CONTRA**: Our model with the contrastive learning; **e) ARAE$_{seq2seq}$ + CLF**: Our model with the cooperative classifier; **f) ARAE$_{seq2seq}$+CLF+CONTRA**: Our model with both the cooperative losses. The closest model to ours is from (Huang et al., 2020). However, we were not able to reproduce the results.[4]

4.4 Results

4.4.1 Overall Results

ARAE$_{seq2seq}$ + CONTRA and ARAE$_{seq2seq}$ + CLF consistently perform better than DRG and ARAE on the AGG score (Table 2). The AGG for YELP is 20.6 (vs. 19.8), for IMDB it is 28.1 (vs. 19.9) and for POLITICAL 25.5 (vs. 11.0). Although cooperative loss reduction aims to satisfy the constraints between two domains, our results show that further regularization of the latent space not only brings advantages in satisfying the constraints but also improves performance (Lavoie-Marchildon et al., 2020).

Effect of Cooperative Loss Reduction on ACC FL and SIM: Across datasets, reducing cooperative losses improves ACC and FL and SIM to ARAE. Although DRG produces sentences with high SIM as most of the text from the original sentence is retained after the delete step, there is a large trade-off with ACC resulting in low AGG scores. Also, compared to ARAE, adding cooperative losses significantly increases the SIM, with the highest increase observed for POLITICAL. The reasons for this could be two-fold: i) since we mine positive sentences from a corpus that is grounded in real world events, most lexically-similar sentences may also be semantically similar (Guu et al., 2018), and ii) since we tie the encoders from the source and target domain, we extract domain-agnostic information before generation, which retains content.

Fluency (FL) also improves over all datasets. We hypothesize that reducing cooperative losses regularizes the latent space bringing fluent sentences closer together, enabling the decoder to produce semantically similar and linguistically acceptable sentences. The improvement for POLITICAL is less; we find these source sentences themselves are less fluent and contain many U.S. political acronyms, and that our system produces many out-of-vocabulary words affecting fluency.

Nucleus Sampling: Our system achieves the highest AGG score with greedy decoding. We also experiment with nucleus sampling (Holtzman et al., 2019) with different p values. We report results for only p=0.6 in Table 2, as it produced the best result.

---

[4] Repeated attempts to obtain the original source code failed.

Model	ACC	FL	SIM	AGG
ARAE$_{seq2seq}$ + CLF	95.0	83.2	34.2	27.5
– generator	96.2	87.2	31.3	26.7
– critic	94.9	84.4	30.8	25.5
ARAE$_{seq2seq}$ + CONTRA	96.1	80.6	36	28.6
– generator	93.5	78.8	34.0	26.0
– critic	90.1	67.8	39.5	24.9
$\|P\| = 1$	92.4	75.5	36.6	26.2
$\|P\| = 2$	96.1	80.6	36.0	28.6
$\|P\| = 5$	96.0	84.0	31.4	26.0
$\|P\| = 10$	95.5	83.3	31.8	26.0

Table 3: Ablation study showing for cooperative losses not added to the generator (–generator) and the critic (–critic) and with different # of positives on IMDB.

With p=0.6, the results are more diverse, increasing ACC as expected. However we find that with higher values of p, there is a trade-off with SIM resulting in a lower AGG score overall — similar to Krishna et al. (2020).

Effect of the Number of Positives: The number of positive and negative samples used for contrastive learning (Eq. 5) have a significant effect on the overall performance (Khosla et al., 2020; Chen et al., 2020; Henaff, 2020). Table 3 (*rows* $|P| \in \{1, 2, 5, 10\}$) shows the AGG scores on IMDB (for one of the runs), for different number of positives. We find that AGG is the highest with 2 positives per sample as also used by Khosla et al. (2020). Although increasing the number of negatives is beneficial for contrastive learning, when more than one positive example is available, using them brings further improvements (Khosla et al., 2020).

Cooperative Losses are Important on Both the Generator and Critic: Table 3 shows the importance of adding the cooperative losses on the generator and critic. First, we see that adding the cooperative losses on both the generator and the critic is crucial for the overall performance. While adding the cooperative contrastive loss to both the generator and critic increases FL and ACC while maintaining similar levels of SIM, adding the cooperative classification loss improves SIM which shows the complementary nature of the losses.

Human Evaluation: We average the results and present it in Table 4. DRG produces marginally better semantically similar sentences. Compared to ARAE, our model performs well except for in YELP. This may be because we use nucleus sampling with 0.9 which optimizes for diversity rather than similarity. On other metrics we perform on par or better than our competing systems. (See Appendix B)

Dataset	Model	ACC	FL	SIM
YELP	DRG	2.3	2.1	2.1
	ARAE	**2.8**	**2.4**	**2.1**
	OURS	**2.8**	**2.4**	2.0
IMDB	DRG	1.9	2.0	**2.2**
	ARAE	2.5	2.1	1.4
	OURS	**2.6**	**2.2**	2.1
POLITICAL	DRG	2.3	2.2	2.1
	ARAE	2.1	2.1	1.5
	OURS	**2.5**	**2.4**	**2.2**

Table 4: Human evaluation of generated sentences.

Qualitative Examples: Table 5 shows examples of the quality of transferred examples (see Appendix A for more). Mistakes made by the model can be attributed to poor understanding of the original semantics, lack of diversity, and not producing attribute-specific words.

4.4.2 Maintaining Constraints

Figure 3 shows that introducing the cooperative losses significantly outperform DRG and ARAE in maintaining constraints. Specifically the ARAE$_{seq2seq}$ + CLF model performs better than ARAE$_{seq2seq}$+ CONTRA. One reason could be that, finding the appropriate positives and strong negatives can be problematic for contrastive learning. On the other hand, the classifier's objective is simpler and forces the encoder to produce representations that satisfy the different constraints effectively.

A seemingly easy to maintain constraint is the length of the sentence. However, *seq2seq* systems have a difficulty of maintaining appropriate lengths (Murray and Chiang, 2018). With no additional regularization ARAE does not maintain the length as well as ARAE$_{seq2seq}$ + CLF. On the other hand, compared to the lexical constraints, syntactic attributes like descriptiveness, tree height and domain specific constraints present challenges, with significantly lower F scores. ARAE$_{seq2seq}$ + CLF produces significantly better results in maintaining them. This shows that obtaining improvements on the overall AGG does not necessarily translate to producing outputs that satisfy constraints. DRG maintains the proper noun for IMDB effectively, because it contains a wide variety of actor and movie names. They are retained verbatim after the delete operation.

Multiple Attribute Datasets: To test whether our model can satisfy constraints across domains where multiple attributes change, we use the multi-attribute dataset released by (Lample et al., 2019).

Dataset	**Input**	**Output (Ours)**	**Output (ARAE)**
YELP	they close earlier than posted hours	they're open late night	they keep me getting better
IMDB	this movie is a very poor attempt to make money using a classical theme.	this movie is a very good example of a film that will never be forgotten.	this is a film that has been a lot of times and it's really good.
POLITICAL	i wish u would bring change	and i wish you would help bring democracy	and i 'm not sure mr.trump.

Table 5: Example outputs generated by the best system according to AGG score.

Constraint		
Personal Pronoun	*Source* (IMDB)	jean seberg had not one iota of acting talent.
	Ours	michael keaton was also great in his role.
	ARAE	john abraham had one of my favorite roles .
Proper Pronoun	*Source* (IMDB)	chris klein's character was unlikable from the start and never made an improvement
	Ours	robert de niro was very good as the man and she's never been
	ARAE	both of his character was made and had a huge smile on me

Table 6: Table showing constraints satisfied by our system compared to ARAE. Our method maintains constraints like number of proper nouns between sentences.

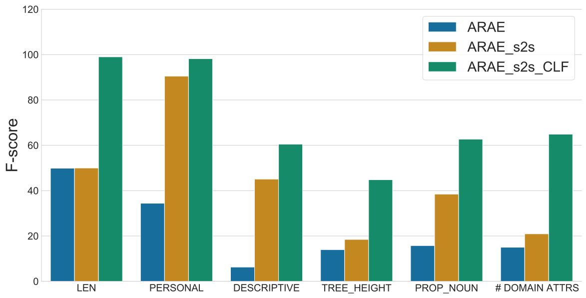


Figure 4: Comparison of ARAE, ARAE$_{seq2seq}$ and ARAE$_{seq2seq}$ + CLF for different constraints.

We chose the ASIAN and MEXICAN as two domains. Each of these domains can have multiple attributes like positive and negative sentiment text, different gender attributions to sentences, etc. We compare our ARAE$_{seq2seq}$ + CLF model with the ARAE$_{seq2seq}$ and ARAE in Figure 4. The results are more pronounced in this case with ARAE$_{seq2seq}$ + CLF having clear advantage over ARAE$_{seq2seq}$. This shows that even with multiple attributes changing between domains, cooperatively reducing losses can satisfy different constraints more effectively.

Qualitative Examples: Table 6 shows examples of our model maintaining constraints compared to ARAE. Sometimes, ARAE hallucinates and adds personal pronouns like "my" to the text even when there are no personal pronouns (*row* 1). Also, our model produces sentences where the number of proper nouns are retained (Chris Klein vs. Robert De Niro), whereas ARAE does not.

5 Discussion and Limitations

Cycle Consistency Loss: a) *In Latent Spaces* - Cycle consistency in latent spaces has been shown to improve word-level tasks, such as cross-lingual dictionary construction (Mohiuddin and Joty, 2019) and topic modeling (Hu et al., 2020). A recent work from (Huang et al., 2020) claims to improve unsupervised style transfer using such losses. In our experiments, however, it did not result in any noticeable performance improvement [5]. Given this, we hypothesize that cycle consistency might be too restrictive for sentence-level tasks. b) *Using Back-Translation*- Back-translation is another alternative to ensure semantic consistency between source and the target sentence (Prabhumoye et al., 2018; Artetxe et al., 2018; Lample et al., 2017). However, in our case, since we are training an ARAE, it would involve an additional inference and auto-encoder training step which is expensive and we defer exploring this.

Using Transformers: We also replace our LSTM auto-encoders with both pre-trained and randomly initialized transformer encoder–decoders (Rothe et al., 2020). Although we found an increase in the AGG, it was mostly because of very high SIM and very low ACC. Reducing the number of layers, attention heads would still result in a large model that is still prone to copying text. This reveals the potential limitations of our method and training using transformers is a future work.

Transferred sentences as Adversarial Examples: We demonstrate an important application of our proposed constrained transfer by considering them as adversarial examples for domain adaptation. Domain Adversarial Neural Network (DANN) (Ganin et al., 2017) is an unsupervised domain adaptation method that improves performance of an end-task (e.g, sentiment analysis) on a target domain considering only supervised data from source domain. We train DANN for sentiment analysis on amazon reviews dataset (He and McAuley, 2016) with DVD as source and ELECTRONICS as the tar-

---

[5] Repeated attempts to obtain source codes failed.

get domain – achieving an accuracy of 83.75% on ELECTRONICS.

Next, we train the best variant of ARAE$_{seq2seq}$ to transfer a separate set DVD reviews to ELECTRONICS reviews and use them as adversarial examples to test the DANN model [6]. We find that the accuracy of DANN on the ELECTRONICS domain reduces by ∼3 points. This shows the potential application of domain transferred sentences as adversarial examples. Similar ideas have been tried for image style transfer (Xu et al., 2020), but needs more investigation in NLP.

6 Related Work

Text attribute transfer has a vast literature (Jin et al., 2020a) with deep learning methods becoming popular. The methods are either supervised (requiring parallel data) or unsupervised. Supervised methods re-purpose Sequence to Sequence models used in machine translation to achieve the goals (Rao and Tetreault, 2018). However, obtaining parallel data is cumbersome and thus unsupervised methods that consider pseudo-parallel data have become popular.

Disentanglement approaches are the prevalent approach to tackle unsupervised attribute transfer: *attributes* and *content* are separated in latent dimension. To disentangle the attributes adversarial methods maximize the loss of a pre-trained attribute classifier (Li et al., 2020; Fu et al., 2018; Zhao et al., 2018a; John et al., 2019). However, the literature has paid little attention in defining and preserving content. Cycle consistency losses – imposing that reconstruction from the target style sentence should resemble the source sentence – is the most prevalent (Prabhumoye et al., 2018; Logeswaran et al., 2018; Dai et al., 2019; Huang et al., 2020; Yi et al., 2020). However, this is expensive and non-differentiable, thus requiring reinforcement learning techniques to enforce it. Our work defines the different constraints that should be preserved and adds simple differentiable contrastive learning losses to preserve them.

In recent times, text style transfer models are moving away from disentanglement approaches (Subramanian et al., 2018). Recent works that use transformers for style transfer also have adopted this (Dai et al., 2019; Krishna et al., 2020). However, these methods do not explicitly maintain the constraints between the two styles which is the main aim of our work.

7 Conclusion

Text style transfer works focuses on retaining content and changing the style of sentences but does not maintain other desirable constraints. We address this by introducing two cooperative losses to the GAN-inspired Adversarially Regularized Autoencoder (ARAE) that further regularizes the latent space. While satisfying the constraints our methods brings significant improvements in overall score. While we focus on simple constraints at the sentence- and word-level, future work can add phrase-level and more fine-grained constraints. Potential future work may explore reinforcement learning losses to directly optimize the constraints.

Acknowledgments

We would like to thank the anonymous reviewers for their useful suggestions. We would also like to acknowledge the support of the NExT research grant funds, supported by the National Research Foundation, Prime Ministers Office, Singapore under its IRC@ SG Funding Initiative, and to gratefully acknowledge the support of NVIDIA Corporation with the donation of the GeForce GTX Titan XGPU used in this research. The work is also supported by the project no. T2MOE2008 titled CSK-NLP: Leveraging Commonsense Knowledge for NLP awarded by Singapore's Ministry of Education under its Tier-2 grant scheme.

A Transfer Results

More transfer results are mention in Table 8. Examples where our system fails with plausible explanation are given in Table 9. Examples of translation from the multi-attribute dataset is shown in Table 10.

B More details on Human Evaluation

For FL, 0 indicates not fluent at all, 1 indicates somewhat fluent and 2 is a completely fluent sentence. We explicitly ask the annotators to consider semantic similarity for SIM, irrespective of whether the target sentence shares some phrases with the source sentence, with 1 indicating no semantic similarity and 3 indicating complete semantic similarity. For ACC, 1 indicates that the target sentence has only the source sentence style while 2 indicates good transfer to the target style.

Dataset	Metric	α
YELP	ACC	0.69
	FL	0.33
	SIM	0.49
IMDB	ACC	0.60
	FL	0.38
	SIM	0.48
POLITICAL	ACC	0.76
	FL	0.71
	SIM	0.71

Table 7: Krippendorff's alpha showing inter annotator agreement for YELP, IMDB and POLITICAL

We calculate the Krippendorff's alpha to assess the inter annotator agreement. Table 7 shows the inter-annotator agreement. An α of 0.4 is considered good agreeement (Hedayatnia et al., 2020). We have moderate to good agreements on all the datasets for different measures. On more inspection we found that the disagreements in fluency mostly arrives for small phrases like "my fav" although is an accepted phrase in social media text is considered 2 by one annotator and 3 by another. We also further note that, smaller sentences were easier to judge and had better agreement rates on SIM compared to longer sentences.

Information about participants: We hire three graduate researchers in NLP (average age 25) for the annotation task who are well versed in English. We obtained permission for their participation and compensated them appropriately according to hourly wages in the country. The specific instruction given to them for the evaluation are as follows.

Consider two sentences

- **Source sentence**: Sentence from the source domain
- **Target sentence**: The transferred sentence produced by one of the systems

For every target sentence you will be asked to rate it according to three measures described below.

Fluency: Indicate how fluent the target sentence is (regardless of whether the sentence is appropriately transferred to the target sentence)

1 - Not fluent at all - Does not look like an English sentence.

2 - Fluent but with some mistakes - Fluent but with some grammatical errors

3 - Entirely fluent. - A good English Sentence

Similarity: Indicate how semantically similar the target sentence is.

1 - Does not share any words/phrases with the source sentence and/or is not semantically similar (does not share high level topics of the sentence)

2 - Shares some words/phrases with the source sentence and/or has moderate level of semantic similarity (talks about similar high level topics)

3 - Shares appropriate words/phrases with the source sentence and is highly semantically similar

Accuracy: Indicate whether the target sentence is accurately transferred to the target domain

Sentiment Transfer

1 - The target sentiment is not evident in the target sentence at all. Has words expressing opposite sentiment

2 - Neutral Sentiment. Choose this option, if it has both positive and negative sentiment

3 - The target sentiment is evident in the target sentiment. Has appropriate sentiment bearing words.

If the sentence itself has no sentiment then chose 2

Political Orientation

1 - Talks about topics with the other orientation. For example, if the target style is democratic and the target sentence talks about conservative issues like abortion, gun control

2 - Neutral.

3 - Talks about topics with the correct orientation. For example, if the target style is democratic and talks about progressive issues like liberty, free speech, Elizabeth Warren, Joe Biden, gay rights etc.

Dataset	Source	Target
YELP	consistently slow.	consistently good.
YELP	so nasty.	so delicious!
YELP	i hate mayonnaise.	i love chipotle!
YELP	i 'm so disappointed!	i 'm so impressed!
YELP	but service was horrible both times.	but service was really good & fast.
YELP	now the service i experienced was bad.	now i have the best service.
YELP	the chicken tenders did n't taste like chicken	wtf?,the chicken marsala , really good tomato , love!
YELP	the food was nothing special and the service was slow.	the food was amazing , the service is good.
YELP	that's why i think its shady .	that's why i think its finest.
YELP	that stuff was awful.	that's delicious!
YELP	disgusting all around.	great , all around.
YELP	the rice was dry.	the rice was delicious.
YELP	the sweet and sour chicken is hit and miss.	the sweet and sour chicken is a winner here.
IMDB	the dialog is poorly written	the writing and direction are so precise, and he captures the spirit.
IMDB	i'm a sucker for a good pirate movie, but this ain't it.	i'm a huge fan of the genre , but this movie is definitely worth it.
IMDB	don't see this movie.	don't miss this movie.
IMDB	terrible movie made on zero budget.	absolutely amazing movie on tv.
IMDB	maybe the worse movie i have ever see.	maybe the best movie i have ever seen.
IMDB	never would i recommend this movie to my worst enemy, yet anybody i actually like.	i would recommend this movie to anyone who enjoys good wholesome, clean fun.
IMDB	tedious, not hilarious.	real, great.
IMDB	this movie is truly one of the worst movies i 've ever seen.	this movie is one of the best movies i 've ever seen.
IMDB	it was one of the shortest movies i 've ever seen, and thank god!	it was one of the most original films i've ever seen, and i'm glad.
IMDB	do not watch this movie sober.	do not miss this movie.
IMDB	wesley snipes is a far more accomplished actor than to be in this.	rob roy is a great actor in his own right to date.
IMDB	this film is a real yawner.	this film is a true delight.
IMDB	my rating : 2/10.	my vote : 9/10.
IMDB	some competent acting talent was squandered.	an excellent performance by everyone.
POLITICAL	support you, rand.	support you, elizabeth.
POLITICAL	borders first.	equal rights
POLITICAL	keep telling yourself that	ted.,keep telling that truth, keith.
POLITICAL	just love the constitution.	just love the dnc.
POLITICAL	for supporting clemson and for working for a balance budget .	for supporting student loans for a working and fair job.
POLITICAL	for you service trey !	for you service kamala!
POLITICAL	save america!	save us elizabeth
POLITICAL	stand with your constituents and vote to defund obama care.	stand with your constituents and vote for bernie sanders' bill!!
POLITICAL	poliquin has been a strong voice for the people of northern maine he has my vote	carol has been doing a great job for the people of this state of ohio.

Table 8: More examples from our best performing model for YELP, IMDB, POLITICAL

Dataset	Source	Target	Explanation
YELP	completely outdated, old hotel.	completely charming and old school.	The model produces mixed sentiments without understanding that “old school” has negative connotations
YELP	bad service, bad food.	great food, amazing food.	Lack of diversity in the generation and the model does not produce outputs with respect to service
IMDB	music is boring, and starts to annoy after 15-20 minutes.	its an epic and very moving film, without being preachy.	The model fails to produce semantically similar sentence. Probably because music is not a frequent topic in the dataset
IMDB	brad pitt overacts appallingly.	john woo does it.	Although the the model reproduces a name, it does not produce a fluent sentence
POLITICAL	obamacare, no one wants it!!	al, no one cares it.	Does not understand that "Obamacare" is an entity and hallucinates and uses "care" as a verb
POLITICAL	are clearly not republican anymore!	are not enough sen booker.	Hallucinates Sen Booker which appears frequently in the dataset

Table 9: Mistakes that ARAE$_{seq2seq}$ makes and plausible explanations

Source	**Target**
by far, the best spot for ramen. simple menu. fast service. silky, creamy chicken broth.	by far the best breakfast tacos in the area. friendly staff. great food. ask for the spicy chicken, and they have a great selection.
try sushi boat. it's totally amazing. they offer good food and high quality. good sake is ready. thank you for good place.	love it. good food. they have good margaritas and good food. good prices. there's a good amount of food for you.
best thai in austin. we love the atmosphere, the service and obviously the food. they did a great job last time we were there since our party had specific requirements like <unk> free and <unk>.	best mexican food in the area. the service was great and the food was so good. we had a party of 10 and they were very accommodating to our group of us. we were there last night and the food was good
fabulous, delicious, authentic. at lunch on a saturday the place was packed! 20 minute wait for a table. i was one of two customers who was not chinese. i 'll be back frequently.	awesome mexican food, a little on the corner of a <unk>. i was here on a saturday night. they were busy, but we were able to get a table. i will definitely be back!
this place is great! i grew up going to china inn in chamblee plaza and it's the same owner! lunch service is fast and delicious! give it a shot, you won't be disappointed !	this place is awesome!! i've been coming to this location for years and it's always clean and the service is fast and friendly. it's a great mexican restaurant, you can't go wrong with the food!
awful. i'm writing this as i eat it now. worst poke bowl i've ever had. the smallest portion of poke possible, <unk> overcooked rice, and barely got any ponzu. most standard toppings cost extra too.	awful! i've never had a bad meal here. i only ordered two of them. the only thing i didn't like was the <unk>. it's not much flavor, but the meat is dry.
worst chinese food experience i ever had. told the manager about my allergies and that all i wanted was vegetable fried rice no soy sauce they couldn't even handle that!!! amateur hour here don't waste your time. go to china blossom	worst experience ever. i ordered the <unk> and they were all wrong with that i couldn't eat the food. that's how i don't care about how they charge you for the fajitas. no one ever came to eat here.
the food was terrible. it definitely was not fresh. the broccoli was over cooked on my beef broccoli. my chicken chow mean fried rice just looked and tasted like last weeks rice. there was one chunk of chicken and <unk> pieces of egg in	the food was just ok. the chicken was dry. it was very dry. i ordered the chicken chimichanga and it was just plain gross. the only thing that was <unk> was the chicken burrito. there was only one other person in the <unk>

Abstract

Understanding causality has vital importance for various Natural Language Processing (NLP) applications. Beyond the labeled instances, conceptual explanations of the causality can provide deep understanding of the causal facts to facilitate the causal reasoning process. However, such explanation information still remains absent in existing causal reasoning resources. In this paper, we fill this gap by presenting a human-annotated explainable CAusal REasoning dataset (e-CARE), which contains over 21K causal reasoning questions, together with natural language formed explanations of the causal questions. Experimental results show that generating valid explanations for causal facts still remains especially challenging for the state-of-the-art models, and the explanation information can be helpful for promoting the accuracy and stability of causal reasoning models.

1 Introduction

Causal reasoning is one of the most central cognitive abilities of human beings (Waldmann and Hagmayer, 2013; Jonassen et al., 2008), which enables one to understand the observed facts and predict the future. However, although recent causal reasoning models have achieved impressive performances on certain hand-crafted datasets, there still remains a considerable gap compared to human performances, as they cannot achieve stable performances across different datasets and are susceptible to adversarial attacks (McCoy et al., 2019; Poliak et al., 2018; Gururangan et al., 2018).

One key factor leading to such drastic contrast is that, present causal reasoning models only learn to induce empirical causal patterns that are predictive to the label, while human beings seek for deep and conceptual understanding of the causality to explain the observed causal facts. The conceptual explanations can not only serve as a touchstone to examine whether the underlying causal mechanism has been thoroughly understood, but it can also in turn support the causal reasoning process. As illustrated in Figure 1, observing the causal fact C_1: *adding rock into hydrochloric acid* causes E_1: *rock dissolved*, one may further ask *why such a causal relationship exists* and reach the plausible *conceptual explanation* that *Acid is corrosive*, which goes beyond the isolated facts and reaches the conceptual nature to reveal the principle of the causal mechanism.

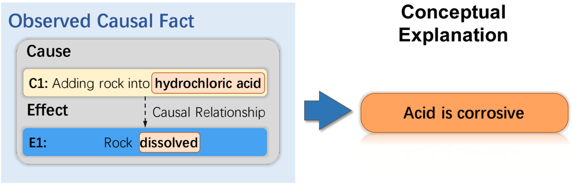

Figure 1: Conceptual explanations of observed causality can be helpful for understanding the unseen causal facts.

However, despite the critical importance of conceptual explanations in causal reasoning, there is still a lack of such an explainable causal reasoning dataset. To fill this gap, we contribute an explainable CAusal REasoning dataset (e-CARE),together with a new causal explanation generation task, and a novel Causal Explanation Quality (CEQ) evaluation metric.

The e-CARE dataset is constructed by crowdsourcing and contains over 21K multiple-choice causal reasoning questions, which makes e-CARE the largest human-annotated commonsense causal reasoning dataset to the best of our knowledge. In addition to the causal reasoning question itself, e-CARE also provides a free-text-formed conceptual explanation for each causal question to explain why the causation exists. On this basis, we propose a new causal explanation generation task that requires models not only to choose the correct causal fact but also to generate the ex-

May 22-27, 2022

planation for the choice. In addition, to directly measure the quality of generated explanations, we propose a novel causal explanation quality evaluation metric (namely, CEQ score). Compared to conventional text generation evaluation metrics such as BLEU (Papineni et al., 2002) and ROUGE (Lin, 2004) which mainly evaluate the textual or semantic similarity between generated explanations with golden annotations, CEQ score focuses on evaluating how much promotion an explanation can bring to understanding the causal mechanism. The dataset is publicly available at `https://github.com/Waste-Wood/e-CARE/`.

Experimental results demonstrate that the causal questions of e-CARE are still challenging for the state-of-the-art (SOTA) pretrained language models, indicating the effectiveness of the e-CARE dataset in evaluating the causal learning ability of models. In addition, the explanation signal received in the training process can enhance the performance and the stability of the reasoning model, while the SOTA baselines still have trouble in explaining the causal facts at a conceptual level. These analyses highlight the importance of the conceptual explanations in causal reasoning, and suggest an avenue for future researches.

2 Related Work

2.1 Commonsense Causal Reasoning Datasets

Existing commonsense causal reasoning corpora differ in their annotation guidelines and how they are constructed: (1) whether the corpus is automatically constructed or built by human annotation; (2) whether the annotation unit of the corpus is word-level, phrase-level, or sentence-level.

To obtain abundant causal knowledge, a natural way is extracting causal knowledge using heuristic rules from large-scale open-domain web text corpora (Luo et al., 2016; Li et al., 2020; Sap et al., 2019). However, the reporting bias may challenge both the coverage and quality of the extracted causal knowledge.

Different from automatic construction, human annotation can endow datasets with higher precision. A line of work focuses on providing word-level causality knowledge (Girju et al., 2007; Mostafazadeh et al., 2016; Do et al., 2011; Hendrickx et al., 2019). However, a word is not a complete semantic unit, which may limit the integrity of causal expressions and lead to ambiguity. To address this issue, other datasets are constructed to provide phrase-level (Caselli and Vossen, 2017; Bethard and Martin, 2008; Mirza et al., 2014; Dunietz et al., 2017) and sentence-level (Ning et al., 2019; Roemmele et al., 2011) causal knowledge. Among these datasets, COPA (Roemmele et al., 2011) has become a widely adopted benchmark. Nevertheless, the size of COPA is rather limited, which may result in overfitting and arouse concerns about the confidence of the results.

Table 1: A list of previous commonsense causal reasoning datasets. In the column “Annotation Unit”, “W”, “P” and “S” are abbreviation of word, phrase and sentence, respectively. “Expl.” is the abbreviation of “Explanation”.

In this paper, we introduce an *e*xplainable CAusal REasoning dataset (e-CARE). As shown in Table 1, to the best of our knowledge, e-CARE is the largest human-annotated causal reasoning dataset. With more than 21,000 instances, the e-CARE dataset can serve as a more reliable benchmark. Furthermore, compared to previous work, e-CARE can provide additional explanation information, which plays a critical role in learning the underlying mechanism of causal knowledge.

2.2 Explainable Textual Inference

Recently, an increasing amount of datasets have been proposed to address the explainability of textual inference tasks, such as textual entailment inference (Camburu et al., 2018), question-answering (QA) (DeYoung et al., 2019; Perez et al., 2019) and multi-hop QA (Ye et al., 2020). The form and content of the explanations vary with the nature of specific tasks.

The QA task requires a model to answer the question based on evidences within given texts. Therefore, the explanation for this task should de-

Number	Train	Dev	Test	Total
Causal Questions	14,928	2,132	4,264	21,324
Uniq. Explanations	10,491	2,102	3,814	13,048

Table 2: Corpus level statistics of the e-CARE dataset. Uniq. Explanations refer to the explanations that only correspond to a single causal fact.

Premise: Tom holds a copper block by hand and heats it on fire.	
Ask-for: Effect	
Hypothesis 1: His fingers feel burnt immediately.	(✓)
Hypothesis 2: The copper block keeps the same.	(×)
Explanation: **Copper is a good thermal conductor.**	

Table 3: An instance from the e-CARE dataset.

scribe where and how an answer can be found (Wiegreffe and Marasović, 2021). The explanations can have various forms, including answer-bearing sentences (Perez et al., 2019), structured information connecting the question and answer (Hancock et al., 2018; Ye et al., 2020), or even human-annotated free-formed sentences (Camburu et al., 2018; Rajani et al., 2019). In contrast, the multi-hop QA task requires the model to infer the correct answer through multiple reasoning steps. Hence, the explanation of this task needs to provide the specific reasoning paths (Wiegreffe and Marasović, 2021; Jhamtani and Clark, 2020).

Our work is quite different from previous work. We notice that all of these previous work only offer explanations that explain a specific question. Whereas we aim at providing a conceptual understanding of the causality, which has the potential to explain *a set of related causal observations*, rather than only explain a specific causal fact.

3 e-CARE: an Explainable Causal Reasoning Dataset

e-CARE contains a total of 21,324 instances, corresponding to 13,048 unique explanations. This also makes e-CARE the largest human-annotated commonsense causal reasoning benchmark. The corpus-level statistics of the e-CARE dataset are shown in Table 2.

As shown in Table 3, each instance of the e-CARE dataset is constituted by two components: (1) a multiple-choice causal reasoning question, composed of a premise and two hypotheses, and one of the hypotheses can form a valid causal fact with the premise; (2) a conceptual explanation about the essential condition that enables the existence of the causal fact. For example, as Table 3 shows, the *explanation* points out the nature of copper that *Copper is a good thermal conductor*, so that holding copper on fire will make fingers feel burnt immediately. The appendix provides more discussion about the explanations within e-CARE. On this basis, we introduce two tasks:

Causal Reasoning Task We formulate the causal reasoning task as a multiple-choice task: given a premise event, one needs to choose a more plausible hypothesis from two candidates, so that the premise and the correct hypothesis can form into a valid causal fact.

Explanation Generation Task It requires the model to generate a free-text-formed explanation for a given causal fact (composed of a premise and the corresponding *correct* hypothesis).

3.1 Data Annotation

To construct the e-CARE dataset, we start by collecting statements that describe conceptual understandings of world knowledge. Then given a statement, we ask different annotators to generate causal facts that can be explained by the statement, and build causal questions based on these causal facts. This is because we hope to provide conceptual explanations with more generality, that can explain a set of correlated causal facts, instead of only applicable to a certain isolated causal fact. Moreover, the statements can serve as clues to help the annotators to come up with causal facts.

Collecting Potential Explanations Two key issues remain in collecting statements as potential explanations: (1) what kind of statements can be potential conceptual explanations of the causal facts; (2) where to find the appropriate statements.

For the first question, Jonassen et al. (2008) concluded that, in general, the explanation of causality mainly describes three categories of information: (1) the nature or attributes of the objectives involved in the causal facts; (2) forces or actions that cause changes and drive transient motions; (3) the goals, intentions, motives or purposes of the causal agents. In addition, to be the conceptual explanation of a causal fact, the statement should be able to involve with a category of objects or people, but not only focus on a specific object or person (Sembugamoorthy and Chandrasekaran, 1986).

Following these principles, we notice that there are already several available knowledge bases containing statements about such generic world knowledge, including ConceptNet (Speer and Havasi, 2013), WordNet (Fellbaum, 2010), Atomic (Sap et al., 2019) and GenericsKB (Bhakthavatsalam et al., 2020). However, ConceptNet and WordNet are structured knowledge graphs, containing only triplet-structured statements with a limited number of predicates. The scope of Atomic is limited in the activities of human beings. Compared to these knowledge bases, GenericsKB is an open-domain, large-scale knowledge base, containing rich generic world knowledge described in free-form text. Therefore, we collect the statements from GenericsKB to ensure the coverage and diversity of the potential explanations.

Specifically, we filter out the statements in GenericsKB with low reliability, and the statements that may disobey the above-mentioned three principles. More details are provided in the Appendix. Thereafter, a total of 19,746 statements are left to form into a potential explanation set, which is further provided to the annotators to generate the causal questions.

Annotating Causal Reasoning Questions Given the potential explanation set, annotators were recruited to generate corresponding causal questions. Specifically, a causal question is generated by two steps:

First, an annotator was presented with a statement as a potential explanation, and was instructed to write a causal fact (composed of a cause and an effect), so that the causal fact can be interpreted by the given statement. In this step, a key issue is controlling the quality of generated causal facts. Thus we demonstrated illustrative examples to guide the annotators to avoid the following mistakes:

(1) The created cause and effect are not in a valid causal relationship;

(2) The created causal fact cannot be explained by the provided statement;

(3) There are factual errors or imaginary contents in the created causal facts.

In the causal fact generation process, each statement is randomly distributed to 1-3 annotators, so that we can find some statements that could explain multiple causal facts. Note that, in this process, we do not assume all statements are necessary to be a valid explanation. In other words, we do not require that the annotators must generate a causal fact for each given statement. Instead, we leave it to the judgment of annotators. In this way, the unreliable statements can be further excluded to promote the quality of our dataset.

Model	Dev	Test
Random	50.1	50.1
GPT2 (Radford et al., 2018)	57.17	56.30
RoBERTa (Liu et al., 2019)	58.38	56.42
BERT (Devlin et al., 2019)	56.19	54.45

Table 4: Model's accuracy (%) of choosing the correct hypothesis without the premise.

After the generation of causal facts, an ask-for indicator $a \in$ ["cause", "effect"] was randomly generated, where $a =$ "cause" ("effect") means that the cause (effect) event is the hypothesis, and the effect (cause) event is the premise of the causal question, respectively. Then given the ask-for indicator, in order to control the grammar and writing style consistency, the same annotator was prompted to write a distract cause (effect) as the implausible hypothesis according to the ask-for indicator. In this process, the annotators were instructed to create the implausible hypothesis as close as possible to the true hypothesis, meanwhile prevent creating uninformative distractors (such as simply adding a "not" into the true hypothesis).

3.2 Refinement and Analysis of the e-CARE Dataset

A significant challenge in dataset construction is avoiding introducing *superficial cues* into the dataset (Gururangan et al., 2018; Poliak et al., 2018), which refers to the unintentional features that leak the label information. To address this issue, following Bhagavatula et al. (2019) and Sakaguchi et al. (2020), we employ an adversarial filtering algorithm to replace the implausible hypotheses that can easily be distinguished with the correct hypotheses using the superficial clues. More details about the adversarial filtering are provided in the Appendix. As Table 4 shows, after the adversarial filtering, without the existence of the premise, the SOTA pretrained language models can hardly distinguish two candidate hypotheses, which indicates that to predict the correct label, a model must understand the causal relationship between the premise and hypothesis, rather than only depend on the superficial cues within the two hypotheses.

After the refinement, we evaluate the quality of the annotated causal questions and collected explanations through crowdsourcing. We assess the quality of causal questions by testing if there is agreement among human raters on the answer of causal questions. Specifically, we randomly sampled 200 causal questions from e-CARE, and enlisted 10 annotators to answer the causal questions. In this process, each causal question was evaluated by three annotators. When answering the causal questions, the raters were allowed to choose an additional option "None of the above" if neither hypothesis was deemed plausible. The human annotators achieve a 92% accuracy with a high agreement (Cohen's κ = 0.935) (Cohen, 1960).

To validate the quality of explanations, we enlisted volunteers to determine whether or not the explanations can explain corresponding causal facts. In total 200 causal facts with corresponding explanations were sampled and distributed to 10 volunteers, and each explanation was evaluated by three volunteers. After the evaluation, on average 89.5% of the explanations were deemed as valid (Cohen's κ = 0.832), showcasing the quality of the explanations in e-CARE.

4 Causal Explanation Quality (CEQ) Score

A number of automatic scores have been proposed to evaluate the quality of generated explanations, such as BLEU (Papineni et al., 2002) and ROUGE (Lin, 2004). However, these metrics evaluate the quality of the generated explanations only through comparing the textual or semantic similarity between the generated explanations and the golden annotation. Alternatively, an ideal causal explanation quality evaluation metric should directly measure if the causal fact is appropriately explained by the explanation.

Hence, we propose a novel causal explanation quality evaluation metric (namely, CEQ score) as a step towards directly measuring the quality of generated explanations. We devise the CEQ score based on the consideration that a better explanation should provide more information for understanding the causality, so that the prediction model can more accurately estimate the reasonableness of the causal fact. Previous literature characterized such reasonableness as the *causal strength* of the given causal fact (Roemmele et al., 2011; Luo et al., 2016), where the *causal strength* is a score in $[0, 1]$. Hence, in theory, for a valid causal fact, its causal strength should be equal to 1. Given a valid causal fact, an explanation should help to increase its estimated causal strength to the ground-truth value 1.

Therefore, we can evaluate the quality of a generated explanation by measuring the increase of causal strength brought by the explanation. Specifically, let C, E, and X denote the cause, the effect and the generated explanation, respectively. Formally, the CEQ score is defined as:

$$\text{CEQ} = \Delta_{\text{cs}} = \text{cs}(C, E|X) - \text{cs}(C, E), \quad (1)$$

where $\text{cs}(C, E)$ is the original causal strength between C and E; $\text{cs}(C, E|X)$ is the causal strength after involvement of the additional explanation information. The explanation enhanced causal strength $\text{cs}(C, E|X)$ is defined as:

$$\text{cs}(C, E|X) = max[\text{cs}(C + X, E), \text{cs}(C, E + X)], \quad (2)$$

where "+" denotes the string concatenate operation. Therefore, the CEQ score is positively related to the *increase of causal strength* between C and E after the involvement of the explanation X.

In this paper, we employ a widely-adopted model-agnostic method proposed by Luo et al. (2016) to calculate the causal strength. The model-agnostic nature enable us to avoid reliance on certain models and keep the fairness of evaluation. Specifically, the phrase-level causal strength is derived through synthesizing the word-level causality.

$$\text{cs}(C_A, E_B) = \frac{1}{N_{C_A} + N_{E_B}} \sum_{w_i \in C_A, w_j \in E_B} \text{cs}(w_i, w_j), \quad (3)$$

where (C_A, E_B) is an arbitrary causal fact; N_{C_A} and N_{E_B} are the number of words within C_A and E_B, respectively; $\text{cs}(w_i, w_j)$ is the causal strength between word w_i and w_j, which is estimated from a large corpus as:

$$\text{cs}(w_i, w_j) = \frac{\text{Count}(w_i, w_j)}{\text{Count}(w_i)\text{Count}(w_j)^{\alpha}}, \quad (4)$$

where α is a penalty coefficient and Luo et al. (2016) empirically set $\alpha = 0.66$.

5 Experiments and Results

We examine the performance of state-of-the-art pretrained language models on the causal reasoning task and the explanation generation task. Furthermore, we investigate the specific role of explanations in causal reasoning by: (1) a predict-and-generate experiment, which requires models to conduct the causal reasoning task and generate corresponding explanations simultaneously; (2) a stability analysis using adversarial attacks.

Model	AVG-BLEU	ROUGE-l	PPL	CEQ	Human Evaluation (%)
GRU-Seq2Seq	18.66	21.32	33.71	0.024	0
GPT2 (Radford et al., 2019)	32.04	31.47	7.14	0.105	20.0
Human Generation	**35.51**	**33.46**	-	**0.144**	**89.5**

5.1 Causal Reasoning

Settings We cast the causal reasoning task as a prediction problem: The input of the model is a candidate causal fact composed of a premise and one of the corresponding candidate hypotheses. The output is a score measuring the reasonableness of the candidate causal fact. We evaluate the causal reasoning ability of several SOTA pretrained language models, including discriminative pretrained language models BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), XLNet (Yang et al., 2019), and ALBERT (Lan et al., 2019); as well as autoregressive generative pretrained language models GPT2 (Radford et al., 2019) and BART (Lewis et al., 2020), which can also be adapted to the predictive causal reasoning task. In this section and the following parts, all experiments are conducted using the base-sized version of the pretrained language models. Additional details about experimental settings are provided in the Appendix.

Results As shown in Table 5, ALBERT achieves the highest accuracy of 73.86% on the causal reasoning task of e-CARE. However, ALBERT can achieve an accuracy of 86.0% on the widely adopted causal reasoning benchmark COPA by our implementation. This is mainly because, on one hand, previous causal reasoning datasets are too small to evaluate the genuine reasoning ability of the model. On the other hand, previous datasets may provide some superficial cues for the reasoning models to achieve superb performances. In contrast, e-CARE is the largest causal reasoning dataset that can provide enough test instances to evaluate the actual ability of the model. Moreover, in the annotating process of e-CARE, we introduced an adversarial filtering process to avoid the influence of superficial cues on the performances of reasoning models. Hence, we believe that e-CARE dataset can serve as a new benchmark for effectively evaluating models’ causal reasoning ability. We also notice that human beings can achieve an accuracy of 92.00% on the e-CARE dataset. The large gap between the human performance and the pretrained language models suggests that the causal reasoning questions provided in our dataset still remain challenging, and calls for more powerful causal reasoning models.

5.2 Explanation Generation

We investigate whether the model can generate correct explanations for given valid causal facts by training a GRU-based Seq2Seq model (Chung et al., 2014), and finetuning a generative pretrained language model GPT2 (Radford et al., 2019) on the e-CARE dataset. Both models take the concatenation of the cause and effect as input. Please refer to the Appendix for more details.

Evaluation Metrics We automatically evaluate the quality of generated explanations using average-BLEU (n=4) (Papineni et al., 2002), ROUGE-l (Lin, 2004), Perplexity (Horgan, 1995), together with our proposed CEQ score.

Human Evaluation We also assess the quality of model-generated explanations through human evaluation. Specifically, we sampled 200 explanations generated by each method. Then three workers were shown with the generated explanations, together with corresponding causal facts, and were asked to label whether the generated explanation can explain the corresponding causal fact.

Quantitative Results As shown in Table 6, 89.5% of human-written explanations are found to be valid, while the generative pretrained language

Causal Facts	**(Generated) Explanation**	**Human Annotation**	**CEQ**
Cause: He was infected with gram-positive bacteria. *Effect:* The doctor raised the lysozyme in his body.	Lysozyme is a chemical produced by the bacterium Bacillus thuringiensis to kill bacteria.	Lysozyme destroys cell wall of bacteria.	0.193
Cause: Pneumonia pervaded in this area. *Effect:* Many people died of Pneumonia.	Pneumonia is a leading infectious disease caused by a bacterium called Pseudomonas aeruginosa.	Pneumonia is the most common infectious disease leading to death.	0.069
Cause: Tom wanted to prevent cancer. *Effect:* The doctor told him to eat more foods containing Vitamin C.	Vitamin C is a naturally occurring amino acid found in many foods.	Vitamin C slow the growth of small cell lung cancer cells.	0.012

Table 8: Examples of explanations generated by GPT2. We highlighted the factual mistakes within the generated explanations and the totally irrelevant explanation in yellow and pink, respectively.

Model	**Accu (%)**	**AVG-BLEU**	**ROUGE-l**	**CEQ**	**Human Eval. (%)**	**ΔAccu. (%) after Adv. Attack**
GPT2$_{\text{CR}}$	69.51	-	-	-	-	-6.40
GPT2$_{\text{EG}}$	-	32.04	31.47	0.035	20.0	-
GPT2$_{\text{CR-EG}}$	**71.06**	**34.83**	**34.22**	**0.042**	**26.5**	**-5.49**

Table 9: Model performance on the test set of Joint Causal Reasoning and Explanation Generation task.

model GPT2 only achieves a correctness of 20.0%. The last row of Table 6 reports the score of held-out human-written explanations, which serves as a ceiling for model performance. The significant gap indicates that, although GPT2 can achieve impressive performance on various natural language generation tasks, it still remains especially challenging for GPT2 to deeply understand the causal facts and then generate explanations like human beings. This may be one of the main obstacles hindering the further improvement of present causal reasoning models.

Moreover, we measure the similarity between the automatic scores with the results of human evaluation using the Spearman correlation coefficient. As Table 7 shows, ROUGH-l and average-BLEU barely have a correlation with the results of human evaluation. This is because average-BLEU and ROUGH-l only implicitly evaluate the quality of generated explanations by measuring the textual similarity with the golden annotations. Compared to average-BLEU and ROUGH-l, the CEQ score has a significant positive relationship with the human evaluation results. This indicates the efficiency of the CEQ score in evaluating the quality of generated explanations.

Qualitative Analysis In Table 8, we provide examples of explanations generated by GPT2. We observe that GPT2 can generate a reasonable explanation for some causal facts, while the generated explanations may still contain factual mistakes, or be totally irrelevant to the given causal fact (highlighted in yellow and pink, respectively). This indicate that the explanation generation still remains challenging for the GPT2 model.

5.3 Joint Causal Reasoning and Explanation Generation

To investigate the role of causal explanations in the causal reasoning process, we trained models to jointly conduct these two tasks.

Settings Since this task requires a model to predict a label meanwhile generate an explanation, we conduct the experiments using the GPT2 model, which can be adapted to conduct the predictive causal reasoning task and explanation generation simultaneously. We denote this multi-task finetuned GPT2 model as GPT2$_{\text{CR-GE}}$. Details for training GPT2$_{\text{CR-GE}}$ is provided in the Appendix.

To make the performance comparable, when evaluating the performance of GPT2$_{\text{CR-GE}}$ on the causal expatiations generation task, the same as the settings in the explanation generation task, the premise and the *correct* hypothesis are taken as the input of GPT2$_{\text{CR-GE}}$ for generating explanations.

Results We measure the quality of generated explanations using the same automatic scores and human evaluation settings as the Explanation Generation experiment. The performance of causal reasoning is also measured using accuracy. The results are shown in Table 9, where GPT2$_{\text{CR}}$ denotes the GPT2 model finetuned for the causal reasoning task, and GPT2$_{\text{EG}}$ refers to the GPT2 model finetuned for the explanation generation task. We observe that compared with GPT2$_{\text{CR}}$, the improved performance of GPT2$_{\text{CR-EG}}$ on causal reasoning indicates that the additional explanation can be helpful for the causal reasoning task, as it prompts model to have a deep understanding of the causal mechanisms. Interestingly, by comparing with GPT2$_{\text{EG}}$ and GPT2$_{\text{CR-EG}}$, we find that learning to predict the label can also be helpful for the explanation generation process. This indicates the synergistic effect of the causal reasoning and the explanation generation on promoting models' understanding of causal mechanism.

5.4 Stability Analysis

Previous studies indicate that models may utilize some superficial cues within the dataset to predict the label. This leads to the vulnerability of models when facing adversarial attacks (Poliak et al., 2018; McCoy et al., 2019). Learning to generate the additional conceptual explanation may promote the understanding of causality to increase the stability of the reasoning model. Hence, we conduct a stability analysis to examine the specific effect of additional explanations.

Following Bekoulis et al. (2018) and Yasunaga et al. (2018), we attack the causal reasoning system by adding a perturbation term on the word embeddings of inputs. The perturbation term is derived using the gradient-based FGM method (Miyato et al., 2016). Table 9 shows the change of causal reasoning accuracy (ΔAccu.) brought by the adversarial attack. For example, $\Delta = -6.40$ means a 6.40% decrease of prediction accuracy after the adversarial attack. We find that, compared to the vanilla GPT2$_{\text{CR}}$ model, the explanation enhanced GPT2 model GPT2$_{\text{CR-EG}}$ demonstrates stronger stability. This suggests that, by training reasoning models to generate correct explanations of the causal facts, the understanding of the causality can be promoted, and then the stability of model performance can be increased.

5.5 Enhancing Pretrained Language Model with e-CARE

Causal knowledge is critical for various NLP applications. In this section, we investigate if the causality knowledge provided by e-CARE can be used as a resource to boost model performance on other causal-related tasks. To this end, we apply transfer learning by first finetuning a BERT model on e-CARE, then adapting the e-CARE-enhanced model (denoted as BERT$_{\text{E}}$) on a causal extraction task EventStoryLine 0.9 (Caselli and Vossen, 2017), two causal reasoning tasks BECauSE 2.0 (Dunietz et al., 2017) and COPA (Roemmele et al., 2011), as well as a commonsense reasoning dataset CommonsenseQA (Talmor et al., 2019). On the EventStoryLine 0.9 dataset, we conduct experiment only on the instances about within-sentence causal relationship. The results are shown in Table 10. We observe that the additional training process on e-CARE can consistently increase the model performance on all four tasks. This indicates the potential of e-CARE in providing necessary causality information for promoting causal-related tasks in multiple domains.

Dataset	Metric	BERT	BERT$_{\text{E}}$
EventStoryLine 0.9	F1 (%)	66.5	**68.1**
BECauSE 2.1	Accu. (%)	76.8	**81.0**
COPA	Accu. (%)	70.4	**75.4**
CommonsenseQA	Accu. (%)	52.6	**56.4**

Table 10: Performance of e-CARE-enhanced BERT.

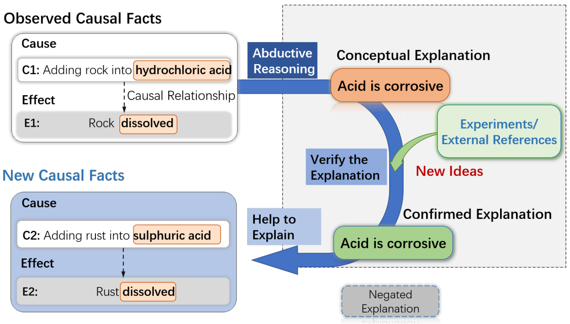

Figure 2: Conceptual explanations of observed causality can be helpful for understanding the unseen causal facts.

6 Discussion

In this paper, we introduce additional explanation information for the causal reasoning process, and propose a corresponding explanation generation task. Previous literature concluded the explanation generation process as an *abductive reasoning* process (Hanson, 1958; Peirce, 1974) and highlighted the importance of the abdutive explanation generation, as it may interact with the causal reasoning process to promote the understanding of causal mechanism, and increase the efficiency and reliability of causal reasoning.

For example, as Figure 2 shows, one may have an observation that C_1: *adding rock into hydrochloric acid* caused E_1: *rock dissolved*. Through abductive reasoning, one may come up with a conceptual explanation for the observation that *acid is corrosive*. After that, one can confirm or rectify the explanation by experiments, or resorting to external references. In this way, new ideas about causality can be involved for understanding the observed causal fact. Then if the explanation is confirmed, it can be further utilized to support the causal reasoning process by helping to explain and validate other related causal facts, such as C_2: *adding rust into sulphuric acid* may lead to E_2: rust dissolved. This analysis highlights the pivotal role of conceptual explanation in learning and inferring causality. In this paper, we introduce the e-CARE dataset to provide causal explanations and support future research towards stronger human-like causal reasoning systems.

7 Conclusion

In this paper, we present an *e*xplainable CAusal REeasoning dataset *e*-CARE, which contains over 21K causal questions, together with over 13K unique conceptual explanations about the deep understanding of the causal facts, which also makes e-CARE the largest causal reasoning benchmark. Experimental results show that both the causal reasoning task and especially the explanation generation task remain challenging for the SOTA pretrained language models. Moreover, the additional explanation signal can promote both the prediction accuracy and stability of models, highlighting the vital importance of the conceptual explanations in causal reasoning.

9 More Discussions about the e-CARE Dataset

9.1 The Generality of the Conceptual Explanation

In this paper, we construct the dataset by first obtaining the conceptual explanations, then obtaining the causal questions. This is because, we also hope to find the conceptual explanations with more generality, that that can explain more than one causal fact, but can explain a set of correlated causal facts. Table 11 demonstrate an example of such conceptual explanation. The *explanation* points out the nature of Copper that *Copper is a good thermal conductor*, so that holding copper on fire will make fingers feel burnt immediately. Additionally, the same explanation can also provide insights about another causal fact seemingly totally different from the case in Table 3 (a), that putting copper tubes into computer can promote thermal dispersion. This is because, the conceptual explanation points out the nature of copper, which drives a set of causal facts into existence.

This example demonstrate the usefulness of the conceptual explanations in providing the deep understanding of causality to support the causal reasoning. However, note that in this paper, we do not assume all the statements we collected can explain multiple causal facts. Instead, we resort to the empirical knowledge of human annotators to find such explanations. Specifically, we distribute statements to several annotators, and require each annotator to generate a causal fact that can be explained by the statement. For a certain statement, if it is distributed to multiple annotators and more than one annotator can generate a corresponding causal fact, then we assume that this statement can be a conceptual statement.

9.2 The Exhaustiveness of the Explanations

Another point we wish to elucidate is about the exhaustiveness of the explanations. In this paper, we only aim at providing *plausible* explanations that can explain the causal fact, but do not assume the provided explanations to be exhaustive or self-sufficient.

(a) *Premise*: Tom held a copper block by hand and heated it on fire.	**(b)** *Premise*:This computer's heat dispersion performance is bad.
Ask-for: Effect	*Ask-for*: Effect
Hypothesis 1: His fingers felt burnt for a short time. (✓)	*Hypothesis 1*: Designers add copper tubes into the computer. (✓)
Hypothesis 2: The copper block kept the same. (×)	*Hypothesis 2*: Designers put the computer into the ice water. (×)
Explanation: **Copper is a good thermal conductor.**	*Explanation*: **Copper is a good thermal conductor.**

Table 11: Two instances from the e-CARE dataset.

9.3 The Relationship between the Unique Explanations and Causal Questions

Due to the practical limits, to ensure the coverage of dataset, only a part of statements are distributed to multiple annotators, as described in Section 3.1.

10 Data Collection Details

10.1 Collection of Explanations

We collect the potential explanations from a commonsense knowledge base GenericsKB (Bhakthavatsalam et al., 2020), which contains naturally occurring generic statements, such as "Trees remove carbon dioxide from the atmosphere", collected from multiple corpora. We first filtered the statements according to their quality score s, which is a human-annotation based metric, provided in the GenericsKB and evaluating the correctness of each statement. To ensure the factual correctness of the potential explanations, we only kept the statements whose quality score are among the highest 1%. In addition, we also excluded the statements including: (1) Overly complex statements. The statements with connective, and statements with more than 20 words are excluded. This is because, by observation, we found that the annotators always struggle with understand and generate plausible causal facts for the over complex explanations. The number 20 is an empirical setting. (2) Statements describing named entities. (3) Statements describing the hypernymy or hyperonymy relationship between the subject and object. For example, the statement *Monkey is a kind of mammal.* describes the hypernymy relationship between the subject monkey and object mammal. This kind of statement does not belong to the three kinds of information that a valid explanation contains, as mentioned in Section 3.1.

After the filtering process, totally 19K statements are remained to be the potential explanations. Note that we do not assume that the statements after the filtering process are necessarily to be valid potential explanation and force the annotators to generate corresponding causal fact(s). Instead, we left the judgment to the annotators. If a statement has already been distributed to three annotators and no annotator can generate a corresponding causal question for this statement, then it is discarded.

10.2 Collection of Causal Questions

We guided the annotators using illustrative examples to avoid the following mistakes:
(1) The generated cause and effect cannot be explained by the statement.

- Wrong Case

  Explanation: Copper is a good The copper block was oxidized and the surface became dark..
  Cause: Tom held a copper block and heated it on fire.
  Effect: The copper block was oxidized and the surface became dark.

- Correct Case

  Explanation: Copper is a good thermal conductor.
  Cause: Tom held a copper block by hand and heated it on fire.
  Effect: His fingers felt burnt for a short time.

(2) The generated "cause" and "effect" do not form a valid causal relationship.

- Wrong Case

  Explanation: Oncologists specialize in the treatment of cancer.
  Cause: Jerry suffered from cancer.
  Effect: Jerry consulted many artists.

- Correct Case

  Explanation: Oncologists specialize in the treatment of cancer.
  Cause: Jerry suffered from cancer.
  Effect: Jerry consulted many oncologists.

(3) The distractor can also form a causal relationship with the premise.

- Wrong Case

  Explanation: Oncologists specialize in the treatment of cancer.
  Cause: Jerry suffered from cancer.
  Effect: Jerry consulted many oncologists.
  Disctractor Cause: Jerry consulted many traditional herbalists.

(4) The generated distractor is uninformative.

- Wrong Case

  Explanation: Copper is a good thermal conductor.
  Cause: Tom held a copper block by hand and heated it on fire.
  Effect: His fingers felt burnt for a short time.
  Disctractor Effect: His fingers did not feel burnt for a short time.

11 Adversarial Filtering

During the annotation process, some superficial clues may be incurred into the dataset, which makes the correct and implausible hypothesis can be distinguished merely using these annotation artifacts. To decrease the influence of potential annotation artifacts, we introduce an Adversarial Filtering algorithm (Bhagavatula et al., 2019) to refine our dataset.

In specific, for an arbitrary causal question $\langle p, a, h^+, h^- \rangle$, where p is the premise, $a \in [``cause'', ``effect'']$ is an ask-for annotator, h^+ and h^- is the correct and wrong hypothesis, respectively, if $\langle p, h^+ \rangle$ and $\langle p, h^- \rangle$ can be easily distinguished by a predictive model, then we replace h^- with another implausible hypothesis $h^{-'}$ sampled from an implausible hypothesis set $\mathcal{H}$, so that $\langle p, h^{-'} \rangle$ is harder to be distinguished from $\langle p, h^+ \rangle$. Where the implausible hypothesis set $\mathcal{H}$ is the collection of all wrong hypotheses within the dataset.

Algorithm 1 provides a formal description of our adversarial filtering algorithm. Specifically, in each iteration i, we randomly split the dataset into a training set $\mathcal{T}_i$ and a validation set $\mathcal{V}_i$. Then a model $\mathcal{M}_i$ is trained on $\mathcal{T}_i$ to update $\mathcal{V}_i$ to make it more challenging for $\mathcal{M}_i$. To this end, given an instance $\langle p_j, a_j, h_j^+, h_{j0}^- \rangle \in \mathcal{V}_i$, we randomly sample K more implausible hypotheses $h_j^- 1', \cdots, h_j^- K'$. Let $\delta_k^{\mathcal{M}_i}$ denotes the difference of model evaluation between $\langle p_j, a_j, h_j^+, h_j^- \rangle$ and $\langle p_j, a_j, h_k^- \rangle$, where $\delta_k^{\mathcal{M}_i} < 0$ means model $\mathcal{M}_i$ favors h_j^+ to be the plausible hypothesis than the implausible hypothesis h_{jk}^-. With probability t_i, we replace h_j^- with the implausible that is hardest to distinguish with h_j^+, i.e., $h_j^- = h_{jl}^-$, $l = \arg\min_l \delta_k^{\mathcal{M}_i}$. In this way, in each iteration, the proportion of easy implausible hypotheses decreases, and then the adversary model is forced to capture more causality knowledge.

Algorithm 1 Adversarial Filtering

```
Input: number of iteration $n$, dataset $\mathcal{D}_0$, implausible hypothesis set $\mathcal{H}^-$, initial and final temperature parameter $t_s$ and $t_e$.
Output: dataset $\mathcal{D}_n$
for iteration $i = 1 \rightarrow (n-1)$ do
    $t_i = t + e + \frac{t_s - t_e}{1+e^{0.3(i-3n/4)}}$
    Random split $M_i$ into training set $\mathcal{T}_i$ and validation set $\mathcal{V}_i$
    Train Model $M_i$ on $\mathcal{T}_i$
    for instance $j \in \mathcal{S}_i$ do
        for $h_{jk}^- \in \mathcal{H}_j^-$ do
            Calculate $\delta_k^{\mathcal{M}_i}(\langle p_j, a_j, h_j^+ \rangle, \langle p_j, a_j, h_{jk}^- \rangle)$
            $l = \arg\min_l \delta_k^{\mathcal{M}_i}$
            Sample $r$ from a Uniform distribution $U(0,1)$
            If $r < t_i$ or $\delta_l^{\mathcal{M}_i} < 0$ then $h_j^- = h_{jl}^-$
            Add instance $j$ into $\mathcal{S}_i$
        end for
    end for
end for
$\mathcal{D}_n = \mathcal{S}_n$
```

We implemented the adversary model using pretrained language model RoBERTa-base (Liu et al., 2019). The AF algorithm is run for 25 iterations and the temperature t_i follows a sigmoid function, parameterized by the iteration number, between $t_s = 1.0$ and $t_e = 0.2$. For each instance, we sampled $K = 20$ more implausible hypotheses from the implausible hypothesis set $\mathcal{H}$.

12 Details of Experiments

12.1 Details of the Causal Reasoning Experiment

Settings In this paper, the causal reasoning task is defined as a multiple-choice problem, which requires the model to choose a more plausible hypothesis from two candidates, so that the premise and hypothesis can form a valid causal fact. Therefore, the causal reasoning task could be formalized as a prediction problem: given a candidate cause fact $\langle cause, effect \rangle$ composed of the premise event and one of the hypothesis events, the prediction model is required to predict a score mea-

Model	Input Format
GPT2	< |startoftext| > C [SEP] E < |endoftext| >
RoBERTa	<s> C <s> E <s>
BART	<s> C <s> E <s>
XLNET	<cls> C <sep> E <sep>
BERT	[CLS] C [SEP] E [SEP]
ALBERT	[CLS] C [SEP] E [SEP]

Table 12: Input format of models in the causal reasoning task.

suring the causality of the event pair. Note that the ask-for indicator decides whether the premise or candidate hypothesis to be the cause or effect, respectively.

To this end, we concatenate the premise with each one of the candidate hypothesis to form two candidate causal facts. Then each of the candidate causal fact is fed into the models, to obtain a probability measuring the plausibility of the candidate causal fact. To satisfy the input format of the pretrained language models, the input candidate causal fact is preprocessed by adding special tokens. Additionally, we adapt GPT2 and BART to predictive causal reasoning task by adding an EOS token to the end of input text, and making predictions based on the representation of the EOS token. The specific input format of the models is listed in Table 12, where C, E denotes the cause and effect of the candidate causal fact, respectively.

Training Details In the causal reasoning task, we optimize all the models with a batch size of 64, learning rate of 1e-5, and the model is finetuned for 3 epochs.

12.2 Details of the Explanation Generation Experiment

Settings In the explanation generation experiment, models are trained to generate an explanation for a given valid causal fact $\langle C, E\rangle$. Hence, the input of GPT2 is formated as:

$$< |startoftext| > C\ [SEP]\ E < |endoftext| >, \quad (5)$$

where < |startoftext| > and < |endoftext| > are two special tokens. The input of the GRU-Seq2Seq model is formated as:

$$< SOS > C\ ,\ E < EOS > . \quad (6)$$

Training Details In the explanation generation task, the GPT2 model is trained with a batch size of 32, learning rate of 1e-5, and the model is finetuned for 10 epochs. For the GRU-Seq2seq model, both the encoder and the decoder contains 2 GRU layers with a dimension of 300×300. The word embedding is initialized using 300-dimension GloVe. During optimazation, the GRU-Seq2seq model is trained for 10 epochs as well.

12.3 Details of Explanation AND Generation Experiment

Settings Given a causal question, we first concatenate the premise with each one of the candidate hypothesis to form two candidate causal facts. Then each of the candidate causal fact is fed into the GPT2 model, to get a distributed representation of the candidate causal fact. Then probability measuring the plausibility of the candidate causal fact is predicted using an MLP based on the distributed representation. After predicting plausibility score of two candidate causal facts, the model is trained to generate an explanation based on only the representation of the candidate causal fact that model thinks is more likely to be valid.

Training Details During the training process, to balance the generation loss and prediction loss, we introduce an balance coefficient λ. Hence, the loss function is formulated as $L = (1 - \lambda)L_{\text{Prediction}} + \lambda L_{\text{Generation}}$. We empirically set $\lambda = 0.1$. The batch size and learning rate are also set as 32 and 1e-5, respectively. While different to the explanation generation process, in the Generate And Prediction experiment, the GPT2 model is trained for 5 epochs, as it receives two kinds of supervision signals.

12.4 Details of Transfer Analysis

Settings

All four tasks in the transfer analysis can be formalized as multiple-choice problem. Specifically, the causal event extraction task EventStoryLine requires model to predict whether two phrase-level events within a sentence can form a causal relationship. While in two causal reasoning tasks BECauSE 2.0 (Dunietz et al., 2017) and COPA (Roemmele et al., 2011), models are required to choose a plausible hypothesis, so that the premise and the hypothesis can form a valid causal fact.

Dataset	**Input Format**
EventStoryLine	[CLS] Statement
BECauSE 2.0	[CLS] C [SEP] E [SEP]
COPA	[CLS] C [SEP] E [SEP]
CommonsenseQA 2.0	[CLS] Q [SEP] A [SEP]

Table 13: Input format of models in the transfer analysis.

The CommonsenseQA (Talmor et al., 2019) task requires model to choose a correct answer for a given question. We list the specific format of the input on these four tasks in Table 13, where C and E denotes the cause and effect, respectively, Q and A denotes the question and answer, respectively.

Training Details To equip model with the causality knowledge within e-CARE, we train a BERT model for 3 epochs, with a batch size of 32 and a learning rate of 1e-5. Then in the following fine-tuning stage, on all four datasets, both BERT and e-CARE enhanced model BERT_E are fine-tuned using a grid search with the following set of hyper-parameters:

- batch size: {16, 32}
- number of epochs: {3,5,10}
- learning rate: {1e-6, 1e-5}

Fantastic Questions and Where to Find Them: FairytaleQA – An Authentic Dataset for Narrative Comprehension

Abstract

Question answering (QA) is a fundamental means to facilitate assessment and training of narrative comprehension skills for both machines and young children, yet there is scarcity of high-quality QA datasets carefully designed to serve this purpose. In particular, existing datasets rarely distinguish fine-grained reading skills, such as the understanding of varying narrative elements. Drawing on the reading education research, we introduce FairytaleQA[1], a dataset focusing on narrative comprehension of kindergarten to eighth-grade students. Generated by educational experts based on an evidence-based theoretical framework, FairytaleQA consists of 10,580 explicit and implicit questions derived from 278 children-friendly stories, covering seven types of narrative elements or relations. Our dataset is valuable in two folds: First, we ran existing QA models on our dataset and confirmed that this annotation helps assess models' fine-grained learning skills. Second, the dataset supports question generation (QG) task in the education domain. Through benchmarking with QG models, we show that the QG model trained on FairytaleQA is capable of asking high-quality and more diverse questions.

Story Title: ***Magic Apples***
Story Text:

`[Sect 1]` Once upon a time there was a lad who was better off than all the others. He was never short of money, for he had a purse which was never empty. ...
...

`[Sect 6]` When the king's daughter had eaten of the apples, she had a pair of horns. And then there was such a wailing in the castle that it was pitiful to hear. ...

But one day a foreign doctor from afar came to court. He was not from their country, he said, and had made the journey purposely just to try his luck here. But he must see the king's daughter alone, said he, and permission was granted him.
...

`[Sect 8]` ...

- Q1:Who will the foreign doctor turn out to be?

`[explicit][prediction][sect 5, sect 6]`
- A: The Lad.

- Q2:How did the princess feel when she had a pair of horns?

`[implicit][feeling][sect 6]`
- A: Upset.
- A: Angry.
- A: Horrified.

Table 1: Story and Question-Answer examples in FairytaleQA. Each question has meta info (implicitness, question type, and section origin), and may have multiple answers and span across multiple sections.

1 Introduction

Reading comprehension is a complex, multidimensional cognitive process (Kim, 2017). Question answering (QA) is fundamental for supporting humans' development of reading comprehen-

sion skills, as questions serve as both instruments for evaluation and tools to facilitate learning. To achieve this goal, comprehension questions should be valid and reliable, meaning that all items are designed to cohesively assess comprehension rather than some other skills (e.g., text matching, paraphrasing, or memorization) (Roberts and Priest, 2006). Moreover, from the educational perspective, given that reading comprehension is a multi-component skill, it is ideal for comprehension questions to be able to identify students' performance in specific sub-skills, thus allowing teachers to provide tailored guidance (Francis et al., 2005).

However, creating a large and suitable set of questions for supporting narrative comprehension is both time-consuming and cognitively demanding. Some researchers have proposed developing models to automatically generate questions or QA-pairs that satisfy the need for a continuous supply of new questions (Kurdi et al., 2020; Yao et al., 2022), which can potentially enable large-scale development of AI-supported interactive platforms for the learning and assessment of reading comprehension skills (e.g., (Zhang et al., 2022)). However, existing datasets are not particularly suitable for training question generation (QG) models for educational purposes (Das et al., 2021). This is primarily because the datasets are not typically structured around the specific dimensions of reading comprehension sub-skills, nor do they provide sufficient information on what sub-skills are tested. Consequently, QG models built on these datasets only yield one single "comprehension" score without a more detailed breakdown of performance on comprehension sub-skills. This issue is compounded by the fact that many benchmarks rely on crowd-sourced workers who may not have sufficient training or education domain knowledge needed to create valid questions in a consistent way.

To bridge the gap, we constructed FAIRYTALEQA, an open-source dataset focusing on comprehension of narratives, targeting students from kindergarten to eighth grade. We focus on narrative comprehension for two reasons. First, narrative comprehension is a high-level comprehension skill strongly predictive of reading achievement (Lynch et al., 2008) and plays a central role in daily life as people frequently encounter narratives in different forms (Goldie, 2003). Second, narrative stories have a clear structure of specific elements and relations among these elements, and there are existing validated narrative comprehension frameworks around this structure, which provides a basis for developing the annotation schema for our dataset.

We employed education experts who generated 10,580 question-answer pairs based on a collection of 278 fairytale stories for young readers, following evidence-based narrative comprehension frameworks (Paris and Paris, 2003; Alonzo et al., 2009). Thereby, FAIRYTALEQA contains questions that focus on several narrative elements and relations, increasing the validity and reliability of the assessment. In addition, FAIRYTALEQA also contains both explicit questions that involve answers found explicitly in the text and implicit questions that require high-level summarization (Table 1), thus representing a relatively balanced assessment with questions of varying difficulty (Zucker et al., 2010; Raphael, 1986). Most importantly, our selection of annotators with education domain knowledge as well as the training and quality control process ensured that the aforementioned annotation protocol was consistently implemented. A subset of questions in our dataset has been validated with 120 pre-kindergarten and kindergarten students (IRB approved from the first author's institution), proving the questions' reliability and validity.

We show the utility of FAIRYTALEQA through two benchmarking experiments. First, we used our data to train and evaluate state-of-the-art (SOTA) QA models and demonstrated that (1) FAIRYTALEQA contains challenging phenomena for existing models, and (2) it can support finer-grained analysis on the different types of comprehension sub-skills, even for models trained on general QA datasets (NarrativeQA (Kočiskỳ et al., 2018)). We further calibrated model performances with human baseline, highlighting the most visible gap in models' reasoning capabilities on recognizing casual relationships and predicting event outcomes. Second, we used FAIRYTALEQA to power question generation and showed that the QG model trained on ours was more capable of asking diverse questions and generating questions with higher quality.

2 Related Work

2.1 QA Datasets Focusing on Narratives

Despite a large number of datasets on reading comprehension, few focus on comprehension of narrative text. Table 2 reviews different narrative-related properties of existing popular QA datasets comparing with our proposed FAIRYTALEQA dataset. Narra-

Dataset	Educ.	Narr.	Q. Type	A. Type	A. Source	Generation	Document Source
NarrativeQA	No	Yes	Open-ended	Natural	Free-form	Crowd-sourced	Movie Scripts, Literature (Full story or summary)
BookTest	No	Yes	Cloze	Mult. Choice	Entity/Span	Automated	Literature (Excerpt)
TellMeWhy	No	Yes	Open-ended	Natural	Free-form	Crowd-sourced	Short Fiction (ROCStories)
RACE	Yes	No	Open-ended	Mult. Choice	Free-form	Expert	(Partially) Literature (Short story or excerpt)
CLOTH	Yes	No	Cloze	Mult. Choice	Span	Expert	(Partially) Literature (Short story or excerpt)
FAIRYTALEQA	Yes	Yes	Open-ended	Natural	Free-form & Span	Expert	Literature (Full story)

Table 2: Properties of existing datasets compared to FAIRYTALEQA.

tiveQA (Kočiskỳ et al., 2018) is one of the representative datasets. It was generated by crowd workers who wrote QA pairs according to summaries of books or movie scripts, while the task takers are supposed to answer these questions based on their reading of original books or movie scripts. As such, this dataset is posited to evaluate a person's understanding of the underlying narrative, with a significant amount of event-related questions (Mou et al., 2021). However, NarrativeQA simply instructed crowd-sourced workers to generate questions as if they were to "test students" without using a detailed annotation protocol. It is questionable whether these workers actually had experiences in testing students, and the lack of protocol may have imposed too little control over the coverage of reading sub-skills.

BookTest (Bajgar et al., 2016) is an automatically constructed cloze-style QA dataset based on a collection of narrative texts retrieved from Project Gutenberg. The questions were generated by automatically removing a noun or entity in a sentence that has appeared in the preceding context. While cloze-style tests can be a valid instrument for assessing reading comprehension, their validity depends on the careful selection of words to be removed so that filling them in requires proper comprehension (Gellert and Elbro, 2013). It is unlikely that automatically constructed cloze tests would meet such standards.

Another dataset, TellMeWhy (Lal et al., 2021), aims to facilitate and assess understanding of *causal relationships*. This dataset contains "why" questions that are relatively challenging, given that they require additional information not directly provided in the text. However, TellMeWhy only addresses one narrative component type (i.e., causal relationship), whereas FAIRYTALEQA provides seven evaluation components. Moreover, TellMeWhy was built upon ROCStories (Mostafazadeh et al., 2016) and thus only examine comprehension on incomplete story exerpts, which may have limited the dataset's ability to assess macro-level summarization and inference making.

2.2 QA Datasets for Reading Education

There are several benchmarks derived from sources for education purposes (e.g., exams or curricula). RACE (Lai et al., 2017) is a large-scale dataset consisting of comprehension questions from English exams for Chinese middle and high school students. RACE uses a mixture of narrative and informational paragraphs. These two genres require slightly different comprehension skills (Liebfreund, 2021), and students perform differently based on what genres of text they read (Denton et al., 2015). Mixing these two together in one dataset without annotating the specific genre of each story/question obscures the ability to offer a precise assessment. Moreover, RACE is in multiple-choice format, and paragraphs are usually shorter. These two characteristics may make the RACE dataset less challenging, and recent models have demonstrated close-to-human performance[2].

CLOTH (Xie et al., 2017) is a cloze-style dataset also collected from English exams with multiple choice fill-in-the-blank questions. CLOTH can be advantageous for educational QG as each question is labeled with the level of reasoning it involves. However, this dataset shares certain limitations inherent to multiple-choice formats (Klufa, 2015).

2.3 Non-QA Datasets for Narrative Comprehension

There are some datasets that are designed for assessing narrative comprehension skills but do not

---

[2] `http://www.qizhexie.com/data/RACE_leaderboard.html`

use QA as a form of evaluation. Several datasets, such as NovelChapters (Ladhak et al., 2020) and BookSum (Kryściński et al., 2021), evaluate models' comprehension through summarization tasks. However, there have been debates of whether comprehension can be assessed solely through summarization (Head et al., 1989), as summarization poses a high demand on writing that confounds the reading skills intended to be assessed. Two other recent datasets focus on singular specific elements in narratives. The LiSCU dataset (Brahman et al., 2021) targets readers' understanding of *characters*, and Sims et al. (2019) propose a dataset for detecting *events* in narratives. Given their focus on single narrative elements, these two datasets may not provide a comprehensive evaluation of narrative comprehension.

3 FAIRYTALEQA

We developed the FAIRYTALEQA dataset to address some of the limitations in existing benchmarks. Our dataset contains 10,580 QA pairs from 278 classic fairytale stories. In the remainder of this section, we report the dataset construction process and its key statistics.

3.1 Source Texts

The narrative texts utilized in the dataset are classic fairytales with clear narrative structures. We gathered the text from the Project Gutenberg website[3], using "*fairytale*" as the search term. Due to a large number of fairytales found, we used the most popular stories based on the number of downloads since these stories are presumably of higher quality.

To ensure the readability of the text, we made a small number of minor revisions to some obviously outdated vocabulary (e.g., changing "ere" to "before") and the unconventional use of punctuation (e.g., changing consecutive semi-colons to periods). For each story, we evaluated the reading difficulty level using the textstat[4] Python package, primarily based on sentence length, word length, and commonness of words. We excluded stories that are at 10th grade level or above.

These texts were broken down into small sections based on their semantic content by our annotators. The annotators were instructed to split the story into sections of 100-300 words that also contain meaningful content and are separated at natural story breaks. An initial annotator would split the story, and this would be reviewed by a cross-checking annotator. Most of the resulting sections were one natural paragraph of the original text. However, sometimes several paragraphs were combined (usually dialogue); and some exceptionally long paragraphs that contained more than one focal event were divided into multiple sections. On average, there are 15 sections per story, and each section has an average of 150 words (Table 4).

3.2 Schema for Question Annotation

Categorization via Narrative Elements or Relations FAIRYTALEQA is intended to include QA pairs that capture the seven narrative elements/relations that are verified in prior educational research (Paris and Paris, 2003). Definitions of question types are shown below. Example questions for each type are in Appendix D.

- **Character** questions ask test takers to identify the character of the story or describe characteristics of characters.
- **Setting** questions ask about a place or time where/when story events take place and typically start with "*Where*" or "*When*".
- **Action** questions ask about characters' behaviors or information about that behavior.
- **Feeling** questions ask about the character's emotional status or reaction to certain events and are typically worded as "*How did/does/do . . . feel*".
- **Causal relationship** questions focus on two events that are causally related where the prior events causally lead to the latter event in the question. This type of questions usually begins with "*Why*" or "*What made/makes*".
- **Outcome resolution** questions ask for identifying outcome events that are causally led to by the prior event in the question. This type of questions are usually worded as "*What happened/happens/has happened...after...*".
- **Prediction** questions ask for the unknown outcome of a focal event, which is predictable based on the existing information in the text.

These labels are to ensure the presence of the variety of questions' sub-skills so that the models trained on this dataset can also generate the variety. The labels are not intended to aid the training of a model to classify questions. Some – but not all – of the labels may be determined by surface features. For example, *feeling* questions typically contain the words "feel" or "feels", while *action* questions

Table 3: Core statistics of the FairytaleQA dataset, which has 278 books and 10580 QA-pairs.

are more broad in their format.

Categorization via Source of Answers Orthogonal to the aforementioned question categories, questions in FairytaleQA are also categorized based on whether or not the answer source can be directly found in the text, namely explicit versus implicit questions. In general, explicit questions revolve around a specific story fact, and implicit questions require summarizing and making an inference based on information that is only implicit in the text. Using a combination of explicit and implicit questions yields an assessment with more balanced difficulty (Raphael, 1986; Zucker et al., 2010). In our data, explicit and implicit questions are defined as below (Examples in Appendix C):

- **Explicit** questions ask for answers that can be directly found in the stories. In other words, the source of answer are spans of text.
- **Implicit** questions ask for answers that cannot be directly found in the text. Answering the questions require either reformulating language or making inference. In other words, the answer source is “free-form”, meaning that the answers can be any free-text, and there is no limit to where the answer comes from.

3.3 Annotation Process

Five annotators were involved in the annotation of QA pairs. All of these annotators have a B.A. degree in education, psychology, or cognitive science and have substantial experience in teaching and reading assessment. These annotators were supervised by three experts in literacy education.

Annotation Guidelines The annotators were instructed to imagine that they were creating questions to test elementary or middle school students in the process of reading a complete story. We required the annotators to generate only natural, open-ended questions , avoiding “yes-” or “no-” questions. We also instructed them to provide a diverse set of questions about 7 different narrative elements, and with both implicit and explicit questions. Each question in the dataset has a label on the narrative element/relation to be assessed and whether it is implicit or explicit.

We asked the annotators to also generate answers for each of their questions. We asked them to provide the shortest possible answers but did not restrict them to complete sentences or short phrases. For explicit questions, annotators extracted the shortest phrase from the text as the answer (i.e., span). For implicit questions, annotators provided at least two possible answers for each question (i.e., free-form). We also asked the annotators to label which section(s) the question and answer was from. We did not specify the number of questions per story to account for story length variability and to allow annotators to create meaningful questions rather than be forced to add unnecessary questions. However, we did ensure that the annotators broadly averaged 2-3 questions per *section* in order to guarantee dataset size.

Annotator Training and Cross-Checking All annotators received a two-week training in which each of them was familiarized with the coding template (described in the section below) and conducted practice coding on the same five stories. The practice QA pairs were then reviewed by the other annotators and the three experts, and discrepancies among annotators were discussed. At the end of the training session, the five annotators had a little disagreement with the questions generated by other coders. During the annotation process, the team met once every week to review and discuss each member’s work. All QA pairs were cross-checked by two annotators, and 10% of the QA pairs were additionally checked by the expert supervisor. This process was to ensure that the questions focused on key information to the narrative and the answers to

	Mean	Min	Max	SD
Story Characteristics				
Sections / story	14.7	2	60	9.2
Tokens / story	2196.7	228	7577	1401.3
Tokens / section	149.1	12	447	63.6
Question Characteristics				
Tokens / question	10.3	3	27	3.3
Tokens / answer	7.2	1	69	6.1
Questions / story	38.1	5	161	29
Questions / section	2.9	0	18	2.4

Table 4: Various descriptive statistics for the length of stories and number of questions in the dataset.

Category	Count	Percentage (%)
Attributes		
character	1172	11.08
causal relationship	2940	27.79
action	3342	31.59
setting	630	5.95
feeling	1024	9.68
prediction	486	4.59
outcome resolution	986	9.32
Explicit vs Implicit		
explicit	7880	74.48
implicit	2700	25.52

Table 5: Breakdown of questions per category based on the schema in Section 3.2.

the questions were correct.

Agreement among Annotators The questions generated by the five coders showed a consistent pattern. All coders' questions have similar lengths (average length ranging from 8 to 10 words among the coders) and have similar readability levels (average readability between fourth to fifth grade among the coders). The distributions in narrative elements focused as well as implicit/explicit questions were also consistent. A detailed description of the distributions by coders is displayed in Appendix E. We chose not to use traditional inter-annotator agreement (IAA) metrics like Kappa coefficients because we explicitly asked the coders to generate questions and answers with variable language to aid QA and QG models based on this dataset. This language variability leads to inaccurate IAA metrics by traditional means (Amidei et al., 2018), leading to our decision.

Second Answer Annotation For the 46 stories used as the evaluation set, we annotate a second reference answer by asking an annotator to independently read the story and answer the questions generated by others. All questions were judged as answerable and thus answered by the second annotator. The second answers are used for both human QA performance estimation and for providing multiple references in automatic QA evaluation.

3.4 Statistics of FairytaleQA

We random split the FairytaleQA dataset into train/val/test splits with a QA ratio of roughly 8:1:1. Table 3 shows the detailed statistics of the FairytaleQA Dataset in train/val/test splits.

Overall, the resulting FairytaleQA dataset contained 10,580 questions from 278 fairytale stories. The description of story and question characteristics is presented in Table 4. In FairytaleQA, *action* and *causal relationship* questions are the two most common types, constituting 31.6% and 27.8%, respectively, of all questions. *Outcome resolution, character,* and *feeling* types each constitute about 10% of all questions. *Setting* and *prediction* questions are about 5% each. Our dataset contains about 75% explicit questions and 25% implicit questions (Table 5 for details).

Validation of FairytaleQA for Comprehension Assessment We validated the questions in FairytaleQA using established procedures in educational assessment development (Özdemir and Akyol, 2019) and have proven that our questions have high reliability and validity. Specifically, we sampled a small subset of the questions in our dataset (11 questions generated for one story) and tested them among 120 students in prekindergartens and kindergartens. This study was pre-approved by the IRB in first author's institution. The Cronbach's coefficient alpha was 0.83 for the items in this story comprehension assessment; suggesting was high internal reliability. We also linked children's performance answering our questions to another validated language assessment (Martin and Brownell, 2011), and the correlation was strong 0.76 (p<.001), suggesting an excellent external validity.

4 Baseline Benchmark: Question Answering

In the following sections, we present a couple of baseline benchmarks on both the Question Answering (QA) task and the Question Generation (QG) task with FairytaleQA. We leveraged both pre-trained neural models and models fine-tuned on different QA datasets, including NarrativeQA and our dataset, FairytaleQA. The baseline results show

Model	Validation / Test ROUGE-L F1
Pre-trained Models	
BERT	0.104 / 0.097
DistilBERT	0.097 / 0.082
BART	0.108 / 0.088
Fine-tuned Models	
BART fine-tuned on NarrativeQA	0.475 / 0.492
BART fine-tuned on FairytaleQA	0.533 / 0.536
Human‡	**0.651 / 0.644**

Table 6: Question Answering benchmarks on FairytaleQA validation and test splits. ‡Human results are obtained via cross-estimation between the two annotated answers, thus are underestimated. Still, they outperform models. We leave a full large-scale human study to future work.

that our FairytaleQA demonstrates challenging problems to existing approaches, and those models fine-tuned on FairytaleQA can benefit from the annotations a lot to achieve significant performance improvement. We also report human performance by scoring one reference answer to the other.

4.1 Question Answering Task and Model

Question Answering (QA) is a straightforward task that our FairytaleQA dataset can contribute to. We leveraged the commonly-used Rouge-L F1 score for the evaluation of QA performances. For each QA instance, we compared the generated answer with each of the two ground-truth answers and took the higher Rouge-L F1 score.

4.2 Main Results

Here in Table 6, we show the QA performance of a few pretrained SOTA neural-model architectures: BERT (Devlin et al., 2018), BART (Lewis et al., 2019), and DistilBERT(Sanh et al., 2019). The quality of answers generated by these pre-trained models is on par with each other. Since BART outperformed other model architectures in the QA task of NarrativeQA (Mou et al., 2021), we decided to use BART as the backbone for our fine-tuned models.

We report the performance of fine-tuned BART models with the following settings: BART fine-tuned on NarrativeQA, which is the SOTA model reported in (Mou et al., 2021), and another BART model fine-tuned on FairytaleQA. We note that for the QA task, the model that was fine-tuned on FairytaleQA dataset performs much better than the model fine-tuned on NarrativeQA by at least 5%. Even the human performance is underestimated here because it is obtained via cross-estimation between two annotated answers, this result still leaves around 12% on both splits between human performance and the model fine-tuned with FairytaleQA, which demonstrates that the QA task is still a challenging problem for existing works on our FairytaleQA dataset. We leave a full large-scale human study for evaluating the accurate human performance to future work.

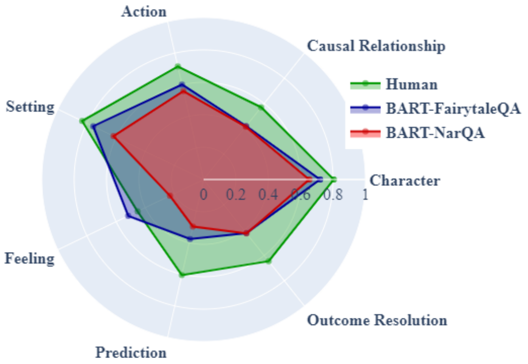

Figure 1: Decomposed QA results (Rouge-L) on 7 narrative elements on the validation split.

4.3 Analysis

Performance Decomposition Given that FairytaleQA has question type annotations on all the question-answer pairs, it supports the decomposition of performance on different types, thus resulting in a comprehensive picture of which reading skills the models lack the most.

Figure 1 presents the QA performance decomposition as a radar visualization. (The full results on both validation and test sets can be found in Table 10 in Appendix A). Compared to the model trained on NarrativeQA, our FairytaleQA led to the biggest improvement on dimensions of `Setting` and `Feeling` with more than 10% increase. The `Character` and `Prediction` dimensions were also improved by a large margin (7-8%). The large improvements in these dimensions suggested that despite the NarrativeQA dataset's overall focus on narrative comprehension, it might not include questions that sufficiently cover some of the fundamental elements, probably due to the lack of detailed annotating protocol and typical crowd workers' limited knowledge in reading assessment.

By comparison, on dimensions of `Action`, `Causal Relationship` and `Outcome Resolution`, our model fine-tuned on FairytaleQA resulted in smaller improvement compared

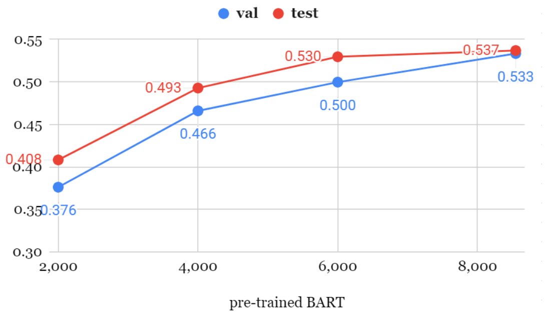

Figure 2: Learning curve of the QA model on FairytaleQA with varying size of training data.

to the model fine-tuned on NarrativeQA. This is likely due to the fact that most of the NarrativeQA questions are about event arguments and causal or temporal relations between events, as suggested by a human study (Mou et al., 2021).

Our performance decomposition also revealed substantial gaps between existing SOTA models and humans. Specifically, humans were 15-20% better on `Causal Relationship`, `Outcome Resolution` and `Prediction`. The model-human performance gaps on `Causal Relationship` and `Outcome Resolution` likely reflected the deficiency of current NLP models in understanding story plots, and the gap on `Prediction` might be due to the fact that this dimension asked the models to envision what would come next in the text, which required connecting commonsense knowledge with the content of the text. The model-human performance gaps on `Character` and `Setting` were also considerable, suggesting that the models' ability to understand these basic reading elements still has much room for improvement.

Finally, it was interesting that the model trained on our dataset outperformed humans on the `Feeling` dimension. This was likely because the answers to these `Feeling` questions were most explicitly described in the story. Therefore, it did not actually require reasoning of the character's mental states, but rather understanding which parts of the texts express the feelings. Another QA performance decomposition result based on explicit/implicit question types is provided in Appendix B.

Learning Curve Finally, we present the learning curve of the BART QA model on our FairytaleQA. Figure 2 plots the model performance on the validation set with different sizes of training data. The curve became flatter after training with 6,000 QA pairs in our dataset. This suggested that our dataset has a reasonably good size for fine-tuning a SOTA pre-trained model, and the performance gap between models and humans requires a more sophisticated reading model design rather than solely augmenting the training examples.

Model	Validation / Test ROUGE-L F1
BART fine-tuned on NarrativeQA	0.424 / 0.442
BART fine-tuned on FairytaleQA	**0.527 / 0.527**
BART fine-tuned on NarrativeQA and FairytaleQA	0.508 / 0.519

Table 7: Question Generation benchmarks on FairytaleQA-validation and test splits.

	Groundtruth	BART-NarQA	BART-FairytaleQA

Table 8: Distribution of question word in QG task for validation split by benchmark models.

5 Baseline Benchmark: Question Generation

5.1 Question Generation Task and Model

In terms of the QG performance on FairytaleQA, the task was to generate questions that correspond to the given answers and the context. This task has important empirical applications that in the future, models may help teachers to create questions in the educational settings.

Similar to the QA task, we fine-tuned a BART model to generate a question conditioned on each human-labeled answer and corresponding story section. The generated question is then evaluated with the corresponding ground-truth question. We used ROUGE-L F1 score as the evaluation metric. For this QG task, we compare the models fine-tuned on NarrativeQA, on FairytaleQA, and on both datasets.

5.2 Results and Analysis

Table 7 displays the QG results. The model fine-tuned on FairytaleQA demonstrated a clear advantage on Rouge-L over the model fine-tuned on NarrativeQA. It is worth noting that the model fine-tuned on both NarrativeQA and FairytaleQA performs worse than the model fine-tuned on FairytaleQA only; we would assume that NarrativeQA

Input story section: the wild people who dwell in the south-west are masters of many black arts. they often lure men of the middle kingdom to their country by promising them their daughters in marriage, but their promises are not to be trusted. once there was the son of a poor family, who agreed to labor for three years for one of the wild men in order to become his son-in-law.
Input Answer 1: The son of a poor family.
Ground-truth Question Who agreed to labor for three years for one of the wild men in order to become his son-in-law?
Outputs ***BART-NarQA:*** What was the son of a poor family? ***BART-FairytaleQA:*** Who agreed to labor for one of the wild men in order become his son-in law?
Input Answer 2: The wild people.
Ground-truth Question Who dwelled in the south-west and were masters of many black arts?
Outputs ***BART-NarQA:*** What dwells in the south-west? ***BART-FairytaleQA:*** Who dwell in the south-west are masters of many black arts?

Table 9: Qualitative analysis of QG models fine-tuned on NarQA or FairytaleQA dataset.

dataset introduces noises in question type distribution or semantics during the training process.

Further analysis (Table 8) examined the distribution of generated question types according to the beginning word of a question (wh- words). The questions generated by FairytaleQA more closely resembled the pattern of the ground-truth questions, suggesting that our dataset was able to improve the model's ability to mimic the education experts' strategy of asking questions that assess the seven elements of reading comprehension.

This result is further supported by qualitative analysis (as seen in examples in Table 9). Compared to the QG model trained with FairytaleQA, the baseline model trained with NarrativeQA dataset tended to generate vague questions that did not build upon specific contextual evidence within the narratives. These kinds of vague questions may not be suitable in educational settings, as improving students' skills to find text evidence to support their comprehension is a crucial aspect of reading education. The disparity between the two models might be attributed to how the QA-pairs were constructed in these two datasets: while NarrativeQA was constructed by crowd workers who only read the abstract of the stories, FairytaleQA required annotators to read the complete story before developing QA-pairs. As such, it is not surprising that models trained on FairytaleQA dataset could generate questions that are more closely related to the contextual evidence within the original text. In addition, we also observed that the model trained on NarrativeQA tended to generate questions with seemingly more correct grammar but were factually inaccurate (Table 12 Appendix C).

6 Conclusion and Future work

In summary, we constructed a large-scale dataset, FairytaleQA, for the context of children's narrative comprehension. The dataset was generated through a rigorous labeling process with educational domain experts. This dataset has been helpful to support preliminary works on QG tasks (Yao et al., 2022; Zhao et al., 2022) and already enabled possibilities for new downstream AI-for-Education applications (Zhang et al., 2022; Xu et al., 2021).

Howerver, we acknowledge our work also has limitations that require future works to continue the exploration. As aforementioned, the human performance results for QA task are underestimated because they are obtained via cross-estimation between the two annotated answers. One possibility for future work is to conduct a large-scale human annotation to collect more answers per each question and then leverage the massive annotated answers to better establish a human performance evaluation. Another avenue of future work is to leverage our dataset to detect and remediate social stereotypes and biases represented in story narratives – the bias analysis in the children storybook corpus has been an underexplored research topic for the ML community, but it has profound societal impacts on the soceity. Through such analysis on our dataset, we may be able to answer "how do social stereotype and bias come into a child's mind?"

In sum, there are many new research and application opportunities enabled by our FairytaleQA dataset, and we welcome researchers from both NLP and education communities to join our effort to continue this endeavor.

Acknowledgements

We thank Schmidt Futures for providing funding for the development of the `FairytaleQA` dataset. This work is also supported by the National Science Foundation (Grant No. 1906321 and 2115382).

Outcome Resolution	0.409	0.486	0.574

Table 10: Decomposed QA results on 7 narrative elements.

Table 10 shows the full decomposed QA results on 7 narrative elements for both validation and test splits, in terms of BART fine-tuned on NarrativeQA, BART fine-tuned on FairytaleQA, and human performance for the experts created ground-truth QA-pairs.

B Decomposed QA results on explicit/implicit question types for val/test splits

Model	**Validation / Test ROUGE-L F1**	
	Implicit	**Explicit**
BART-NarQA	0.280/0.278	0.548/0.563
BART-FairytaleQA	0.304/0.286	0.619/0.620
Human	0.363/0.330	0.760/0.750

Table 11: Decomposed QA results on implicit/explicit types.

We provided another QA performance decomposition based on explicit/implicit question types in Table 11. We noticed that the implicit questions are much more difficult for both humans and models to answer, which only achieves roughly half the performance compared with explicit questions. This result is consistent with our expectation, where answers to explicit questions can be directly found in the content while implicit questions require high-level summarization and inference.

Input story section: you see from this that the sparrow was a truthful bird, and the old woman ought to have been willing to forgive her at once when she asked her pardon so nicely. but not so.the old woman had never loved the sparrow, and had often quarreled with her husband for keeping what she called a dirty bird about the house, saying that it only made extra work for her. now she was only too delighted to have some cause of complaint against the pet. she scolded and even cursed the poor little bird for her bad behavior, and not content with using these harsh, unfeeling words, in a fit of rage she seized the sparrow-who all this time had spread out her wings and bowed her head before the old woman, to show how sorry she was-and fetched the scissors and cut off the poor little bird's tongue.

Input Answer: Cut off the poor little bird's tongue.

Ground-truth Question
What did the woman do to punish the bird?

Outputs
BART-NarQA: What did the old woman do in her rage?
BART-FairytaleQA: What did the old woman do after she seized her sparrow?

Input story section: "do not be sparing of the silver pieces in your pocket!" she cried after him as he went off.he went to the village, attended to everything, and came back. the woman tore the cloth apart, made a coat of it and put it on. no sooner had they walked a few miles before they could see a red cloud rising up in the south, like a flying bird."that is my mother," said the woman.in a moment the cloud was overhead. then the woman took the black tea-cups and threw them at it. seven she threw and seven fell to earth again. and then they could hear the mother in the cloud weeping and scolding, and thereupon the cloud disappeared.they went on for about four hours. then they heard a sound like the noise of silk being torn, and could see a cloud as black as ink, which was rushing up against the wind."alas, that is my father!" said the woman. "this is a matter of life and death, for he will not let us be! because of my love for you i will now have to disobey the holiest of laws!"

Input Answer: Took the black tea-cups and threw them at it.

Ground-truth Question
What did the wife do when she saw her mother?

Outputs
BART-NarQA: What did the woman do to try and kill her father?
BART-FairytaleQA: What did the woman do after she saw her mother?

Table 12: Question Generation examples with event-related input answers by benchmark models.

C QG examples by benchmark models on event-based answers

Table 12 shows two QG examples that have an input of event-related ground-truth answers. We may notice that BART fine-tuned on NarrativeQA is able to generate questions that seem to be in a cor-

Category	Example QA Pair
Character	Q: *How did the man's daughter look?* A: *beautiful* Q: *Who were the brother and sister living with after their mom died?* A: *their stepmother*
Setting	Q: *Where did the man and his wife and two girls live?* A: *near the forest*
Action	Q: *What did the cook do after she opened the hamper?* A: *unpacked the vegetables* Q: *How did Johnny Town-Mouse and his friends treat Timmy Willie when they met him?* A: *Johnny Town-Mouse and his friends treat Timmy Willie poorly.*
Causal relationship	Q: *Why did the two mice come tumbling in, squeaking, and laughing?* A: *They were being chased by the cat.*
Outcome resolution	Q: *What happened to Timmy after he got in the hamper?* A: *The hamper takes him to the garden.*
Feeling	Q: *How did the princess feel in her new home?* A: *happy*
Prediction	Q: *How will the other animals treat the duckling?* A: *The other animals will look down on the duckling.*
Explicit	Q: *How did the girl feel when she saw the old woman's teeth?* A: *terrified* Context: *...but she had such great teeth that the girl was terrified...* Q: *What happened when the door of the stove was opened?* A: *The flames darted out of its mouth.* Context: *...when the door of the stove was opened, the flames darted out of its mouth. This is customary with all stoves...*
Implicit	Q: *What happened when the prince broke open one of the crow's eggs?* A1: *The prince found a beautiful palace inside.* A2: *There was a beautiful palace inside.* A3: *A little palace was inside and it grew until it covered as much ground as seven large barns.* Context: *The Swan Maiden lit in a great wide field, and there she told the prince to break open one of the crow's eggs. The prince did as she bade him, and what should he find but the most beautiful little palace, all of pure gold and silver. He set the palace on the ground, and it grew and grew and grew until it covered as much ground as seven large barns.*

Table 13: Example QA-pairs of FairytaleQA. We show one QA-pair for each narrative element as well as implicit and explicit.

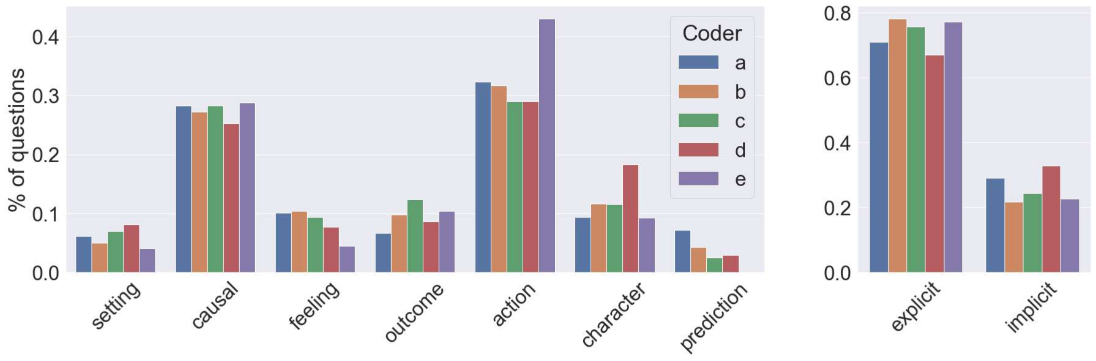

Figure 3: Percent of each question type by coder.

rect format but suffer from fact error, while BART fine-tuned on FairytaleQA is able to generate questions that are very similar to ground-truth questions and are semantically correct. Since the crowd workers only read the abstracts to create QA-pairs in NarrativeQA, in comparison, we ask our coders to read the complete story. This may lead to an issue with models fine-tuned on NarrativeQA where the evidence of the answer in the original text content is not detailed and obvious enough for QA-pairs in NarrativeQA so that the QG model fine-tuned on NarrativeQA is not ad good as models fine-tuned on FairytaleQA in locating evidence.

D Example questions by category in FairytaleQA
