Here, N is the total number of sentence-pairs in SSSB and $\mathbb{I}$ is the indicator function, which returns 1 if its argument is True and 0 otherwise. AUL score given by (6) falls within the range $[-50, 50]$ and an unbiased embedding would return bias scores close to 0, whereas bias scores less than or greater than 0 indicate bias directions towards respectively the anti-stereotypical or stereotypical examples.

6 Experiments

6.1 Bias in Static Embeddings

To evaluate biases in static sense embeddings, we select two current SoTA sense embeddings: LMMS[5] (Loureiro and Jorge, 2019) and ARES[6] (Scarlini et al., 2020). In addition to WEAT and WAT datasets described in § 3, we also use SSSB to evaluate static sense embeddings using the manually assigned sense ids for the target and attribute words, ignoring their co-occurring contexts. LMMS and ARES sense embeddings associate each sense of a lexeme with a sense key and a vector, which we use to compute cosine similarities as described in § 3. To compare the biases in a static sense embedding against a corresponding sense-insensitive static word embedding version, we compute a static word embedding $\boldsymbol{w}$, for an ambiguous word w by taking the average (**avg**) over the sense embeddings $\boldsymbol{s}_i$ for all of w's word senses as given in (7), where $M(w)$ is the total number of senses of w:

$$\boldsymbol{w} = \frac{\sum_i^{M(w)} \boldsymbol{s_i}}{M(w)} \tag{7}$$

This would simulate the situation where the resultant embeddings are word-specific but not sense-specific, while still being comparable to the original sense embeddings in the same vector space. As an alternative to (7), which weights all different senses of w equally, we can weight different senses by their frequency. However, such sense frequency statistics are not always available except for sense labelled corpora such as SemCor (Miller et al., 1993). Therefore, we use the unweighted average given by (7).

From Table 3 we see that in WEAT[7] in all categories considered, sense embeddings always report a higher bias compared to their corresponding sense-insensitive word embeddings. This shows that even if there are no biases at the word-level, we can still observe social biases at the sense-level in WEAT. However, in the WAT dataset, which covers only gender-related biases, we see word embeddings to have higher biases than sense embeddings. This indicates that in WAT gender bias is more likely to be observed in static word embeddings than in static sense embeddings.

In SSSB, word embeddings always report the same bias scores for the different senses of an ambiguous word because static word embeddings are neither sense nor context sensitive. As aforementioned, the word "black" is bias-neutral with respect to the colour sense, while it often has a social bias for the racial sense. Consequently, for *black* we see a higher bias score for its racial than colour sense in both LMMS and ARES sense embeddings.

---

[4] The attention-weighted variant (AULA) is not used because contextualised sense embeddings have different structures of attention from contextualised embeddings, and it is not obvious which attention to use in the evaluations.

[5] `https://github.com/danlou/LMMS`

[6] `http://sensembert.org`

[7] Three bias types (European vs. African American, Male vs. Female, and Old vs. Young) had to be excluded because these biases are represented using personal names that are not covered by LMMS and ARES sense embeddings.

Table 3: Bias in LMMS and ARES Static Sense Embeddings. In each row, between sense-insensitive word embeddings and sense embeddings, the larger deviation from 0 is shown in bold. All results on WEAT are statistically signiciant ($p < 0.05$) according to (3).

In the bias scores reported for *nationality* vs. *language* senses, we find that *nationality* obtains higher biases at word-level, while *language* at the sense-level in both LMMS and ARES. Unlike *black*, where the two senses (colour vs. race) are distinct, the two senses *nationality* and *language* are much closer because in many cases (e.g. Japanese, Chinese, Spanish, French etc.) languages and nationalities are used interchangeably to refer to the same set of entities. Interestingly, the *language* sense is assigned a slightly higher bias score than the *nationality* sense in both LMMS and ARES sense embeddings. Moreover, we see that the difference between the bias scores for the two senses in *colour* vs. *race* (for black) as well as *nationality* vs. *language* is more in LMMS compared to that in ARES sense embeddings.

Between noun vs. verb senses of occupations, we see a higher gender bias for the noun sense than the verb sense in both LMMS and ARES sense embeddings. This agrees with the intuition that gender biases exist with respect to occupations and not so much regarding what actions/tasks are carried out by the persons holding those occupations. Compared to the word embeddings, there is a higher bias for the sense embeddings in the noun sense for both LMMS and ARES. This trend is reversed for the verb sense where we see higher bias scores for the word embeddings than the corresponding sense embeddings in both LMMS and ARES. Considering that gender is associated with the noun than verb sense of occupations in English, this shows that there are hidden gender biases that are not visible at the word-level but become more apparent at the sense-level. This is an important factor to consider when evaluating gender biases in word embeddings, which has been largely ignored thus far in prior work.

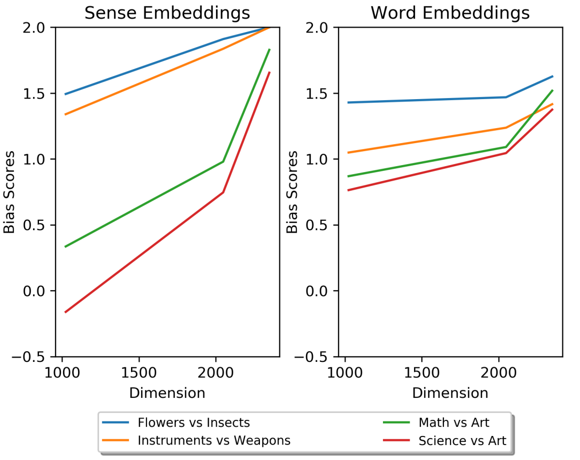

Figure 2: Effect of the dimensionality of sense embeddings (LMMS) and word embeddings (LMMS-average).

To study the relationship between the dimensionality of the embedding space and the social biases it encodes, we compare 1024, 2048 and 2348 dimensional LMMS static sense embeddings and their corresponding word embeddings (computed using (7)) on the WEAT dataset in Figure 2. We see that all types of social biases increase with the dimensionality for both word and sense embeddings. This is in agreement with Silva et al. (2021) who also reported that increasing model capacity in contextualised word embeddings does not necessarily remove their unfair social biases. Moreover, in higher dimensionalities sense embeddings show a higher degree of social biases than the corresponding (sense-insensitive) word embeddings.

6.2 Bias in Contextualised Embeddings

To evaluate biases in contextualised sense embeddings, we use SenseBERT[8] (Levine et al., 2020), which is a fine-tuned version of BERT[9] (Devlin et al., 2019) to predict supersenses in the WordNet. For both BERT and SenseBERT, we use base and large pretrained models of dimensionalities respectively 768 and 1024. Using AUL, we com-

Table 4: Bias in BERT and SenseBERT contextualised word/sense embeddings. In each row, between the AUL bias scores for the word vs. sense embeddings, the larger deviation from 0 is shown in bold.

pare biases in BERT and SenseBERT using SSSB, CrowS-Pairs and StereoSet[10] datasets. Note that unlike SSSB, CrowS-Pairs and StereoSet *do not* annotate for word senses, hence cannot be used to evaluate sense-specific biases.

Table 4 compares the social biases in contextualised word/sense embeddings. For both base and large versions, we see that in CrowS-Pairs, BERT to be more biased than SenseBERT, whereas the opposite is true in StereoSet. Among the nine bias types included in CrowS-Pairs, *gender* bias related test instances are the second most frequent following *racial* bias. On the other hand, gender bias related examples are relatively less frequent in StereoSet (cf. gender is the third most frequent bias type with 40 instances among the four bias types in StereoSet following *race* with 149 instances and *profession* with 120 instances out of the total 321 intrasentence instances). This difference in the composition of bias types explains why the bias score of BERT is higher in CrowS-Pairs, while the same is higher for SenseBERT in StereoSet.

In SSSB, in 8 out of the 12 cases SenseBERT demonstrates equal or higher absolute bias scores than BERT. This result shows that even in situations where no biases are observed at the word-level, there can still be significant degrees of biases at the sense-level. In some cases (e.g. *verb* sense in base models and *colour*, *language* and *verb* senses for the large models), we see that the direction of the bias is opposite between BERT and SenseBERT. Moreover, comparing with the corresponding bias scores reported by the static word/sense embeddings in Table 3, we see higher bias scores reported by the contextualised word/sense embeddings in Table 4. Therefore, we recommend future work studying social biases to consider not only word embedding models but also sense embedding models.

7 Gender Biases in SSSB

In this section, we further study the gender-related biases in static and contextualised word and sense embeddings using the noun vs. verb sense instances (described in §4.3) in the SSSB dataset. To evaluate the gender bias in contextualised word/sense embeddings we use AUL on test sentences in SSSB noun vs. verb category. To evaluate the gender bias in static embeddings, we follow Bolukbasi et al. (2016) and use the cosine similarity between (a) the static word/sense embedding of the occupation corresponding to its noun or verb sense and (b) the gender directional vector $\boldsymbol{g}$, given by (8):

$$\boldsymbol{g} = \frac{1}{|\mathcal{C}|} \sum_{(m,f)\in\mathcal{C}} (\boldsymbol{m} - \boldsymbol{f}) \tag{8}$$

Here, (m, f) are male-female word pairs used by Kaneko and Bollegala (2019) such as (*he*, *she*) and $\boldsymbol{m}$ and $\boldsymbol{f}$ respectively denote their word embeddings. Corresponding sense-insensitive word embeddings are computed for the 2048 dimensional LMMS embeddings using (7).

Figure 3 shows the gender biases in LMMS embeddings. Because static word embeddings are not sense-sensitive, they report the same bias scores for both noun and verb senses for each occupation. For all noun senses, we see positive (male) biases, except for *nurse*, which is strongly female-biased. Moreover, compared to the noun senses, the verb senses of LMMS are relatively less gender biased. This agrees with the intuition that occupations and not actions associated with those occupations are related to gender, hence can encode social biases. Overall, we see stronger biases in sense embeddings than in the word embeddings.

Figure 4 shows the gender biases in BERT/SenseBERT embeddings. Here again, we see that for all noun senses there are high stereotypical biases in both BERT and SenseBERT embeddings, except for *nurse* where BERT is slightly anti-stereotypically biased whereas SenseBERT shows a similar in magnitude but a stereotypical bias. Recall that *nurse* is stereotypically associated with the female gender, whereas other occupations are

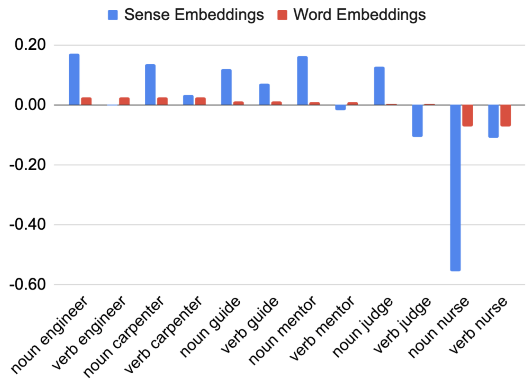

Figure 3: Gender biases found in the 2048-dimensional LMMS static sense embeddings and corresponding word embeddings computed using (7). Positive and negative cosine similarity scores with the gender directional vector (computed using (8)) represent biases towards respectively the *male* and *female* genders.

predominantly associated with males, which is reflected in the AUL scores here.

Despite being not fine-tuned on word senses, BERT shows different bias scores for noun/verb senses, showing its ability to capture sense-related information via contexts. The verb sense embeddings of SenseBERT of *guide*, *mentor* and *judge* are anti-stereotypical, while the corresponding BERT embeddings are stereotypical. This shows that contextualised word and sense embeddings can differ in both magnitude as well as direction of the bias. Considering that SenseBERT is a fine-tuned version of BERT for a specific downstream NLP task (i.e. super-sense tagging), one must not blindly assume that an unbiased MLM to remain as such when fine-tuned on downstream tasks. *How social biases in word/sense embeddings change when used in downstream tasks* is an important research problem in its own right, which is beyond the scope of this paper.

A qualitative analysis is given in Table 5 where the top-two sentences selected from SSSB express the noun sense of *nurse*, whereas the bottom-two setences express its verb sense. From Table 5, we see that SenseBERT has a higher preference (indicated by the high pseudo log-likelihood scores) for stereotypical examples than BERT over anti-stereotypical ones (indicated by the higher diff values).

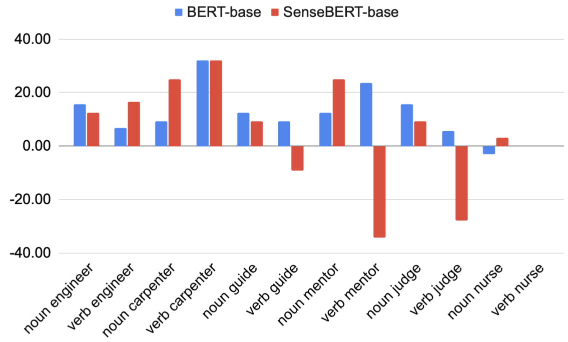

Figure 4: Gender biases found in 768-dimensional BERT-base and SenseBERT-base contextualised embeddings. Positive and negative AUL scores represent bias towards respectively the stereotypical and anti-stereotypical sentences.

8 Conclusion

We evaluated social biases in sense embeddings by extending existing word-level bias evaluation datasets (WEAT, WAT) and by creating a novel sense-specific contextualised dataset (SSSB). Our experiments show that sense embeddings are also socially biased similar to word embeddings. Extending the analysis beyond English and developing debiasing methods for sense embedding are identified as important future research directions.

9 Ethical Considerations

In this paper we considered the relatively underexplored aspect of social biases in pretrained sense embeddings. We created a new dataset for this purpose, which we name the Sense-Sensitive Social Bias (SSSB) dataset. The dataset we create is of a sensitive nature. We have included various sentences that express stereotypical biases associated with different senses of words in this dataset. We specifically considered three types of social biases in SSSB: (a) racial biases associated with a nationality as opposed to a language (e.g. *Chinese people are cunning*, *Chinese language is difficult*, etc.), (b) racial biases associated with the word *black* as opposed to its sense as a colour (e.g. *Black people are arrogant*, *Black dress is beautiful*, etc.) and (c) gender-related biases associated with occupations used as nouns as opposed to verbs (e.g. *She was a careless nurse*, *He was not able to nurse the crying baby*, etc.). As seen from the above-mentioned examples, by design, SSSB contains many offensive, stereotypical examples. It is intended to facilitate evaluation of social biases in sense embeddings and is publicly released for this purpose only. We argue that SSSB should not be used to train sense embeddings. The motivation behind creating SSSB is to measure social biases so that we can make more progress towards debiasing them in the future. However, training on this data would defeat this purpose.

It is impossible to cover all types of social biases related to word senses in any single dataset. For example, the stereotypical association of a disadvantaged group with a positive attribute (e.g. *All Chinese students are good at studying*) can also raise unfairly high expectations for the members in that group and cause pressure to hold upto those stereotypes. Such *positive biases* are not well covered by any of the existing bias evaluation datasets, including the one we annotate in this work.

Given that our dataset is generated from a handful of manually written templates, it is far from complete. Moreover, the templates reflect the cultural and social norms of the annotators from a US-centric viewpoint. Therefore, SSSB should not be considered as an ultimate test for biases in sense embeddings. Simply because a sense embedding does not show any social biases on SSSB according to the evaluation metrics we use in this paper *does not* mean that it would be appropriate to deploy it in downstream NLP applications that require sense embeddings. In particular, task-specific fine-tuning of even bias-free embeddings can result in novel unfair biases from creeping in.

Last but not least we state that the study conducted in this paper has been limited to the English language and represent social norms held by the annotators. Moreover, our gender-bias evaluation is limited to binary (male vs. female) genders and racial-bias evaluation is limited to Black as a race. Extending the categories will be important and necessary future research directions.

Hybrid Semantics for Goal-Directed Natural Language Generation

Connor Baumler

`sray@case.edu`

Abstract

We consider the problem of generating natural language given a communicative goal and a world description. We ask the question: is it possible to combine complementary meaning representations to scale a goal-directed NLG system without losing expressiveness? In particular, we consider using two meaning representations, one based on logical semantics and the other based on distributional semantics. We build upon an existing goal-directed generation system, S-STRUCT, which models sentence generation as planning in a Markov decision process. We develop a hybrid approach, which uses distributional semantics to quickly and imprecisely add the main elements of the sentence and then uses first-order logic based semantics to more slowly add the precise details. We find that our hybrid method allows S-STRUCT's generation to scale significantly better in early phases of generation and that the hybrid can often generate sentences with the same quality as S-STRUCT in substantially less time. However, we also observe and give insight into cases where the imprecision in distributional semantics leads to generation that is not as good as using pure logical semantics.

1 Introduction

We consider the problem of goal-directed natural language generation (NLG) (Gatt and Krahmer, 2018). Here, the agent intends to communicate some information about its world to another entity. It has semantic representations for its world, its goal, and a grammar to realize the language. Given this input, the goal is to generate (realize) a syntactically correct representation of the semantic goal without omissions or additions (see Figure 1). This task is different from open ended text generation that fills in text after a prompt or the problem of filling in a blank given some context.

Many previous systems for goal-directed NLG use first-order logic (FOL) extended with the λ-calculus to represent semantics (Church, 1985).

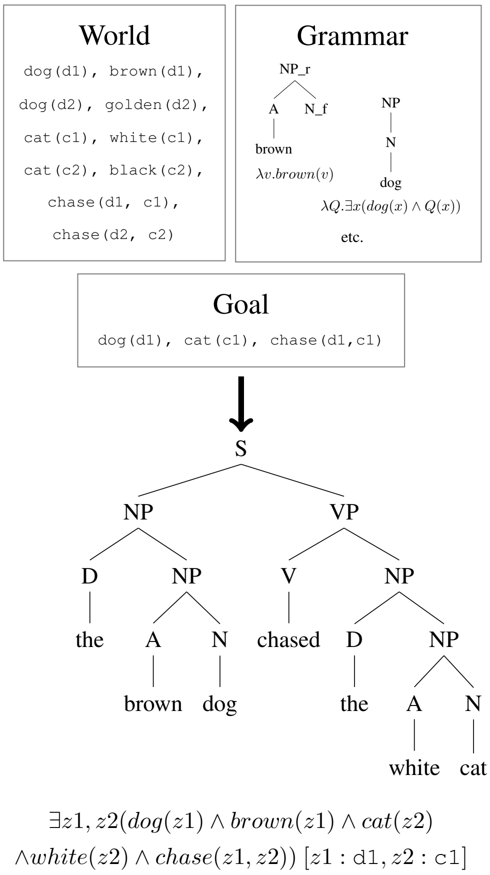

Figure 1: Example of the goal-directed NLG task. Given a world of facts, a grammar, and a communicative goal, generate a grammatical sentence that unambiguously expresses the goal.

This semantic representation allows for very precise generation. However, the process is usually slow, primarily because each step of the generation process needs to check that the semantics of the partially realized text is compatible with the eventual goal. This step typically involves checking all possible compatible *bindings*, which is combinatorial. Using distributional semantic representations (Deerwester et al., 1990; Mikolov et al., 2013; Pennington et al., 2014) may allow us to sidestep this combinatorial process through checks via sim-

ple algebraic operations. However, these semantics may lack precision and introduce errors in generation with respect to the goal. In this paper we ask whether it is possible to combine these two different semantic representations in a single generation system that takes advantage of their strengths while mitigating their weaknesses. In particular our insight is that, early in the generating process, we may not need to be very precise. We can use distributional semantics to quickly add in the main elements of a sentence and then use logical semantics to fill in the details more slowly and precisely. Our goal is to balance these elements to get a more scalable generation system while not sacrificing much, if any, expressiveness.

A rich literature exists for generation systems. Overgeneration and ranking systems derive possible sentences from word lattices (Langkilde-Geary, 2002; Langkilde, 2000; Bangalore and Rambow, 2000). These word lattices are directed acyclic graphs whose edges correspond to single words. To generate a valid sentence, the system can traverse a path in the lattice. Then, they rank the candidate sentences using a language model. An alternative approach is to view generation as an AI planning problem. The planner can apply grammar "actions" to take planning steps until it finds a state that fulfils some communicative goal. One such system is SPUD (Sentence Planner Using Descriptions) which answers questions using a knowledge base (Stone and Doran, 1997). The CRISP system builds on SPUD by applying an off-the-shelf planner instead of using a greedy search (Koller and Stone, 2007; Koller and Hoffmann, 2021). This allows for the application of search heuristics and other advances in classical planning. A further improvement is PCRISP which allows probabilistic actions by translating probabilities into costs (Bauer and Koller, 2010).

Other work uses neural networks with an encoder and/or decoder architectures. For instance, a transformer will already have the semantics of individual words as static word vectors (Vaswani et al., 2017; Peters et al., 2018; Radford et al., 2018; Devlin et al., 2019; Lewis et al., 2020). The overall meaning is calculated using attention and feedforward layers. These approaches create a complex representation of the language model in the encoder and employ a variety of sampling strategies in the decoder. While they can be much faster than logic-based systems, it can be difficult to guarantee that the generated string will be consistent with some world or goal. Recent work has started to explore hybrid approaches in this space. One approach adds logical constraints and plans to transformers and LSTMs. DualEnc models are provided "content plan" traversals through RDF graphs as input (Zhao et al., 2020). While these plans provide the model with the information that is supposed to be included in the generated text, there is no guarantee the model will include all of it or that the information is truly consistent with the original RDF graph.

Rather than providing a plan before generation, NeuroLogic Decoding constrains generated transformer output based on logical constraints during the decoding step (Lu et al., 2021). By leveraging predicate logic, this allows the output to be more precisely constrained to include any necessary true facts and leave out any extra, potentially incorrect, information. This precision is added at a cost asymptotically equivalent to a conventional beam search. However, the logical constraints in this work are syntactic rather than semantic, and ensure that, for example, certain words are not used by the decoded string.

In contrast to such approaches, in our work, we modify S-STRUCT (McKinley and Ray, 2014; Pfeil and Ray, 2016), a planning based system for goal-directed NLG, to use both distributional as well as logical semantics. S-STRUCT is described in detail in the next section. This system models generation as planning in a Markov decision process (MDP). We show experimentally that our approach scales better than pure logical semantics in many cases. We also identify and discuss tradeoffs that arise from the use of distributional semantics, that in some cases lead to worse generation quality.

2 S-STRUCT

Scalable Sentence Tree Realization using UCT (Upper Confidence bounds applied to Trees), or S-STRUCT, is a planning based NLG system that generates single sentences, using a world of facts, a communicative goal, and a grammar. The world and goal are both specified semantically in FOL. The world describes all entities and relations known to the generator while the goal specifies information to communicate. The grammar consists of a semantically annotated probabilistic lexicalized tree adjoining grammar (PLTAG) derived from the XTAG project (XTAG Research Group, 1998).

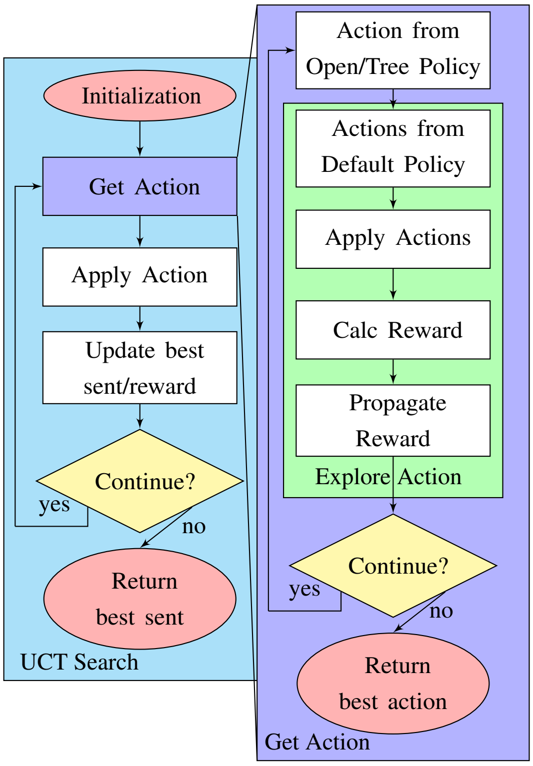

Figure 2: S-STRUCT algorithm. UCT is used to find the best action (PLTAG tree substitution/adjoin) at each step until the goal is satisfied (reward is maximized).

Before S-STRUCT begins the generation process, it finds an expanded communicative goal. The expanded goal includes any extra information necessary to make the goal entities unambigiuous from the other entities in the world. Then, S-STRUCT prunes the grammar of lexicalized trees that, given the goal, will never be used. The resulting pruned grammar will be able to express relations between goal entities and will contain trees that satisfy semantic constraints that may not be explicitly mentioned in the goal (e.g., a complementizer "that" tree). It will also be able to express at least one referring-expression for each unique entity (e.g., if we need to generate a "cat" entity, we may need to clarify whether it is *black* or *brown*).

We observe that once trees are pruned, any associated entities and relations in the world can be pruned as well. This world pruning reduces the space of possible bindings, which we have empirically verified results in a significant speed increase without impacting accuracy. We call this version of S-STRUCT with world pruning S-STRUCT v2.

Once this pruning is completed, to generate a sentence, S-STRUCT uses the UCT (Kocsis and Szepesvári, 2006) procedure (see Figure 2) to plan in an MDP. States in the MDP are semantically annotated partial trees reflecting the partial sentence constructed so far. Actions adjoin or substitute a single PLTAG tree. At each step, S-STRUCT ranks actions to add a new fragment to the current partial tree. If there are unexplored actions, it chooses such an action to explore. Otherwise, it chooses actions based on the UCT ranking, which balances explore/exploit criteria.

To estimate the downstream quality of the action, S-STRUCT looks ahead by a number of exploratory actions that are uniformly sampled. For each action, S-STRUCT finds the reward of each state reached, propagating the rewards up the search tree. These rewards identify the best action at a state. The reward is largely determined by how well the partial sentence matches the semantics of the goal. To do this, S-STRUCT considers bindings between entities in the partial sentences and the goal. Here, a valid binding between entities is one in which the stated semantic information does not disagree (e.g., we have a cat in the partial sentence that is *white* and a cat in the goal that is *white* and *long-haired*). In the reward, S-STRUCT only receives credit when a goal entity has a valid biding to a partial-sentence entity.

The reward also considers the number of entities missing a determiner, the number of partial-sentence entities with no goal bindings, the number of world bindings, and the length of the sentence. The first two characteristics penalize missing information. The number of world bindings reflects potential ambiguity in the sentence. Finally, the last criterion reflects the fact that given two sentences, both of which express the goal semantics precisely, we prefer the shorter sentence.

The action search procedure returns the action with the best reward. S-STRUCT applies this action and updates the partial sentence. If a terminal state is reached in which adding more actions will not improve the reward or the generation process runs out of time, then this sentence is returned. If not, the action search repeats. In subsequent searches, we may be able to reuse parts of the search tree of exploratory actions as some will still be relevant in the new state.

To improve search efficiency, the search in S-STRUCT is carried out in two phases. First, only substitution actions are considered until all substitution nodes in the PLTAG tree are filled. Then, adjoin actions (and some substitutions if required by the added adjoins) are considered to complete the generation. This reduces the branching factor of the search considerably, speeding up the process.

3 HS-STRUCT: S-STRUCT with Hybrid Semantics

In this section, we describe how we modify S-STRUCT to use distributional semantics. We first describe how we compose distributional semantics and how the distributional reward is computed. Then, we describe additional modifications required by using imprecise semantics in the search, including a step to correct word ordering errors and using a beam search instead of a greedy search in UCT.

3.1 Distributional Composition

We must be able to compose embeddings to obtain the semantics of the goal and each state. We first note that we cannot use order-dependent composition of word vectors to obtain state or goal embeddings. Say our goal is to express $dog(x) \wedge cat(y) \wedge rat(z) \wedge chase(y, z) \wedge chase(x, y)$. If we have generated to the point of, for example, "dog chase cat," then we can use an order dependent method to compose the semantics of the *dog*, *chase*, and *cat* vectors to represent the fragment. However, the logical goal does not order relations in a meaningful way. In fact, figuring out the syntactic structure to realize the goal is a problem S-STRUCT itself solves. So, to compose the goal embedding, we will need a method that is not order dependent. To be consistent, we need to apply the same method for state embeddings as well.

In our approach, we find goal or state embeddings by averaging the components. In other words, we map the entities and relations in our goal or state to word embeddings (for example, the relation "chase" is mapped to the vector for the word *chase*) and then average these to create an embedding for the state or the goal.

3.2 Distributional Reward

For each partial state, we need to compute a reward that measures how close we are to realizing the goal. This is described in Algorithm 1. First, we calculate the distance between the partial state and the goal as the Euclidean norm of the difference between the embeddings (line 2). We next add a penalty for the number of missing or extra conditions (line 3) and the sentence length (line 4). Thus the best states will be short sentences that do not have missing or extra conditions and that have embeddings close to the goal. C_1, C_2 and C_3 are weight factors that modify the relative importance of these factors (hand-selected as 100, 15 and 10 and consistent in all experiments). Finally, for S-STRUCT we need the reward to be positive. This is because S-STRUCT's tree policy chooses actions in part based on the total reward over all the times it has been applied. Here, a negative reward will penalize actions that we see more often. To fix this, we add a large constant to the reward (line 1), making the reward always positive. This reward shaping will not affect the optimal plan (Ng et al., 1999).

Algorithm 1: calcReward

```
Input: Partial Sentence $S$, World $W$, Goal $G$
1 $score \leftarrow R_{max}$
2 $score \mathrel{-}= C_1 \|S.Sem - G.Sem\|$
3 $score \mathrel{-}= C_2 |G.conds - S.conds|$
4 $score \mathrel{-}= C_3 |S.sentence|$
5 return $score$
```

3.3 Integrating Distributional and Logical Semantics

Each semantic representation has its strengths and weaknesses. How should we integrate the two? First, consider an alternative in which we only use distributional semantics. This version (let us call it "PureDist") would be fast, but runs into several issues. First, in the absence of word-order-sensitive composition, PureDist cannot identify which sentences have the wrong word ordering.

Additionally, a problem arises with the stopping criterion. Generation should stop when not taking an action leads to a better reward than taking one. For PureDist, since our embedding vectors are high dimensional, there are many degrees of freedom to slightly improve the reward. So, while S-STRUCT can only get reward for fulfilling a goal relation or adding a determiner to an entity once, PureDist can keep generating by adding new, potentially repetitive words that are not adding any new information but instead are moving the state slightly closer to the goal vector. Without a strong way to determine whether or not the current state has reached the goal, PureDist's generation quality is more heavily tied to the balance of the sentence length penalty.

If the sentence length penalty is too high, PureDist will cut generation off before useful information has been expressed. If it is too low, generation can continue to add irrelevant words that move the state slightly closer to the goal. As a result, using a purely distributional semantic search is not a viable alternative (this is validated in our experiments).

This leaves two options: we can use distributional semantics to start, and then switch to logical, or vice versa. Of these, the first is more suitable. The key intuition is that early in generation, the work done to compute bindings and to validate partial sentences in S-STRUCT is overkill. A less precise semantic representation could do just as well, while being more efficient. Further, by switching to logical semantics *after* distributional we will have the opportunity to correct word ordering errors. Conversely, using logical semantics in the early phase means we are potentially doing unnecessary work. Therefore we decide to use distributional semantics to start, and then switch to logical semantics.

When should we switch? As mentioned above, S-STRUCT has a natural transition point. The first part of the search focuses only on substitution actions (a "substitution phase") before switching to an "adjoin phase." We choose to use distributional semantics in the substitution phase. In our example in Figure 3, we use our distributional reward in the initial and substitution actions getting us to "cat chased dog." At this point, we cannot add more information without adjoin actions, so we can move to the next phase.

3.4 Swap Actions

Since our state/goal composition is word order independent, the output of the first phase may have ordering errors, such as in Figure 3b. We address this by adding a Swap phase in between the distributional and logical semantic phases. In this phase, we find all pairs of entities in the tree output by the distributional phase that have the same type (such as a noun phrase), and consider the trees that result if we exchange them. For each such tree, we compute the original S-STRUCT reward with logical semantics. This means that we consider exact bindings of the sentence entities to their world and goal counterparts to determine the reward of the sentence. We greedily apply the best swaps we can find until doing no swap yields a better reward. Unlike with Dist, Swap will only get credit for adding an entity if it is being used correctly, meaning Swap will get a better reward when word ordering mistakes are fixed.

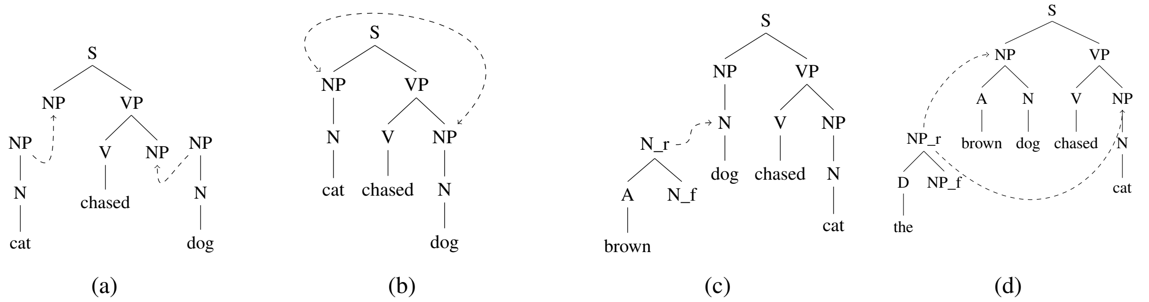
3.5 Beam Search

While Swap actions can mitigate some of the mistakes caused by the first phase, they may not account for all possible errors, such as the use of incorrect substitutions. So we use a beam search within the UCT search of the first phase of HS-STRUCT instead of greedily selecting the best state. This means HS-STRUCT can keep track of multiple states that may seem sub-optimal when using the distributional reward but will be more successful under the formal logic reward. The resulting beam after the first phase is passed into Swap as described above. Each partial state is processed by Swap, and the best state found is then input to the third phase, which is regular S-STRUCT, to perform adjoins and finish the generation process (shown in Figure 3c and 3d). By adding this beam search, we allow HS-STRUCT to partially underspecify substitution decisions during the distributional phase.

To keep generation efficient, we split trials of exploratory actions between all states in the beam. In other words, each beam search state uses an equal portion of the overall exploratory actions, keeping the total number of exploratory actions the same as without the beam search.

3.6 HS-STRUCT Algorithm

Our HS-STRUCT algorithm is shown in Algorithm 2. We begin by using distributional semantics (Dist) from the initial (empty) state. This search follows the general structure of the original S-STRUCT search (Figure 2) though with a beam search (line 4 and Figure 3a). We only allow initial and substitution actions in this phase as we are only trying to block out the main ideas. Then, we consider swap actions to correct for word order issues (lines 5 and 6 and Figure 3b). Now that we have our swapped states, we down select into a single state for the remainder of generation (line 7). Finally, we use our original FOL-based S-STRUCT to add any details that would have required adjoin actions to finish out our generation (line 8 and Figures 3c and 3d).



(a) (b) (c) (d)

Figure 3: Example of HS-STRUCT generation of "The brown dog chased the cat." (a) Using the distributional reward, we do the initial "chased" action and substitute the "dog" and "cat". (b) We use a swap action to fix the word ordering mistake. (c&d) Using the logical reward, we adjoin the "brown" detail and the determiners.

Algorithm 2: HS-STRUCT

```
Input: Grammar $R$, World $W$, Goal $G$,
       NumTrials $N$, Lookahead $D$,
       Timeout $T$, Beam Width $B$
$R \leftarrow pruneGrammar(R)$
$W \leftarrow pruneWorld(W, R)$
$states \leftarrow$ a size $B$ empty list
$states \leftarrow Dist(R, W, G, N, D, T, states)$
for i in [1,B] do
    $states[i] \leftarrow Swap(states[i])$
$state \leftarrow$
    $\arg\max_{s \in states} calcLogicalReward(s)$
$bestSentence, state \leftarrow$
    $FOL(R, W, G, N, D, T, state)$
return $bestSentence$
```

4 Empirical Evaluation

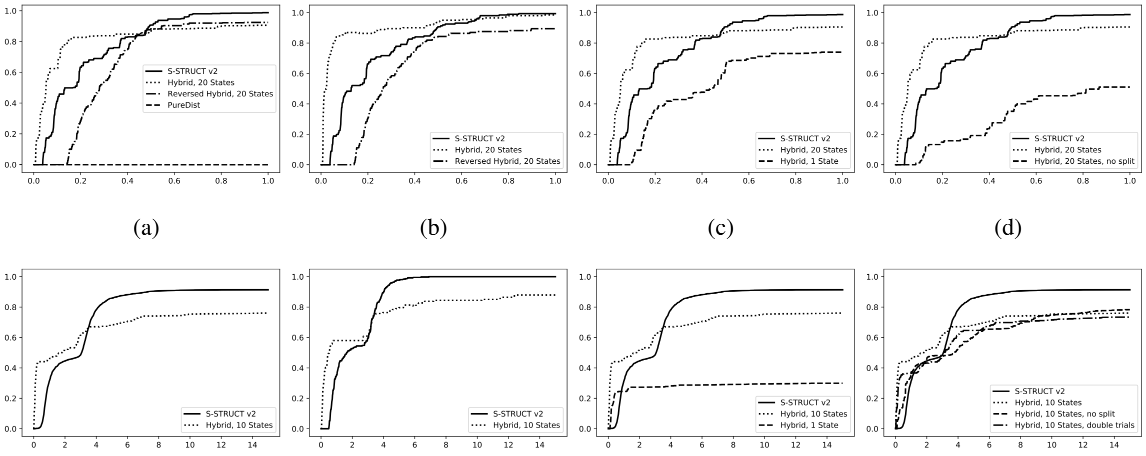
Our primary hypothesis is that integrating distributional and logical semantics through HS-STRUCT will scale better (i.e. generate better quality sentences in less time) than either S-STRUCT v2 (S-STRUCT with world pruning), PureDist or using distributional semantics after logical semantics. We will also evaluate the impacts of design choices such as the beam search. We have not compared against contextual language models in our experiments because, as described in Section 1, the most related such approaches that we know of still do not address the goal-directed NLG task.

Data. We follow prior work and focus on generation of English sentences, pulling world facts and goals from the WSJ section of the Penn TreeBank corpus (McKinley and Ray, 2014; Marcus et al., 1999). The sentences were parsed with an LTAG parser (Sarkar, 2000; XTAG Research Group, 1998) to find the best parse trees for each sentence. A subset of the most frequently occurring XTAG trees were chosen and manually semantically annotated with FOL semantics. Together, these trees could parse 74% of the corpus. For our distributional semantic representation, we use pre-trained OLIVE word vectors trained on the Wikipedia English corpus (Seonwoo et al., 2019). While HS-STRUCT is agnostic to the distributional semantic representation used, OLIVE vectors are trained to have additive compositionality, so we know we can compose our partial sentence and goal embeddings. Some sentences in our dataset had to be removed because of the lack of OLIVE vectors to cover them.

Test Set	Goals	World Entities	World Relations	Avg. Goal Entities	Avg. Goal Relations
Simple	32	48	36	1.50	1.13
Complex	750	1224	1245	1.63	1.66

Table 1: Summary statistics for evaluation datasets

For our experiments, we choose goals from the semantic annotations of sentences in the dataset, with the world being a combination of facts from the semantics of all goals (sentences). These worlds and goals are split into a "simple" and a "complex" dataset based on the complexity of the goals with the complex dataset having more world entities, relations, average relations and entities in the goal (Table 1). These datasets are made from non-overlapping goals. An example simple goal is $bank(z1) \wedge acquiesced(z1)$ which could mean "The bank acquiesced.", and an example complex goal is $siliconvalley(z1) \wedge sigh(z2) \wedge relief(z3) \wedge heaved(z1, z2) \wedge of(z2, z3)$ which could mean "Silicon Valley heaved a sigh of relief."



(a) (b) (c) (d)

(e) (f) (g) (h)

Figure 4: Comparison of reward gained or ROUGE-1 score and time to generate using various versions of S-STRUCT. (a-d) and (e-f) use the simple and complex datasets respectively. The x-axes show time in seconds and the y-axes show the percentage of the best metric at a given time. In all cases, scores are averaged over all goals in the given dataset. (a) and (e) show the overall reward gain on HS-STRUCT vs other versions of S-STRUCT. (b) and (f) similarly show the changes in ROUGE-1 score. (c) and (g) look at the effect of using the beam search. (d) and (h) show the effect of splitting or not splitting trials between stored states of HS-STRUCT.

Metrics. There are two possible ways to evaluate our generation quality: syntactic and semantic. The reward assigned by S-STRUCT v2 and HS-STRUCT is primarily based on a semantic match between the goal and the partial sentence. However, in some cases a semantic difference can be misleading if the syntactic realization is similar. So, in addition to our semantic reward, we also evaluate our sentences using ROUGE-1 (Recall-Oriented Understudy for Gisting Evaluation)(Lin, 2004). ROUGE is designed to evaluate summaries of texts by comparing them to ideal summaries created by humans. We use it to compare the result of each approach after each action to the "ideal" sentence with the best possible reward.

All experiments were implemented in Python 3.7.1. They were run on a single core of an Intel(R) i5-8250 processor clocked at 1.60GHz with access to 8GB of RAM. The results of our evaluation are shown in Figure 4a to 4h. In each case the x-axis is time in seconds and the y-axis is the percentage of the best metric at a given time. The results are averaged over all goals in each dataset.

4.1 HS-STRUCT vs. PureDist

As we can see in Figure 4a, HS-STRUCT gains a much higher reward than the method that only uses the distributional reward, PureDist. As we discussed in Section 3.3, there are a number of issues like word ordering and stopping criteria which makes generation with only distributional semantics difficult. This result provides empirical validation of these observations. Because PureDist performed so poorly on even simple goals, we did not run it on complex goals.

4.2 HS-STRUCT vs. Reversed Hybrid

We also consider reversing the order of distributional and formal semantics within the hybrid, starting with the logic-based FOL and then using the distributional Dist. As we can see in Figure 4a, reversed hybrid is less efficient than either HS-STRUCT or S-STRUCT v2. Reversed HS-STRUCT needs to spend twice the time switching between semantic systems and potentially much more time completing swap actions than regular HS-STRUCT. While we chose the sentence length tradeoff hyperparameter to allow for the reversed HS-STRUCT to achieve a good reward, in general using a distributional reward for adjoin actions leads to issues with deciding when to cut generation off. Overall, this shows that simply reversing HS-STRUCT does not yield an improvement in performance.

4.3 HS-STRUCT vs. S-STRUCT v2

On the simple dataset (Figures 4a and 4b), HS-STRUCT initially creates sentences with a higher syntactic and semantic quality faster than S-STRUCT v2. The final syntactic quality (4b) is the same as S-STRUCT v2, though there is a small gap in the final semantic quality. On the complex dataset, (Figures 4e and 4f), while HS-STRUCT again produces sentences with a higher reward faster than S-STRUCT v2 early on in generation. But there is a decrease in the final metric obtained by HS-STRUCT both syntactically and semantically by about 12% syntactically and about 17% semantically. The reason for the gap in the final metric values is analyzed further below. Overall, we find that HS-STRUCT sometimes produces lower quality sentences on high complexity goals than S-STRUCT v2 given enough time. However, even when the goal is complex, HS-STRUCT can produce higher quality sentences than S-STRUCT v2 under a short time limit, and consistently achieves this when the goal is simple.

4.4 Effect of Beam Search

Figures 4c and 4g show the effect of using a beam search in the distributional phase of HS-STRUCT as opposed to a greedy search. On the simple dataset (Figure 4c), allowing HS-STRUCT to choose between stored states in the formal logic phase improved the average final reward by 22%. On the complex dataset, this change resulted in a 154% increase. This indicates as well that the distributional phase may not be very accurate at selecting the single best state in the search process.

When a beam search is used, a decision must be made how to allocate the UCT rollouts to different states in the beam. Instead of giving each state the same number of trials as the single, greedy search approach, which would make the beam search much less efficient, we hypothesize that we can split the overall number of trials between each state to receive a comparable reward in significantly less time. As we can see in Figure 4d, splitting the number of trials has a very significant effect on the speed and quality of generation on the simple dataset. Simply providing each state in the beam the same number of trials as greedy search slows generation considerably. Again in Figure 4h, we observe that not splitting trials slows generation substantially in the early phases while having no significant impact on quality. Increasing the number of trials to 2x also slowed generation with no significant increase in quality. Thus, a broad and shallow search seems well suited to the early phase of generation, which agrees with our intuition.

4.5 Discussion

Our results show that HS-STRUCT can produce sentences that are around 12% lower in terms of syntactic quality than S-STRUCT v2 under no time constraints. In this section we discuss why we see this gap and whether it is due to fundamental aspects of distributional semantics.

The reward gap between HS-STRUCT and S-STRUCT v2 results from a number of issues such as incorrect parts of speech, incorrect verb valence, and over-generation. These errors can co-occur, but we report them without overlap, prioritizing part of speech errors. This means that the reported error frequencies are a lower bound for every error type except part of speech.

Parts of Speech. The same word may be used as different parts of speech. This is important in generation, but distributional semantics has difficulty telling this apart. A common problem for HS-STRUCT was using an entity as a verb. These mistakes will not be fixed by the Swap phase and will not allow for valid bindings in the logical phase. This means that we cannot recover if all beam search states contain this error. S-STRUCT v2 does not make such mistakes, since it does not use distributional semantics.

On the complex dataset, these part of speech mistakes account for about 50% of cases in which HS-STRUCT earns a worse reward than S-STRUCT v2. Such errors could potentially be fixed with improved embeddings considering different vectors for different parts of speech.

Verb Valence. Our grammar has multiple possible verb trees which will be lexicalized with the possible verbs in our lexicon. This means that, as appropriate, verbs can lexicalize multiple trees, representing the different number of arguments the verb could take (also known as the verb's valence). In S-STRUCT, this valence distinction will not cause issues. Using the wrong tree with the correct root will not count toward the goal satisfaction portion of the reward since the number of arguments in the semantic representation has to match. For HS-STRUCT, however, the reward calculation does not explicitly check for the correct valence as the verb is the same, with the same embedding, so the same goal distance will be given to partial sentences using either tree.

In the simple dataset, this leads to a partially artificial reward gap. In 60% of cases in which HS-STRUCT received a lower reward, the final sentences produced by HS-STRUCT and S-STRUCT v2 are identical. In the complex dataset, valence issues accounted for about 20% of cases in which S-STRUCT v2 outperformed HS-STRUCT. This issue could be alleviated by computing different embeddings for different valences of a verb.

Over-generation. On the complex dataset, we also see a number of cases in which the overall content of the two generated sentences were nearly identical, with HS-STRUCT adding in unneeded additions like extra complementizers. Since extra complementizers do not change the semantic content, this mistake will barely affect the logical reward but does decrease ROUGE-1 scores. This over-generation may also stem from the "incremental benefit" of HS-STRUCT's reward function as described in Section 3.3, and accounts for about 15% of cases in which HS-STRUCT earns a worse reward than S-STRUCT v2 on the complex dataset. It could potentially be alleviated by more carefully tuning the sentence length penalty in the reward.

Examples. Consider the sentence "The rates in the secondary market are typical," which is expressed as the goal $rates(z1) \wedge typical(z1) \wedge market(z2) \wedge secondary(z2) \wedge in(z1, z2)$. As we can see, there is no verb listed in the goal semantics. The copula "are" would not make sense as an FOL relation as $typical(z1)$ already implies that the rates *are* typical. We also run into issues with the preposition "in". Since it could also feasibly be an abbreviation for "inch", our grammar includes it as a noun as well.

HS-STRUCT begins by choosing a "typical" declarative adjective small clause tree (αnx0Ax1) with "typical" as the AP and the NP and V substitution nodes left open. It cannot tell the difference between noun and preposition "in", so it sees substituting "in" for the remaining NP node (essentially creating the string "in␣typical"). Using our OLIVE vectors, the combination of "in" and "typical" is closer to the goal than the correct "rates" and "typical" (because "in" is present in the goal), so this part-of-speech mistake is seen as beneficial. HS-STRUCT may also store the "rates" substitution, but this is a function of the beam width. It leaves the copular verb "are" location blank, as this verb does not appear in the goal.

While the "in" substitution helped the distributional reward, it will hurt the logical reward in future since there is no "in" entity in the world or goal to bind to (there is only an "in" relation). Since HS-STRUCT will not be able to find valid bindings, it will not be able to add additional information, forcing the generation to stop at "in␣typical". Here, generation can be improved by increasing the beam states until the "rates" substitution is also chosen, or by having the distributional phase represent preposition "in" and inches "in" separately.

Another such error is shown by the sentence "Investors dumped any technology shares." Here, the "shares" are an entity in the goal (i.e., written as $instance\_of(x, shares)$ not $shares(x, y)$). HS-STRUCT will represent both the verb "shares" and the noun "shares" the same way, so it does not know that it should not consider the initial tree using the verb "shares". In this case, HS-STRUCT ends the distributional phase with the best sentence "Investors share technology." Again, such an error is not recoverable in the logical semantics phase.

A different issue that may contribute to HS-STRUCT's lower reward in some cases is that of copular verbs. These do not appear in the goal semantics. However, if there is some non-copular verb in the goal, HS-STRUCT may incorrectly substitute in a verb in the copular verb slot, as doing so will decrease the goal distance. If the beam search did not keep a state without one of these incorrect substitutions, then HS-STRUCT will not be able to recover in the logical phase.

5 Conclusion

We have presented HS-STRUCT, which uses both distributional and logical semantics for goal-directed language generation. By taking a hybrid approach HS-STRUCT's generation scales significantly better in early phases. However, in some cases, the quality of the final generation can be lower than a pure logical approach. HS-STRUCT is available through GitHub upon request.

Predicting Intervention Approval in Clinical Trials through Multi-Document Summarization

Georgios Katsimpras and **Georgios Paliouras**
NCSR Demokritos, Athens, Greece
{gkatsibras,paliourg}@iit.demokritos.gr

Abstract

Clinical trials offer a fundamental opportunity to discover new treatments and advance the medical knowledge. However, the uncertainty of the outcome of a trial can lead to unforeseen costs and setbacks. In this study, we propose a new method to predict the effectiveness of an intervention in a clinical trial. Our method relies on generating an informative summary from multiple documents available in the literature about the intervention under study. Specifically, our method first gathers all the abstracts of PubMed articles related to the intervention. Then, an evidence sentence, which conveys information about the effectiveness of the intervention, is extracted automatically from each abstract. Based on the set of evidence sentences extracted from the abstracts, a short summary about the intervention is constructed. Finally, the produced summaries are used to train a BERT-based classifier, in order to infer the effectiveness of an intervention. To evaluate our proposed method, we introduce a new dataset which is a collection of clinical trials together with their associated PubMed articles. Our experiments demonstrate the effectiveness of producing short informative summaries and using them to predict the effectiveness of an intervention.

1 Introduction

Clinical Trials (CT) present the basic evidence-based clinical research tool for assessing the effectiveness of health interventions. Nevertheless, only a small number of interventions make it successfully through the process of clinical testing. Approximately, 39%-64% of interventions actually advance to the next step of each phase of clinical trials (DiMasi et al., 2010). The uncertainty of a CT outcome could lead to increased costs, prolonged drug development and ineffective treatment for the participants. At the same time, the volume of published scientific literature is rapidly growing and offers the opportunity to explore a valuable knowledge. Therefore, there is a need to develop new tools which can i) integrate such information and ii) enhance the process of intervention approval in CT.

Predicting the approval of an intervention, a task that describes the ability of a system to predict whether an intervention will reach the final stage of clinical testing, is a topic that has been studied before (Gayvert et al., 2016; Lo et al., 2018). The majority of these studies use various traditional machine learning methods and rely on structured data from various sources, including biomedical, chemical or drug databases (Munos et al., 2020; Heinemann et al., 2016). However, only a few studies take into account the textual information that is available online, and mostly in a supplementary manner (Follett et al., 2019; Geletta et al., 2019). In fact, employing natural language processing (NLP) techniques to address the outcome prediction task has been hardly explored.

Recognising this lack of related studies, the work presented here addresses the task of predicting intervention approval with the use of NLP. Particularly, we relied on generating concise and informative summaries from multiple texts that are relevant to the intervention under evaluation. In a sense, we built an intervention-specific narrative which combines key information from multiple inter-connected documents. The benefit of using multiple articles to generate summaries is that they can cover the inherently multi-faceted nature of an intervention's clinical background.

More precisely, given an intervention, our system retrieves all PubMed abstracts that are relevant to the intervention and refer to a clinical study. It then extracts the evidence sentences from each abstract using a BERT-based evidence sentence classifier, in a similar fashion to (DeYoung et al., 2020). This set of evidence sentences, which captures the consolidated narrative about the intervention, can

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 1947 - 1957
May 22-27, 2022 ©2022 Association for Computational Linguistics

grow gradually, as new articles become available. Thus, further analysis is necessary in order to select the most important information. Using the set of evidence sentences for each intervention, we generate short summaries by leveraging the power of language models (BERT or BART). The resulted summaries are then fed to a BERT-based binary sequence classifier which makes a prediction about the likely approval or not of the intervention.

Overall, the main contributions of the paper are the following:

- We propose a new approach for predicting the approval of an intervention which is based on a three-step NLP pipeline.
- We provide a new dataset for the task of intervention approval prediction that consists of 704 interventions and 15,800 PubMed articles in total.
- We confirm through experimentation the effectiveness of the proposed approach.

2 Related Work

Intervention Success Prediction The prediction of intervention approval belongs to a broader category of medical prediction tasks. Relevant work includes clinical trial outcome prediction (Munos et al., 2020; Tong et al., 2019; Hong et al., 2020), drug approval (Gayvert et al., 2016; Lo et al., 2018; Siah et al., 2021; Heinemann et al., 2016), clinical trial termination (Follett et al., 2019; Geletta et al., 2019; Elkin and Zhu, 2021), predicting phase transition (Hegge et al., 2020; Qi and Tang, 2019). All these studies rely either on specific types of structured data or on combining structured data with limited unstructured data.

Differently from this line of work, the authors of (Lehman et al., 2019) proposed an approach that employs NLP to infer the relation between an intervention and the outcome of a specific clinical trial. Their method is based on extracting evidence sentences from unstructured text. An extension of this work suggests the use of BERT-based language models for the same task (DeYoung et al., 2020). Another closely related study (Jin et al., 2020), performs a large-scale pre-training on unstructured text data to infer the outcome of a clinical trial. Our approach builds upon this related work, aiming to incorporate information from multiple articles. This extension is motivated by the assumption that the inter-connected clinical knowledge, coming from multiple sources can provide a more holistic picture of the intervention, facilitating more precise analysis and accurate prediction.

Although all these prior efforts tackle, more or less, the problem of intervention approval, none of them attempted to predict the effectiveness of an intervention using summarization methods.

Summarization The goal of summarization is to produce a concise and informative summary of a given text. There are two main categories of approaches: i) *extractive*, which tackles summarization by selecting the most salient sentences from the text without changing them, and ii) *abstractive*, which attempts to generate out-of-text words or phrases instead of extracting existing sentences. Early systems were primarily extractive and relied on sentence scoring, selection and ranking (Allahyari et al., 2017). However, both extractive and abstractive approaches have advanced significantly due to the novel neural network architectures, such as Transformers (Vaswani et al., 2017). The Transformers architecture is utilized by the BERT (Devlin et al., 2018) and BART (Lewis et al., 2019) language models which are used by the state-of-the art solutions for multiple NLP tasks, including summarization. Although most of the summarization literature focuses on single-document approaches, there is also a line of work that applies summarization on a set of documents, i.e. multi-document summarization (Ma et al., 2020). Such approaches are of particular relevance to our work, as we aim to summarize a set of sentences about a particular intervention.

Summarization in the Medical Domain Summarization has been used to address various problems in the field of medicine. These include electronic health record summarization (Liang et al., 2019), medical report generation (Zhang et al., 2019; Liu et al., 2021), medical facts generation (Wallace et al., 2021; Wadden et al., 2020) and medical question answering (Demner-Fushman and Lin, 2006; Nentidis et al., 2021).

Our work is inspired by recent work on multi-document summarization of medical studies (DeYoung et al., 2021). Apart from introducing a new summarization dataset of medical articles, that work also proposed a method to generate abstractive summaries from multiple documents. Their model is based on the BART language model, appropriately modified to handle multiple texts. Our model differs in the way it handles the input texts. Instead of concatenating all texts into a single representative document, we order them chronologically and split them into equal-size chunks. Doing so, we expect the clinical studies that were conducted during a similar time period, to reside in the same chunk.

3 Task Overview

According to the U.S. Food and Drug Administration (FDA), a CT addresses one of five phases of clinical assessment: Early Phase 1 (former Phase 0), Phase 1, Phase 2, Phase 3 and Phase 4. Each phase is defined by the study's objective, the interventions under evaluation, the number of participants, and other characteristics[1]. Notably, Phase 4 clinical trials take place after FDA has *approved* a drug for marketing. Therefore, we can assume that a CT in Phase 4 assesses effective intervention. On this basis, our task is to predict whether an intervention will advance to the final stage of clinical testing (Phase 4), as shown in Figure 1.

We model the task of predicting the success or failure of an intervention as a binary classification task. All data relevant to Phase 4 are omitted from the training stage.

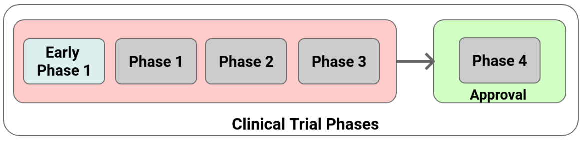

Figure 1: The phases of a clinical trial.

4 Data

In this work, we introduce a new dataset[2] for the task of predicting intervention approval. The dataset is a collection of structured and unstructured data in English derived from clinicaltrials.gov and PubMed during May-June 2021.

As a first step in the construction of the dataset, we retrieve all available CT studies from clinicaltrials.gov that satisfy some criteria. Then, we associate each CT with PubMed articles based on the CT study identifier. Following some cleaning process (i.e. deduplication and entity resolution) we generate the final dataset.

Clinical Trials Studies At the time of writing, more than 350,000 studies were available online at *clinicaltrials.gov*. We focused on *cancer* related clinical testing and we retrieved approximately 85,000 studies related to this topic using a list of associated keywords[3].

From this set, we were interested in interventional clinical trials and specifically in two categories that indicate the status of the trial: i) *"Completed"*, meaning that the trial has ended normally, and ii) *"Terminated"*, meaning that the trial has stopped early and will not start again. The resulting set of studies contains 34,517 completed and 6,872 terminated trials.

Interventions Dataset Using the selected CTs, we associated each intervention with its corresponding trials. Therefore, a clinical trial record was formed for each intervention. Then, we selected all interventions that are assessed in at least one Phase 4 CT to form our positive target class (i.e. approval). Likewise, we built our negative target class (i.e. termination) using interventions that led to a trial termination. In total, our dataset contains 404 approved and 300 terminated interventions.

For each intervention, we collect all articles from PubMed that are explicitly related to one of the CTs of the intervention. To achieve this, we combine two approaches. First, we search for eligible articles (or links to articles) in the corresponding structured results of *clinicaltrials.gov*. Secondly, we use the CT unique identifiers to query the PubMed database. Then, the selected PubMed articles are associated with the intervention. This way an intervention is linked with multiple studies that are inter-connected, and thus an intervention-specific narrative is developed. In our dataset, an intervention is associated on average with 22.4 pubmed articles, though for terminated interventions this number is just 1.4. This is because terminated interventions are usually not assessed in many CTs. Overall, our dataset contains 15,800 pubmed articles. The details of the dataset are presented in Table 1.

In addition, we attempted to evaluate[4] our approach on a previously used dataset (Gayvert et al., 2016), which consists of 884 (784 approved, 100 terminated) drugs along with a set of 43 features, including molecular properties, target-based properties and drug-likeness scores.

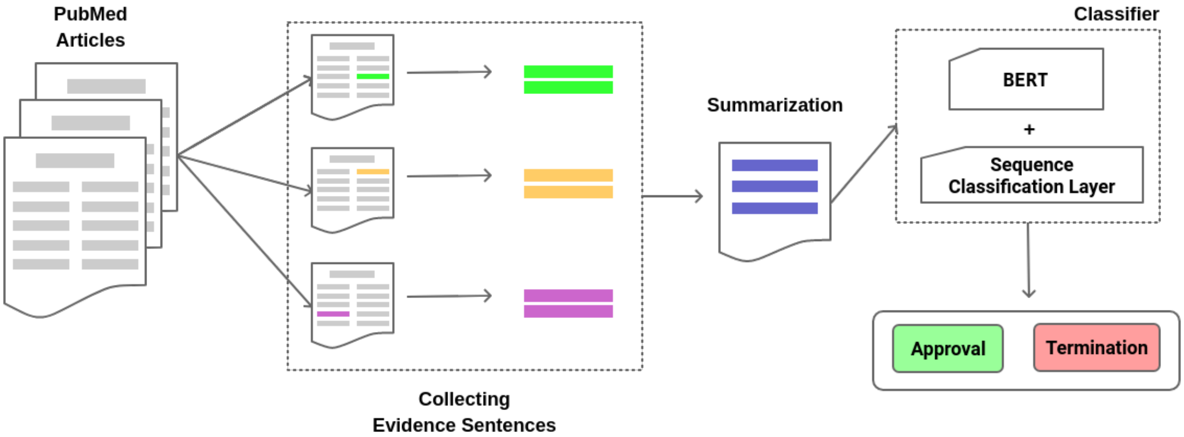

Figure 2: Overview of the proposed approach for classifying an intervention.

Type	|I|	|A|	avg
Approved	404	15,379	38.1
Terminated	300	421	1.4
Total	704	15,800	22.4

Table 1: The details of the interventions dataset. |I|, |A| and *avg* denote the number of interventions, the number of articles and the average number of articles per intervention respectively.

5 Methodology

In Figure 2, we illustrate the proposed approach, which consists of three main steps. Initially, we use the abstracts of the intervention's clinical trial record to extract evidence sentences. These sentences are then used to generate a short summary that contains information about the efficacy of the intervention. The summary is then processed by a BERT-based sequence classifier to make the final decision about the intervention. Each of the three steps is detailed in the following subsections.

5.1 Evidence Sentences

Identifying evidence bearing sentences in an article for a given intervention is an essential step in our approach. Differently from other sentences in an article, evidence sentences contain information about the effectiveness of the intervention (Figure 3). Therefore, it is crucial that our model has the ability to discriminate between evidence and non-evidence sentences.

First, all abstracts related to the given intervention are broken into sentences. The sentences of each abstract are then processed one-by-one by a BERT-based classifier that estimates the probability of each sentences containing evidence about the effectiveness of the intervention. For the classifier, we selected a version of the PubMedBERT (Gu et al., 2020) model, which is pre-trained only on abstracts from PubMed. We tested several models, including BioBERT (Lee et al., 2020), clinical-BERT (Alsentzer et al., 2019) and RoBERTa (Liu et al., 2019), but PubMedBERT performed the best in our task. On top of PubMedBERT, we trained a linear classification layer, followed by a Softmax, using the dataset from (DeYoung et al., 2020). This dataset is a corpus especially curated for the task of evidence extraction and consists of more than 10,000 annotations. The classifier is trained with annotated evidence sentences (i.e. positive samples) and a random sample of non-evidence sentences (i.e. negative samples). Regarding the ratio of positive to negative samples, cross-validation on the training set showed 1:4 to be a reasonable choice. The evaluation of the different BERT-based models was done based on the same data splits (train, test and validation) as in (DeYoung et al., 2020).

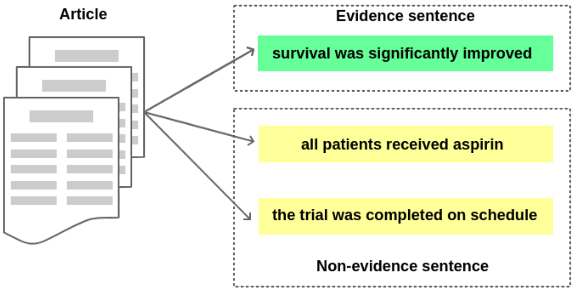

Figure 3: Evidence sentence identification. The evidence sentences constitute the positive instances whereas the non-evidence sentences the negative ones.

Once scored by the classifier, the highest scoring sentence is selected from each abstract. Therefore, for each intervention we extract as many sentences as the number of abstracts in its clinical record.

5.2 Short Summaries

To generate short and informative summaries we explore both extractive and abstractive approaches.

Extractive Summaries were based on the evidence sentences extracted in the previous step. Specifically, we re-rank them and choose the top k ($k = 5$) to compose our final summary. The model we use here is the same BERT-based model as in Section 5.1.

Abstractive Considering that an intervention is linked to multiple abstracts and thus to multiple evidence sentences, we first order all evidence sentences chronologically and combine them into a single text. Then, we split them to equal chunks[5] and each chunk then is fed to a BART-based model to produce the final summary.

BART has been shown to lead to state-of-the-art performance on multiple datasets (Fabbri et al., 2021). Specifically, we used the pre-trained distilBART-cnn-12-6 model which is trained on the CNN summarization corpus (Lins et al., 2019). Since abstractive summarization produces out-of-text phrases, it needs to be fine-tuned with domain knowledge. In our case, we fine-tuned the BART model with the MS2 dataset (DeYoung et al., 2021), which contains more than 470K articles and 20K summaries of medical studies.

We limited the length of the output summary to 140 words. For the extractive setting, in case the top k sentences exceeded this limit, we removed the extra words. For the abstractive setting we iteratively summarized and concatenated the chunks for each intervention until the expected number of 140 words was accomplished.

5.3 Inferring Efficacy

We model the task of inferring the approval of an intervention as a binary classification task. In our approach, each intervention is represented by a short summary. For the classification of the summaries, we used again a PubMedBERT model. On top of it, we trained a linear classification layer, followed by a sigmoid, using the summaries generated in the previous step: Our positive training instances were the summaries of interventions that have been approved, and correspondingly, the negative ones were the summaries of interventions that have been terminated. Hence, the model decides on the approval of the interventions.

5.4 Technical set-up

All models were pre-trained and fine-tuned for the corresponding task. The maximum sequence size was 512 and 1024 for BERT-based and BART-based models respectively. The Adam optimizer (Kingma and Ba, 2015) was used to minimize the cross-entropy losses with learning rate 2e-5 and epsilon value 1e-8 for all models. We trained all models for 5 epochs, with batch sizes of 32, except the abstractive summarizer for which the batch size was decreased to 4 due to RAM memory limitations of our system. The implementation was done using the HuggingFace library (Wolf et al., 2020) and Pytorch(Paszke et al., 2019).

6 Results and Analysis

We followed different training approaches for the different trainable components of our pipeline. For the evidence sentence selection and the abstractive summarization models we split the data into development and test and then split the development set further into training (90%) and validation (10%). We kept the model that performed best on the validation set and evaluated it on the held-out test set of each task respectively, averaged over three random data splits. Considering the small size of the interventions dataset, we applied a 10-fold cross validation for the final classification task. For this task, we report macro averages of the evaluation metrics over the ten folds.

6.1 Ablation Study

Our experimentation started with a comparison of different variants and choices that were available for the various modules of our approach.

Evidence Classifier Coming early in the pipeline, the performance of the evidence classifier can play a significant role in downstream tasks. The chosen approach relied on domain-specific BERT models. As domain-specific training that can affect the performance of BERT-based models, we conducted a comparison between different variants of BERT. The results in Table 2 demonstrate that the performance of the models is comparable, with all models obtaining scores over 90% in terms of F1 and AUC. PubMedBERT model achieved the best

---

[5] A chunk has length equal to the maximum input length of the BART model (1024).

scores and was used in the rest of the experiments.

Model	P	R	F1	AUC
BioBERT	.928	.938	.933	.957
ClinicalBERT	.913	.925	.919	.945
RoBERTa	.905	.919	.912	.931
PubMedBERT	**.931**	**.956**	**.943**	**.969**

Table 2: The results of the domain-specific BERT variants that were used for the evidence classifier. All models were trained with negative sampling ratio 1:4. The results denote the averages over three random train-test splits.

Summarization Adequacy We assess the performance of the summarization methods on the MS2 dataset which is a collection of summaries extracted from medical studies. The task of the summarizers is to produce texts that approximate the target summaries. We measure the performance of the summarization methods using ROUGE and the results are presented in Table 3. As expected, the abstractive method achieves higher scores, as it has more flexibility in forming summaries. We also observed that domain-specific training improves performance. The $abstractive_{no}$ model is a generic BART model without fine-tuning in the domain. Comparing its performance to the $abstractive$ model, which was fine-tuned on a small sample of the MS2 dataset that was excluded from the evaluation process, we notice a statistically significant improvement.

Model	R-1	R-2	R-L
abstractive$_{no}$	24.85	4.34	15.48
abstractive	**39.38**	**11.98**	**20.13**
extractive	19.24	3.22	13.19

Table 3: Evaluation of summarization methods on the MS2 dataset. The abstractive$_{no}$ refers to the generic BART model without any fine-tuning in the domain.

Abstractive methods seem to provide better summaries, however, whether these are more useful than the extractive summaries for our donwstream task is still to be determined.

6.2 Predicting Intervention Efficiency

Having made the choices for the individual modules, we now turn to the ultimate task, which is the prediction of the efficiency of the intervention. We evaluate two variations of our proposed method; i) with abstractive summarization denoted as PIAS$_{abs}$ and ii) with extractive summarization denoted as PIAS$_{ext}$. We compare their performance against two baselines:

- **BS**: This is a PubMedBERT model that is trained with a single evidence sentence per intervention (instead of a summary). The sentence is extracted from the most recent PubMed article relevant to the intervention.
- **BN**: This is similar to BS but instead of using a single sentence for each intervention it is trained with n evidence sentences extracted from n different articles ($n = 3$). The articles are selected randomly among the ones referring to the intervention.

The performance of all models is shown in Table 4. The proposed method outperforms the baselines independent of the summarization methods that is used. Interestingly, even selecting randomly selected evidence sentences seem to help, as BN achieved a higher performance than BS. Still, the use of summarization provides a significant boost over both baseline methods, validating the value of using short summaries to evaluate the efficiency of an intervention. Models that do not take advantage of the inter-connected documents suffer a significant drop in performance. Thus, this result justifies the design of the proposed method.

We can also observe that the best performance of the proposed method is achieved when using the extractive summarization method. Extractive summaries have demonstrated low ROUGE scores in Section 6.1. Still, they can properly capture the properties involved in the data for the classification task. On the other hand, although the abstractive summarizer achieved better ROUGE scores, it seems that the generated summaries cannot discriminate the target classes (approved or terminated) as well as the extractive ones. This indicates that the quality of the summary, in terms of the ROUGE score, is not decisive in the classification of the intervention.

Model	P	R	F1
BS	.717	.706	.702
BN	.732	.731	.731
PIAS$_{abs}$	.781	.774	.773
PIAS$_{ext}$	**.796**	**.793**	**.792**

Table 4: The classification results of all models. The reported precision, recall and f1 scores the macro averages over ten folds.

Analyzing further the performance of our best model, PIAS$_{ext}$, we report macro average scores for each target class in Table 5. We notice that the model is slightly better at predicting the approval of an intervention rather than its termination. This can be explained by the fact that the approved interventions are associated with a considerably larger number of articles than the terminated ones. This leads to richer summaries for the approved interventions and thus to a more informed decision.

class	P	R	F1
positive (approved)	.808	.819	.815
negative (terminated)	.778	.765	.772

Table 5: The performance of our best model, i.e. PIAS$_{ext}$, for each target class. The scores denote macro averages over ten folds.

6.3 Predicting Phase Transition

Early prediction of approval To build our models, we considered all the available data from Phase 1, Phase 2 and Phase 3. However, predicting the success of an intervention at the earliest phase possible is compelling. Therefore, we examine the ability of our model in making early predictions. More precisely, we evaluate PIAS$_{ext}$ model on the following three transitions: Phase 1 to Approval, Phase 2 to Approval and Phase 3 to Approval.

To perform this experiment, we select the interventions that have CTs in various stages and there is least one article for each phase. In total, this subset contains 249 interventions (193 approved and 56 terminated). Then, we use 80% for training and 20% for testing. For each transition, we train our model only with training instances from the corresponding phase. In Table 6, we report the macro average scores over ten random splits of the data.

transition	P	R	F1
phase1$\xrightarrow{to}$approval	.39	.50	.44
phase2$\xrightarrow{to}$approval	.78	.70	.72
phase3$\xrightarrow{to}$approval	.81	.84	.82

Table 6: The performance of our best model, i.e. PIAS$_{ext}$, in predicting phase-to-approval transitions. The scores denote the averages over ten random runs.

The results indicate that prediction of approval, while at Phase 1 is very hard, but the transition from Phase 2 and Phase 3 to approval can be predicted with considerable success. The large gap in performance between Phase 1 and Phase 2, 3 transitions is explained by the lack of clinical evidence in early phases.

Phase to Phase Another interesting and challenging task is to predict the transition of an intervention to the next phase of the clinical trial process. In this experiment, we want to predict Phase 1 to Phase 2 and Phase 2 to Phase 3 transitions. For each transition, we use data only from the former phase for training (e.g. for Phase 2 to Phase 3 transition we use data from Phase 2) for both target classes. Again, we use 80% for training and 20% for testing and present the average scores over ten random splits.

transition	P	R	F1
phase2$\xrightarrow{to}$phase3	.84	.82	.83
phase1$\xrightarrow{to}$phase2	.77	.76	.77

Table 7: The performance of our best model, i.e. PIAS$_{ext}$, in predicting phase-to-phase transitions. The scores denote the averages over ten random runs.

Table 7 shows the results for the two transitions, which are comparable to the overall predictive performance of the model. Considering the small size of the datasets used in both phase transition tasks, these results can serve only as an indication of how our model behaves. Further analysis and experiments should be conducted for a more thorough evaluation.

6.4 Explainability of Predictions

It is clinically very valuable to identify the factors that contribute most to a particular decision of the classifier. Interestingly, the summaries generated from our models can also serve that purpose very well.

Table 8 illustrates some examples of interventions along with their abstractive and extractive summaries as produced by our pipeline. For the first intervention, *pertuzumab*, it is notable that both summaries report a improved median progression-free survival which somewhat explains the prediction. For the second intervention, *taxane*, the summaries mention the greater incidence of serious adverse events and lower median overall survival, which counts against the approval of the intervention. We also notice that many numerical entities are randomly placed or changed in

Intervention		**PIAS**$_{abs}$	**PIAS**$_{ext}$
pertuzumab	✓	the primary endpoint of the study is progression-free survival. median progression- free survival was 12.4 months in the control group, as compared with 18.5months in the pertuzumab group. median survival was <dig> months, 12.3 months, and 12.5 months, respectively, in the p=0·0141 group and p =0·0% in the qtl group, respectively. the p <dig) group had a significantly improved pathological complete response rate compared with the group without complete response. p=dig> month and qtl were the most significantly different groups in both groups. p =dig>	Disease-free survival results were consistent with progression-free survival results and were 81% (95% CI 72-88) for group A, 84% (72-91) for group B, 80% (70-86) for group C, and 75% (64-83) for group D. the abstractive summary. This contributes to the tendency of the abstractive methods to generate "hallucinated" evidence, as observed in the literature (Cao et al., 2018). However, the abstractive summaries look more readable. A more exhaustive analysis, including also a human evaluation, is needed to assess the ultimate explainability of these summaries.

7 Conclusion

Predicting intervention approval in clinical trials is a major challenge with significant impact in healthcare. In this paper, we have proposed a new pipeline to address this problem, based on state-of-the-art NLP techniques. The proposed method consists of three steps. First, it identifies evidence sentences from multiple abstracts related to an intervention. Then, these sentences are used to produce short summaries. Finally, a classifier is trained on the generated summaries in order to predict the approval or not of an intervention.

Moreover, we introduced a new dataset for this task which contains 704 interventions associated with 15,800 abstracts. This data was used to evaluate our pipeline against other baseline models. The experimental results verified the effectiveness of our approach in predicting the approval of an intervention and the contribution of each step of the proposed pipeline to the final result. Further evaluation on predicting phase transitions, showed that our model can assist in all stages of a clinical trial. Besides, the generated multi-document summaries can be naturally used to explain the predictions of the model.

There are multiple ways to extend this work. In terms of multi-document summarization, there is room to explore more advanced summarization models, quality and performance metrics as well as better explainability assessment. In the bigger picture, we shall also consider to expand the dataset by extending its size and incorporating different types of resources (e.g. drug interaction networks). Finally, we are interested in enhancing the proposed method to incorporate temporal information associated with the CTs to maintain the history of clinical changes.

A Results on Proctor Dataset

To further evaluate our method, we attempted a comparison with the method presented in (Gayvert et al., 2016) using their data. The data contains a list of approved and terminated drugs together with various features. Using this dataset, we experienced two issues that made the comparison incomparable: i) For many drugs we could not find relevant articles in PubMed. The original dataset contains 828 drugs whereas we managed to collect information only for 537. Thus, the scores of our method are not directly comparable to the ones reported in (Gayvert et al., 2016) ii) Four important features that were used in (Gayvert et al., 2016) are missing in the dataset. Therefore, the reproduction of the exact model is not possible.

Despite these facts, we performed a comparison of the methods for the subset that we collected:

- **RF**$_1$: This model reports the scores from (Gayvert et al., 2016).
- **RF**$_2$: This is a Random Forest model similar to the original one, but it is trained only with the available features.

The overall performances of all models are depicted in Table 9.

Model	**AUC**
RF$_1$	.826
RF$_2$	.484
PIAS$_{ext}$	.586

Table 9: The classification results of all models on the Proctor dataset. The reported precision, recall and f1 scores are macro averages over ten folds.

BiTIIMT: A Bilingual Text Infilling Method for Interactive Machine Translation

Abstract

Interactive neural machine translation (INMT) is able to guarantee high-quality translations by taking human interactions into account. Existing IMT systems relying on lexical constrained decoding (LCD) enable humans to translate in a flexible translation manner beyond left-to-right. However, they typically suffer from limitations in translation efficiency and quality due to the reliance on LCD. In this work, we propose a novel **BiTIIMT** system, **Bi**lingual **T**ext-**I**nfilling for **I**nteractive Neural **M**achine **T**ranslation. The key idea to BiTIIMT is the Bilingual Text-infilling (BiTI) task which aims to fill missing segments in a manually revised translation for a given source sentence. We propose a simple yet effective solution by casting this task as a sequence-to-sequence task. The benefits of our solution are that it performs efficient decoding with the same complexity as the standard decoding in NMT and makes full use of revised words for better translation prediction. Experiment results show that BiTiIMT performs significantly better and faster than state-of-the-art LCD-based IMT on three translation tasks.

1 Introduction

Recent years have witnessed significant development in neural machine translation(NMT) (Bahdanau et al., 2015; Vaswani et al., 2017). Despite their success, their translation in quality still can not meet the requirements in industrial applications. On the other hand, interactive neural machine translation (IMT) (Foster et al., 1997; Langlais et al., 2000; Simard et al., 2007; Barrachina et al., 2009; González-Rubio et al., 2013; Cheng et al., 2016; Weng et al., 2019; Huang et al., 2021) is able to guarantee high-quality translation: it is an iterative collaboration process between human and machine that involves multiple interactive steps to obtain a satisfactory translation.

Traditional IMT generates a translation in the left-to-right completing paradigm (Langlais et al., 2000; Sanchis-Trilles et al., 2014; Peris et al., 2017a; Knowles and Koehn, 2016; Zhao et al., 2020) where human translators are required to revise words in the translation prefix. This strict left-to-right manner limits its flexibility because some human translators may enjoy their translation manners beyond left-to-right. As a result, another part of works (Weng et al., 2019; Huang et al., 2021) propose an alternative IMT paradigm under which human translators can revise words at arbitrary positions of a translation. The essential technique to this paradigm is lexically constrained decoding (LCD) (Hokamp and Liu, 2017; Post and Vilar, 2018), which extends beam search in the decoding stage to include revised words as constraints.

Unfortunately, LCD-based IMT suffers from two major shortcomings on efficiency and translation quality in practice. Firstly, LCD-based IMT usually involves multiple interactions between a human translator and machine and runs the LCD algorithm multiple times to translate a sentence. Since each LCD run takes considerable time compared with NMT decoding, the human translator will encounter severe latency, leading to poor user experience. In addition, LCD is based on the standard translation model, which is defined on top of the prefix context, and thus cannot make use of the revised words to assist the model in predicting target words to their left. Hence this characteristic limits its overall translation quality.

This paper proposes a simple yet effective IMT approach, BiTIIMT, which addresses the issues above. The core idea to BiTIIMT is the Bilingual Text-infilling (BiTI) task which extends text-infilling (Zhu et al., 2019) from monolingual setting to bilingual setting and aims to fill missing segments in a revised translation for a given source sentence. Unlike Zhu et al. (2019) carefully designing a model, we simply cast the bilingual text-infilling

task as a sequence-to-sequence task and then employ the standard NMT model to perform this task. To train the model, we construct simulated data by randomly sampling revised sentences from a bilingual corpus and augment the simulated data with bilingual corpus for further improvements. In this way, our model is able to yield a valid output that can be seamlessly filled in the revised translation in an efficient way similar to the standard NMT decoding. Moreover, the proposed model makes full use of all revised words to predict a target word and thus has the potential to obtain better translation than LCD.

We conduct extensive experiments on WMT14 En-De, WMT14 En-Fr, and Zh-En tasks. Our simulated experiments demonstrate that the proposed model indeed outperforms LCD in terms of translation quality and efficiency, and the proposed BiTIIMT is better than LCDIMT according to both translation quality and human editing costs. The advantages of BiTIIMT over LCDIMT are also verified in real-world IMT experiments with human translators.

This paper makes the following contributions:

- It proposes the bilingual text-infilling task and provides a simple yet effective solution to address this task.

- It proposes a novel IMT system on top of bilingual text-infilling which empirically outperforms a strong baseline in both translation quality and efficiency.

2 Background

2.1 Neural Machine Translation

Neural machine translation (NMT) (Sutskever et al., 2014; Bahdanau et al., 2015; Vaswani et al., 2017) is based on a sequence to sequence model which adopts an encoder-decoder architecture. The encoder summarizes the source sentence into an intermediate representation, and the decoder generates the target sentence.

Given a source sentence $X = \{x_1, \cdots, x_i, \cdots\}$, a NMT model factorizes the distribution over possible output $Y = \{y_1, \cdots, y_T\}$ into a chain of conditional probabilities from left to right:

$$P(Y \mid X; \theta) = \prod_{t=1}^{T+1} P(y_t \mid y_1, y_2, \cdots, y_{t-1}, X; \theta) \tag{1}$$

where the special tokens y_0 (e.g. <bos>) and y_{T+1} (e.g. <eos>) are used to represent the beginning and end of all target sentences.

2.2 Text Infilling

Text infilling (Zhu et al., 2019) is a task that fills missing text segments of a sentence or paragraph by a model (Berglund and Leo; Fedus et al., 2018; Zhu et al., 2019) trained on a large amount of data in a fill-in-the-blank format. The input text $X = \{x_1,$ <blank>, x_i, ..., <blank>, ...$\}$ has an unknown number of blanks whose positions are arbitrary, and each blank has an arbitrary unknown length.

To address this task, a text infilling model fills in each blank from left to right by predicting a target word y_j at each time step j. As a solution, Zhu et al. (2019) proposes a variant model based on Transformer, whose position encoding takes both segment positions and token positions into account.

3 Proposed BiTIIMT

This section illustrates the overview of the proposed BiTIIMT system and accordingly presents its essential technique (i.e., bilingual text-infilling) to take human interactions into NMT.

3.1 Overview of BiTIIMT

In general, the proposed BiTIIMT enjoys a human-in-the-loop manner to output the final translation, similar to conventional IMT systems (Cheng et al., 2016). Specifically, for a given source sentence X, BiTIIMT iteratively performs the following two steps:

- A human translator edits a translation Y from the translation engine;

- Then the engine updates Y based on the edited translation as well as its source X.

This procedure terminates until the human translator is satisfied with the quality of Y. This procedure is illustrated in Figure 1. The key to BiTIIMT is its second step which relies on Bilingual Text-infilling to update a translation Y. In the rest of this section, the details about bilingual text-infilling will be described.

3.2 Bilingual Text-infilling

3.2.1 Problem Statement and Model

Problem Statement Generally, bilingual text-infilling extends text-infilling from the monolingual setting (Zhu et al., 2019) to the bilingual setting. Suppose $\bar{Y}$ is a template, i.e., the edited (partial) translation, which includes some blanks to be filled in; $Y^b = \{y_1^b, y_2^b, \cdots, \}$ is a sequence of segments used to fill the blanks in $\bar{Y}$. BiTI aims to generate Y^b for filling the blanks in $\bar{Y}$, to obtain a translation Y for a source sentence X.

Take Figure 2 as an example, the template $\bar{Y}$ is a partial translation edited by a translator which contains three blanks. Y^b includes three segments to fill each blank in $\bar{Y}$, and Y is the translation after filling $\bar{Y}$ with Y^b. It is worth noting that Y^b contains three special tokens "<eob>", indicating the end of a segment, which correspond to the blanks in $\bar{Y}$, respectively.

$\bar{Y}$: It is an inherent right __ all measures __ preserve __

Y^b: that must be upheld by all Member States, and <eob> must be taken to <eob> it. <eob>

Y: It is an inherent right that must be upheld by all Member States, and all measures must be taken to preserve it.

Figure 2: Main notations of bilingual text-infilling where __ represent a blank based on example in Figure 1.

Model Definition Formally, bilingual text-infilling can be addressed by the following probabilistic model:

$$P(Y^b|X, \bar{Y}; \theta) = \prod_t P(y_t^b \mid X, \bar{Y}, Y_{<t}^b; \theta) \quad (2)$$

X<sep>$\bar{Y}$: 所有会员国必须支持这项固有的权利,并且必须采取一切措施来维护这种权利。<sep> It is an inherent right __ all measures __ preserve __

Y^b: that must be upheld by all Member States, and <eob> must be taken to <eob> it. <eob>

Figure 3: Bilingual text-infilling as the sequence-to-sequence task. The input is "X <sep> $\bar{Y}$" and the output is Y^b.

To implement this model, it is possible to extend the Transformer (Vaswani et al., 2017) by using two encoders (i.e., one is for X, and the other is for $\bar{Y}$) and taking both segment and token positions into account similar to Zhu et al. (2019). However, for simplicity, we instead cast this task as a standard sequence-to-sequence task by format manipulation and employ an NMT model to address it. Specifically, we treat two input sequences X and $\bar{Y}$ as one input sequence "X <sep> $\bar{Y}$", where "<sep>" is a speck token for concatenation, and Y^b as the output sequence, as shown in Figure 3. Then we employ the Transformer model to accomplish this task as the conventional NMT task.

Relation to Previous Work Our method is similar to previous works, including lexically constrained decoding (LCD) (Hokamp and Liu, 2017; Post and Vilar, 2018), MT with soft constraints (Dinu et al., 2019) and code-switch enhanced MT (Song et al., 2019; Chen et al., 2020) in the sense that all of them generate translations based on given constraints which are $\bar{Y}$ in our work. However, LCD imposes hard constraints on beam search during the decoding stage, leading to the suffering of decoding speed. In addition, the other two series of works can not guarantee the constraints $\bar{Y}$ will be in the output translation, and the code-switch method even requires word alignment information whereas human translators do not provide such alignment information in our scenario.

3.2.2 Training via Data Augmentation

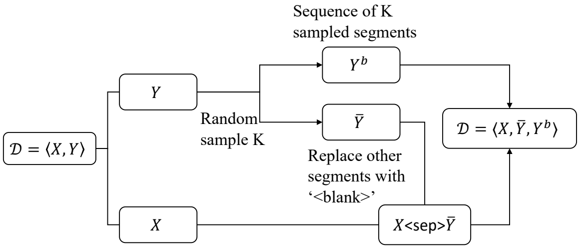

Figure 4: Sampling procedure to get synthetic bilingual text-infilling data.

Typically, to train the model in Eq.(2), one needs to obtain large amount of data consisting of triples $\mathcal{D} = \{\langle X, \bar{Y}, Y^b \rangle\}$. Unfortunately, this is impractical because both $\bar{Y}$ and Y^b are obtained by human translators. To this end, we apply a simple simulation method to obtain $\{\langle X, \bar{Y}, Y^b \rangle\}$ on top of bilingual corpus $\{\langle X, Y \rangle\}$ through random sampling. Specifically, for each oracle target sentence Y in bilingual data, we randomly sample an integer $k \in [0, 5]$ and randomly sample k non-overlapped segments in Y. Then $\bar{Y}$ can be obtained by replacing each remaining segment with "<blank>" in Y, and Y^b can be obtained by wrapping k sampled segments and then joining them together in the same order. This sampling procedure is shown in Figure 4.

Given a training data $\mathcal{D} = \{\langle X, \bar{Y}, Y^b \rangle\}$, it is straightforward to optimize the following objective function according to maximum likelihood estimation:

$$\ell = - \sum_{\langle X, \bar{Y}, Y^b \rangle} \log P(Y^b \mid X, \bar{Y}; \theta)$$

where the model P is defined in Eq. (2).

Models trained on training data $\mathcal{D} = \{\langle X, \bar{Y}, Y^b \rangle\}$ possess the ability to translate sentences with constraints in fill-in-blank format style, but it may lose its strength in translating normal sentences. As a result, for the first iteration in IMT, the initial translation maybe not good as expected, leading to more interactive iterations between humans and machines. One possible solution is to build an additional NMT model to generate the initial translation. Instead, we apply the data augmentation (DA) technique, making our model perform both tasks. For the standard bilingual parallel data $\{\langle X, Y \rangle\}$, we construct its trivial triple data $\mathcal{D}' = \{\langle X, \emptyset, Y \rangle\}$, where $\emptyset$ means that no revised words are provided in $\bar{Y}$ for each bilingual sentence. Then we combine the sampled data D and the trivial data D' as the augmented data to train the model P in our experiments.

Actually, our method is slightly different from classical data augmentation for NMT (Novak et al., 2018; Wang et al., 2018; Li et al., 2019) because the input in the augmented data is different from that for bilingual text infilling task. In addition, because the augmented data is used for bilingual text infilling task and the other data is used for translation task, our training method resembles an instance of multi-task learning (MTL) framework(Caruana, 1997; Dong et al., 2015; Liu et al., 2016; Wang et al., 2020b), where both tasks are modeled by the same Transformer architecture.

3.3 Decoding

The task of bilingual text-infilling is reduced to decode Y^b according to the model P in Eq. (2) via maximum a posteriori (MAP) estimation as follows:

$$\underset{Y^b : \#_b(Y^b) = \#_b(\bar{Y})}{\arg\max} \quad P(Y^b \mid X, \bar{Y}; \theta) \tag{3}$$

where $\#_b$ denotes the number of blanks, i.e., $\#_b(Y^b)$ is the number of "<eob>" in Y^b and $\#_b(\bar{Y})$ counts the number of "__" in $\bar{Y}$. The constraints in the above equation are used to guarantee that all blanks in $\bar{Y}$ can be exactly filled by Y^b to obtain a valid translation Y, otherwise, Y^b would lead to an invalid Y.

Theoretically, the constrained optimization in Eq. (3) is more difficult than the unconstrained one in standard NMT decoding. In practice, since the constraint in Eq. (3) is about the number of blanks in Y^b, it is easy to satisfy by extending the standard beam search algorithm. Specifically, in the standard beam search algorithm, one only needs to maintain a number to restore the number of blanks in the partial output Y^b. If this number is equal to $\#_b(\bar{Y})$, Y^b is the final output; otherwise, Y^b should be extended until the constraint is satisfied. As a result, our decoding algorithm is very efficient, and it shares the same complexity as the standard beam search algorithm. In fact, thanks to the powerful Transformer architecture and sufficient training data in our scenario, our model is able to implicitly learn the constraint $\#_b(Y^b) = \#_b(\bar{Y})$ with about 99.39% accuracy in our preliminary experiments. In other words, for almost all sentences, the standard beam search algorithm is able to yield a valid Y, even without explicitly imposing the constraint during decoding.

4 Experiments

Following previous works (Peris et al., 2017b; Cheng et al., 2016; Weng et al., 2019; Li et al., 2020), we experiment on two simulated scenarios and a real-world scenario.

4.1 Experiment Settings

4.1.1 Dataset

We conduct experiments on the English-German dataset (En-De), English-French (En-Fr), and a

	#Raw		#Augmented	
	Train	Valid	Train	Valid
En-De	4M	2,737	8M	5,474
En-Fr	36M	3,003	72M	6,006
Zh-En	2M	2,000	4M	4,000

Table 1: Statistics on three datasets: WMT14 En-De, WMT14 En-Fr, and Zh-En. (Augmented: a combination of the raw bilingual parallel dataset and their corresponding artificial dataset with constructed templates.)

Chinese-English dataset (Zh-En), which includes about 2 million bilingual sentences from the news domain in total. For En-De and En-Fr, the datasets are from WMT14 and we use newstest13 as the valid dataset and use newstest14 filtered by Stanford (Bojar et al., 2014) as the test dataset. For Zh-En, the datasets are the same as Li et al. (2020). We utilize the approach mentioned in Section 3.2 to construct synthetic bilingual parallel sentence pairs based on all the datasets above. To set up the data augmentation strategy, we combine original training datasets and their corresponding synthetic datasets. As Table 1 shows, we get an 8M English-German dataset based on the WMT14 En-De, a 72M English-French dataset based on WMT14 En-Fr, and a 4M Chinese-English dataset based on a Zh-En dataset mentioned above. Valid sets are obtained the same as training datasets.

For all datasets mentioned above, we use Moses toolkit to tokenize and clean data. Besides, we use BPE (Sennrich et al., 2015) to process all the source and target sentences.

4.1.2 System Configurations

We train and evaluate the following systems for comparison.

- **Transformer.** We set Transformer (Vaswani et al., 2017) using fairseq (Ng et al., 2019). The Transformer model is trained on the bilingual datasets: WMT14 En-De, WMT14 En-Fr, and the Zh-En dataset.
- **LCDIMT.** Since LCD-based decoding is widely used in IMT scenario (Weng et al., 2019; Huang et al., 2021), we build an LCD-based IMT as our strong baseline. Because the original LCD algorithm is very slow, we implement its efficient version (Post and Vilar, 2018) which achieves comparable translation quality to the original version but 5x speedup in decoding.
- **Our System.** Our BiTiIMT model is based on the base Transformer architecture and trained on the synthetic datasets mentioned in Section 3.3.

All baselines (Transformer and LCDIMT) and the BiTIIMT models are based on the architecture with $d_{model} = 512$, $d_{hidden} = 2048$, $n_{heads} = 8$, $n_{layers} = 6$, and $p_{dropout} = 0.1$. We use the Adam Optimizer (Kingma and Ba, 2015) with $\beta_1 = 0.9$ and $\beta_2 = 0.98$ to train our models. We adopt a warm-up of 10,000 steps and set the initial learning rate to 0.0007. We set the maximum tokens in batch to 4096, and we share both source and target embeddings for all models. Training stops until the maximum update is 400,000 and the checkpoint used for testing is selected according to its performance on the valid dataset. We train all models on 16 NVIDIA V100 Tensor Core GPUs. We use a beam size of 10 throughout our experiments.

4.1.3 Evaluation Metrics

Following prior work (Cheng et al., 2016; Weng et al., 2019; Zhao et al., 2020; Huang et al., 2021), two criteria are used to evaluate INMT systems: one is translation quality and the other is efficiency to yield the translation. We employ BLEU (Papineni et al., 2002) to measure translation quality, and human editing cost to measure efficiency, which is calculated as the edit distance by counting deletions on word level and insertions on char level. In addition, we take the decoding time into account because it is directly related to the latency for human translators, which is critical for user experience.

4.2 Simulated Scenario

We conducted two different simulated experiments, including IMT with a single iteration and IMT with multiple iterations, to validate the effectiveness of our method in terms of translation quality and editing and decoding costs mentioned above.

4.2.1 IMT with a Single Iteration

Since IMT with a single iteration can be seen as machine translation with lexical constraints where human interactions are considered as constraints, we first conduct an experiment to evaluate the performance of BiTIIMT by following Hokamp and

		Number of constraint segments				
		1	2	3	4	5
En-De	Transformer	27.36 / 1×				
	LCDIMT	29.56 / 1.22×	31.33 / 1.68×	32.98 / 1.73×	36.18 / 1.79×	38.78 / 1.88×
	BiTIIMT	**32.51 / 0.93×**	**37.86 / 0.9×**	**43.01 / 0.83×**	**47.09 / 0.81×**	**52.33 / 0.73×**
En-Fr	Transformer	39.9 / 1×				
	LCDIMT	44.53 / 1.56×	47.76 / 1.82×	48.35 / 1.83×	48.64 / 1.84×	48.96 / 1.85×
	BiTIIMT	**46.02 / 0.99×**	**51.26 / 0.93×**	**51.96 / 0.91×**	**52.66 / 0.9×**	**53.18 / 0.89×**
Zh-En	Transformer	46.71 / 1×				
	LCDIMT	47.83 / 1.35×	49.18 / 1.59×	49.34 / 1.83×	49.13 / 2.02×	49.73 / 2.08×
	BiTIIMT	**49.61 / 1.08×**	**51.62 / 1.08×**	**53.86 / 0.99×**	**56.05 / 0.97×**	**56.59 / 0.95×**

Table 2: **BLEU / Relative decoding time cost w.r.t Transformer baseline** for five settings with 1 to 5 constraint segments on WMT14 En-De, WMT14 En-Fr, and Zh-En datasets. For each setting, the boldface denotes the top BLEU score and the best time cost among all systems.

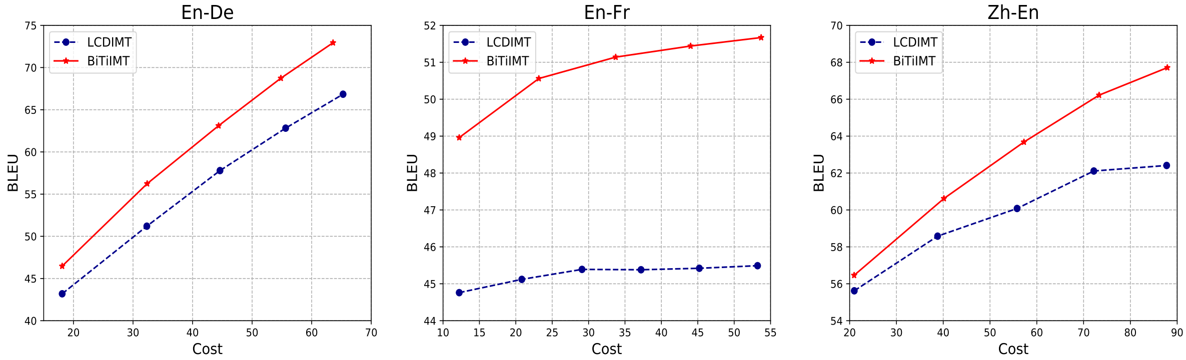

Figure 5: **BLEU** and **Interactive cost** comparison on WMT14 En-De, WMT14 En-Fr, and Zh-En datasets.

Liu (2017); Post and Vilar (2018). We use the reference as oracle to sample constraints for all datasets and we consider five settings: they include gradually increasing constraint segments from one to five. In more detail, we randomly add a constraint segment with a random length between 1 to 3 for each setting. To ensure fairness, the constraints provided to both BiTIIMT and LCDIMT are exactly the same. We measure decoding cost by using the time required to translate the whole test set with a batch size of one (excluding the time of model loading).

As shown in Table 2, with only one constraint segment, both BiTIIMT and LCDIMT obtain substantial improvements compared with Transformer and BiTIIMT significantly outperforms LCDIMT with a margin of +2.2, +4.63, and +1.12 BLEU points for En-De, En-Fr, and Zh-En tasks, respectively. This finding clearly verifies our hypothesis: BiTIIMT indeed makes full use of the constraint segments and thus yields better translations than LCDIMT.

Table 2 also reports the results of relative decoding cost with respect to the Transformer baseline. As we can see, in the first setting with one constraint segment, BiTIIMT achieves modest speedup in decoding time compared with the Transformer baseline. With the growing number of constraint segments, BiTIIMT keeps reducing the decoding time, and it gives 0.27x decrease in decoding time cost on En-De when running on five constraint segments. Meanwhile, the time cost of LCDIMT keeps growing, and it is almost twice as that of the baseline in the 5th setting. Similar results can be found on En-Fr and Zh-En datasets. It is worth noting that the decoding efficiency of LCDIMT seems not an issue for one iteration. In fact, decoding efficiency indeed is a severe issue for multiple iterations as in real-world scenarios, where more constraint segments are involved especially at the late stage of iterations.

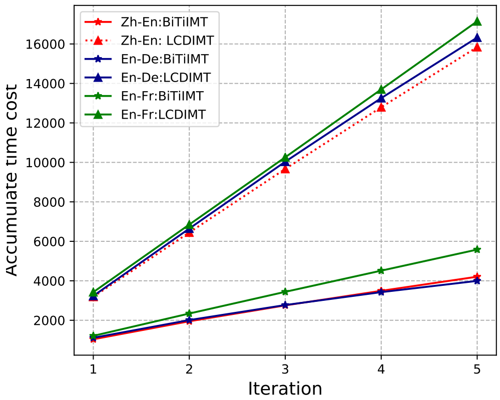

Figure 6: Accumulated decoding time cost comparision on WMT14 En-De, WMT14 En-Fr, and Zh-En datasets.

4.2.2 IMT with Multiple Iterations

We now turn to the evaluation of BiTIIMT in a simulated IMT scenario where multiple iterations of interactions are allowed. To simulate the human interactive process of IMT, at each iteration, we use the reference as oracle and match the oracle with a translation from each system to calculate $\bar{Y}$. Specifically, we delete unmatched words in the translation as simulated deletion and add a word from oracle as a simulated revision. By using the edit distance algorithm, which includes only deletion and revision operators, we can figure out $\bar{Y}$ given a translation and its reference. We use the edit cost mentioned in Section 4.1.3 to qualify human interaction cost.

Figure 5 shows BLEU scores and interaction costs along with all iterations on En-De, En-Fr, and Zh-En datasets. As expected, BLEU scores consistently increase with the increase of interaction costs. As we can see on En-De, BiTIIMT obtains improvements of about 5 BLEU points over the baseline LCDIMT when using similar human interaction costs. The BLEU gap between BiTIIMT and LCDIMT is further enlarged in the late stage of the interactive process. Results on En-Fr and Zh-En give similar conclusions. These facts show that BiTIIMT outperforms LCDIMT as it can reduce the human interaction cost to get a satisfying translation.

Figure 6 reports the accumulated decoding time cost on three datasets. As we can see, results on three datasets give similar conclusions with the conclusions in section 4.2.2 that BiTIIMT has a lower decoding time cost compared to LCDIMT for all interactive iterations. Furthermore, the accumulated decoding time cost of BiTIIMT after 5 iterations is lower than the time cost of LCDIMT with only 2 iterations. The facts indicate that BiTIIMT has its outstanding advantage in efficiency.

4.3 Real-world Scenario

We conduct two kinds of IMT experiments to validate the effectiveness of BiTIIMT in a real-world scenario. First, we use the post-editing data from a valid dataset of WMT21 Automatic Post-Editing Shared Task on En-De (Sharma et al., 2021), where the words are edited by humans are natural constraints instead of simulated constraints. By using these constraints, we compare the proposed IMT method with baselines involve a single iteration of human-machine interactions. Results in table 3 show that BiTIIMT can obtain much better translations than LCDIMT. Since in this dataset there are many constraints edited by humans and the post-edited translation is used as the reference, the improvements of BiTIIMT over LCDIMT are substantial in terms of BLEU (up to 9 BLEU points).

Furthermore, we conduct another real-world experiment that involves multiple iterations of human-machine interactions. Specifically, we randomly sample 200 sentences from the Zh-En test set and then ask two professional human translators to interact with both systems. Translators are asked to do interactions (deletions, revisions, and insertions) multiple times until they get a satisfactory translation. We compared LCD-based and BiTI-based IMT systems on averaged BLEU, averaged decoding time cost, and averaged editing cost of deletions, revisions, and insertions supplied by human translators. As shown in Table 4, BiTIIMT can reach higher BLEU points with less decoding time cost, editing cost, as well as fewer interaction rounds. Note that our BLEU gains over LCDIMT in Table 4 are relatively small compared with those in Table 3. One main reason is that the constraints edited by human translators may not appear in the reference translation.

4.4 Analysis

Effect of Data Augmentation As the description in Section 3.2.2, we train our model (#Augmented in Table 5) on the augmented data which includes synthetic bilingual data $\mathcal{D} = \{\langle X, \bar{Y}, Y^b \rangle\}$ and their corresponding bilingual parallel data $\mathcal{D}' = \{\langle X, \emptyset, Y \rangle\}$ by data augmentation. For com-

Method	BLEU
Transformer	41.92
LCDIMT	46.96
BiTIIMT	**56.02**

Table 3: Results on the real-world dataset from WMT21 En-De Automatic Post-Editing shared task.

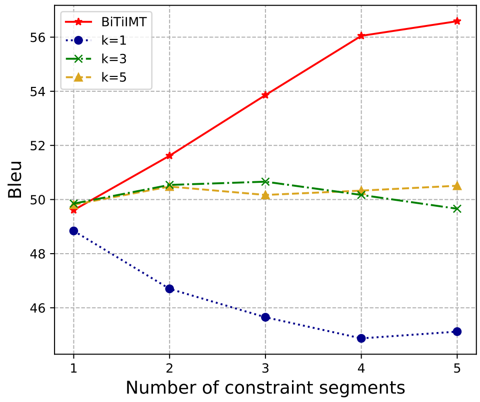

Figure 7: Effectiveness of Random Sampling Strategy. "k" denotes the models trained on augmented Zh-En datasets, which includes k constraint segments. BiTiIMT is trained on a dataset with a random number of constraint segments. The x-coordinate denotes testing with a different number of constraint segments.

parison, we train two additional models: one is on $\mathcal{D}$ only (#Synthetic Only in Table 5) and the other is trained on $\mathcal{D}'$ (#Raw in Table 5). We compare all these three models according to their BLEU on the Zh-En dataset. Note that in this experiment, we do not provide any human interactions to all three models, i.e., $\bar{Y} = \emptyset$, during testing.

Table 5 summarizes the results of the three models. The model trained on the only synthetic dataset almost collapses on automatic machine translation task: it is worse than # Raw model by a substantial margin of 18 BLEU points. In addition, it can be found that the model trained on the augmented dataset achieves +0.68 BLEU improvements over # Raw model. Although such improvements are not that large, it still shows that data augmentation or the application of multiple task learning plays a critical role in making BiTiIMT successful.

Effect of Random Sampling Strategy When training the model for BiTIMT in section 3.2.2, we employ a random strategy to sample $\bar{Y}$ such that it contains a random number of constraint segments. We are also curious about the effect of such a random strategy. In comparison, we fix the number of constraint segments and then train three models for $k = \{1, 3, 5\}$. Under all five settings as in Section 4.2.1, we compare BiTIIMT with these three models on the Zh-En task. Figure 7 shows that, by training on data with a diverse number of constraints, our model achieves increasing BLEU on all five settings while the BLEU of the model ($k = 1$) gradually decreases and another two models could not give continuous improvement. Results suggest that our random sampling strategy assists BiTIIMT to translate with a various number of constraints.

5 Related Work

Since the period of statistical machine translation (SMT), IMT has been widely exploited to reduce human effort by using human's feedback to improve translation quality (Foster et al., 1997; Langlais et al., 2000; Simard et al., 2007; Barrachina et al., 2009; González-Rubio et al., 2013; Cheng et al., 2016; Li et al., 2021). Recently, with the development of NMT (Bahdanau et al., 2015; Vaswani et al., 2017), researchers turned to employ IMT on it (Hokamp and Liu, 2017; Wang et al., 2020a).

A classical type of IMT uses a left-to-right sentence completing framework proposed in Langlais et al. (2000), in which human translators can only revise the translation generated by models from left to right. Generally, the text portion from the beginning to the current modified part is called prefix, and the system will generate a new translation based on the given prefix (Sanchis-Trilles et al., 2014; Peris et al., 2017a; Knowles and Koehn, 2016).

Cheng et al. (2016) propose a pick-revise framework that enables translators to do revisions on arbitrary positions to improve efficiency. Huang et al. (2021) allow users to make any interaction at random positions by using LCD algorithms (Hokamp and Liu, 2017; Post and Vilar, 2018) in the decoding stage which can integrate lexical constraints into translation. However, LCD can not achieve a win-win result in terms of decoding speed and translation quality. Weng et al. (2019) propose a bidirectional IMT framework on top of LCD, which could fix mistakes by using two constrained decoding procedures with opposite directions. However, it needs to train two decoders, and in each con-

Methods	BLEU	Decoding Time Cost	Editing Cost	Rounds

LCDIMT	51.36	1.44	19.79	1.46
BiTIIMT	**53.48**	**0.27**	**15.815**	**1.27**

Table 4: Results in the real-world IMT scenario for different methods.

Dataset	BLEU
#Raw	46.71
#Synthetic Only	28.96
#Augmented	**47.39**

Table 5: Results of routine machine translation task over models trained on different dataset settings. (Raw: Zh-En dataset; Synthetic Only: artificial dataset with constraint segments based on Zh-En; Augmented: a combination of the raw dataset and synthetic dataset).

strained decoding, the model can only use part of the constraints supplied by translators, making it inefficient both in using human knowledge and decoding speed. Instead, BiTIIMT puts all constraints into a template as part of the input, which makes it possible for the model to use all human knowledge and meanwhile fix mistakes automatically in the whole sentence.

Other works (Alkhouli et al., 2019; Song et al., 2020; Chen et al., 2021) apply alignment information to improve the decoding efficiency of LCD. Alkhouli et al. (2019) use alignment extracted by vanilla transformer, which is poor as argued by Garg et al. (2019). Song et al. (2020) apply an external aligner to train the alignment module. These works can only perform constrained decoding based on a constraint pair, which means a burden for human translators.

In order to address the issue of decoding speed for LCD, some works use a non-autoregressive approach to integrate constraints. Susanto et al. (2020) propose Levenshtein Transformer (Gu et al., 2019) to inject terminology constraints at inference time. Xu and Carpuat (2021) propose a novel re-position operator to replace deletion in Levenshtein Transformer to exploit lexical constraints more effectively and efficiently. However, non-autoregressive models are still worse than autoregressive models in translation quality currently. Compared to these efforts in NAT, BiTIIMT is essentially based on an auto-regressive translation model.

6 Conclusion

Traditional IMT systems often use LCD to incorporate manually revised words into translations. In this paper, we propose BiTIIMT, a novel IMT method that outperforms LCD-based IMT in both translation quality and efficiency. The key to BiTIIMT is the bilingual text-infilling task which extends text-infilling from a monolingual setting to a bilingual one. We cast this task as a sequence-to-sequence task and propose a simple yet effective solution to address it. Experiments show that BiTIIMT achieves a significantly improved efficiency in the area of IMT.

Distributionally Robust Finetuning BERT for Covariate Drift in Spoken Language Understanding

Abstract

In this study, we investigate robustness against covariate drift in spoken language understanding (SLU). Covariate drift can occur in SLU when there is a drift between training and testing regarding *what* users request or *how* they request it. To study this we propose a method that exploits natural variations in data to create a covariate drift in SLU datasets. Experiments show that a state-of-the-art BERT-based model suffers performance loss under this drift. To mitigate the performance loss, we investigate distributionally robust optimization (DRO) for finetuning BERT-based models. We discuss some recent DRO methods, propose two new variants and empirically show that DRO improves robustness under drift.

1 Introduction

A common assumption in machine learning is that training data and test data are independent and identically distributed (i.i.d.). Unfortunately, this may not hold in practice and the test distribution might have drifted from the training distribution which can lead to a significant drop of performance in real-world applications (Moreno-Torres et al., 2012).

Consider spoken language understanding (SLU), i.e., the task of mapping an utterance to a machine readable semantic interpretation, which is commonly used in voice controlled devices like Alexa, Siri or Google Assistant. Distributional drifts can be caused by seasonal and non-seasonal factors. For example, festive holidays can lead to many requests outside the daily routine. New users might use an uncommon phrasing to express their intent or they might request an uncommon song to be played. Such drifts in the input distribution are referred to as covariate drift. When users' requests fail to be recognized by the device they might rephrase their intent until they succeed, essentially adapting to the SLU model's distribution. This means that, even when new training samples are drawn from new user utterances, the dominance of the old distribution already present in the SLU model is reinforced. Fine-tuned pre-trained language models (PLM), such as BERT (Devlin et al., 2019) yield strong performance on SLU benchmarks (Chen et al., 2019). Yet, it has been observed that also PLMs are vulnerable to drifts, and there is a high interest in understanding the robustness of PLMs (Oren et al., 2020a; McCoy et al., 2019; Tu et al., 2020; Cao et al., 2020).

The goals of this study are to investigate the impact of covariate drift on BERT's performance, and to experimentally investigate distributionally robust optimization (DRO) for finetuning BERT. While we focus on sequence classification for SLU, i.e., intent classification (IC) and slot filling (SF), we expect the insights of this study to be applicable also to other sequence classification tasks.

To study the impact of covariate drift on model robustness, we require a dataset with known properties of the drift. However, real data for this setting is not publicly available. Therefore, we devised a method to create a train/test split with a controlled drift for sequence labeling data, which we call SEQDRIFT. Roughly speaking, SEQDRIFT creates clusters of examples based on the example's tokens and sequence labels. Then those clusters are used to create a new train/test split while leaving the label distribution intact. Notably, SEQDRIFT does not artificially alter the utterances and only exploits natural lexical variations in the data in a non-adversarial manner. Our experiments on publicly available SLU datasets repartitioned with SEQDRIFT showed that a state-of-the-art BERT-based model for SLU (Chen et al., 2019) trained with standard optimization suffers up to 5% absolute performance loss.

Currently, it is an open question which range of measures are helpful to improve the generalization under drift. In this study, we investigated distributionally robust optimization (DRO), which has

recently gained interest in NLP for overparameterized models (Oren et al., 2019; Sagawa et al., 2020; Liu et al., 2021; Michel et al., 2021). It is an optimization concept which assumes that the training data is a mixture of distributions, e.g., different user demographics. The objective is to be optimal under each distribution. For example, the methods proposed by Oren et al. (2019) and Sagawa et al. (2020) assume knowledge about groups of training instances —such as topics or ethnic origin— that can be used by the optimization. Roughly speaking, they propose to compute the loss across groups instead across individual instances. However, such group knowledge might not be available and there are other methods which do not require such prior knowledge. TOPK (Levy et al., 2020; Kawaguchi and Lu, 2020), for example, simply uses the top-k largest losses in a batch and was shown to obtain robust models.

We performed an extensive experimental analysis to investigate the usefulness of several DRO methods across different scenarios. Most studies only evaluate DRO methods in one setting with in-distribution validation data and one drift type per dataset. To achieve a broader insight into the usefulness of the investigated methods we evaluated them in 8 scenarios per dataset, i.e., for different types of drift, or model selection with in-distribution and out-of-distribution validation data. Additionally, we propose an intuitive variant of TOPK, namely TOPK-GROUP or TOPK-AUTOENCODER to investigate if prior group knowledge or latent group knowledge could improve TOPK. We found that TOPK, TOPK-GROUP and TOPK-AUTOENCODER can significantly improve robustness in many scenarios, where TOPK is more reliable in terms of significant improvement, while TOPK-AUTOENCODER can be better in terms of relative improvement.

2 Background

In this section, we provide a brief background to spoken language understanding. Subsequently, we discuss common categorizations of dataset drifts, empirical analyses of drifts and then describe distributionally robust optimization.

2.1 Spoken Language Understanding

In this study, we focus on SLU for single-turn utterances and non-nested intents. Parsing utterances into API calls is broadly either done by task oriented semantic parsing (TOP), or as intent classification (IC) and slot filling (SF). IC is the task to classify an utterance into user intents, such as *PlayMusic*, *FindBook* or *GetWeather*. Meanwhile, SF is a sequence tagging task to identify spans of tokens that represent the intent's slot fillers, such as *ArtistName*, *AlbumName* or *TrackNumber*. In state-of-the-art approaches, IC and SF are typically modeled jointly using deep neural networks (Chen et al., 2019).

2.2 Distributional Drifts

A common assumption in machine learning is that the training and test data are independent and identically distributed (i.i.d.) and that the distributions are the same between training and test, i.e. $P_{train}(x, y) = P_{test}(x, y)$. Unfortunately, in practice, the test data is often out of distribution (o.o.d.), i.e. $P_{train}(x, y) \neq P_{test}(x, y)$. This can be caused by sampling bias, such that subpopulations are not equally represented in the samples of the two distributions. As this phenomenon is often caused by time-varying covariates, i.e., seasonal and non-seasonal changes, this phenomenon is referred to as a *drift*. However, this can be a general mismatch between the sampled subpopulations, which can be of geographic or demographic type, or they can be topics or domains. Drifts can also be caused by noise or automatic training data generation, in which filtering heuristics introduce a systematic issue, or by adversaries that exploit weaknesses of a specific model or model class.

Distributional drifts can be categorized into (Moreno-Torres et al., 2012): concept drift, i.e., when the meaning changes, prior probability drift and covariate drift.

Covariate drift. When $P_{train}(x) \neq P_{test}(x)$, then there is a drift in the input distribution, and when the concept $P(y|x)$ does not change between training and testing, this is referred to as covariate drift. The challenge is that the population and its subpopulations are unknown because only samples are observed and thus $P(x|y)$ cannot be perfectly learned. For covariate drift a model has to generalize to samples from subpopulations that are almost unseen, e.g., a spam classifier should generalize to a new spam campaign $(x, y)_{test}$ = (word_in_email="cheap", is_spam=True) while only observing $(x, y)_{train} =$ (word_in_email="money", is_spam=True). One of the conjectures for transfer learning using PLMs is that task finetuning PLMs can generalize to inputs that are semantically similar to training instances. One reason for a lack of robustness to covariate drift is when models overfit on patterns between the input and the desired labels, e.g., when they would learn that only "cheap" is a predictor for spam. Another reason can be spurious correlations between patterns in the input and the label. Sagawa et al. (2020); Tu et al. (2020) showed this for entailment prediction. They grouped instances by a certain input attribute (does or does not contain negation) and target labels (is or is not entailment). The attribute did not have any direct relation to the label. Then they partitioned the data in such a way that there was a correlation between the polarity of the attribute and the label in the training data and an inverse correlation in the test data: $D_{train} = [(negation = +, entailment = -), (negation = -, entailment = +)]$ and $D_{test} = [(negation = +, entailment = +)], (negation = -, entailment = -)]$. They showed that models learn this correlation instead of the semantics of the actual task and then fail on test instances.

2.3 Empirical Analyses of Drifts

Currently, there is a rising interest to investigate distributional drifts in various domains (Tu et al., 2020; Sagawa et al., 2020; Koh et al., 2021; Dunn et al., 2020; Shankar et al., 2019; Oren et al., 2020b), most prominently in Computer Vision (CV), but also in NLP. To study distributional drifts, researchers need datasets with a controlled drift between training and test data. This can be broadly achieved in two ways:

Synthetic methods. A dataset drift is created by corrupting the input features with synthetic noise, for example, adding pixel noise (Goodfellow et al., 2015), perturbing the input with generative models (Dunn et al., 2020) or perturbing characters and words (Cao et al., 2020). It has been observed that robustness against synthetic noise does not imply robustness against semantically meaningful perturbations (Koh et al., 2021; Dunn et al., 2020).

Natural variations. Another option is to exploit natural variations, for example, using video frames for which a model's object prediction flips between adjacent frames (Shankar et al., 2019). Koh et al. (2021) collected a large benchmark for naturally occuring drifts in CV and NLP, e.g., user demographics for toxicity detection in online comments. Søgaard et al. (2021) investigated the difference of model performance comparing random splits with heuristics like splitting the data based on sentence length or by maximizing the divergence of the token feature vectors of the train and test split. In this work, we exploit natural variations in the data to create a drift in a non-adversarial manner. Our conjecture is that this setting is a good proxy to a realistic evaluation scenario.

2.4 Distributionally Robust Optimization

Robustness. The robustness of a machine learning model is the property that characterizes how effective the model is while being tested on a new dataset. In this paper, robustness is formally defined as follows. Let D be a dataset split into $D_{train}, D_{valid}, D_{test}$ and let E be a performance measure $E : \theta \times D \rightarrow R$ (w.l.o.g. greater is better). We assume that there is a covariate drift between D_{train} and D_{test}. Given two models A and B with parameters $\theta_A, \theta_B \in \Theta$ estimated on D_{train}. We call a model B more robust than model A when $E(\theta_B, D_{test}) > E(\theta_A, D_{test})$ and $E(\theta_B, D_{valid}) - E(\theta_B, D_{test}) < E(\theta_A, D_{valid}) - E(\theta_A, D_{test})$

Empirical Risk Minimization (ERM). Commonly used optimization algorithms assume that all examples are from the same population. This assumption stems from ERM's optimization objective which treats each example in $D_{train} \sim P$ with equal importance, i.e., $\hat{\theta} = inf_\theta E_P[l(x, y; \theta)]$. This optimization may have a negative impact on model robustness. For example, Tu et al. (2020) found that using ERM for finetuning PLMs learns spurious correlations even in the presence of a few helpful counter examples.

Distributionally Robust Optimization (DRO). DRO is based on the assumption that D_{train} consists of samples from many subpopulations, i.e., distributions Q from an uncertainty set $U(x, y)$. The objective in DRO is then to optimize the parameters such that they are optimal under the worst case distribution in $U(x, y)$, i.e., $\hat{\theta} = inf_\theta sup_Q \mathbb{E}_Q[l(x, y; \theta)]$. DRO is effective when the proportions of the distributions Q are highly skewed in D_{train}. For example, this can help to avoid learning spurious correlations, because even very few counter examples in the data are amplified. The challenge in applying the DRO concept is that the subpopulations are not observable and $U(x, y)$ has to be modeled by some prior knowledge about the data.

O	B-SONG	O	B-ARTIST	I-ARTIST	O	O	B-PLAYLIST	O

3 The SEQDRIFT Method to create Covariate Drift Benchmarks

Our goal is to study the impact of *covariate drift* on model performance. Therefore, we need a benchmark with controlled drift, but currently there are no publicly available SLU benchmarks in which real drifts can be studied. As motivated in Section 2.3, we do not want to employ synthetic noise, i.e., our goal is to design a method that exploits natural variations in the data. Moreover, the method should not be adversarial, i.e., not designed or optimized to target a specific model or model class. Instead, we target two semantic drifts that might occur in real data due to: *how* users express their intent, and *what* users request.

We conjecture that it is possible to capture *how* users express themselves by creating clusters of utterances with similar slot contexts. To capture *what* users request could be achieved by clusters of utterances with similar slot values. A drift can then be created by partitioning the data based on those clusters into training and testing. We avoid creating a mismatch of the label distributions between training and testing. If a mismatch would occur, it would not be possible to derive conclusions about covariate drift from changes in performance because the shift in the label distribution also leads to changes in the measured performance. In the following, we describe our approach in detail.

3.1 Overview

The high-level overview for creating a drift dataset version is as follows: (i) Join all splits from the original data. (ii) Transform examples into feature representations. (iii) Use spectral clustering to obtain K clusters based on the feature representations. (iv) Create the test split based on the clusters by sampling clusters instead of sampling examples.

3.2 Feature representation for clustering

We propose two variants of feature representations to capture different drift types.

Slot value drift To cluster examples by “*what* users request" we chose the feature representation of slot value n-grams. Table 1 shows an example in which only the slot values (the non-gray cells) are used to generate n-grams for an utterance, e.g. “`song`” or “`too poetic`”. The expected effect of splitting the data based on clusters of examples using this representation is that the training split is missing certain slot values, and thus we encounter unseen artists during testing.

Slot context drift The feature representation to cluster training examples by “*how* users express an intent or slot" are n-grams of slot labels and the tokens around them. For example, using only the non-gray cells in Table 2 to generate n-grams would yield “`add B-SONG by B-ARTIST`” or “`to my B-PLAYLIST`” as features to represent the example. The expected effect of this drift is that the test data contains phrases which are not seen during training.

3.3 Creating new train/valid/test splits

Now, using the feature representation for either the *slot value drift* or *slot context drift*, we use spectral clustering to create K clusters and proceed to create the data splits.

Test split. First the test split is created by sampling *clusters* and all the clusters' examples are added to the test split. To avoid a mismatch of the label distribution between training and the new test split, the method uses a projected label count per split to decide whether a cluster can be used. For example, let's assume we defined a 5% test split percentage and there are 1000 examples with the intent-slot label PLAYMUSIC-ARTIST. Then the test split should have ≈ 50 examples with the intent-slot label PLAYMUSIC-ARTIST. Hence, a cluster which contains 70 examples with the intent-slot label PLAYMUSIC-ARTIST cannot be used for the test split because it would exceed the projected label count. Thus, when a cluster is sampled *all* of its examples are added to the test split if they do not disturb the projected label count. This is repeated until all clusters have been sampled once and have been added to the test split or not. When the test split does not match the projected label count, it is filled using random *examples* from clusters that have not been used for test so far. These examples do not count into the controlled drift.

Train and validation split. The training and validation splits are created by sampling from the remaining *examples*.

3.4 Drift dataset variants

We also considered the following variations of the proposed algorithm to measure various effects.

O.O.D. validation One variation is that the validation data could be o.o.d. instead of distributed like the training data. This is a hypothetical setting in which we have access to o.o.d. data for validation and can observe to what degree hyperparameter tuning and model selection do factor into the drift effect. To achieve this we create the validation data in the same way as the test data, but validation and test do not share drift clusters.

Full drift and partial drift In the default behavior *all* the examples of a cluster are shifted into the test split which we call a **full drift**. However, a natural question is what happens when a small percentage of a test cluster leaks into training. We call this setting a **partial drift**.

4 DRO for Overparameterized Models

In the experiments in Section 5 we will show that using ERM optimization on the SEQDRIFT partitioned datasets is not robust. There might be many measures to mitigate this effect, and the best solution will most likely consist of a mix of methods. One candidate is DRO that has seen a rising interest to be applied to overparameterized models. In the following, we first briefly discuss the setting of finetuning a pretrained language model (PLM), and subsequently we describe existing and proposed DRO methods.

4.1 Finetuning Pretrained Language Models

In our setup, a pretrained language model M consists of a pretrained encoder ENC, and one (or more) task classifier head(s) C_{task}. Let X be a batch of inputs of size b, then the hidden representations of M are the output of the encoder $X_{enc} = ENC(X)$. For example, in our study we denote the averaged hidden token representations of size d after the last layer of BERT as $X_{enc} \in \mathbb{R}^{b \times d}$. To finetune M for a new task, the parameters of the encoder and the task classifier heads are optimized with a loss function L_{task} to obtain the task batch loss $l_{task} = L_{task}(C_{task}, X_{enc}) \in \mathbb{R}^{b}$. The following methods differ mainly in the way they manipulate the task batch loss l_{task}.

4.2 Existing DRO methods

The following DRO methods are by no means exhaustive. They represent either methods proposed so far in NLP or have a desirable property, e.g., being simple or conceptually interesting. The main differences between the methods is that they either use or do not use group knowledge in their objective. Those models that do require knowledge about groups in the data will use the clusters created by the SEQDRIFT algorithm. However, using the SEQDRIFT clusters is somewhat artificial because this is perfect information. Therefore, we are especially interested in methods that do not require group knowledge.

TOPIC-CVAR This method was proposed by Oren et al. (2019) for language modeling. They use a topic model to obtain a distribution over topics for each sentence to model the uncertainty set. The core idea is to accumulate the losses for each topic over the course of training. In each update a subset of losses in l_{task} is selected, i.e., the losses of those batch items that are assigned to the topic that currently lies in the upper α percentile of accumulated losses.

GROUP-DRO This method was proposed by Sagawa et al. (2020) for data where groups are known such that each example is assigned to one group. Similar to TOPIC-CVAR their method keeps statistics of the accumulated losses, but for groups rather than for topics. In GROUP-DRO the batch losses in l_{task} are first averaged per group and the final loss is a weighted average over group losses. For batch construction their method upsamples groups reciprocally to their frequency.

	Prec.	Adapt.	Impl.
TopK-AE (our)		x	
TopK-Group (our)	x		
TopK			x
Group-Dro	x		
Topic-CVar	x		

Table 3: How the group knowledge is modeled in DRO methods: precomputed, adaptive, implicit.

TopK This method does not require group knowledge and is simple to implement: it simply computes the loss as an average over the top-k largest losses in l_{task} (Levy et al., 2020; Kawaguchi and Lu, 2020).

4.3 Our proposed variants

We found TopK to be very effective in initial experiments. By contrast, Group-Dro and Topic-CVar did not perform well in our setting, even though both have been shown to work well. Thus, we propose the following TopK variants:

TopK-Group. If group information is available, can TopK be improved by it? Here the idea is —similar to Topic-CVar and Group-Dro— to use the precomputed SeqDrift clusters as groups and compute the TopK loss per group. Then only the largest TopK group loss is picked, which has the effect of upsampling “difficult” groups and downsampling “easy” groups over the course of training. However, when the precomputed SeqDrift clusters are used, this is more an oracle, i.e., an upper bound of how much can be inferred from the training data using perfect information.

TopK-Autoencoder (TopK-AE). What if we do not have access to the precomputed clusters? Could we approximate them using the PLM’s hidden representations X_{enc}? Our idea is to use the X_{enc} representations to cluster the b batch items into c latent groups. The latent groups are then used in the loss computation like in TopK-Group. The clustering is obtained from an autoencoder which is trained on X_{enc} and is continuously updated during training. Thus, the group assignment of a training example can change over the course of training according to the model’s changing hidden representations. We investigated hard cluster assignment TopK-AE-Bin and soft cluster assignment TopK-AE-Prob. See Appendix B for all the details regarding the autoencoder and its training.

Discussion Table 3 compares the different methods discussed in this study, and shows if the method relies on precomputed groups or if the groups are implicit or adaptively inferred during training.

5 Experiments

In this section, we present our experiments to investigate the following questions: **(Q1)** Does the standard optimization Erm suffer a performance loss under the SeqDrift covariate drift? **(Q2)** How well can Erm and DRO methods exploit a scarce signal about the test distribution, i.e., when is DRO relevant? **(Q3)** As all optimization methods come with hyperparameters, how much better could each method perform with access to o.o.d. validation data to optimize hyperparameters and perform early stopping? Would DRO still be better than Erm? **(Q4)** Are the DRO methods more robust than Erm against the SeqDrift covariate drift, and which DRO method is the most effective?

SLU Model. We use the JointBERT model for SLU (Chen et al., 2019). Two small changes that we introduce are: (i) an intent loss scaler γ for the joint tasks loss $L = L_{slot} + \gamma * L_{intent}$ and (2) using softmax layer instead of CRF for the sequence tagging classifier. We established the usefulness of those two changes with a hyperparameter study[1].

5.1 SeqDrift Datasets

The source datasets for SeqDrift are four commonly used SLU benchmarks, which are listed in Table 6. All technical details and settings for SeqDrift are discussed in Appendix A. Table 5 shows an excerpt from a cluster from the ATIS dataset and demonstrates how the *slot context drift* cluster contains examples with similar phrases, in this case utterances with the phrase "`between B-from.city and B-to.city`".

Use of datasets. To study robustness it is inevitable to look at test performance. Thus, we did not use all datasets for all stages of experimentation: Prototyping of SeqDrift was only done on ATIS, and then final experiments with Erm were done on all four datasets. The prototyping and initial experiments for the DRO methods were mostly done on ATIS and a few trials on SNIPS. The final DRO experiments were conducted on SNIPS and TOP.

---

[1] We found that CRFs did not help and task loss scalers for good models had a ratio of slot:intent of 100:1.

Table 5: An excerpt from a cluster from the ATIS dataset for the slot context drift.

All dataset scenarios In total we can evaluate a method in eight different *scenarios* per dataset, i.e., the cross product of

{slot value drift, slot context drift} ×
{partial drift, full drift} ×
{i.i.d. validation, o.o.d. validation}.

Table 4 shows the resulting statistics for the datasets SNIPS and TOP-NN. The percentage of examples resulting from a *controlled drift* in the test set are 66 – 79% for SNIPS and 44 – 47% for TOP. For the scenario with *partial drift* 2-3% of the training data split belong to clusters that have been deliberately shifted into the test split.

Metrics. We use the following metrics: F1 - the slot F1 metric; ACCURACY - the intent accuracy; COMBINED-IC-SF - the average of F1 and Accuracy.

Hyperparameters. To ensure a fair comparison of methods in the experiments, we performed a hyperparameter search with the objective to optimize for COMBINED-IC-SF for each optimization method for four scenarios {slot value drift, slot context drift} × {i.i.d. validation, o.o.d. validation} with partial drift (see Section 3.4). For each setting we ran 8 hyper-parameter optimization steps[2], then picked the two best hyper-parameter settings and retrained them with a different random seed. Then we reused the best hyper-parameters for the full drift. See Appendix C and Table C.9 for the remaining details about the hyperparameters.

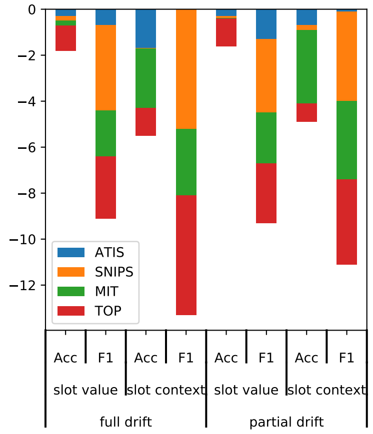
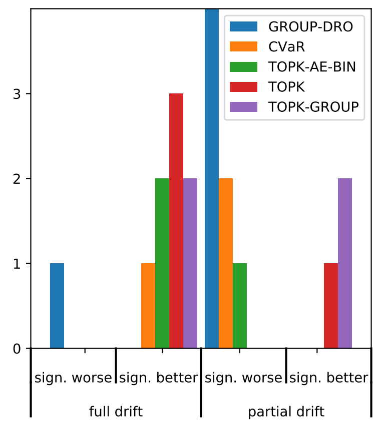
---

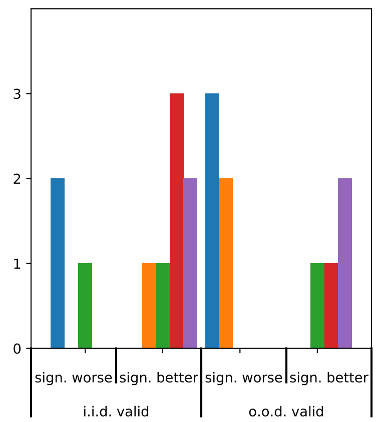
[2] using Optuna



(a) Drop in absolute ERM performance from validation to test on four datasets with two drift types (slot value, slot context) and drift percentage (full, partial).



(b) Amount of times a method was significantly worse or better than ERM on SNIPS for either full drift or partial drift out of 4 scenarios each.



(c) Amount of times a method was significantly worse or better than ERM on SNIPS when the validation data is i.i.d. or o.o.d., i.e. out of 4 scenarios each.

5.2 Results

The reported results for each scenario are always averaged from four models, i.e., the models obtained with the two best hyperparameter settings that each have been trained with two random seeds. We computed significance with $p < 0.05$ between models with approximate randomization (Noreen, 1989). Due to the repetition with different random seeds, this effectively results in a family-wise error rate of 0.185. In Figures 1b and 1c we count in how many scenarios a DRO method was significantly better or worse than ERM. The remaining instances performed the same as ERM.

(Q1) Does the SEQDRIFT covariate drift lead to a drop in performance for ERM? In Figure 1a, it can be observed that ERM's performance does drop up to 5% in slot F1 between validation and test. However, the amount of change varies between datasets. In most scenarios, slot F1 suffers a higher drop in performance than intent accuracy. *Slot context drift* yields a higher loss than the *slot value drift*, so it seems that it is easier to generalize to unseen slot values than to unseen phrases. This makes intuitively sense, e.g., *"Please play New Unknown Artist."* can be recognized by just knowing the sequence "`please play B-ARTIST I-ARTIST ...`", but it is more difficult to generalize to a new unseen phrase. See Appendix D Table 10 for the numerical results.

(Q2) How well can ERM and DRO methods exploit a scarce signal about the test distribution? In Section 3.4 we described the *partial drift*, in which $2 - 3\%$ of the training data are leaked examples from test clusters. Thus, during training there is some information about test clusters that could be exploited. For ERM, Figure 1a shows indeed that the *partial slot context drift* leads to a smaller drop in performance than the *full slot context drift*. Thus, we conclude that ERM can exploit this information.

For DRO, Figure 1b shows that there are less scenarios with significant improvement from DRO methods over ERM with a *partial drift* than with a *full drift* (see numerical results Appendix D Table 14). It is important to note that all methods —ERM and DRO— do improve, but ERM improves more than most of the DRO methods. Only TOPK-GROUP and TOPK still improve over ERM. Anecdotally, in a SEQDRIFT setting in which only 80% or less of the clusters are drifted into the test split and the percentage of the drift cluster examples make up more than 5% of the training data, the significant improvement of all the DRO methods vanishes.

(Q3) Does o.o.d. validation data help hyperparameter optimization and early stopping? In Figure 1c, we observe that the amount of significant improvement over ERM shrinks when the validation data is o.o.d. and thus contains information how to perform well for the test split. This affects hyper-parameter optimization and early stopping which also helps ERM to obtain a model from the training data that performs better on the test distribution. This can serve as an upper bound of possible improvement that can be derived from the

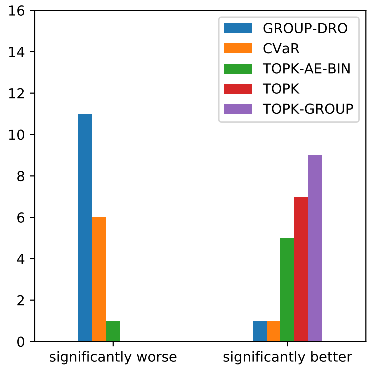


Figure 2: Amount of times a method was significantly worse or better than ERM on SNIPS and TOP out of 16 scenarios.

training data alone. See Appendix D Table 13 for the detailed numerical results.

(Q4) Are the DRO methods more robust against the drifts than ERM? Figure 2 shows in how many scenarios the DRO methods improved significantly over ERM on the SNIPS and TOP dataset. TOPK and TOPK-GROUP only improve significantly over ERM and do not perform worse. TOPK-AE-BIN only performs worse one time but otherwise the same or better. The results indicate that TOPK-based methods do improve robustness. TOPK-GROUP performs best amongst all methods, i.e., group information helps TOPK-based methods. TOPK-AE-BIN performs slightly worse in terms of significant improvement than TOPK, however, in terms of average relative improvement over ERM it is on par or better than TOPK (see Tables 11 and 12 in the Appendix). Yet, the lesser amount of significant improvement of TOPK-AE-BIN in comparison to TOPK-GROUP shows that approximating the group information is difficult. Without perfect group information a simple method like TOPK might be the most reliable method to obtain a robust model. See more detailed results in Appendix D Table 11 and Table 12.

Discussion GROUP-DRO, TOPIC-CVAR and TOPK-GROUP use the SEQDRIFT clusters in their optimization. Therefore, these results should be rather seen as an upper bound of how much can be inferred from the training data using perfect information. Still, GROUP-DRO and TOPIC-CVAR both fail to perform well in this experiment. Note that both methods had the same amount of budget for hyper-parameter optimization as other methods. For GROUP-DRO we used the authors' published code[3] and also their implementation of TOPIC-CVAR. Our conjectures about this finding are: (1) GROUP-DRO and TOPIC-CVAR both have been proposed and studied for groups that have much higher lexical variance than the groups in our data. The groups in our dataset consist by construction of many examples with similar lexical patterns and can be of small size, i.e., as little as 10 examples. This might explain why they seem to overfit heavily. (2) Another difference to our methods is that our proposed methods do not use an exponential average of historical group loss statistics.

6 Conclusions

We studied finetuning BERT for SLU datasets with covariate drift. We presented the SEQDRIFT method to induce a covariate drift for SLU sequence classification tasks. The experimental results showed that this drift in the input distribution leads to a drop in performance on four SLU datasets for a common BERT-based SLU model finetuned with ERM. We investigated DRO methods that either use or do not use knowledge about groups in the data. Our empirical results in an extensive study indicate that TOPK-based DRO methods are successful in improving robustness on the drift datasets.

	Partial	90%	90%

Table 7: Hyperparameters for the creation of the SNIPS and TOP drift datasets.

A Drift dataset creation

The procedure described in Section 3 has a range of hyperparameters that we did set manually. Our goal was to improve the clustering not in an adversarial way. Thus those hyperparameter choices were picked by inspecting the clusters and assessing if they did display desired properties independently of the downstream experiments. For example, the number of clusters was set to 100 as shown in Table 7 and was set large enough such that the clustering algorithm did not have to mix clusters into each other.

Clustering algorithm The clustering algorithm we used was the spectral clustering implementation in `https://scikit-learn.org/stable/modules/generated/sklearn.cluster.SpectralClustering.html`. The feature vector of an example was a weighted indicator vector over the top most frequent n-grams in the dataset. If an example contains the kth most frequent n-gram, then the kth component of this vector was set to n^2, otherwise it was set to 0. The effect of the n^2 weighting is to create a higher affinity between examples that share longer n-grams than shorter n-grams. The affinity matrix for the spectral clustering was computed with cosine similarity.

Settings for the dataset The following settings were used in the dataset creation in our experiments and are listed in Table 7: (a) The number of clusters. (b) Thresholds to filter out low frequency intents and low frequency slot label types, i.e., the minimum frequency of intent labels and slot labels in the dataset. (c) The minimum size of projected label counts that we attempt to match. If this parameter is set too low then many clusters might be discarded because they would violate the projected label count. Even when we did not match some of the projected label counts we did achieve correlations $\geq 98\%$ between training and testing. (d) The range of n-gram sizes. (e) How many of the top most frequent n-grams will be used for the feature vector of an example. (f) We either create a full drift in which 100% of the examples in a cluster are assigned to the test split and a partial drift in which we assign only 90% of the examples in a cluster to the test split.

Discussion Table 4 lists the statistics for the drift versions of SNIPS and TOP. As can be seen in the "% drift" column of the train splits, the partial shift leads to around 2-3% of training data containing examples from the clusters that have been shifted into test. Our main objectives during the creation of the drift splits was to shift entire clusters into the splits and to match the intent distribution. We did not constrain the amount of examples in the test split that have been deliberately shifted into the test split, i.e., observe in Table 4 that the "% drift" on the validation and test splits varies from 23-79%.

B TOPK-AUTOENCODER

In Algorithm 1 we present our proposed strategy to train a BERT-based SLU model (Chen et al., 2019) with TOPK-AE. In the following we will first describe the autoencoder and its optimization and then the training steps to train a model with TOPK-AE.

Autoencoder. The input to the autoencoder are the averaged token representation X_{enc} each batch item. Let $X_{enc} \in \mathbb{R}^{b \times d}$, with b being the batch size and d the hidden size. Let the layers of the autoencoder be defined as $A_{enc} \in \mathbb{R}^{d \times c}$ and $A_{dec} \in \mathbb{R}^{c \times d}$ with c being the size of the latent code, i.e. the number of latent groups. The autoencoder is then defined as:

$$\begin{aligned} H &= softmax(X_{enc} A_{enc}) \\ R &= H A_{dec} \end{aligned} \tag{1}$$

Notably, we employ a softmax in the bottleneck H such that the auto-encoder's latent code is a distribution over c latent groups. R is the reconstruction of the autoencoder's input.

The auto-encoder is optimized with two losses:

i) a *reconstruction loss*, i.e. the cross entropy loss of the objective that each reconstruction R_i should be closer to its original input X_{enc_i} than to

Intent Type	Slot Type	Train	Valid	Test	Test-Valid
DepartureTime	B-Criterion	57	5	5	0
	B-StationStart	62	6	6	0
	B-Vehicle	61	5	6	1
FindConnection	B-Criterion	11	3	3	0
	B-StationStart	99	10	10	0
	B-StationDest	106	11	11	0

Algorithm 1 Training SLU with Online Auto-encoder DRO

```
$M$ is the main model (SLU) with two task losses (slot and intent)
$\theta_M$ are the main model's parameters
$\theta_{AE}$ are the auto-encoder's parameters
for data_batch (X, Y) in training_data do
    $X_{enc} = ENC(X)$
    $l_{slot}, l_{intent}$ = compute the task losses of $M$ on $(X, Y)$
    $l_{AE} = L_{Recon}(X_{enc}, \theta^t_{AE}) + \beta L_{Divers}(X_{enc}, \theta^t_{AE})$
    $\theta^{t+1}_{AE} = update(\theta^t_{AE}, \nabla L_{AE})$
    $\hat{l}_{slot}$ = compute group loss$(A^{t+1}_{enc}, X_{enc}, L_{slot})$
    $\hat{l}_{intent}$ = compute group loss$(A^{t+1}_{enc}, X_{enc}, L_{intent})$
    $\theta^{t+1}_{M} = update(\theta^t_{M}, \nabla(\hat{L}_{slot} + \hat{L}_{intent}))$
    $t = t + 1$
end for
```

other batch items in X_{enc}. θ_{AE} denote the auto-encoder's parameters:

$$L_{Recon}(X_{enc}, \theta_{AE}) = \\ -\frac{1}{b}\sum_{i=1}^{b} log(softmax(X_{enc}R^{\top}))_i \quad (2)$$

For regularization we apply dropout to R before computing the reconstruction loss.

ii) a *diversity loss* to prevent the auto-encoder from collapsing into one mode, which is similar to the loss used in T-SNE (van der Maaten and Hinton, 2008).

$$\mathrm{L}_{Divers}(X_{enc}, \theta_{AE}) = \frac{\sum_{i \neq j} KL(H_i, H_j)}{b(b-1)} \quad (3)$$

where θ_{AE} denote the auto-encoder's parameters and KL the Kullback-Leibler divergence.

This method adds the following hyper-parameters for the autoencoder: size c of the autoencoders bottleneck, learning rate λ_{AE} and weight decay α_{AE}, and β_{AE} a scalar for the reconstruction loss.

We considered the following TopK-AE variants:

TopK-AE-Pr The bottleneck output of the autoencoder is $H \in [0,1]^{b \times c}$, i.e. a distribution over c groups for each batch item. Let $\circ$ denote elementwise multiplication along a matching mode. Then $\hat{H} = H \circ l_{task}$, i.e. $\hat{H} \in \mathbb{R}^{b \times c}$ are the losses weighted according to each latent group. Instead of averaging over all losses per latent group, $\hat{H}$ is truncated to the top-k largest weighted losses per group, i.e. $\hat{H} \in \mathbb{R}^{k \times c}$ and then averaged per group to yield $\hat{l} \in \mathbb{R}^{c}$. The final batch loss is $max(\hat{l})$.

TopK-AE-Bin Convert H into one-hot distributions, i.e. hard assignments to a latent group for each batch item, then proceed like in TopK-AE-Pr.

Algorithm. The model is finetuned for two task losses, one for the intent classification task and one for the sequence tagging classifier for the slot filling task. While it would be possible to use a separate autoencoder for each task, we found it beneficial to share one autoencoder for both task losses.

One update step is as follows: (i) For each batch during training, first the auto-encoder's parameters are updated. (ii) Subsequently, we compute the group losses for the two SLU's tasks (i.e. slot and intent) based on H, i.e. the latent groups. This yields a vector $\hat{l}_{task}$ of loss-aggregations over the latent groups. $H \in \mathbb{R}^{b \times c}$ is a distribution over c groups for each batch item. $\hat{l}_{task} = H^{\top} l_{task}$ is the vector of group losses in which each batch item is weighted according to the autoencoder's distribution over latent groups. In other words, each component in $\hat{l}$ contains the accumulated losses of all batch items that the autoencoder considers to be similar. Finally, we update the SLU model's parameters using the task group losses.

C Hyperparameters

See Table 9 for a detailed list for all hyperparameters and their search range. The hyper-parameters that were tuned for all methods are the learning rate λ and the intent loss scaler γ. Each optimization method can have additional hyper-parameters: GROUP-DRO (Sagawa et al., 2020) has a step size to compute the exponential average of group losses. As we discussed in Section 5.2 we observed overfitting of the GROUP-DRO method and not producing good results on many occasions. We did attempt to address this and added a geometric decay of the exponential average as an option in the hyperparameter search, which did help a little bit. TOPIC-CVAR (Oren et al., 2019) has the CVaR percentage and also a step size for the exponential average of losses. The batch size, weight decay, maximum number of epochs and the intent loss scaler (see 5.1) were determined in a prior larger hyperparameter search. We did not find a lot of variance for their preferred setting, also not in interplay with the other DRO methods, which is why we fixed them to save computation from this point on. See Section 4.2 and 4.3 for the hyperparameters of TOPK-AE and TOPK-AE-PR/BIN respectively. Anecdotally the hyper-parameter k determining the topk losses in their objective which was tuned for TOPK and TOPK-AE-PR/BIN typically ended up in the lower regions of the range, i.e. between $2-8$.

D Results

In the following tables we report the numerical results for the experiments from Section 5 with the metrics reported in Section 5.1. Additional metrics we report here is the macro average over intents, i.e. "MA INT. COMBINED", and SEMER (semantic error rate) - a metric which is defined as follows:

$$\mathit{SEMER} = \frac{\#(\text{slot+intent errors})}{\#\text{slots in reference + 1}} \tag{4}$$

The columns containing a "%" indicate relative change to ERM.

Optimization	description	name	type	range
ERM + all	learning rate	λ	loguniform	1.e-5 - 1.e-4
	intent loss scaler	γ	loguniform	1.e-2 - 10.0
	batch size		fixed	32
	weight decay		fixed	SNIPS: 0.02, TOP: 0.002
	max epochs		fixed	100
	max warmup steps		fixed	0
TOPIC-CVAR	alpha		uniform	1.e-4 - 0.5
	gamma		loguniform	1.e-4 - 0.5
GROUP-DRO	step size		loguniform	1.e-4 - 1.
	geometric decay		categorical	True, False
TOPK	topk	k	logint	1 - 16
TOPK-AE-PR/BIN	topk	k	logint	2 - 16

Abstract

Chinese pre-trained language models usually exploit contextual character information to learn representations, while ignoring the linguistics knowledge, e.g., word and sentence information. Hence, we propose a task-free enhancement module termed as **H**eterogeneous **L**inguistics **G**raph (**HLG**) to enhance Chinese pre-trained language models by integrating linguistics knowledge. Specifically, we construct a hierarchical heterogeneous graph to model the characteristics linguistics structure of Chinese language, and conduct a graph-based method to summarize and concretize information on different granularities of Chinese linguistics hierarchies. Experimental results demonstrate our model has the ability to improve the performance of vanilla BERT, BERTwwm and ERNIE 1.0 on 6 natural language processing tasks with 10 benchmark datasets. Further, the detailed experimental analyses have proven that this kind of modelization achieves more improvements compared with previous strong baseline MWA. Meanwhile, our model introduces far fewer parameters (about half of MWA) and the training/inference speed is about 7x faster than MWA. Our code and processed datasets are available at `https://github.com/lsvih/HLG`.

1 Introduction

Pre-trained Language Models (PLM) (Peters et al., 2018; Devlin et al., 2019; Radford et al., 2018; Yang et al., 2019) have recently demonstrated the effectiveness on a variety of natural language processing (NLP) tasks, such as machine translation and text summarization. For a specific downstream task, the parameters of PLMs can be fine-tuned with accurately labeled instances or weakly labeled instances of the task to achieve better performance.

In recent, there are a series of studies on adapting PLMs for Chinese (Meng et al., 2019; Sun et al., 2019; Cui et al., 2019a; Sun et al., 2020; Wei et al., 2019; Diao et al., 2020; Lai et al., 2021). Many researchers introduce the Chinese-specific linguistics knowledge such as word information into PLMs by conducting elaborate self-supervised tasks to pre-train Chinese PLMs from scratch. Nevertheless, pre-training a PLM is computationally expensive and time-consuming since it needs large-scale Chinese corpus and heavy computational resources. The high cost makes it difficult for researchers to pre-train a PLM from scratch.

An alternative way is to integrate the Chinese-specific linguistics knowledge into pre-trained PLMs in the fine-tuning stage in downstream tasks directly. Following this idea, the task-free enhancement module is widely used in the fine-tuning stage by adding an additional adapter in PLMs to integrate external knowledge (Li et al., 2020). As shown in Figure 1, the enhancement module is inserted between PLMs and task-specific module, and its inputs are the hidden representations of PLMs and embeddings of external knowledge. To achieve the goal of integrating external knowledge into PLMs in the fine-tuning stage, the enhancement module should have the following characteristics. First, as a plug-in adapter module in fine-tuning stage, it should maintain consistent output formulation with PLM. Second, it should not introduce unacceptable time or space complexity for training and inference. Third, it should improve the performance of downstream tasks universally.

With the core idea of the enhancement module, Li et al. (2020) proposed a multi-source word-aligned model (MWA) to enhance PLMs by integrating Chinese Word Segmentation (CWS) bound-

aries information implicitly. It first exploits various CWS tools to generate multiple word sequences and then utilizes word-aligned attention with a mixed pooling to integrate the word information into characters. Experimental results show that MWA has the ability to utilize CWS segmentation information to enhance Chinese PLMs to achieve SOTA performance in many downstream NLP tasks. However, MWA has two weaknesses: 1) **Efficiency Degradation**: The model structure of MWA is naturally non-parallel and cannot benefit from GPU acceleration (detailed in §4.3.3), which results in time inefficiencies in both training and inference processes. 2) **Linguistic Information Loss**: MWA utilizes a pooling-based mechanism to perform interaction between characters and words. Such a heuristic method could not make full use of information, resulting in sub-optimal results.

To tackle the aforementioned limitations, we propose **H**eterogeneous **L**inguistics **G**raph (**HLG**), which is Graph Neural Network (GNN) based method to integrate CWS information to enhance PLMs. Specifically, the hierarchical CWS information is first conducted by a heterogeneous graph, which contains character nodes, word nodes and sentence nodes. The edge between nodes indicates the inclusion relationship of the grammatical structure between the linguistic hierarchies. Then, a simple but effective multi-step information propagation (MSIP) is proposed to incorporate the linguistics knowledge of heterogeneous graph to enhance Chinese PLMs inductively. In this way, we can obtain adequate information interaction among characters, words and sentences. Furthermore, the internal implementation of HLG is highly parallelized, which is conducive to GPU accelerate and raises the operating efficiency.

In summary, we abstract out an adapter component named enhancement module for PLMs to integrate external knowledge during the fine-tuning stage. In this paradigm, we further introduce HLG to integrate CWS information delicately and model it via an effective MSIP. Extensive experiments conducted on 10 benchmark datasets of 6 NLP tasks demonstrate that our model outperforms the BERT, BERTwwm and ERNIE 1.0 significantly and steadily. Comparing with MWA, a strong baseline that also incorporates CWS information to enhance PLMs, our model achieves a steady improvement with the same information. Meanwhile, compared with previous work, MWA, our proposed HLG introduces only half additional parameters and the training/inference speed is about 7x faster.

2 Preliminaries

2.1 Pre-trained Language Model (PLM)

As mentioned in §1, the pre-trained language models (PLMs) have achieved great success in many NLP applications with the 2-stage paradigm of pre-training and fine-tuning. The PLMs usually perform pre-training on large-scale unlabeled corpus in virtue of self-supervised reconstruction tasks. For example, BERT (Bidirectional Encoder Representations from Transformers) (Devlin et al., 2019) is a typical well-known PLM, which conducts masked language modeling and next sentence prediction as pre-training tasks. After completing the pre-training, the PLMs learn substantial contextualized text representations, and then adapt fine-tuning on specific downstream tasks.

In Chinese NLP, PLMs are generally character-based models (Li et al., 2019; Cui et al., 2019a). Specifically, given a character sequence:

$$S = [c_1, c_2, ..., c_n] \tag{1}$$

the outputs of Chinese PLMs can be treated as the character-level representations $\mathbf{H} \in \mathbb{R}^{n\times d}$, where the d is the dimension of representation.

2.2 Chinese Word Segmentation

As the same as most East-Asian languages, Chinese language is written without explicit word delimiters and the character is the smallest morpheme unit in Chinese linguistic (Cai and Zhao, 2016). Although character-based models could achieve good performance (Li et al., 2019), Li et al. (2020) point out that introducing Chinese Word Segmentation

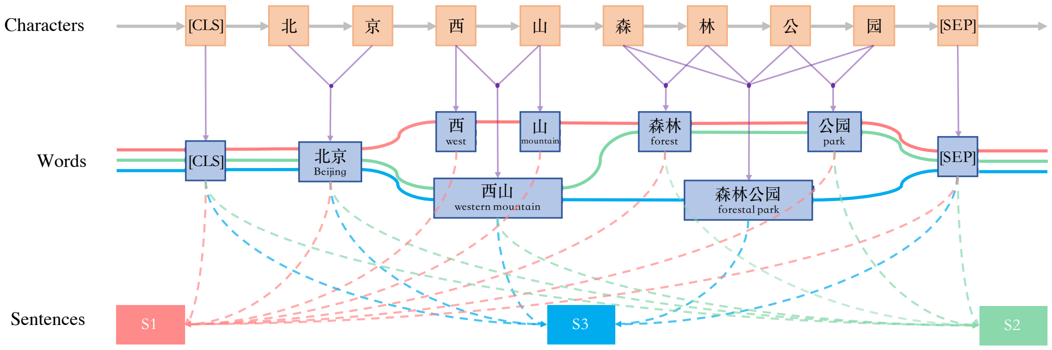

Figure 2: Overview of HLG structure. Different colored lines represent sentences formed by different CWS tools.

(CWS) information to character-based models can effectively improve the model performance.

We give a formality definition of segmenter and its partition strategy π. Given a sentence consisting of a sequence of characters as Eq. 1, a segmenter is defined as:

$$\textsc{Segmenter} \equiv \pi : S \rightarrow S'$$

where π is a partition strategy of sentence. Specifically, π partition and group the character sequence S into the word sequence S':

$$\pi(S) = S' = [w_1, w_2, ..., w_m] \tag{2}$$

where $m \leq n$ and $w_i = [c_s, c_{s+1}, ..., c_{s+l-1}]$ is the i-th segmented word with a length of l and s is the index of w_i's first character in S. Namely, the word w_i is a sequence of characters $\{c_s, c_{s+1}, ..., c_{s+l-1}\}$, and the sentence S' is a sequence of words $\{w_1, w_2, ..., w_m\}$.

2.3 MWA for Enhancing Chinese PLM

Li et al. (2020) carried out researches on integrating CWS information into Chinese PLMs. The authors brought an architecture named Multi-source Word-aligned Attention (MWA) to incorporate multi-granularity segmentation via pooling attention weights among characters within the word.

Formally, given a character sequence S as Eq. 1 and its partition strategy π as Eq. 2. The character-based representation $\mathbf{H}$ could be gained via PLM, MWA conducted self-attention between characters:

$$\mathbf{A} = \texttt{softmax}\left(\frac{(\mathbf{K}\mathbf{W}_k)(\mathbf{Q}\mathbf{W}_q)^T}{\sqrt{d}}\right)$$

where $\mathbf{Q}$ and $\mathbf{K}$ are both $\mathbf{H}$, d is defined in §2.1, and $\mathbf{A}$ represents the attention score matrix. We decompose $\mathbf{A}$ over columns as $[\mathbf{a}^1, \mathbf{a}^2, ..., \mathbf{a}^n]$, and then perform partition π on it: $\pi(\mathbf{A}) = [\{\mathbf{a}^1, \mathbf{a}^2\}, \{\mathbf{a}^3\}, ...\{\mathbf{a}_c^s, ..., \mathbf{a}_c^{s+l-1}\}..., \{\mathbf{a}^{n-1}, \mathbf{a}^n\}]$ where s and l are defined in §2.2. Pooling each group of partitioned columns:

$$\mathbf{a}_w^i = \texttt{MixPooling}(\{\mathbf{a}_c^s, ..., \mathbf{a}_c^{s+l-1}\})$$

in which `MixPooling` is defined in Yu et al. (2014). The gained $\mathbf{A}_w = [\mathbf{a}_w^1, \mathbf{a}_w^2, ..., \mathbf{a}_w^m] \in \mathbb{R}^{n \times m}$ is the character-to-word attention weight matrix. After performing alignment-wise multiply (Li et al., 2020) between character-to-word attention weight matrix $\mathbf{A}_w$ and the character-based representation $\mathbf{H}$, the enhanced character-based representation which integrates CWS information can be obtained.

In essence, the MWA conducts interaction between characters and words via character-to-word attention weight matrix $\mathbf{A}_w$, implicitly summary the information from characters, and performs MixPooling to aggregate the word-based segmentation information and concrete the character-level representation.

3 Heterogeneous Linguistics Graph

This section introduces the components of our model **HLG** which instantiates the enhancement module by exploiting the CWS information. We first briefly explain the graph convolutional network as our base encoder, and then describe the graph construction of HLG. Finally, we give the details of the multi-step information propagation (MSIP) to integrate the CWS information into PLMs.

3.1 Graph Convolutional Network

Graph Convolutional Network (GCN) (Bruna et al., 2014; Kipf and Welling, 2017; Defferrard et al., 2016) is a powerful tool to extend the convolution operation from the grid data to irregular graph data.

The basic idea of GCN is to aggregate the representations of neighbors to obtain better representation expression of nodes in the graph. For instance, consider a homogeneous graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ constructed by nodes set $\mathcal{V}$ and edges set $\mathcal{E}$. $\mathbf{A} \in \mathbb{R}^{|\mathcal{V}|\times|\mathcal{V}|}$ is a binary adjacency matrix where each element A_{ij} denotes whether node i has an edge with node j in the edge set $\mathcal{E}$. Formally, a standard GCN layer can be abstracted as:

$$\mathbf{H}_{out} = \sigma(\hat{\mathbf{A}}\mathbf{H}_{in}\mathbf{W}), \quad \hat{\mathbf{A}} = \texttt{Norm}(\mathbf{A}) \qquad (3)$$

where $\mathbf{H}_{in}$ denotes the input representation matrix, $\mathbf{H}_{out}$ is the updated representation matrix, $\texttt{Norm}(\cdot)$ means row normalizing function, $\hat{\mathbf{A}}$ is the normalized adjacency matrix, $\sigma(\cdot)$ is the ReLU function and $\mathbf{W}$ is a parameter matrix. After such convolution operation, the representation $\mathbf{H}_{in}$ were aggregated rely on edge connections defined by $\mathbf{A}$, and transformed into $\mathbf{H}_{out}$ by linear multiplication and active function.

3.2 Graph Construction

We build a heterogeneous graph $\mathcal{G} = (\mathcal{C}, \mathcal{W}, \mathcal{S}, \mathcal{E})$ to model the structure of Chinese linguistic, where $\mathcal{C}$, $\mathcal{W}$, $\mathcal{S}$, $\mathcal{E}$ denote the character nodeset, word nodeset, sentence nodeset and edge set, respectively. Besides, different from homogeneous graph, HLG models relationship between three granularities of linguistic in a hierarchical way.

As presented in Figure 2, $\mathcal{G}$ is composed of three hierarchies including characters, words and sentences. In this case, we employed three different CWS tools, and got three different segmentation results, which resulted in three sentences with slightly different semantics. Note that the same word segmentation results in the same position obtained by different CWS tools will be regarded as the same word node to enhance the interaction (e.g., Beijing and park in Figure 2). This purpose is to **denoise** the mistake word nodes brought by segmenter error. If a word is segmented by multiple segmenters at the same time, the corresponding word node will have a higher vertex degree. Such nodes with higher betweenness centrality will lead to a stronger influence on the followed information propagation and achieve the effect of denoising intuitively, like the vote-based multi-model ensemble.

In HLG, only one adjacency matrix $\mathbf{A}$ is not enough to describe the hierarchical relationships between characters, words and sentences. Hence, we conduct two interaction matrices $\bar{\mathbf{A}}^{c2w} \in \mathbb{R}^{|\mathcal{W}|\times|\mathcal{C}|}$ and $\bar{\mathbf{A}}^{w2s} \in \mathbb{R}^{|\mathcal{S}|\times|\mathcal{W}|}$ to indicate aforementioned relationships. To be specific, we take the $\bar{\mathbf{A}}^{c2w}$ as an example (the one for $\bar{\mathbf{A}}^{w2s}$ is analogous), the element $\bar{A}^{c2w}_{ij}$ denotes whether **word** i has an edge with **character** j in the edge set $\mathcal{E}$. Similar to Eq. 3, we also denote normalized interaction matrices as $\hat{\mathbf{A}}^{c2w}$ and $\hat{\mathbf{A}}^{w2s}$.

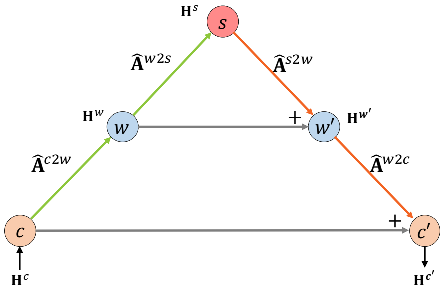

Figure 3: Illustration of learning procedure of MSIP. The colored circles denote characters, words or sentences representations. The green, orange and gray lines describe the summarization (Eq. 4), concretization (Eq. 6) and skip connection (Eq. 7) operations, respectively.

3.3 Multi-Step Information Propagation

To model the granularities hierarchical relationships in $\mathcal{G}$, we devise a multi-step information propagation to learn the linguistics knowledge. In CWS, the partition and group processes could be considered as the partition of semantic representation and the aggregation of separated semantic respectively (detailed in §2.2). Inspired by CWS processes, we introduce two operations into MSIP to simulate such processes and named as summarization and concretization. Figure 3 shows the information propagation procedure of MSIP.

Summarization. The summarization operation focuses on generalizing hierarchical word and sentence representations (e.g., from character-level to word-level). Specifically, given a heterogeneous graph $\mathcal{G}$ and corresponding character representations $\mathbf{H}^c$ from PLM, the summarization operation can be formulated as follows:

$$\begin{aligned} \mathbf{H}^w &= \sigma(\hat{\mathbf{A}}^{c2w}\mathbf{H}^c\mathbf{W}^{c2w}), \\ \mathbf{H}^s &= \sigma(\hat{\mathbf{A}}^{w2s}\mathbf{H}^w\mathbf{W}^{w2s}), \end{aligned} \qquad (4)$$

where the $\mathbf{W}^{c2w}$, $\mathbf{W}^{w2s}$ are parameter matrices, $\mathbf{H}^w$, $\mathbf{H}^s$ are the interim representations of words and sentences.

Concretization. Concretization is the inverse operation of summarization, it is used to repartition the semantics from high-level to low-level (e.g. from sentence-level to word-level). To do so, we first calculate the normalized interaction matrices $\hat{\mathbf{A}}^{s2w}$ and $\hat{\mathbf{A}}^{w2c}$, which can be simply obtained by first transposed then normalized the predefined interaction matrices $\bar{\mathbf{A}}^{w2s}$ and $\bar{\mathbf{A}}^{c2w}$, respectively. Thus, we have:

$$\begin{aligned}\hat{\mathbf{A}}^{s2w} &= \texttt{Norm}\big((\bar{\mathbf{A}}^{w2s})^{\top}\big),\\ \hat{\mathbf{A}}^{w2c} &= \texttt{Norm}\big((\bar{\mathbf{A}}^{c2w})^{\top}\big),\end{aligned} \tag{5}$$

where $(\cdot)^{\top}$ is the transpose function. Afterward, the concretization operation is defined as follows:

$$\begin{aligned}\overline{\mathbf{H}}^{w'} &= \sigma(\hat{\mathbf{A}}^{s2w}\mathbf{H}^{s}\mathbf{W}^{s2w}),\\ \overline{\mathbf{H}}^{c'} &= \sigma(\hat{\mathbf{A}}^{w2c}\mathbf{H}^{w'}\mathbf{W}^{w2c}),\end{aligned} \tag{6}$$

where $\mathbf{W}^{s2w}$ and $\mathbf{W}^{w2c}$ are parameter matrices, $\overline{\mathbf{H}}^{w'}$ and $\overline{\mathbf{H}}^{c'}$ are also interim word and character representations, $\mathbf{H}^{w'}$ denote the final word representations defined in Eq. 7.

Skip Connection. Intuitively, it is difficult to generate satisfied low-level representations from the high-level representations directly. For example, it is easy to learn a few sentence representations from dozens of word representations, but hard to generate dozens of word representations from a few sentence representations.

To mitigate this problem, in this paper, we introduce the skip connection to enhance the MSIP, which is to simulate the self-loop in vanilla GCN. As shown in Figure 3, we add skip connections between the summarization representations and the concretization representations directly. Formally, the skip connection can be simply expressed as:

$$\begin{aligned}\mathbf{H}^{w'} &= \overline{\mathbf{H}}^{w'} + \sigma(\mathbf{H}^{w}\mathbf{W}^{w}),\\ \mathbf{H}^{c'} &= \overline{\mathbf{H}}^{c'} + \sigma(\mathbf{H}^{c}\mathbf{W}^{c}),\end{aligned} \tag{7}$$

where $\mathbf{W}^{w}$ and $\mathbf{W}^{c}$ are parameter matrices. Furthermore, $\mathbf{H}^{c'}$ denote the final representations for characters, which incorporates the fine-grained linguistics knowledge in $\mathcal{G}$.

4 Experiments

4.1 Experimental Setting

For a fair comparison with MWA, which also gives an enhancement module by incorporating CWS information. We conduct the same experiments on five NLP tasks with various benchmark datasets. Three frequently-used Chinese PLMs: BERT (Devlin et al., 2019), ERNIE 1.0 (Sun et al., 2019) and BERTwwm (Cui et al., 2019a) are employed as the basic PLM to enhance. Three CWS tools: thulac (Sun et al., 2016a), ictclas (Zhang et al., 2003) and hanlp (He, 2014) are employed to gain the segmentation information. The time of pre-processing including applying CWS tools is ignored in the experimental report. In the production, preprocessing and inference can be asynchronously executed in parallel (while inference a batch of data, the subsequence data can be preprocessed with multiprocess) (Cheng et al., 2019), all three of the CWS tools we've introduced are fast enough to achieve this effect. According to rough estimates and technical reports, the processing speed of these tools are thulac 1221KB/s, ictclas 769KB/s, hanlp 1375KB/s, respectively.

Specifically, we instantiate the enhancement module as HLG and incorporate with downstream task-specific model. To verify the effectiveness of HLG, we execute 5 times fine-tuning on 10 benchmark datasets of 6 NLP tasks and report the average score. The tasks include Sentiment Classification (SC), Document Classification (DC), Named Entity Recognition (NER), Sentence Pair Matching (SPM), Natural Language Inference (NLI) and Machine Reading Comprehension (MRC). Specifically, the following benchmark datasets are chosen to evaluate the performance: 1) **SC**: ChnSenti[1] and weibo100k[2] sentiment datasets are used for evaluating the capacity of short text classification. 2) **DC**: THUCNews (Sun et al., 2016b) dataset contains 10 types of news for performing long text classification. 3) **NER**: Ontonotes 4.0 (Weischedel et al., 2011) and MSRA-NER (Levow, 2006a) are used for testing model in sequence tagging task. 4) **SPM**: LCQMC (Liu et al., 2018) and BQ (Chen et al., 2018) are used to evaluate the text matching ability of model. 5) **NLI**: We conduct experiments on the Chinese part of XNLI (Conneau et al., 2018) dataset, and adopt the same pre-processing strategy as ERNIE (Sun et al., 2019). 6) **MRC**: Commonly used datasets DRCD (Shao et al., 2018) and CMRC2018 (Cui et al., 2019b) are tested. CMRC2018 is only evaluated on dev set as same as (Wei et al., 2019; Sun et al., 2020).

Table 1: The experimental results on various datasets. All of the experiments except CMRC2018 are conducted on test set, the reported values are F1 unless specified (EM means exact match score). We run each experiment with a random seed for five times and report the average score. Numbers in brackets indicate the relative increment brought by enhancement module. The bold numbers mark the highest value within the same base-model.

We implement the presented approach in PyTorch and fine-tune the downstream tasks on multiple Nvidia Tesla V100 GPUs. The basic architecture of PLMs and pre-trained parameters are provided by Huggingface (Wolf et al., 2020). The initial learning rate and other hyper-parameters refer to the previous works reported (Cui et al., 2019a; Li et al., 2020; Sun et al., 2020). Since the parameters of PLMs have been optimized, while the parameters of HLG and the downstream tasks are untrained. Hence, the learning rate of HLG part is larger than PLM part, we manually tuned the learning rates of PLM and HLG separately.

4.2 Experimental Results

The experimental results are shown in Table 1. Overall, we can observe that both HLG and MWA outperform baseline models (BERT, BERTwwm and ERNIE 1.0). Comparing with WMA, HLG achieves further improvement and significantly outperforms baseline models on 10 tasks. In detail, HLG outperforms MWA on ChnSent, weibo100k, MSRA-NER, ontonotes, LCQMC, BQ, THUCNews and XNLI tasks, and obtains comparable results on DRCD and CMRC2018 datasets.

For the text classification tasks, namely **SC** and **DC**, HLG respectively achieves 0.88% and 0.84% average improvement on ChnSenti and weibo100k dataset, while MWA gains 0.53% and 0.82%. Meanwhile, HLG obtains 0.35% improvement on the long text multi-classification benchmark THUCNews, and MWA gets 0.31% points.

Comparing with text classification tasks, the improvements over **NER** tasks are more obvious. The main reason may be that CWS explicitly provides the word boundaries, which are important to recognize entities accurately. On the ontonotes dataset, the promotion of HLG (1.28% averagely) is distinctly higher than that of MWA (0.92% averagely). Compared to the strong baseline models, the F1 scores of MSRA-NER have improved average 0.13% and 0.10% by HLG and MWA, respectively.

HLG achieves the best results on the text matching tasks (**SPM**) and its variant **NLI**, which brings 1.28% average improvement to LCQMC, 0.26% average improvement to BQ, and 0.78% average improvement to XNLI. The improvements of HLG are much higher than that of MWA (0.3%, 0.23% and 0.55%). As described in Chen et al. (2020) and

No.	CWS tool	Accumulative Word Count	
		ChnSenti	weibo100k
0	None	0	0
1	thulac(Sun et al., 2016a)	69,877	398,046
2	ictclas(Zhang et al., 2003)	78,695	452,059
3	hanlp(He, 2014)	82,768	479,134
4	pkuseg(Luo et al., 2019)	84,273	481,201
5	jieba(Sun, 2013)	85,062	483,390

Table 2: Adding the CWS tools one by one, and accumulate the total number of word nodes.

Lyu et al. (2021), text matching tasks can benefit from the interaction between the paired sentences. HLG follows them to construct graphs over sentence pairs collectively, which naturally obtains advantages in text matching tasks.

For **MRC** task, HLG and MWA achieve comparable results on those datasets. HLG gets an average improvement of 1.41 in EM and 0.85 in F1 score, while MWA gets 1.4 EM and 0.86 F1 score. However, HLG has dominant advantage in training speed and inference speed. Detail analysis of time efficiency is in §4.3.3.

4.3 Analyses

4.3.1 Ablation Study

We conduct ablation experiments to explore the effectiveness of the number of CWS tools. The ablation experiments are organized on sentiment classification task, ChnSenti and weibo100k dev set. As shown in Table 2, 5 popular CWS tools are added into our model successively according to the order, and we also show the total number of word nodes in our HLG. Meanwhile, the information from multiple word segmentation tools can be integrated at the same time without increasing parameter size in HLG (only the **A** is changed).

Figure 4 shows the performance of BERT+HLG with different numbers of CWS tools on ChnSenti and weibo100k dev sets. Experimental results demonstrate the effectiveness of introducing word segmentation information. We can observe that when the number of CWS tools is larger, the number of generated word nodes gradually increasing to converge, and the performance of the model slightly is not always increasing as the word count.

The more CWS tools introduced will bring more diversity but also bring noise caused by segmenter error. In practice, we find using 4 or more CWS tools can slightly increase the performance but take much longer preprocessing time, hence we select the elbow of the curve as the number of CWS tools.

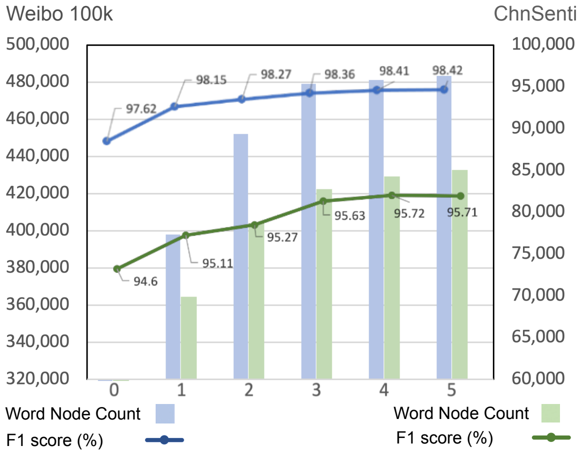

Figure 4: The histogram chart is the cumulative number of word nodes obtained by CWS tools, and the line chart is the performance of the model (BERT+HLG) in dev-set with the corresponding number of CWS tools.

Model	Params. $(K = 3)$	F1
BERT	110M	79.28
+MWA	117.7M(+7.7M)	79.68(+0.40)
+HLG	113.5M(+**3.5M**)	79.75(+0.47)
BERTwwm	110M	79.32
+MWA	117.7M(+7.7M)	79.77(+0.45)
+HLG	113.5M(+**3.5M**)	80.16(+0.84)
ERNIE 1.0	110M	79.75
+MWA	117.7M(+7.7M)	79.98(+0.23)
+HLG	113.5M(+**3.5M**)	80.21(+0.46)

Table 3: The amount of additional parameters and performance improvement of MWA and HLG.

That is, using 3 as the number of CWS tools might be a balance between the performance of model and the cost of preprocessing. This number also coincides with the configuration in MWA.

4.3.2 Parameter-Efficient Analysis

In general, the enhancement module should be able to bring performance improvements without unacceptable space complexity. Therefore, we conduct a comparative experiment on XNLI dev set to explore the performance improvement and the space overhead between MWA and HLG.

To be specific, the number of parameters in MWA depends on the dimension of PLM's representation and the number of CWS tools K. Concretely, MWA contains K transformer layers and 1 aggregation layer. Nevertheless, our HLG only depends on the dimension of PLM's representation and simply contains 4 basic GCN layers and 2 skip connections. Thus, the number of parameters of

Model	Params.	F1
BERTwwm-base	110M	79.32
+HLG(`random tokenizer`)	113.5M	79.16(-0.16)
+HLG(`character tokenizer`)	113.5M	79.41(+0.09)
+HLG(`thulac`)	113.5M	79.68(+0.36)
+HLG(`ictlas`)	113.5M	79.91(+0.59)
+HLG(`hanlp`)	113.5M	79.81(+0.49)
+HLG(`thulac+ictlas+hanlp`)	113.5M	80.16(+0.84)

Table 4: The performance comparison between random tokenizer, character tokenizer that segments each character into a single word, and sole segmenters.

them can be calculated as:

$$size(\text{MWA}) = K \times (4 \times d^2)_{\text{Transformer}} + d^2$$

$$size(\text{HLG}) = (4 \times d^2)_{\text{GCN}} + 2 \times d^2$$

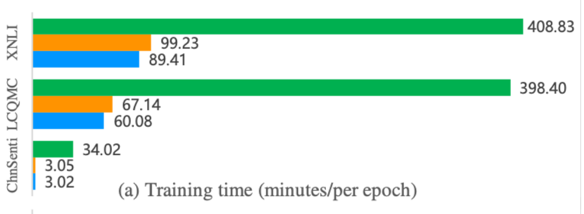
As discussed before, we employ 3 CWS tools in both MWA and HLG. Table 3 reports the performance of BERT, BERTwwm, and ERNIE 1.0 on the XNLI dev set. Obviously, HLG can get a greater performance improvement with only half additional parameters. It shows that as an enhancement module, HLG is superior to MWA in terms of parameter utilization efficiency.

In addition, **to verify the impact of the additional parameters**, we also conduct an ablation experiment on XNLI dev set that utilizes the random tokenizer, the single-character tokenizer, and sole segmenter to obtain the different word segmentation results, and send those results to HLG to eliminate the additional benefit from the change of neural network structure and the increase of parameters. The results are shown in Table 4, which indicates that the increment of parameters can slightly affect character-based model performance, and the CWS information is significantly useful to promote the performance of character-based PLM.

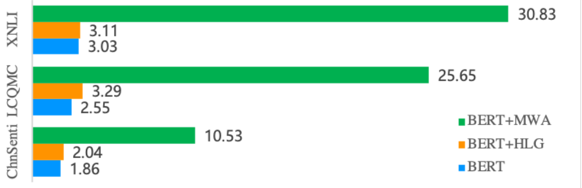
4.3.3 Time Efficiency Analysis

Time efficiency is an important indicator in the real-world production. Less training time and inference time means lower costs. In order to analyze the additional time cost of different enhancement modules, we conduct comparative experiments among BERT, BERT+MWA, and BERT+HLG on ChnSenti, LCQMC and XNLI datasets. For the fair comparison, we remain other hyper-parameters consistent for the three models.

As shown in Figure 5, we compare time cost during training and inference between vanilla BERT, BERT+MWA and BERT+HLG. We can observe that the training time and inference time of BERT+HLG are basically consistent with vanilla BERT. However, when MWA is introduced, the average training time increases by 7 times, and the average inference time increases by 7.6 times. This is because MWA must calculate aligned attention weights token by token, and it cannot benefit from CUDNN parallelization, resulting in terrible operating efficiency. On the contrary, HLG is composed of GCNs, and its internal implementation is basically the simplest non-linear transformation. Therefore, HLG could be maximally accelerated through the optimized matrix operation of CUDNN primitive, which only produces a negligible impact on time efficiency.



(a) Training time (minutes/per epoch)



(b) Inference time (seconds/1,000 samples)

Figure 5: The training time, inference time of vanilla BERT, BERT+MWA and BERT+HLG on ChnSenti, LCQMC and XNLI benchmarks. All of these time dose not include CWS process.

5 Related Works

Pre-training language models, such as ELMo (Peters et al., 2018), BERT (Devlin et al., 2019), XLNET (Yang et al., 2019) and GPT (Radford et al., 2018), have shown their powerful performances on various natural language processing tasks and have been applied in many applications.

In recent past, there are studies adapting PLMs for Chinese with Chinese-specific features such as word information. Glyce (Meng et al., 2019) proposed to use the glyph information of Chinese characters to enhance PLMs. ERNIE 1.0/2.0 (Sun et al., 2019, 2020) and BERTwwm (Cui et al., 2019a) used the whole word mask to learn the structure of words or entities in the pre-training stage and conducted more and better pre-training tasks to perceive large-scale data. NEZHA (Wei et al., 2019) used a series of methods such as functional relative positional encoding and whole word masking to improve the pre-training tasks, which had brought improvement. ZEN (Diao et al., 2020) adopted n-gram masking to enhance pre-trained encoder and obtained outstanding performance. Lattice-BERT (Lai et al., 2021) introduced word lattice information (Zhang and Yang, 2018) into pre-training framework via lattice position attention.

As a fundamental feature of Chinese, word segmentation information is flexibility, granularity, and easy-to-get (Sproat and Emerson, 2003; Levow, 2006b). Further, Zhang et al. (2018); Li et al. (2019, 2020) conducted detailed research and experiments on the application of CWS in deep learning, and found that CWS information can effectively improve the performance of Chinese character-based PLMs.

Recently, a lot of works have been proposed to prompt NLP applications by constructing graph on text and modeling with graph neural networks. Yao et al. (2019) first constructed word co-occurrence graph between documents and introduced GCN to modeling and aggregating document representation for text classification. Chen et al. (2020); Lyu et al. (2021) constructed lattice graph to maintain multi-granularity information and external knowledge in Chinese short text matching task. Nguyen and Grishman (2018) proposed performing GCN over dependency trees to extract event trigger. Sui et al. (2019) conducted a character-word interaction graph and performed graph attention network on it to recognize Chinese named entities. Shu et al. (2020) introduced a bipartite-graph based transformer PLM for integrating hierarchical semantic information.

6 Conclusion

In this paper, we propose HLG which acts as the enhancement module to enhance Chinese PLMs with CWS information. The HLG firstly constructs heterogeneous graph based on multiple word segmentations to model the hierarchy of Chinese. Then, the MSIP is proposed to model the fine-grained linguistics knowledge of the heterogeneous graph. Experimental results on 6 NLP tasks with 10 benchmark datasets demonstrate that the performance of our model outperforms previous work, MWA. Besides the performance improvements, HLG introduces only half the additional parameters of MWA and its training/inference speed is 7x faster than MWA. At present, the experimental results of HLG are lagging behind SOTA, and we will try to migrate it to some of the latest PLMs. Besides, HLG has the expansibility to introduce the representation layer of the CWS model directly, or introduce some other information sources such as the knowledge graph, etc. We leave these further improvements to the future.

Divide and Denoise: Learning from Noisy Labels in Fine-Grained Entity Typing with Cluster-Wise Loss Correction

Abstract

Fine-grained Entity Typing (FET) has made great progress based on distant supervision but still suffers from label noise. Existing FET noise learning methods rely on prediction distributions in an instance-independent manner, which causes the problem of confirmation bias. In this work, we propose a clustering-based loss correction framework named Feature Cluster Loss Correction (FCLC), to address these two problems. FCLC first train a coarse backbone model as a feature extractor and noise estimator. Loss correction is then applied to each feature cluster, learning directly from the noisy labels. Experimental results on three public datasets show that FCLC achieves the best performance over existing competitive systems. Auxiliary experiments further demonstrate that FCLC is stable to hyperparameters and it does help mitigate confirmation bias. We also find that in the extreme case of no clean data, the FCLC framework still achieves competitive performance.

1 Introduction

Fine-grained entity typing (FET) is the task of classifying named entity mentions in a sentence over the given class set (typically a hierarchical class structure as shown in Fig. 1. FET serves as an important component in many down-stream NLP applications, e.g., relation extraction (Liu et al., 2014), entity linking (Raiman and Raiman, 2018) and question answering (Dong et al., 2015). FET task has a more wide range of entity types (usually over 100 classes) compared to entity typing, and hence neural-based FET systems require large-scale annotated training corpus.

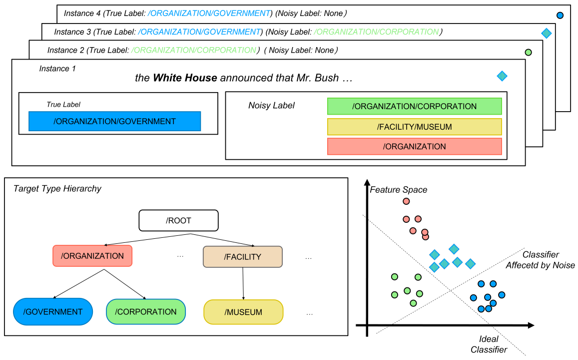

Figure 1: An Example of noisy labels and feature space illustration in FET task.

Recent studies apply distant supervision to label the corpora automatically by linking mentions to knowledge base entities and using all entity types as the ground-truth labels. Although large-scale annotated data is provided, it brings about label noises in training. To overcome the problem of noisy label, some works directly pruned noisy instances (Gillick et al., 2014; Onoe and Durrett, 2019a). The others retain noisy training data but further improve by choosing (Ren et al., 2016a; Xu and Barbosa, 2018), weighting (Wu et al., 2019), and relabeling (Zhang et al., 2020) noisy labels using the prediction distribution.

However, these noise combating methods have two major limitations. 1) They rely on the prediction distribution. As a result, they ought to cope with instance-agnostic noise better. The previous works expirically show (Zheng and Yang, 2021) that the prediction distribution is more likely to be affected by noisy instances and suffer from **confirmation bias**. This bias problem is also verified in our Sec. 3.5. The limitation leads to the intriguing question: ***Besides prediction distribution and entropy, what other information can we use to model label noise?***

2) They mostly aim to modify each instance isolatedly and only use instance-level information. Meanwhile, typical anti-noise machine learning (Patrini et al., 2017; Hendrycks et al., 2018) uses instance-agnostic global statistics. The latter is

more robust to noise but might be too general. Local information is potentially more informative. For example, when the distant supervision introduces similar noise in some instances, these noises form a locality in feature space. The noisy instances are near to each other and are separate from instances with the same but true labels. Our experiment result is similar to Fig. 1, even when the feature extractor is trained to fit noisy labels, they are still easily separable due to underlying semantic differences.

These two limitations are inter-related, causing noise-learning-based FET methods to still suffer from distantly supervised noise. To alleviate the label noise and avert these limitations, we propose a novel framework ***FCLC*** for noisy label learning inspired by weighted training and loss correction (Hendrycks et al., 2018) in machine learning. Our method utilizes feature representations from the model and learns global (local) information, i.e. a cluster-level label confusion matrix. Firstly, we use a backbone learner on noisy data. It serves as a feature extractor and a noise estimator. Secondly, all training data, including noisy data and a small portion of clean data are clustered. The clean data serve as anchors in the feature space to estimate label corruption and sample quality of each cluster. Finally, label corruption and sample quality are used for label correction.

Our main contributions are three-fold: (i) This study provides fresh insight into instance dependent label noise in FET. We pointed out a novel training method to further exploit feature space and global information. (ii) We designed a framework with feature clustering, estimating cluster-level confusion matrix, and loss correction. (iii) We experimented the proposed method on three datasets. Results show that we made significant improvements over previous state-of-the-art, thus proving the effectiveness of our model. Ablation studies further prove the robustness and wide applicability of our framework.

2 Framework

2.1 Definition

Given a finite set of types, $T = \{t_1, t_2, ..., t_{|T|}\}$, where $|T|$ denotes the number of candidate types. The task is to assign appropriate types to each mention under context. Formally, an instance is a triplet, $(m, c, \boldsymbol{y})$. $c = \{w_1, w_2, ..., w_n\}$ is the context of m, usually the original sentence. $m = \{w_{p_1}, ..., w_{p_l}\}$ is the mention. obviously, m is a continuous subsequence of c.

$Y \subseteq T$ denotes appropriate types for (m, c). For convenience, denote Y's vector form $\boldsymbol{y} \in \{0, 1\}^{|T|}$, $y_j = 1$ means $t_j \in Y$.

When the instance is produced with crowdsourcing or distant supervision, annotated labels might contain so-called noise. We denote labels with noise $\tilde{\boldsymbol{y}}$. The instance is thus $(m, c, \tilde{\boldsymbol{y}})$. Denote the corpus with noisy instances $\tilde{\mathcal{D}}$, the corpus with trusted instances $\mathcal{D}_t$.[*] The two corpus form the whole training corpus $\mathcal{D}$.

The task is to predict the appropriate types for given (m, c).

2.2 Training Procedure

As shown in Fig. 2, the **FCLC** framework consists of the following steps :

Step 1. (Phase 1) Train the backbone model with noisy data $\tilde{\mathcal{D}}$ for e_1 epochs and get M_1. It serves as a feature extractor and a noise estimator. (Sec. 2.3)

Step 2. Cluster all training samples $\mathcal{D}$ with the feature extracted by E_1, and estimate confusion matrix for each cluster with predictions of M_1. (Sec. 2.4)

Step 3. (Phase 2) The calculated clustering-aware confusion matrix and FCLC loss are used to continue training the backbone model. (Sec. 2.5)

2.3 Backbone

For fair comparison, the backbone of our model has the same structure as NFETC (Xu and Barbosa, 2018).

For an instance $(m, c, \boldsymbol{y})$, for each word w_i in c, word embedding is $\boldsymbol{e_i^w} \in \mathbb{R}^{d_w}$ looked up in word embedding matrix $\mathbf{W} \in \mathbb{R}^{d_w \times |V|}$.

A position embedding $\boldsymbol{e_i^p} \in \mathbb{R}^{d_p}$ is used to model the context word position i and mention position (p_1, p_l) by looking up relative position in position embedding matrix $\mathbf{P} \in \mathbb{R}^{d_p \times 2N}$. The final embedding is the concatenation $\boldsymbol{e_i} = [\boldsymbol{e_i^w}, \boldsymbol{e_i^p}]$.

Context Representation A Bi-LSTM (Hochreiter and Schmidhuber, 1997) is used to model the context representation. Feeding the embedding of c i.e. $\{\boldsymbol{e_1}, \boldsymbol{e_2}, ..., \boldsymbol{e_n}\}$ into BiLSTM gets the two directional hidden states $\overrightarrow{\boldsymbol{h_i}}$ and $\overleftarrow{\boldsymbol{h_i}}$ for each word w_i. Word level attention weighted sum following (Zhou et al., 2016) is applied on $\boldsymbol{h_i} = [\overrightarrow{\boldsymbol{h_i}} \oplus \overleftarrow{\boldsymbol{h_i}}]$, resulting in the final context representation $\boldsymbol{r_c} \in \mathbb{R}^{d_c}$,

---

[*] Normally $|\mathcal{D}_t| \ll |\tilde{\mathcal{D}}|$, as in all the datasets we reported in this paper.

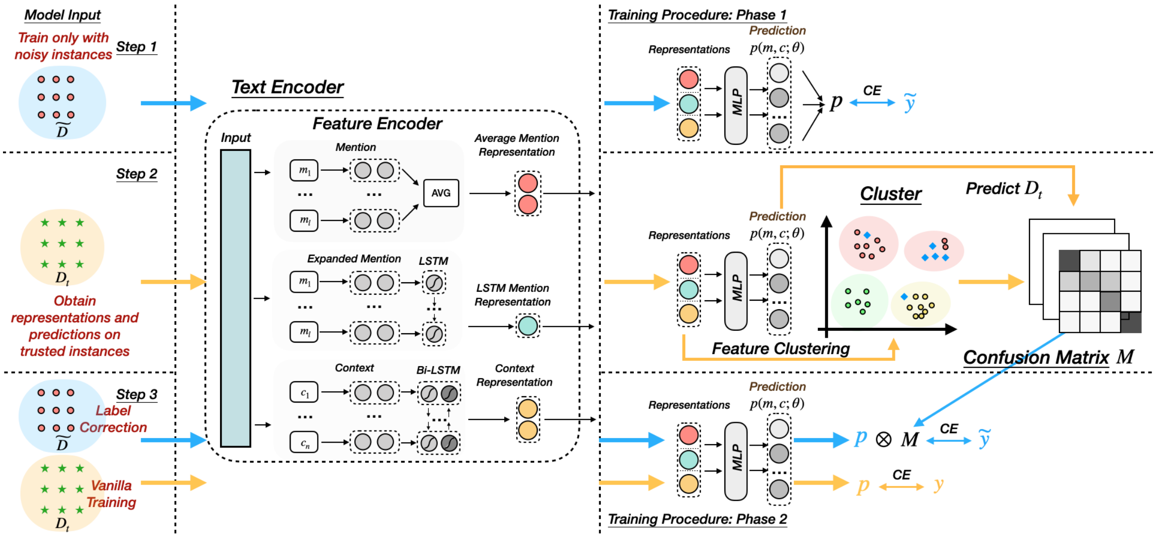

Figure 2: Model architecture.

where $\oplus$ means element-wise sum and d_c is the hidden size of the BiLSTM and the dimension of the context embedding.

Mention Representation The average encoder of a mention takes word embeddings of the mention $\{\boldsymbol{e_{p_1}}, \boldsymbol{e_{p_2}}, ..., \boldsymbol{e_{p_l}}\}$ and takes the average: $\boldsymbol{r_w} = \frac{1}{l}\sum_{k=1}^{l} \boldsymbol{e_{p_k}}$. The LSTM encoder of a mention takes an extended mention with one more token before and after the original mention and produces hidden state features $\{\boldsymbol{h_{p_1-1}}, ..., \boldsymbol{h_{p_l+1}}\}$. Take the last output $\boldsymbol{h_{p_l+1}}$ as $\boldsymbol{r_l}$. The final representation of the mention is $\boldsymbol{r_m} = [\boldsymbol{r_w}, \boldsymbol{r_l}]$

Classification Softmax classifier and cross-entropy are used based on the feature $\boldsymbol{r_{m,c}} = [\boldsymbol{r_c}, \boldsymbol{r_m}]$ of x:

$$\boldsymbol{s}(x) = \mathbf{W}\boldsymbol{r_{m,c}} + \mathbf{b} \tag{1}$$

$$\hat{p}(\boldsymbol{y}|x) = \text{softmax}(\boldsymbol{s}(x)) \tag{2}$$

$$\ell(x, \boldsymbol{y}; \theta) = -log(\hat{p}(\boldsymbol{y}|x)) \tag{3}$$

With a given dataset D, the model is trained with all samples $(x, \boldsymbol{y})$ in D. For baseline, $D = \mathcal{D}$. For **FCLC** step 1, $D = \tilde{\mathcal{D}}$:

$$\mathcal{L}_{base}(\theta) = \frac{1}{|D|}\sum_{(x,\boldsymbol{y})\in D} \ell(x, \boldsymbol{y}; \theta) \tag{4}$$

2.4 Feature Clustering

We make the assumption that the noise $(\boldsymbol{y}, \tilde{\boldsymbol{y}})$forms locality in the feature space, especially when the feature is calculated from the original mention and context(m, c), (m, c) determines $\boldsymbol{y}$, and the feature is trained with $\tilde{\boldsymbol{y}}$.

We adopt clustering to utilize local statistics as smaller-grained feature information. To be specific, we perform k-means with $\boldsymbol{r_{m,c}}$ on the whole training set $\mathcal{D}$, and separate $\mathcal{D}$ into K clusters. Denote the k-th cluster $\bar{\mathcal{C}}_k$, $\mathcal{C}_{t-k} = \bar{\mathcal{C}}_k \cap \mathcal{D}_t$, $\tilde{\mathcal{C}}_k = \bar{\mathcal{C}}_k \cap \tilde{\mathcal{D}}$.

We mainly utilize the two following statistics:

$$\tau_k = \frac{|\mathcal{C}_{t-k}|}{|\mathcal{D}_k|} \tag{5}$$

τ_k estimates the quality of the cluster k. It acts as a soft cluster sieving.

$$\widehat{C}_{ijk} = \frac{1}{|A_{ik}|}\sum_{(x,y)\in A_{ik}} \widehat{p}(\boldsymbol{y}_j = 1|x) \tag{6}$$

where $A_{ik} = \{(x, \boldsymbol{y})|(x, \boldsymbol{y}) \in \mathcal{C}_{t-k}$ and $\boldsymbol{y}_i = 1\}$, $\widehat{C}_{ijk}$ estimates the probability in cluster k to annotate noise j for true label i.

2.5 Loss Correction

The idea of forward loss correction is proposed by Patrini et al. (2017). The basic idea is to modify the loss with the noise transition matrix T. Such that the minimizer under the new loss with noisy labels is the same as the minimizer of the original loss under clean labels. The modification relies on the assumption that the label noise is independent from instances, i.e. $\tilde{\boldsymbol{y}} \perp x \mid \boldsymbol{y}$. Hendrycks et al. (2018) proposed to estimate $\mathbf{T}$ with a small set of clean labels, under the assumption that $\tilde{\boldsymbol{y}} \perp \boldsymbol{y} \mid x$. While these assumptions do not hold globally for distantly supervised FET, they hold better in clusters. We introduce the cluster-wise loss correction in the following sections.

Transition Matrix Estimation Assuming the backbone model is well trained, i.e. $\hat{p}(\tilde{\boldsymbol{y}}_j = 1|x)$ is close enough to $p(\tilde{\boldsymbol{y}}_j = 1|x)$. We use the predicted probability on trusted instances in cluster-k to estimate the transition probability.

$$\begin{aligned} C_{ijk} &= p(\tilde{\boldsymbol{y}}_j = 1 \mid \boldsymbol{y}_i = 1, x \in \tilde{\mathcal{C}_k}) \\ &\approx p(\tilde{\boldsymbol{y}}_j = 1 \mid \boldsymbol{y}_i = 1, x \in \mathcal{C}_{t-k}) \\ &\approx \frac{1}{|A_{ik}|} \sum_{(x,y) \in A_{ik}} \hat{p}(\tilde{\boldsymbol{y}}_j = 1|x) \\ &= \widehat{C}_{ijk} \end{aligned} \tag{7}$$

Forward Loss Correction Cross-entropy is composite (Reid and Williamson, 2010),denote it as ℓ_ψ, its inverse link function ψ^{-1} is $\mathrm{softmax}$.

Notice C_{ijk} can bridge the loss with noisy label $\tilde{\boldsymbol{y}}, (x \in \tilde{\mathcal{C}_k}, \tilde{\boldsymbol{y}}_i = 1)$, to predictions for the true label:

$$-log(\hat{p}(\tilde{\boldsymbol{y}}|x)) \approx -\log \sum_{j=1}^{c} C_{jik} \hat{p}(\boldsymbol{y_j} = 1 \mid x) \tag{8}$$

Let $T_k = C_{**k}$, define the forward loss as:

$$\boldsymbol{\ell}_\psi^{\rightarrow}(\boldsymbol{s}(\boldsymbol{x})) = \boldsymbol{\ell}_\psi(T_k^\top \boldsymbol{s}(x)) \tag{9}$$

The property holds on each cluster similar as in (Patrini et al., 2017), with all $x \in \tilde{\mathcal{C}_k}$, training with noisy label $\tilde{\boldsymbol{y}}$ on $\boldsymbol{\ell}_\psi^{\rightarrow}$ is the same as with true label $\boldsymbol{y}$ on the original loss $\boldsymbol{\ell}_\psi$:

$$\underset{\boldsymbol{s}}{\mathrm{argmin}} \mathbb{E}_{\boldsymbol{x},\tilde{\boldsymbol{y}}} \boldsymbol{\ell}_\psi^{\rightarrow}(\boldsymbol{s}(\boldsymbol{x})) = \underset{\boldsymbol{s}}{\mathrm{argmin}} \mathbb{E}_{\boldsymbol{x},\boldsymbol{y}} \boldsymbol{\ell}_\psi(\boldsymbol{s}(\boldsymbol{x})) \tag{10}$$

Different from global forward loss correction, the parameters that minimize the loss in each cluster are not the same. We balance the clusters with τ_k. The trusted samples $(x, y) \in \mathcal{D}_t$ are also used. The loss of the full model is:

$$\begin{aligned} \mathcal{L}_{\mathbf{FCLC}} &= \textstyle\sum_{(x,y) \in \mathcal{D}_t} \ell_\psi(\boldsymbol{s}(x)) \\ &+ \beta \textstyle\sum_{k=1}^{K} \tau_k \sum_{(x,\tilde{y}) \in \tilde{\mathcal{C}_k}} \ell_\psi^{\rightarrow}(\boldsymbol{s}(x))) \\ &+ (1-\beta) \textstyle\sum_{k=1}^{K} \tau_k \sum_{(x,\tilde{y}) \in \tilde{\mathcal{C}_k}} \ell_\psi(\boldsymbol{s}(x))) \end{aligned} \tag{11}$$

Where β is the hyperparameter to balance FCLC loss and the original loss.

Our introduced framework has several advantages: 1) **Lightweight**. This method does not include extra trainable parameters to the backbone model. 2) **Stable**. The framework involves two hyperparameters, β and phase-1 train epochs e_1 and we empirically find them stable. 3) **Flexibility**. Our improvement is orthogonal to the backbone model. It only requires that the backbone model is sufficiently expressive and uses an appropriate composite loss (Reid and Williamson, 2010). Thus, it is pluggable to a large number of FET models.

3 Experiments

We evaluate the proposed model on three different FET datasets and compare it to several state-of-the-art models. In addition, to support our claims we also conduct several subsidiary experiments to analyze the impacts of our proposed module in detail.

Table 1: Fine-Grained Entity Typing datasets Statistics.

3.1 Datasets

The datasets are described below, we use exactly the same train/dev/test split with previous works (Ren et al., 2016a; Chen et al., 2019). Detailed statistics of the three datasets are also shown in Table 1. **BBN** It contains sentences extracted from the Wall Street Journal and distantly labeled by DBpedia Spotlight (Weischedel and Brunstein, 2005). **OntoNotes** It was constructed using sentences in the OntoNotes corpus and distantly supervised by DBpedia Spotlight (Weischedel et al., 2013). **Wiki/FIGER** It was derived from Wikipedia articles and news reports, entities of the training samples are distantly annotated using Freebase (Ling and Weld, 2012).

3.2 Evaluation Metrics

We follow prior work and use the strict accuracy (Acc), Macro F1 (Ma-F1), and Micro F1 (Mi-F1) scores. During the experiment, all these metrics are calculated by running the model five times and computing the mean and standard deviation values.

3.3 Baselines

We consider the following competitive FET systems as our baselines: (1) AFET (Ren et al., 2016a); (2) Attentive (Shimaoka et al., 2016); (3) NFETC/NFETC$_{hier}$ (Xu and Barbosa, 2018); (4) CLSC/CLSC$_{hier}$ (Chen et al., 2019); (5) NFETC-AR/NFETC-AR$_{hier}$ (Zhang et al., 2020); (6) NFETC-VAT/CLSC-VAT (Shi et al., 2020); (7) Multi Level Learning to Rank (ML-L2R) (Chen et al., 2020); (8) Box (Onoe et al., 2021).

These baselines are compared with several variants of our proposed model: (1) **FCLC**: proposed model without the hierarchical loss; (2) **FCLC**$_{hier}$ proposed model with the hierarchical loss; (3) **FCLC**(without τ_k) our proposed model trained without cluster quality estimation, i.e. $\tau = 1$ for all clusters; (4) **FCLC**(without loss correction) our proposed model without loss correction, only cluster quality estimation working; (5)**FCLC**(without cluster) our proposed model without clustering, i.e. calculated a globally-uniform confusion matrix; (6) **FCLC**(with reinit): our proposed model with fresh parameters before the start of step 3 as suggested by Patrini et al. (2017). (3)-(6) are implemented based on and should be compared with the best configuration between **FCLC** and **FCLC**$_{hier}$ on each dataset, that is, compared with **FCLC** on BBN and compared with **FCLC**$_{hier}$ on Wiki and OntoNotes.

3.4 Implementation Details

To make an equal comparison, following (Xu and Barbosa, 2018; Chen et al., 2019; Zhang et al., 2020), we use exactly the same pre-trained 300-dimensional GloVe word embeddings (Pennington et al., 2014) and fix the embedding vectors during training. The model parameters are optimized using the Adam (Kingma and Ba, 2014) optimizer. All of our models are implemented in Tensorflow. †

As NFETC and NFETC$_{hier}$ are our backbone models, we follow the hyper-parameters of the backbone except for our introduced hyper-parameters β and e_1. The detailed hyper-parameter settings on the three datasets are shown in Table 2, we also report hyper-parameter impact curves in Fig. 3.

3.5 Results and Analysis

Main Result Table 3 shows the results of our proposed approach (**FCLC**) and several competitive FET systems. We highlight the statistically significant best scores of each metric in bold. According to the experimental results, we make two main observations:

(1) The performances of our proposed model surpass the backbone NFETC model by a remarkable large margin (improving Micro F1 by 2.1%, 3.8%, and 7.8% separately), demonstrating the benefits of the proposed two-phase FCLC module. The relative performance improvements are consistent with or without the hierarchy loss (compared **FCLC** and **FCLC**Chier to the corresponding baselines).

(2) Compared to other noisy learning methods such as CLSC, NFETC-AR, and VAT, our model still achieves considerable improvements under most metrics when using the same backbone and very similar hyper-parameter settings. For example, compared to NFETC-AR, our model improves Micro-F1 by 1.25% to 6.38% on three datasets. It indicates that, by utilizing both the feature space representations and the global and local statistical information, the model can reduce the impact of noisy labels more effectively.

Ablation Study To study the detail of our models, we explore the performances of three main model variants, shown in the last several rows of Table 3. We find that the cluster quality τ_k, the loss correction module and the feature cluster process are all critical to model performances in some situations. Specifically, as shown in **FCLC** (without cluster), feature clustering has minor impacts on Wiki and Ontonotes. This is probably because the noisy distribution on these two datasets is relatively simple and the global confusion matrix is sufficient. Moreover, we observe that the re-initialization before Step 3 has a great impact on all metrics. Staring Step 3 with a fresh re-initialized FET model degrades the accuracy by 3.2% on Ontonotes. It denotes that the learner trained in the first phase is beneficial for the noisy robust learning process, by providing optimal parameters initialization.

---

(d) Varying e_1 on BBN

Figure 3: Performance change with respect to β and e_1 on the Ontonotes (sub-figure a, c) and BBN (sub-figure b, d) dataset. The horizontal lines hereinafter denotes for previous SOTA performances and our reported performances.

Sensitivity of the introduced hyper-parameters Using the same setting for model training, Fig. 3 analyses the sensitivity of **FCLC** to the introduced hyper-parameters: the **FCLC** objective weight β, the Step-1 training epochs e_1 . Fig. 3(a, b) shows the performance trend on the Ontonotes and BBN datasets when changing β. While selecting a proper ratio between loss-correction loss and the original loss is important, the performance near optimum β is stable and steadily outperforms the baseline. Fig. 3(c, d) analyses the sensitivity with respect to e_1. the Micro-F1 improves as e_1 increases but stops improving and become unstable when e_1 is large enough, since the model starts to overfit noise. It is also reasonable that the optimal range of β and e_1 in BBN and Ontonotes are different as they have different training set sizes and different distance supervision noise distribution.

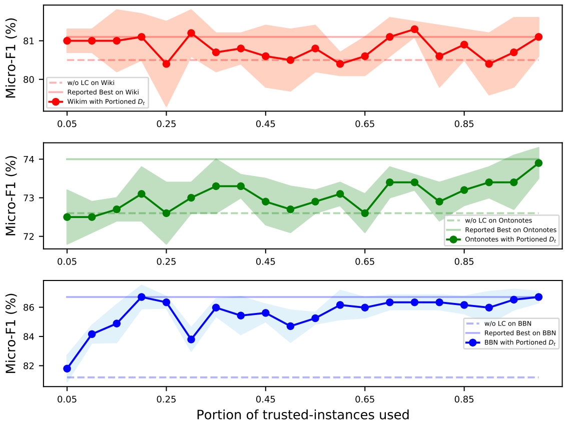

Figure 4: Performance curves with different trusted instance set $\mathcal{D}_t$ sizes on three datasets.

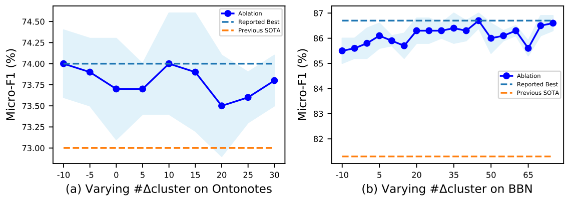
Will cluster number affect performance? We investigate how much the **FCLC** model benefits from different values of feature cluster number k. Fig. 5 demonstrates that under a reasonable feature cluster range (near $|T|$), the model can achieve competitive and similar performances.

How many trusted instances does the model need? We examine the robustness of the model to the amount of clean data by comparing the performances with 5% to 100% trusted instances. Refer to Fig. 4, we observe that due to the differences of the training set, our model achieves comparable accuracy with 30%, 40%, and 70% $\mathcal{D}_t$ samples on



(a) Varying #Δcluster on Ontonotes

(b) Varying #Δcluster on BBN

Figure 5: Performance curves under different feature-cluster numbers k on the Ontonotes (a) and BBN (b), #Δcluster represents $k - |T|$.

Wiki, Ontonotes, and BBN separately. With only a very small size of trusted instances, e.g. 20% BBN trusted set, or 128 samples, the model begins to improve significantly.

What if we did not have any trusted instances? Although a small number of clean samples is always practical to obtain or relabel with an expert, we push the limit to no trusted instances at all. What performance can our model achieve in such a situation? We performed the "no clean training set" experiment to test the robustness of our model. In Table 4, **FCLC** (w/o $\mathcal{D}_t$) indicates for the variant that the trusted instances are not used for phase 2 training but only in feature clustering and confusion matrix calculation. In that situation, our approach still has similar performances with previous SOTA models on most metrics[‡].

FCLC (w/ pl) variant means that, during the clustering process, instead of using the trusted instance set $\mathcal{D}_t$ split from the training set, we introduce a simple and classic pseudo labeling method (Lee et al., 2013) to generate the labels needed by clustering and training. We find that compared to the baseline method, **FCLC** with pseudo labeling still achieves much better performances.

It is proved by results in Table 4 that **FCLC** does not rely on a clean training subset, thus having a wide range of applications.

Models	Wiki			Ontonotes		
	Acc	Ma-F1	Mi-F1	Acc	Ma-F1	Mi-F1

Table 4: The model performances with no trusted instances on phase 2 (w/o $\mathcal{D}_t$) or on the whole training process (w/ pl).

Visualization of the representations We analyze the role of **FCLC** module by visualizing the feature vectors.

Fig. 6 illustrates samples in a cluster (circled in all 4 sub-figures). From Fig. 6(a), we observe that the backbone model fails to distinguish some samples of class A (/ORGANIZATION/GOVERNMENT, red) and class B (/GPE/COUNTRY, blue), due to noisy labels. Fig. 6(b) shows that our model learns to correct these instances. With **FCLC** the classifier is corrected to predict the right label. Meanwhile, in feature space, the boundary between these samples and the confusing class is also clearer, which means **FCLC** also helps to refine feature extraction with loss correction. Fig. 6(e) shows the row of '/GPE/COUNTRY'. Managing to notice the confusion from '/GPE/COUNTRY' to '/ORGANIZATION/GOVERNMENT' enables our model to perform the appropriate correction. Due to this, **FCLC** are resistant to the noisy labels.

Quantitative Results of Confirmation Bias To further verify our claim that our model can alleviate the *confirmation bias* in the noisy FET task, we analyze the prediction confidence on test set samples, as shown in Fig. 7. The average confidence of correct and wrong test samples is calculated after each training epoch. The results show that, on the Wiki dataset, after phase one the wrong sample average confidence is 0.700 but the backbone model reached 0.833 at the end of the training (with early stopping). Also, after phase two **FCLC** improves the correct sample confidence from backbone's 0.939 to 0.950 on Wiki.

4 Related Work

4.1 Noisy Learning

The usage of datasets collected with distant supervision often results in so-called noisy labels. Several studies have investigated deep learning approaches with noise. Existing noisy learning methods include designing robust loss functions (Wang et al., 2019), designing robust architectures by adding noise adaptation layers (Chen and Gupta, 2015; Goldberger and Ben-Reuven, 2017), selecting samples (Onoe and Durrett, 2019b), and adding noise-robust regularization (Shi et al., 2020). Among them, Patrini et al. (2017) and Hendrycks et al. (2018) proposed forward loss correction. It avoided explicit relabeling and matrix inversion. These noisy learning methods are mostly restricted to the

---

[‡] It is worth pointing out that it means our model is trained with fewer instances than previous SOTA, since $\mathcal{D}_t$ is a part from the training set they use.

noise that is conditionally independent of the data features (Frénay and Verleysen, 2014). However, in real-world applications such as FET, noise distributions are more complex and instance-dependent, requiring more powerful noisy learning methods.

4.2 Fine-Grained Entity Typing

FET is studied based on the distant supervision training data (Mintz et al., 2009; Ling and Weld, 2012). Various features (Yogatama et al., 2015; Xu and Barbosa, 2018), network structures (Dong et al., 2015; Shimaoka et al., 2016), and feature space (Ali et al., 2021; Onoe et al., 2021)are explored to refine the mention and type representation. Label inter-dependency (Lin and Ji, 2019) and type hierarchy (Chen et al., 2020) are often used, added by relations among instances and labels (Ali et al., 2020; Li et al., 2021; Liu et al., 2021). Label noise is the main problem brought by distance supervision. Besides common noisy learning methods discussed in Sec. 4.1 (Onoe and Durrett, 2019b; Shi et al., 2020; Wu et al., 2019), FET-specific noise combat methods are proposed. Ren et al. (2016a,b) utilized partial-label embedding. Xu and Barbosa (2018) modified hierarchical loss to cope with *overly-specific* noise. Zhang et al. (2020) automatically generated pseudo-truth label distribution for each sample. Additional resource also help to improve the performance. The resource include external knowledge base (Xin et al., 2018; Dai et al., 2019), and with BERT-like pipeline (Patel and Ferraro, 2020; Ding et al., 2021). Choi et al. (2018) proposed a way to utilize more distance supervision and crowd source, followed by Onoe and Durrett (2019b). Apart from the above, (Chen et al., 2019) and (Ali et al., 2020) are the closest to our proposed method. They both select some instances by feature distance to modify labels or refine mention representation for noisy instances. However, their refinement is still explicit and isolated to each instance. Thus the quality relies on the instances they retrieve for label propagation/mention reference. Different from these studies, we do not rely on any of these external resources and aim to impose label noise with only the original data without explicit sieving or label changing.

5 Conclusion

In this work, in order to tackle the instance-dependent label noise in fine-grained entity typing tasks, we present a neural FET noisy learning framework that utilizes the feature space information and global information jointly. Experimental results on three publicly available datasets demonstrate that our proposed model achieves the best performance compared with competitive existing FET systems. Furthermore, based on extensive auxiliary experiments, we study the impact of our proposed noisy learning framework in-depth with qualitative and quantitative analysis. In the future, the proposed approach can motivate the need for further understanding of the relationships between dataset noise distribution estimation and the instance features. More work can be done towards this direction. In addition, performances of the proposed framework under different backbone models can be dug to validate the flexibility of the framework.

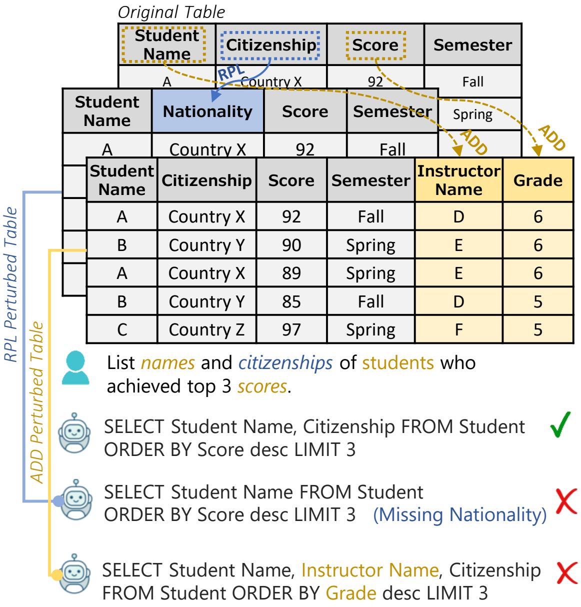
Abstract

The robustness of Text-to-SQL parsers against adversarial perturbations plays a crucial role in delivering highly reliable applications. Previous studies along this line primarily focused on perturbations in the natural language question side, neglecting the variability of tables. Motivated by this, we propose the **A**dversarial **T**able **P**erturbation (**ATP**) as a new attacking paradigm to measure the robustness of Text-to-SQL models. Following this proposition, we curate ADVETA, the first robustness evaluation benchmark featuring natural and realistic ATPs. All tested state-of-the-art models experience dramatic performance drops on ADVETA, revealing models' vulnerability in real-world practices. To defend against ATP, we build a systematic adversarial training example generation framework tailored for better contextualization of tabular data. Experiments show that our approach not only brings the best robustness improvement against table-side perturbations but also substantially empowers models against NL-side perturbations. We release our benchmark and code at: https://github.com/microsoft/ContextualSP.



Student Name	Citizenship	Score	Semester	Instructor Name	Grade
A	Country X	92	Fall	D	6
B	Country Y	90	Spring	E	6

SELECT Student Name FROM Student ORDER BY Score desc LIMIT 3 (Missing Nationality) ✗

SELECT Student Name, Instructor Name, Citizenship FROM Student ORDER BY Grade desc LIMIT 3 ✗

Figure 1: Adversarial examples based on table perturbations for a Text-to-SQL parser. Leaving the NL question unchanged, both replacement of column names (e.g., replace "Citizenship" with "Nationality") and addition of associated columns (e.g., add "Instructor Name" based on "Student Name"; add "Grade" based on "Score") mislead the parser to incorrect predictions.

1 Introduction

The goal of Text-to-SQL is to generate an executable SQL query given a natural language (NL) question and corresponding tables as inputs. By helping non-experts interact with ever-growing databases, this task has many potential applications in real life, thereby receiving considerable interest from both industry and academia (Li and Jagadish, 2016; Zhong et al., 2017; Affolter et al., 2019).

Recently, existing Text-to-SQL parsers have been found vulnerable to perturbations in NL questions (Gan et al., 2021; Zeng et al., 2020; Deng et al., 2021). For example, Deng et al. (2021) removed the explicit mentions of database items in a question while keeping its meaning unchanged, and observed a significant performance drop of a Text-to-SQL parser. Gan et al. (2021) also observed a dramatic performance drop when the schema-related tokens in questions are replaced with synonyms. They investigated both multi-annotations for schema items and adversarial training to improve parsers' robustness against permutations in NL questions. However, previous works only studied the robustness of parsers from the perspective of NL questions, neglecting variability from the other side of parser input – tables.

We argue that a reliable parser should also be robust against table-side perturbations since they are inevitably modified in the human-machine interaction process. In business scenarios, table main-

---

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 2007 - 2022

tainers may *(i)* rename columns due to business demands and user preferences. *(ii)* add new columns into existing tables when business demands change. Consequently, the extra lexicon diversity introduced by such modifications could harm performances of unrobust Text-to-SQL parsers. To formalize these scenarios, we propose a new attacking paradigm, **A**dversarial **T**able **P**erturbation (**ATP**), to measure parsers' robustness against *natural and realistic* ATPs. In accordance with the two scenarios above, we consider both **RE**P**L**ACE (**RPL**) and **ADD** perturbations in this work. Figure 1 conveys an intuitive understanding of ATP.

Ideally, ATP should be conducted based on two criteria: *(i)* Human experts consistently write correct SQL queries before and after table perturbations, yet parsers fail; *(ii)* Perturbed tables look natural and grammatical, and are free from breakage of human language conventions. Accordingly, we carefully design principles for RPL/ADD and manually curate the **ADVE**rsarial **T**able perturb**A**tion (**ADVETA**) benchmark based on **three** existing datasets. All evaluated state-of-the-art Text-to-SQL models experience drastic performance drops on ADVETA: On ADVETA-RPL, the average relative percentage drop is as high as 53.1%, whereas on ADVETA-ADD is 25.6%, revealing models' lack of robustness against ATPs.

Empirically, model robustness can be improved by adversarial training, i.e. re-train models with training set augmented with adversarial examples (Jin et al., 2020). However, due to the different natures of structured tables and unstructured text, well-established text adversarial example generation approaches are not readily applicable. Motivated by this, we propose an effective **C**ontextualized **T**able **A**ugmentation (CTA) approach that better leverages tabular context information and carry out ablation analysis. To summarize, the contributions of our work are three-fold:

- To the best of our knowledge, we are the *first* to propose definitions and principles of **A**dversarial **T**able **P**erturbation (**ATP**) as a new attacking paradigm for Text-to-SQL.

- We contribute **ADVETA**, the first benchmark to evaluate the robustness of Text-to-SQL models. *Significant performance drops* of state-of-the-art models reveals that there is much more to explore beyond high leaderboard scores.

- We design **CTA**, a systematic adversarial training example generation framework tailored for better contextualization of tabular data. Experiments show that our approach brings model *best robustness gain* and *lowest original performance loss*, compared with various baselines. Moreover, we show that adversarial robustness brought by CTA generalizes well to NL-side perturbations.

2 Adversarial Table Perturbation

We propose the **A**dversarial **T**able **P**erturbation (**ATP**) paradigm to measure robustness of Text-to-SQL models. For an input table and its associated NL questions, the goal of ATP is to fool Text-to-SQL parsers by perturbing tables naturally and realistically. More specifically, human SQL experts can consistently maintain their correct translations from NL questions to SQL with their understanding of language and table context. Formally, ATP consists of two approaches: **RE**P**L**ACE (**RPL**) and **ADD**. In the rest of this section, we first discuss our consideration of table context, then introduce conduction principles of RPL and ADD.

2.1 Table Context

Tables consist of explicit and implicit elements – both are necessary for understanding table context. "Explicit elements" refer to table captions, columns, and cell values. "Implicit elements", in our consideration, contains **T**able **P**rimary **E**ntity (**TPE**) and domain. (Relational) Tables are structured data recording domain-specific attributes (columns) around some central entities (TPE) (Sumathi and Esakkirajan, 2007). Without the explicit annotation, humans could still make correct guesses on them. For example, it's intuitive that tables in Figure 1 can be classified as "education" domain, and all of the columns center around the TPE "student". Combining both explicit and implicit elements, people achieve an understanding of table context, which becomes the source of lexicon diversity in column descriptions.

2.2 REPLACE (RPL) Principles

Given a target column, the goal of RPL is to seek an alternative column name that makes sense to humans but misleads unrobust models. Gold SQL, as illustrated in Figure 1, should be correspondingly adapted by mapping the original column to its new name. In light of this, RPL should fulfill the following two principles:

ADVETA Statistics	Spider			WTQ			WikiSQL		
	Orig.	*RPL*	*ADD*	*Orig.*	*RPL*	*ADD*	*Orig.*	*RPL*	*ADD*
Basic Statistics									
#Total tables	81	81	81	327	327	327	2,716	2,716	2,716
#Avg. columns per table	5.45	–	–	6.31	–	–	6.41	–	–
#Avg. perturbed columns per table	–	2.62	3.64	–	2.65	3.27	–	3.70	4.44
#Avg. candidates per column	–	3.33	3.97	–	2.90	3.55	–	3.32	3.97
#Unique columns	211	911	1,061	527	1,656	2,976	2,414	10,787	10,474
#Unique vocab	199	598	782	596	1,156	1,459	2,414	4,147	5,099
Analytical Statistics									
#Unique semantic meanings	144	144	**683**	156*	156*	**702***	203*	203*	818*
#Avg. col name per semantic meaning	1.35	**6.33**	1.55	1.59*	**5.87***	1.64*	1.67*	**6.12***	1.52*

Table 1: ADVETA statistics comparison between original and RPL/ADD-perturbed dev set. The * mark denotes that results are based on at most 100 randomly sampled tables and obtained by manual count.

Semantic Equivalency: Under the table context of target column, substituted column names are expected to convey equivalent semantic meaning as the original name.

Phraseology Correctness: ATP aims to be natural and realistic and does not target worst-case attacks. Therefore, replaced column names are expected to follow linguistic phraseology conventions: *(i)* Grammar Correctness: Substituted column names should be free from grammar errors. *(ii)* Proper Collocation with TPE: New column names should collocate properly with TPE. For example, *height* and *tallness* both collocate well with student (TPE), but conventionally not *altitude*. *(iii)* Idiomaticity: New column names should sound natural to a native speaker to address target columns. For example, *runner-up* means *second place*, and *racer-up* is a bad replacement despite *runner* is synonymous to *racer*.

2.3 ADD Principles

ADD perturbs tables with introductions of new columns. Instead of adding random columns that fit well into the table domain, we pertinently add adversarial columns with respect to a target column for the sake of adversarial efficiency. Gold SQL should remain unchanged after ADD perturbations [1]. Below states ADD principles:

Semantic-association & Domain-relevancy: Given a target column and its table context, newly added columns are expected to *(i)* fit nicely into the table context; *(ii)* have high semantic associations with the target column yet low semantic equivalency (e.g. *sales vs. profits*, *editor vs. author*).

Phraseology Correctness: Same as RPL, columns should obey human language conventions.

Irreplaceability: Unlike RPL, any added columns should be irreplaceable with any original table columns. In other words, ADD requires semantic equivalency to be filtered out from highly semantic associations. Otherwise, the original gold SQL will not be the single correct output, which makes the perturbation unreasonable.

3 ADVETA Benchmark

Following RPL and ADD principles, we manually curate the **ADVE**rsarial **T**able perturb**A**tion (**ADVETA**) benchmark based on three mainstream Text-to-SQL datasets, Spider (Yu et al., 2018), WikiSQL (Zhong et al., 2017) and WTQ (Papernot et al., 2017). For each table from the original *development set*, we conduct RPL/ADD annotation separately, perturbing only table columns. For its associated NL-SQL pairs, we leave the NL questions unchanged and adapt gold SQLs accordingly. As a result, ADVETA consists of 3 (Spider/WTQ/WikiSQL) $*$ 2 (RPL/ADD) = 6 subsets. We next introduce annotation details and characteristics of ADVETA.

3.1 Annotation Steps

Five vendors join the annotation process. Each base dev set is split into small chunks and is manually annotated by one vendor and reviewed by another, with an inter-annotator agreement to resolve annotation inconsistency.

Before annotation, vendors are first trained to understand table context as described in § 2, then are further instructed of the following details.

RPL: RPL principles are the mandatory requirements. During annotation, vendors are given full Google access to ease the conception of synonymous names for a target column. **ADD**: ADD principles will be the primary guideline. Unlike free-style RPL annotations, vendors are provided with

---

[1] We omit cell value alignment in ADD for simplicity.

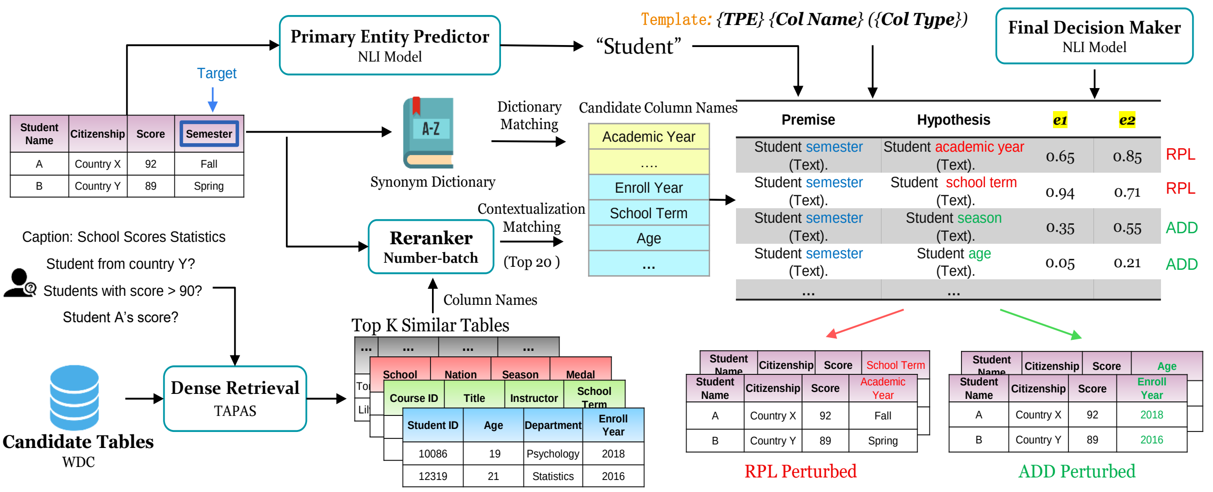

Figure 2: Overview of our CTA framework. In rare cases where TPE is missing, we apply *Primary Entity Predictor* (addressed in B.2). Otherwise we simply use annotated TPE. e_1 is obtained with premise-hypothesis as input; e_2 with hypothesis-premise.

a list of 20 candidate columns from where they select 3-5 based on semantic-association[2] Notice that we only consider columns mentioned at least once across NL questions to avoid vain efforts. In Appendix A, We display some representative benchmark annotation cases.

3.2 ADVETA Statistics and Analysis

We present comprehensive benchmark statistics and analysis results in Table 1. Notice that we limit the scope of statistics only to perturbed columns (as marked by *#Avg. perturbed col per table*).

Basic Statistics reflects elementary information of ADVETA. ***Analytical Statistics*** illustrate highlighted features of ADVETA compared with original dev-sets: *(i)* Diverse column names for a single semantic meaning: each table from the RPL subset contains approximately five times more lexicons which are used to express a single semantic meaning[3]. *(ii)* Table concept richness: each table from ADD subset contains roughly five times more columns with unique semantic meanings.

4 Contextualized Table Augmentation

In this section, we introduce our **C**ontextualized **T**able **A**ugmentation (CTA) framework as an adversarial training example generation approach tailored for tabular data. The philosophy of adversarial example generation is straightforward: Pushing augmented RPL/ADD lexicon distributions closer to human-agreeable RPL/ADD distributions. This requires maximization of lexicon diversity under the constraints of domain relevancy and clear differentiation between semantic association & semantic equivalency, as stated in ADD principle from § 2.

Well-established text adversarial example generation approaches, such as TextFooler (Jin et al., 2020) and BertAttack (Li et al., 2020), might fail to meet this objective because: *(i)* They rely on syntactic information (e.g. POS-tag, dependency, semantic role) to perform text transformations. However, such information is not available in structured tabular data, leading to poor-quality adversarial examples generated by these approaches. *(ii)* They perform sequential word-by-word transformations, which could narrow lexicon diversity (e.g. *written by* will not be replaced by *author*). *(iii)* They cannot leverage tabular context to ensure domain relevancy. *(iv)* They generally fail to distinguish semantic equivalency from high semantic association according to our observations (e.g., fail to distinguish *sales vs. profits*).

To tackle these challenges, we construct the CTA framework. Given a **target column** from a table with NL questions, *(i)* a **dense table retriever** properly contextualizes the input table, thereby pinpointing top-k most *domain-related* tables (and columns) from a large-scale database while *boosting lexicon diversity*. *(ii)* A **reranker** further narrows down *semantic-association* and produces coarse-grained ADD/RPL candidates. *(iii)* **NLI decision maker** *distinguishes semantic equivalency from semantic association* and allocates candidate

---

[2] We generate the candidate list with a retriever-reranker combo from § 4.

[3] For example, column names {*Last name, Family name, Surname*} express a single semantic meaning. In practice, we random sample at most 100 tables from each split, and obtain the number of unique semantic meanings by manual count.

columns to RPL/ADD buckets. A detailed illustration of our CTA framework is shown in Figure 2. We next introduce each component of CTA.

4.1 Dense Retrieval for Similar Tables

The entire framework starts with a dense retrieval module to gather most domain-related tables of user queries. We utilize the Tapas-based (Herzig et al., 2020) dense retriever in this module (Herzig et al., 2021), due to its better tabular contextualization expressiveness over classical retrieval methods such as Word2Vec (Mikolov et al., 2013) and BM25 (Robertson, 2009). Following the original usage proposed by Herzig et al. (2020), we retrieve the top 100 most domain-related tables from the backend Web Data Commons (WDC) (Lehmberg et al., 2016) database consisting of 600k non-repetitive tables with at most $five$ columns.

4.2 Numberbatch Reranker

From these retrieved domain-related tables, we further narrow down the range of most semantically associated candidate columns. This is done by a ConceptNet Numberbatch word embedding (Speer et al., 2017) reranker, who computes the cosine similarity score for a given column pair. We choose ConceptNet Numberbatch due to its advantage of far richer (520k) in-vocabulary multi-grams compared with Word2Vec (Mikolov et al., 2013), GloVe (Pennington et al., 2014), and Counter-fitting (Mrkšić et al., 2016), which is especially desirable for multi-gram columns. We keep the top 20 similar among them as RPL/ADD candidates for each column of the original table.

4.3 Word-level Replacement via Dictionary

Aside from candidates obtained from retriever-reranker for whole-column level RPL, we consider word-level RPL for a target column as a complement. Specifically, we replace each word in a given target column with its synonyms recorded in the Oxford Dictionary (noise is more controllable compared with synonyms gathered by embedding). With a probability 25% for each original word to remain unchanged, we sample until the max pre-defined number (20) of candidates is reached or 5 consecutively repeated candidates are produced.

4.4 NLI as Final Decision Maker

So far we have pinpointed candidate columns whose domain relevancy and semantic association are already guaranteed. The final stage is to determine which one of RPL/ADD candidates is more suitable for based on its semantic equivalent against target column. Therefore, we leverage RoBERTa-MNLI (Liu et al., 2019; Williams et al., 2017), the expert in *differentiating semantic equivalency from semantic association*[4]. Practically, we construct premise-hypothesis by contextualized columns and judge semantic equivalency based on output bidirectional entailment scores e_1 and e_2.

NLI Premise-Hypothesis Construction The Quality of premise-hypothesis plays a key factor for NLI's functioning. We identify three potentially useful elements for contextualizing columns with surrounding table context: TPE, column type, and column cell value. Through manual experiments, we observe that: *(i)* Adding cell value significantly hurt decision accuracy of NLI models. *(ii)* TPE is the most important context information and cannot be ablated. *(iii)* Column type information can be a desirable source for word-sense disambiguation. Thus the final template for premise-hypothesis construction as python formatted string is expressed as: **f**"{**TPE**} {**CN**} ({**CT**}).", where **CN** is column name, and **CT** is column type.

RPL/ADD Decision Criterion In practice, we observe a discrepancy in output entailment scores between *premise-hypothesis* score e_1 and *hypothesis-premise* score e_2. Thus we take scores from both direction into consideration. For RPL, we empirically choose $min(e_1, e_2) >= 0.65$ (Figure 2) as the final RPL acceptance criterion to reduce occurrences of false positive entailment decision. For ADD, the criterion is instead $max(e_1, e_2) <= 0.45$ to reduce false negative entailment decisions[5].

5 Experiments and Analysis

5.1 Experimental Setup

Datasets and Models The five original Text-to-SQL datasets involves in our experiments are: Spider (Yu et al., 2018), WikiSQL (Zhong et al., 2017), WTQ (Shi et al., 2020)[6], CoSQL (Yu et al., 2019a) and SParC (Yu et al., 2019b). Their corresponding perturbed tables are from our ADVETA

---

[4] We ***highly recommend*** reading our pilot study in B.1.

[5] To avoid semantic conflict between a new column $\tilde{c}$ and original columns $c_1, \cdots, c_n$, we apply to each pair of $(\tilde{c}, c_i)$.

[6] Note that we use the version with SQL annotations provided by Shi et al. (2020) here, since the original WTQ (Pasupat and Liang, 2015) only contains answer annotations.

Dataset	Baseline	Dev	RPL	ADD
Spider	DuoRAT	69.9	23.8 ± 2.1 (-46.1)	36.4 ± 1.3 (-33.5)
	ETA	70.8	27.6 ± 1.8 (-43.2)	39.9 ± 0.9 (-30.9)
WikiSQL	SQLova	81.6	27.2 ± 1.3 (-54.4)	66.2 ± 2.3 (-15.4)
	CESQL	84.3	52.2 ± 0.9 (-32.1)	71.2 ± 1.5 (-13.1)
WTQ	SQUALL	44.1	22.8 ± 0.5 (-21.3)	32.9 ± 0.8 (-11.2)
CoSQL	EditSQL	39.9	13.3 ± 0.7 (-26.6)	30.5 ± 1.1 (-9.4)
	IGSQL	44.1	16.4 ± 1.2 (-27.7)	32.8 ± 2.1 (-11.3)
SParC	EditSQL	47.2	30.5 ± 0.9 (-16.7)	40.2 ± 1.2 (-7.0)
	IGSQL	50.7	34.2 ± 0.5 (-16.5)	42.9 ± 1.7 (-7.8)

Table 2: Results on original dev and ADVETA (RPL and ADD subsets). Red fonts denote *absolute percentage* performance drop compared with original dev.

benchmark. WikiSQL and WTQ are single-table, while Spider, CoSQL, and SParC have multi-tables. CoSQL and SParC are known as multi-turn Text-to-SQL datasets, sharing the same tables with Spider. Dataset statistics are shown in Appendix Table 11.

We evaluate open-source Text-to-SQL models that reach competitive performance on the aforementioned datasets. DuoRAT (Scholak et al., 2021) and ETA (Liu et al., 2021) are baselines for Spider; SQUALL (Shi et al., 2020) is the baseline for WTQ; SQLova (Hwang et al., 2019) and CESQL (Guo and Gao, 2019) are baselines for WikiSQL. For the two multi-turn datasets (CoSQL & SParC), baselines are EditSQL (Zhang et al., 2019) and IGSQL (Cai and Wan, 2020). *Exact Match* (**EM**) is employed for evaluation metric across all settings. Training details are shown in C.2.

5.2 Attack

Attack Details All baseline models are trained from scratch on corresponding original training sets, and then independently evaluated on original dev sets, ADVETA-RPL and ADVETA-ADD. Since columns have around $three$ manual candidates in ADVETA-RPL/ADD, the number of possible perturbed tables scales exponentially with column numbers for a given table from the original dev set. Therefore, models are evaluated on ADVETA-RPL/ADD by sampling perturbed tables. For ***each*** NL-SQL pair and associated table(s), we sample ***one*** RPL-perturbed table and ***one*** ADD-perturbed table in each attack. **Each** column mentioned from gold SQL is perturbed by a randomly sampled manual candidate from ADVETA. For performance stability and statistical significance, we run five attacks with random seeds for each NL-SQL pair.

Attack Results Table 2 presents the performance of models on original dev sets, ADVETA-RPL and ADVETA-ADD. Across various task formats, domains, and model designs, state-of-the-art Text-to-SQL parsers experience dramatic performance drop on our benchmark: by RPL perturbations, the relative percentage drop is as high as 53.1%, whereas on ADD the drop is 25.6% on average[7]. Another interesting observation is that RPL consistently leads to higher performance drops than ADD. This is perhaps due to models' heavy reliance on lexical matching, instead of true understanding of language and table context. Conclusively, Text-to-SQL models are still far less robust than desired against variability from the table input side.

Attack Analysis To understand the reasons for parsers' vulnerability, we specifically analyze their schema linking modules which are responsible for recognizing table elements mentioned in NL questions. This module is considered a vital component for Text-to-SQL (Wang et al., 2020; Scholak et al., 2021; Liu et al., 2021). We leverage the oracle schema linking annotations on Spider (Lei et al., 2020) and test ETA model on ADVETA using the oracle linkings. Note that we update the oracle linkings accordingly when testing on RPL. Table 4 compares the performance of ETA with or without the oracle linkings, from which we make two observations: *(i)* When guided with the oracle linkings, ETA performs much better on both RPL (27.6% → 55.7%) and ADD (39.9% → 71.3%). Therefore, the failure in schema linking is one of the essential causes for the vulnerability of Text-to-SQL parsers. *(ii)* Even with the oracle linkings, the performance of ETA on RPL and ADD still lags behind its performance on the original dev set, especially on RPL. Through a careful analysis on failure cases, we find that ETA still generates table elements that have a high degree of lexical matching with NL questions, even though the correct table elements are specified in the oracle linkings.

5.3 Defense

Defense Details We carry defense experiments with SQLova, SQUALL and ETA on WikiSQL, WTQ and Spider, respectively. We compare CTA

Table 5: The schema linking analysis of attacking with ETA and two defense approaches, namely W2V and CTA on Spider; Col as column and Tab as table. P, R, F is short for precision, recall and F1 score, respectively.

with three baseline adversarial training approaches: Word2Vec (W2V), TextFooler (TF) (Jin et al., 2020), and BERT-Attack (BA) (Li et al., 2020) (details found in D.). Models are trained from scratch on corresponding *augmented* training sets. Specifically, for ***each*** NL-SQL pair, we keep the original table while generating ***one*** RPL and ***one*** ADD adversarial example. As a result, augmented training data is three times as large in the sense that each NL-SQL pair is now trained against three tables: original, RPL-perturbed, and ADD-perturbed. In addition to the adversarial training defense paradigm, we also include the manual version of Multi-Annotation Selection (MAS) by Gan et al. (2021) on Spider, using their released data. The rest evaluation process is same as attack.

Defense Results Table 3 presents model performance through various defense approaches. We get two observations: *(i) CTA consistently brings better robustness.* Compared with other approaches, CTA-augmented models have the best performance across all ADVETA-RPL/ADD settings, as well as on all original dev sets. These results demonstrate CTA can effectively improve the robustness of models against RPL and ADD perturbations while introducing fewer noises into original training sets. Interestingly, we observe that textual adversarial example generation approaches (BA, TF) are outperformed by the simple W2V approach. This verifies our analysis stated in § 4. We include a case study in Appendix B.3 on characteristics of various baselines.

(ii) CTA fails to bring models back to their original dev performance. Even if trained with high-quality data augmented by CTA, models could still be far worse than their original performance. This gap is highly subjected to the similarity of lexicon distribution between train and dev set. Concretely, on WikiSQL and WTQ where train and dev set have a similar domain, both RPL performance and ADD performance are brought back closer to original dev performance when augmented with CTA. On the contrary, on Spider where train-dev domains overlap less, there is still a notable gap between performance after adversarial training and the original dev performance. In conclusion, more effective defense paradigms are yet to be investigated.

Defense Analysis Following attack analysis, we conduct schema linking analysis with ETA model augmented with top 2 approaches (i.e. W2V & CTA) on Spider. We follow metric calculation of (Liu et al., 2021) and details are shown in § C.4. As shown in Table 5, both approaches improve the schema linking F$_1$. Specifically, CTA improves column F$_1$ by $3\% \sim 8\%$, and table F$_1$ by $13\% \sim 20\%$, compared with vanilla ETA. This reveals that improvement of robustness can be primarily attributed to better schema linking.

Some might worry about the validity of the CTA's effectiveness due to data leakage risks in-

Model	Spider	Spider-Syn
RAT-SQL$_{\text{BERT}}$ (Wang et al., 2020)	69.7	48.2
RAT-SQL$_{\text{BERT}}$+MAS (Gan et al., 2021)	67.4	62.6
ETA (Liu et al., 2021)	70.8	50.6
ETA+CTA	69.8	60.4

Table 6: EM on Spider/Spider-Syn dev-sets.

curred by the annotation design that vendors are given CTA-retrieved candidate list for ADD annotations. However, we emphasize that: *(i)* RPL have *NO* vulnerability to data leakage since it is entirely independent of CTA. *(ii)* The leakage risk in ADD is negligible. On the one hand, our vast-size (600k tables) backend DB supplies tremendous data diversity, maximally reducing multiple retrievals of a single table; On the other hand, CTA's superior performance on Spider, the representative feature of which is cross-domain & cross-database across train-test splits (thus makes performance gain from data leakage hardly possible), further testifies its authentic effectiveness.

5.4 CTA Ablation Study

We carry out an ablation study to understand the roles of two core components of CTA: dense retriever and RoBERTa-MNLI. Results are shown in Table 3.

CTA w/o Retriever RPL candidates are generated merely from the dictionary; ADD generation is the same as W2V baseline. Compared with complete CTA, models augmented with this setting experience $1.1\% \sim 1.2\%$ and $1.8\% \sim 7.6\%$ performance drop on RPL and ADD, respectively. We attribute RPL drops to loss of real-world lexicon diversity and ADD drops to loss of domain relevancy.

CTA w/o MNLI RPL and ADD candidates are generated in the same way as CTA, but without denoising of MNLI. RPL/ADD decisions solely rely on ranked semantic similarity. Compared with complete CTA, models augmented by this setting experience significant performance drops ($4.9\% \sim 7.9\%$) on all RPL subsets, and moderate drops ($1.5\% \sim 2.8\%$) on all ADD subsets. We attribute these drops to the inaccurate differentiation between semantic equivalency and semantic association due to lack of MNLI, which results in noisy RPL/ADD adversarial examples.

5.5 Generalization to NL Perturbations

Beyond CTA's effectiveness against table-side perturbations, a natural question follows: could re-training with adversarial table examples improve model robustness against perturbations from the other side of Text-to-SQL input (i.e., NL questions)? To explore this, we directly evaluate ETA (trained with CTA-augmented Spider train-set) on Spider-Syn dataset (Gan et al., 2021), which replaces schema-related tokens in NL question with its synonym. We observe an encouraging 9.8% EM improvement compared with vanilla ETA (trained with Spider train-set). This verifies *CTA's generalizability to NL-side perturbations*, with comparable effectiveness as the previous SOTA defense approach MAS, which fails to generalize to table-side perturbations on ADVETA in Table 3.

6 Related Work

Robustness of Text-to-SQL As discussed in § 1, previous works (Gan et al., 2021; Zeng et al., 2020; Deng et al., 2021) exclusively study robustness of Text-to-SQL parsers against perturbations in NL question inputs. Our work instead focuses on variability from the table input side and reveals parsers' vulnerability to table perturbations.

Adversarial Example Generation Existing works on adversarial text example generations can be classified into three categories: (1) Sentence-Level. This line of work generates adversarial examples by introducing distracting sentences or paraphrasing sentences (Jia and Liang, 2017; Iyyer et al., 2018). (2) Word-Level. This dimension of work generates adversarial examples by flipping words in a sentence, replacing words with their synonyms, and deleting random words (Li et al., 2020; Ren et al., 2019; Jin et al., 2020). (3) Char-Level. This line of work flips, deletes, and inserts random chars in a word to generate adversarial examples (Belinkov and Bisk, 2018; Gao et al., 2018). All the three categories of approaches have been widely used to reveal vulnerabilities of high-performance neural models on various tasks, including text classification (Ren et al., 2019; Morris et al., 2020), natural language inference (Li et al., 2020) and question answering (Ribeiro et al., 2018). Previous work on robustness of Text-to-SQL and semantic parsing models primarily adopt word-level perturbations to generate adversarial examples (Huang et al., 2021). For example, the Spider-Sync adversarial benchmark (Gan et al., 2021) is curated by replacing schema-related words in questions with their synonyms.

Despite these methods' effectiveness in generating adversarial text examples, they are not readily applicable for structural tabular data, as we discussed in § 4. Apart from this, table-side perturbations enjoy ***much higher attacking efficiency***: the attack coverage of a single table modification includes all affiliated SQLs, whereas one NL-side perturbation only affects a single SQL. Combined with the lighter cognitive efforts of tabular context understanding than NL-understanding, ATP is ***arguably lower in annotation costs***.

Previous work on table perturbations (Cartella et al., 2021; Ballet et al., 2019) focuses on table cell values; another work, (Ma and Wang, 2020) study impacts of naively (i.e., without consideration of table context information and without human guarantee) renaming irrelevant columns and adding irrelevant columns. In this work, we focus on table columns and propose an effective CTA framework that better leverages tabular context information for adversarial example generation, as well as manually annotate ADVETA benchmark.

7 Conclusion

We introduce **A**dversarial **T**able **P**erturbation (**ATP**), a new paradigm for evaluating model robustness on Text-to-SQL and define its conduction principles. We curate the ADVETA benchmark, on which all state-of-the-art models experience dramatic performance drop. For defense purposes, we design the CTA framework tailored for tabular adversarial training example generation. While CTA outperforms all baseline methods in robustness enhancement, there is still an unfilled gap from the original performance. This calls for future exploration of the robustness of Text-to-SQL parsers against ATP.

Ethical Considerations

Our ADVETA benchmark presented in this work is a free and open resource for the community to study the robustness of Text-to-SQL models. We collected tables from three mainstream Text-to-SQL datasets, Spider (Yu et al., 2018), WikiSQL (Zhong et al., 2017) and WTQ (Papernot et al., 2017), which are also free and open datasets for research use. For the table perturbation step, we hire professional annotators to find suitable RPL/ADD candidates for target columns. We pay the annotators at a price of 10 dollars per hour. The total time cost for annotating our benchmark is 253 hours.

All the experiments in this paper can be run on a single Tesla V100 GPU. Our benchmark will be released along with the paper.

A Benchmark Examples

We display some representative benchmark annotation cases for to convey readers a intuitive feeling on our RPL and ADD subsets. As reflected in Figure 3, RPL reflects the following characteristics beyond RPL principles: *(i)* Abbreviation of common words. e.g. *Cell number* vs. *Tel. (ii)* Idiomatic transformation e.g. *Air date* vs. *Release time (iii)* Part of speech structure transformation e.g. *Written by* vs. *Author*. ADD perturbations faithfully obey ADD principles and additions demonstrate high coherency with respect to original domain.

B CTA Details

B.1 NLI-based Substitutability Verification

Approach	e_1	e_2	Δ_{e_1}	Δ_{e_2}
Roberta-RTE				
human	**48.5**	48.1	0.65	0.46
embedding	45.7	45.6	0.26	0.30
ranodm	43.0	42.8	0.53	0.70
Roberta-SNLI				
human	74.5	74.1	0.48	0.61
embedding	56.7	66.0	0.75	0.37
ranodm	31.2	30.9	0.78	0.64
Roberta-MNLI				
human	**77.1**	76.4	0.86	0.36
embedding	**52.2**	58.7	0.34	0.69
ranodm	**16.5**	14.8	0.50	0.49

Table 7: Average foward entailment score e_1, backward entail e_2, and corresponding standard deviations across 9 settings. In all human annotation cases, higher entailment is better. In all random replacement cases, lower is better.

Implementation Details For each pair of target column and candidate column, we contextualize each column with the template described in Premise-Hypothesis Construction from section § 4. Then with the contextualized target column as the premise and the contextualized RPL candidate as the hypothesis, the NLI model computes both forward entailment score $e1$ and backward score $e2$. Notice that $e2$ computation takes the contextualized RPL candidate as premise and the contextualized target column as hypothesis in input. We obtain entailment scores from both directions because of the observed score fluctuation caused by reversion in practicable cases.

Pilot Study for Model Ability We carry out a pilot study to test NLI models' capability of differentiating semantic equivalency and similarity in this section. RoBERTa (Liu et al., 2019) is chosen as the backbone model due to its outstanding performance and computational efficiency across various NLI datasets. Fine-tuned RoBERTa on three well-known NLI datasets: RTE (Dagan et al., 2013), SNLI (Bowman et al., 2015), and MNLI (Williams et al., 2017) are compared to demonstrate model ability difference due to training data,.

We consider three levels of substitutability, from highest to lowest: human manual substitution (human-annotated replacements sampled from benchmark RPL subsets), embedding-based substitution (top-10 similar multi-grams from ConceptNet Numberbatch word embedding (Speer et al., 2017)), and random substitution (randomly sampled columns across benchmark(Speer et al., 2017)). Practically, we randomly sample 1000 pairs of data each time and repeat each setting five times.

We report the both average forward e_1 and backward entailment scores e_2, as well their standard deviations for each setting across five runs (table 8). It is immediately obvious that RoBERTa-MNLI surpasses other models in verbal dexterity: the entailment score correlates best with true degrees of substitutability.

Approach	ρ
Word2Vec (Mikolov et al., 2013)	0.37
Glove (Pennington et al., 2014)	0.41
Glove + Counter-fitting (Mrksic et al., 2016)	0.58
NMT Emedding (Hill et al., 2015a)	0.58
aragram-SL999 (Wieting et al., 2015)	0.69
RoBERTa-MNLI (ours)	**0.70**

Table 8: Results on SimLex-999. ρ (Perason correlation) is used as the primary metric.

Performance on SimLex-999 *SimLex-999* (Hill et al., 2015b) is a gold standard resource for measuring how well models capture similarity, rather than relatedness or association between a input pair of words (e.g. *cold* and *hot* are closely associated but definitely not similar). Thus it is especially suitable for our purpose of further testing RoBERTa-MNLI's ability of semantic discrimination. We treat the entailment score produced by the model as its judgment of semantic similarity and report its Pearson correlation against the ground truth similarity score. Results suggest that RoBERTa-MNLI is quite competitive at discriminating association and relatedness from similarity.

Case Study To test the hard case performance of RoBERTa-MNLI, we come up with some tricky examples as shown in Table 9. The upper half of the table presents hard ***replaceable*** cases that emphasize idiomatic transformations or word-sense disambiguation. The lower half contains hard ***irreplaceable*** cases in which phrases have a high degree of conceptual association, yet still not semantically equivalent. Results reveal the surprisingly abundant and accurate lexicon knowledge condensed in RoBERTa-MNLI.

Table 9: Hard cases we come up with to explore upper-bounds of Roberta-MNLI ability. ENT as entaiment score, NON-ENT as contradiction + neutral score. Score of expected label is bolded.

B.2 Zero-shot TPE Classification

We build the previous premise-hypothesis construction in § 4.4 based on the assumption of availability of TPE, which is frequently not true. Thus our goal is to make a reasonable prediction on TPE for those missing cases. Practically, we make use HuggingFace (Wolf et al., 2020) implementation of zero-shot text classification (Yin et al., 2019) to classify missing TPE into 48 pre-defined categories with the input of concatenated table caption, columns, and cell values.

Implementation Details Based on the 60+ fine-grained categories defined in Few-NERD (Ding et al., 2021), We modify and integrate them into 48 classes as candidate labels ($|L| = 48$). With a Roberta-MNLI as the workhorse model, our overall modeling process is modeled as

$$\tilde{c_t} = \arg\max_i \frac{\exp(f_\theta(\mathbf{L}_i \mid d; \mathbf{c}; \mathbf{v}; d)_{ent})}{\sum_{j\in|L|}\exp(f_\theta(\mathbf{L}_j \mid d; \mathbf{c}; \mathbf{v})_{ent})}$$

where $\mathbf{c}$ is column names, $\mathbf{v}$ is a randomly selected column value affiliated with a given column, and d is table captions for a given table. Roberta-MNLI (annotated as f_θ) outputs raw logits of contradiction, neutral, and entailment scores. Softmax is finally applied entailment logits across 48 categories, with the top 1 label as final the primary entity prediction.

Human evaluation We randomly sample 100 tables from our benchmark and ask three vendors to rate the reasonability of each predicted TPE from a scale of $1-5$. 1 as totally unreasonable, 3 as mildly acceptable, and 5 as perfectly parallel with human guesses. We average out the rating from all three vendors and get a result of *4.13*. This indicates the practicability of zero-shot TPE classification.

B.3 Perturbation Case Study

In this section, we present a case study on adversarial training examples generated by CTA and baseline approaches in Table 10. We can make the following observations: *(i)* CTA tend to produce less low-frequency words (e.g. *padrone, neosurrealist*) in both RPL and ADD i.e. lower perplexity. *(ii)* CTA-generated samples fit better with the specificity level of table columns. For example, RPL pair *(region, sphere)* is overly broadened, whereas names such *ballads denomination, supermanager, thespian* might be overly specified to fit into table headers. *(iii)* CTA incurs least semantic drift in RPL. In all baseline methods, there is a good chance to observe semantic-distinctive pairs such as *(region, member)*, *(type, number)*, *(type, guy)*. With CTA, such risk is minimal.

C Experimental Details

C.1 Original Datasets statistics

The detail statistics of five Text-to-SQL datasets are shown in Table 11. According to CoSQL (Yu et al., 2019a) and SParC (Yu et al., 2019b) paper, the two multi-turn Text-to-SQL datasets share the same tables with Spider (Yu et al., 2018).

C.2 Baseline Details

SQLova For all defense results of the WikiSQL dataset, we employ the SQLova model, whose official codes are released in (Hwang et al., 2019). We use uncased BERT-large as the encoder. The learning rate is 1×10^{-3} and the learning rate of BERT-large is 1×10^{-5}. The training epoch is 30 with a batch size of 12. The training process lasts 12 hours on a single 16GB Tesla V100 GPU.

SQUALL We employ the SQUALL model, following (Shi et al., 2020), to get all defense results of the WTQ dataset. The training epoch is 20 with a batch size of 30; The dropout rate is 0.2; The training process lasts 9 hours on a single 16GB Tesla V100 GPU.

ETA We implement the ETA model following (Liu et al., 2021). We use an uncased BERT-large whole word masking version as the encoder. The learning rate is 5×10^{-5} and the training epoch is 50. The batch size and gradient accumulation steps

are 6 and 4. The training process lasts 24 hours on a single 32GB Tesla V100 GPU.

C.3 Attack Performance Calculation Details

Table 12 shows the attack performance of RPL and ADD perturbations. In this section, we show the calculation details of the average attack relative performance drop. For example, on the Spider dataset, the relative performance drop of the DuoRAT model against RPL perturbation is 65.9%, and 61.0% for the ETA model. For RPL perturbation, we average out the relative performance drop of 9 models and report the average relative percentage drop (53.1%). Same as RPL, we get the average relative percentage drop (25.6%) for ADD perturbation.

Dataset	**Baseline**	**Dev**	**RPL**	**ADD**
Spider	DuoRAT	69.9	23.8 ± 2.1 (-46.1 / -65.9%)	36.4 ± 1.3 (-33.5 / -47.9%)
	ETA	70.8	27.6 ± 1.8 (-43.2 / -61.0%)	39.9 ± 0.9 (-30.9 / -43.6%)
WikiSQL	SQLova	81.6	27.2 ± 1.3 (-54.4 / -66.7%)	66.2 ± 2.3 (-15.4 / -18.9%)
	CESQL	84.3	52.2 ± 0.9 (-32.1 / -38.1%)	71.2 ± 1.5 (-13.1 / -15.5%)
WTQ	SQUALL	44.1	22.8 ± 0.5 (-21.3 / -48.3%)	32.9 ± 0.8 (-11.2 / -25.4%)
CoSQL	EditSQL	39.9	13.3 ± 0.7 (-26.6 / -66.7%)	30.5 ± 1.1 (-9.4 / -23.6%)
	IGSQL	44.1	16.4 ± 1.2 (-27.7 / -62.8%)	32.8 ± 2.1 (-11.3 / -25.6%)
SParC	EditSQL	47.2	30.5 ± 0.9 (-16.7 / -35.4%)	40.2 ± 1.2 (-7.0 / -14.8%)
	IGSQL	50.7	34.2 ± 0.5 (-16.5 / -32.5%)	42.9 ± 1.7 (-7.8 / -15.4%)

Table 12: The Exact Match Accuracy on the development set and ADVETA. Red font denotes the absolute(left) and relative(right) performance drop percentage compared with original dev accuracy.

C.4 Schema Linking Calculation

We follow the work of Liu et al. (2021) to measure the performance of ETA schema linking predictions. Let Ω_{col} be a set $\{(c, q)_i | 1 \leq i \leq N\}$ which contains N gold (column-question token) tuples. Let $\overline{\Omega}_{col}$ be a set $\{(\overline{c}, \overline{q})_j | 1 \leq j \leq M\}$ which contains M predicted (column-question token) tuples. We define the precision(Col_P), recall(Col_R), F1-score(Col_F) as:

$$\frac{|\Gamma_{col}|}{|\overline{\Omega}_{col}|}, \frac{|\Gamma_{col}|}{|\Omega_{col}|}, \frac{2\text{Col}_P\text{Col}_R}{\text{Col}_P + \text{Col}_R}$$

where $\Gamma_{col} = \Omega_{col} \bigcap \overline{\Omega}_{col}$. The definitions of Tab_P, Tab_R, Tab_F are similar.

D Baseline Approach Details

W2V To generate candidates for a given column, W2V randomly samples $five$ candidates from the top 15 cosine-similar (Numberbatch word embeddings) for RPL and 15-50 for ADD. Textfooler and BERT-Attack also follow this hyper-parameter setting. For both TextFooler and BERT-Attack, we skip their word importance ranking (WIR) modules while only keeping the word transformer modules for candidate generation[8].

TextFooler TextFooler is one of the state-of-the-art attacking frameworks for discriminative tasks on unstructured text. We skip its word importance ranking (WIR) step since our target column has already been located. Its word transformer module is faithfully re-implemented to generate candidates for a target column. Counter-fitted word embedding (Mrksic et al., 2016) are used for similarity computation, and modified sentences are constrained by both POS-tag consistency and Sim-CSE (Gao et al., 2021) similarity score.

BERT-Attack BERT-Attack is another representative text attacking framework. Similar to our adaptation of TextFooler, we skip WIR and only keep the core masked language model-based word transformation. Following original work, low-quality or sub-word tokens predicted by BERT-Large are discarded; perturbed sentence similarities compared with the original are guaranteed by Sim-CSE.

---

[8] We contextualize columns with templates that additionally considers cell values and POS-tag consistency.

Overcoming Catastrophic Forgetting beyond Continual Learning: Balanced Training for Neural Machine Translation

Chenze Shao[1,2], **Yang Feng**[1,2*]

`{shaochenze18z, fengyang}@ict.ac.cn`

Abstract

Neural networks tend to gradually forget the previously learned knowledge when learning multiple tasks sequentially from dynamic data distributions. This problem is called *catastrophic forgetting*, which is a fundamental challenge in the continual learning of neural networks. In this work, we observe that catastrophic forgetting not only occurs in continual learning but also affects the traditional static training. Neural networks, especially neural machine translation models, suffer from catastrophic forgetting even if they learn from a static training set. To be specific, the final model pays imbalanced attention to training samples, where recently exposed samples attract more attention than earlier samples. The underlying cause is that training samples do not get balanced training in each model update, so we name this problem *imbalanced training*. To alleviate this problem, we propose Complementary Online Knowledge Distillation (COKD), which uses dynamically updated teacher models trained on specific data orders to iteratively provide complementary knowledge to the student model. Experimental results on multiple machine translation tasks show that our method successfully alleviates the problem of imbalanced training and achieves substantial improvements over strong baseline systems.[1]

1 Introduction

Neural Machine Translation (NMT) has achieved impressive translation performance on many benchmark datasets in the past few years (Cho et al., 2014; Sutskever et al., 2014; Bahdanau et al., 2015; Vaswani et al., 2017). In the domain adaptation task where we have large-scale out-domain data to improve the in-domain translation performance, continual learning, which is also referred to as fine-tuning, is often employed to transfer the out-domain knowledge to in-domain (Luong and Manning, 2015). After fine-tuning, the model performs well in in-domain translation, but there is significant performance degradation in out-domain translation because it "forgets" the previously learned knowledge. This phenomenon is called catastrophic forgetting (McCloskey and Cohen, 1989; French, 1999) and has attracted a lot of attention (Goodfellow et al., 2013; Kirkpatrick et al., 2017; Li and Hoiem, 2017; Lee et al., 2017).

In this work, we observe that catastrophic forgetting not only occurs in continual learning but also affects the traditional static training. To be specific, the final model pays imbalanced attention to training samples. At the end of training, the recently exposed samples attract more attention and tend to have lower losses, while earlier samples are partially forgotten by the model and have higher losses. In short, training samples receive imbalanced attention from the model, which mainly depends on the time when the model last saw the training sample (i.e., the data order of the last training epoch).

The underlying cause of this phenomenon is mini-batch gradient descent (LeCun et al., 2012), that is, we do not simultaneously use all training samples to train the model but divide them into mini-batches. Therefore, training samples do not get balanced training in each update step, so we name this problem *imbalanced training*. This problem is less severe in some tasks (e.g., image classification and text classification), but it has a significant impact on NMT as machine translation is a challenging task containing numerous translation rules, which are easily forgotten during the training process. Besides, we find that the imbalanced training problem is especially severe and non-negligible on low-resource machine translation.

To demonstrate that the imbalanced training problem does affect the model accuracy, we first review a widely used technique called checkpoint averaging technique, which has proved to be effec-

tive in improving model accuracy but its internal mechanisms are not fully understood. We analyze it from the perspective of catastrophic forgetting and find that their success can be attributed to the alleviation of imbalanced training. We also notice that checkpoint averaging has some limitations, leaving room for further improvements.

Inspired by the existing solution of checkpoint averaging which leverages the complementarity of checkpoints to improve model accuracy, we propose Complementary Online Knowledge Distillation (COKD) to address the problem of imbalanced training. As the model tends to forget knowledge learned from early samples, the main idea of COKD is to construct complementary teachers to re-provide this forgotten knowledge to the student. Specifically, we divide the training set into mutually exclusive subsets and reorganize them in a specific orders to train the student and teachers. We perform COKD in an online manner where teachers are on-the-fly updated to fit the need of student. When training the student on a subset, teachers can always provide the student with complementary knowledge on the other subsets, thereby preventing the student from catastrophic forgetting.

Experimental results on multiple machine translation tasks show that our method successfully alleviates the problem of imbalanced training and achieves substantial improvements over strong baseline systems. Especially, on the low-resource translation tasks that are severely affected by imbalanced training, our method is particularly effective and improves baseline models by about 2 BLEU points on average.

In summary, our contribution is threefold:

- We observe the problem of *imbalanced training* that training samples receive imbalanced attention from the model. We find that NMT, especially low-resource translation tasks, is seriously affected by imbalanced training.
- We rethink the widely used checkpoint averaging technique and explain its success from the perspective of imbalanced training, which also demonstrates that the imbalanced training problem does affect the model accuracy.
- We propose Complementary Online Knowledge Distillation for NMT, which can successfully alleviate the imbalanced training problem and improve the translation quality.

2 Background

2.1 Knowledge Distillation

Knowledge distillation (Hinton et al., 2015) is a class of methods that transfers knowledge from a pre-trained teacher network to a student network. Assume that we are training a classifier $p(y|x;\theta)$ with $|\mathcal{V}|$ classes, and we can access the pre-trained teacher $q(y|x)$. Instead of minimizing the cross-entropy loss between the ground-truth label and the model output probability, knowledge distillation uses the teacher model prediction $q(y|x)$ as a soft target and minimizes the loss:

$$\mathcal{L}_{\text{KD}}(\theta) = -\sum_{k=1}^{|\mathcal{V}|} q(y=k|x) \times \log p(y=k|x;\theta). \tag{1}$$

In neural machine translation, the standard training objective is the cross-entropy loss, which minimizes the negative log-likelihood as follows:

$$\mathcal{L}_{\text{NLL}}(\theta) = -\sum_{t=1}^{T} \log(p(y_t|y_{<t}, \boldsymbol{X}, \theta)), \tag{2}$$

where $\boldsymbol{X} = \{x_1, ..., x_N\}$ and $\boldsymbol{Y} = \{y_1, ..., y_T\}$ are the source sentence and the target sentence, respectively. Kim and Rush (2016) proposed to train the student model to mimic the teacher's prediction at each decoding step, which is called Word-level Knowledge Distillation (Word-KD) and its loss is calculated as follows:

$$\mathcal{L}_{\text{Word-KD}}(\theta) = -\sum_{t=1}^{T}\sum_{k=1}^{|\mathcal{V}|} q(y_t = k|y_{<t}, \boldsymbol{X}) \times \log p(y_t = k|y_{<t}, \boldsymbol{X}, \theta). \tag{3}$$

Conventional offline knowledge distillation only allows the student to learn from static pre-trained teacher models. On the contrary, online knowledge distillation trains teachers from scratch and dynamically updates them, so the student learns from different teachers during the training process. Zhang et al. (2018) first overcame the offline limitation by training peer models simultaneously and conducted an online distillation in one-phase training between peer models. Since mutual learning requires training multiple networks, Lan et al. (2018); Song and Chai (2018) proposed to use a single multi-branch network for online knowledge distillation, which treats each branch as a student and the ensemble of branches as a teacher. The multi-branch architecture subsequently became the mainstream for online knowledge distillation (Guo et al., 2020; Chen et al., 2020; Wu and Gong, 2021). Besides, Furlanello et al. (2018) performed iterative self-distillation where the student network is identical to the teacher in terms of the network graph. In each new iteration, under the supervision of the earlier iteration, a new identical model is trained from scratch. In NMT, Wei et al. (2019) on-the-fly selected the best checkpoint from the training path as the teacher to guide the training process.

2.2 Catastrophic Forgetting

Catastrophic forgetting is a problem faced by many machine learning models during continual learning, as models tend to forget previously learned knowledge when being trained on new tasks (McCloskey and Cohen, 1989). A typical class of methods to mitigate catastrophic forgetting is based on regularization which constrains the update of model parameters. Goodfellow et al. (2013) empirically find that the dropout regularization can effectively alleviate the catastrophic forgetting phenomenon. Kirkpatrick et al. (2017) proposed elastic weight consolidation, which implements the modified regularization term that imposes constraints on the update of important parameters in the previous task. Lee et al. (2017) proposed drop-transfer, which is a variant of dropout that drops the weight vector of turned off nodes to the weight learned on the previous task instead of a zero vector. Learning without Forgetting (LWF) (Li and Hoiem, 2017) is the approach most relevant to our work. They only use new task data to train the network but preserve the original capabilities by distilling knowledge from the pre-trained model.

There are also a number of efforts to address the catastrophic forgetting problem for the domain adaptation of NMT. Kirkpatrick et al. (2017); Thompson et al. (2019) added regularization terms to constrain the update of parameters. Dakwale and Monz (2017) proposed to minimize the KL-divergence between the predictions of general-domain model and fine-tuned model. Zeng et al. (2018); Gu et al. (2019) introduced a discriminator to preserve the domain-shared features. Liang et al. (2021); Gu et al. (2021); Xie et al. (2021) fixed important parameters during the fine-tuning to preserve the general-domain performance. Gu and Feng (2020) investigated the cause of catastrophic forgetting from the perspectives of modules and parameters.

3 Imblanced Training

Before drawing any conclusions, we first conduct experiments on three different tasks, namely, image classification, text classification, and machine translation, to show that the problem of imbalanced training does exist. For image classification, we conduct experiments on CIFAR-10 and CIFAR-100 (Krizhevsky, 2009), both of which contain 50,000/10,000 training/testing images with 32×32 pixels drawn from 10/100 classes. For text classification, we conduct experiments on AG-News, which contains 120,000/7,600 training/testing sentences drawn from 4 classes. For machine translation, we conduct experiments on three translation tasks: WMT14 English-German (En-De), IWSLT15 English-Vietnamese (En-Vi), and WMT17 English-Turkish (En-Tr). We use the ResNet-32 network (He et al., 2016) for image classification, the VDCNN network (Conneau et al., 2017) for text classification and Transformer-base (Vaswani et al., 2017) for machine translation. All the models are trained using cross-entropy loss. We refer readers to Appendix A and section 6.1 for the detailed configurations.

We train the model until convergence and then take the last checkpoint to calculate losses of training samples in the data order of the last training epoch. If there is a problem of imbalanced training, then training samples at the end of the epoch, which are recently exposed to the model, will tend to have lower losses. In contrast, training samples at the beginning will tend to have higher losses.

For quantitative analysis, we use the Spearman correlation coefficient between the data order and loss to measure the degree of imbalanced training. Specifically, we assign each batch in the training dataset with a batch-id according to the order they appear in the last training epoch, where batch i is the i-th trained batch. We disable regularization techniques such as dropout and label smoothing and calculate the loss for each batch. The correlation coefficient between the batch-id and the loss is used to measure the degree of imbalanced training, and a large negative correlation coefficient indicates that this problem is severe. Figure 1 illustrates the relationship between the batch-id and loss. By comparing the loss curves and correlation coefficients on these six datasets, we obtain the following three main observations.

The problem of imbalanced training does exist. Among the six datasets in our experiments, only

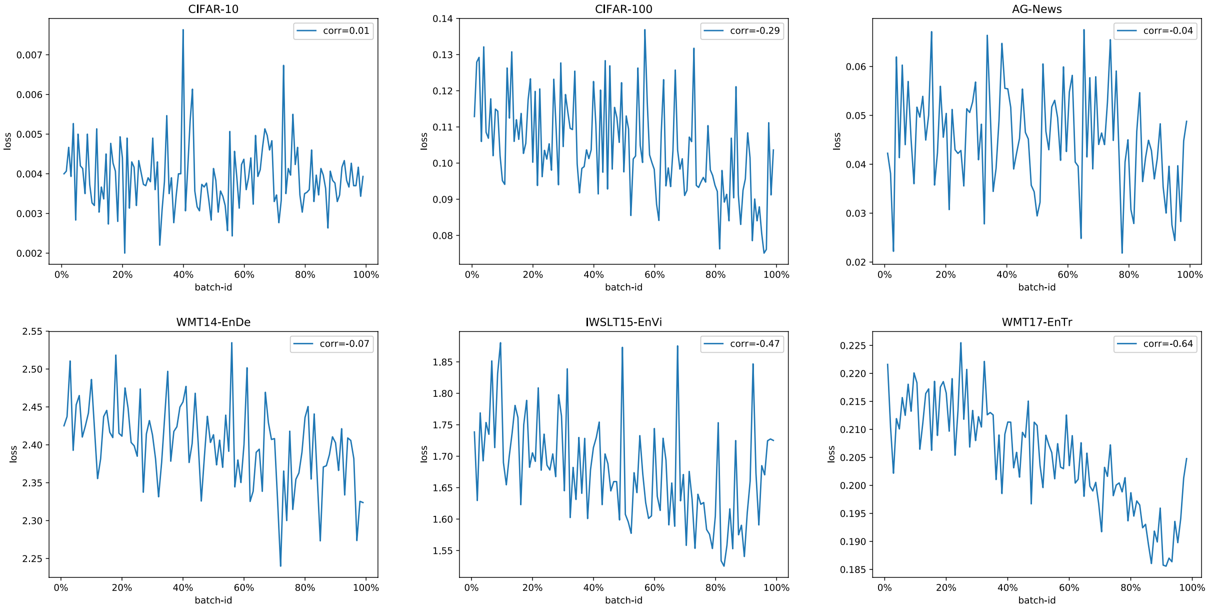

Figure 1: The relationship between the batch-id and loss on three different types of tasks. The Spearman correlation coefficient (corr) is presented in the upper right corner of charts. Batch-id i indicates the i-th trained batch in the last epoch. Batch-id in the x-axis is normalized to [0,1]. Image Classification: CIFAR-10 and CIFAR-100; Text Classification: AG-News; Machine Translation: WMT14 En-De, IWSLT15 En-Vi, and WMT17 En-Tr.

CIFAR-10 has a positive correlation coefficient. Two datasets (i.e., AG-News and WMT14 En-De) have small negative correlation coefficients. Three datasets (i.e., CIFAR-100, IWSLT15 En-Vi, and WMT17 En-Tr) have an apparent decline in losses accompanied by large negative correlation coefficients. Therefore, we can conclude that the problem of imbalanced training does exist, but the degree of impact varies.

Imbalanced training is related to task complexity. Intuitively, imbalanced training is more likely to occur on complex tasks where previously learned knowledge may be easily forgotten during the learning of numerous new knowledge. Comparing the two image classification datasets, CIFAR-10 and CIFAR-100 have the same dataset size but a different number of classes. The correlation coefficient on the complex task CIFAR-100 is -0.29, while the correlation coefficient on CIFAR-10 is 0.01. The text classification task, which only contains 4 classes, has a small correlation coefficient -0.04. Machine translation is generally considered a complex task with exponential search space and numerous translation rules. Notably, WMT17 En-Tr has the largest correlation coefficient of -0.64. These results are consistent with our intuition that imbalanced training has a greater impact on complex tasks like machine translation.

Low-resource translation suffers from imbalanced training. Comparing the three machine translation datasets, the imbalanced training problem has a much larger impact on low-resource datasets (i.e., IWSLT15 En-Vi and WMT17 En-Tr), where the high-resource dataset WMT14 En-De is less affected. To eliminate the influence of language, we randomly select 100K sentences from the WMT14 En-De dataset for the training to simulate the low-resource scenario. We show the loss curve in Appendix B, where the corresponding correlation coefficient is -0.63, which also supports the conclusion. This is counter-intuitive since when there are many training samples, the early samples seem to be more easily forgotten. Actually, as Figure 1 shows, the loss curves are generally less steep at the beginning, indicating that early samples are nearly “equally forgotten” by the model. For high-resource datasets, most samples are nearly “equally forgotten” and only the losses of a few samples at the end are highly correlated with the batch-id, so the overall correlation is low. In comparison, nearly the whole loss curve of low-resource datasets is steep, so the model may simultaneously overfit recent samples and underfit early samples due to imbalanced training. Therefore, the problem of imbalanced training is more serious and nonnegligible in low-resource machine translation.

Loss rises in the end due to the momentum of optimizer. On CIFAR-100, IWSLT15 En-Vi, and WMT17 En-Tr, though their loss curves are generally downward, they all have a sudden rise at the end. This abnormal phenomenon is actually consistent with our conclusion. Because of the momentum factor in the adam optimizer, the impact of a model update is not limited to the current step. The optimizer retains the gradient in the form of momentum, which will affect the gradient updates in the next few steps. Therefore, the impact of momentum is not fully released in the last few training steps, so the loss rises in the end.

4 Checkpoint Averaging

Checkpoint averaging, which directly takes the average of parameters of the last few checkpoints as the final model, is a widely used technique in NMT (Junczys-Dowmunt et al., 2016; Vaswani et al., 2017). The averaged checkpoint generally performs better than any single checkpoint. However, to the best of our knowledge, its internal mechanism is not fully understood.

In this section, we analyze the success of checkpoint averaging from the perspective of imbalanced training. Though training samples receive imbalanced attention from each checkpoint, this imbalance is different among checkpoints. If we understand the imbalanced training as the noise on each checkpoint, noises among different checkpoints can be approximately regraded as i.i.d. random variables. By averaging checkpoints, the variance of random noise is reduced and thereby alleviating the problem of imbalanced training. Based on the above analysis, we make the following hypothesis and verify it through experiments.

Hypothesis *Checkpoint averaging improves the model performance through alleviating the problem of imbalanced training.*

Experiments We conduct experiments on the six datasets to study the relationship between checkpoint averaging and imbalanced training. We average the last five epoch checkpoints and compare their performance with the best single checkpoint. Table 1 reports the model performance along with the correlation coefficient on the six datasets. We can see that checkpoint averaging achieves considerable improvements on datasets where the problem of imbalanced training is severe. On datasets with small correlation coefficients, the improvements of checkpoint averaging are very limited. These results confirm our hypothesis and also demonstrate that the imbalanced training problem does affect the model accuracy.

Dataset	**Corr**	**Best**	**Ave**
Image Classification & Text Classification			
CIFAR-10	0.01	93.51%	93.47%
CIFAR-100	-0.29	70.89%	71.36%
AG-News	-0.04	91.61%	91.70%
Machine Translation			
WMT14 En-De	-0.07	27.29	27.45
IWSLT15 En-Vi	-0.47	28.52	29.08
WMT17 En-Tr	-0.64	12.79	13.42

Table 1: Model performance on the test sets of six datasets. For classification tasks, we report the Top-1 accuracy. For translation tasks, we report the BLEU score. **Corr** is the Spearman correlation coefficient calculated in section 3. **Best** and **Ave** represent the best and average checkpoint performance, respectively.

Limitations Though checkpoint averaging can alleviate the problem of imbalanced training and improve the model performance, it also has some limitations and its success largely depends on the empirical choice of checkpoint interval. If the checkpoint interval is small, then the i.i.d. assumption does not hold, so the imbalance cannot be effectively eliminated and may even become stronger (Appendix C). If the checkpoint interval is large, then checkpoints may not lie in the same parameter space, making the direct averaging of checkpoints problematic.

5 Approach

In this section, we propose Complementary Online Knowledge Distillation (COKD) to alleviate the problem of imbalanced training. We apply knowledge distillation with dynamically updated complementary teachers to re-provide the forgotten knowledge to the student model.

5.1 Complementary Teachers

We first introduce the construction of complementary teachers. Assume that we have n teacher models $\mathcal{T}_{1:n}$ and the student model is $\mathcal{S}$, and both teacher models and the student model are randomly initialized. We expect that teacher models should be dynamically updated so that they are always complementary to the student. While the student learns from new training samples and gradually forgets early samples, teacher models should re-provide the forgotten knowledge to the student.

Recall that the model pays imbalanced attention to different training samples depending on the data order of the training. Therefore, a natural way to obtain complementary teachers is to train teachers in different data orders. Specifically, in each epoch, we divide the training dataset $\mathcal{D}$ into $n+1$ mutually exclusive splits $(\mathcal{D}_1, \mathcal{D}_2, ..., \mathcal{D}_{n+1})$. The student model sequentially learns from $\mathcal{D}_1$ to $\mathcal{D}_{n+1}$, where the data order is different for teacher models.

We use a ordering function $\mathcal{O}(i, t)$ to denote the training data for teacher $\mathcal{T}_i$ at time t. After teacher models $\mathcal{T}_{1:n}$ learn from data splits $\mathcal{D}_{\mathcal{O}(1:n,t)}$ respectively, the student $\mathcal{S}$ learn from both $\mathcal{D}_t$ and teachers. To make teachers complementary with the student, the ordering function $\mathcal{O}(\cdot, t)$ should cover all data splits except $\mathcal{D}_t$. To ensure that each teacher can access the whole training data, the ordering function $\mathcal{O}(i, \cdot)$ should also cover all data splits. Fortunately, we find that a simple assignment of $\mathcal{O}$ satisfies the above requirements:

$$\mathcal{O}(i, t) = \begin{cases} i+t, & i+t \leq n+1 \\ i+t-n-1, & i+t > n+1 \end{cases}. \quad (4)$$

where $i \in \{1, 2, ..., n\}$ and $t \in \{1, 2, ..., n+1\}$. Under this assignment, teacher $\mathcal{T}_i$ simply uses the data split that has offset i from the student, which ensures that all teachers are complementary with the student and can access the whole training set.

5.2 Complementary Training

The knowledge of n complementary teachers can be transfered to the student through word-level knowledge distillation:

$$\mathcal{L}_{\text{KD}}(\theta) = -\sum_{t=1}^{T} \sum_{k=1}^{|\mathcal{V}|} \sum_{i=1}^{n} \frac{q_i(y_t = k | y_{<t}, \boldsymbol{X})}{n} \times \log p(y_t = k | y_{<t}, \boldsymbol{X}, \theta), \quad (5)$$

where p is the prediction of student $\mathcal{S}$ and q_i is the prediction of teacher $\mathcal{T}_i$. We use a hyperparameter α to interpolate the distillation loss and the cross-entropy loss:

$$\mathcal{L}(\theta) = \alpha \cdot \mathcal{L}_{\text{KD}}(\theta) + (1 - \alpha) \cdot \mathcal{L}_{\text{NLL}}(\theta). \quad (6)$$

In this way, the student model learns both new knowledge from the training set and complementary knowledge from teacher models. With an appropriate α, we can achieve a balance between the two kinds of knowledge and alleviate the problem of imbalanced training. However, this method is based on knowledge distillation where knowledge is transferred unidirectionally from teachers to the student. Though the student can benefit from balanced training, these complementary teachers also set an upperbound to the student and prevent it from performing better.

Algorithm 1 COKD

```
Input: training set $\mathcal{D}$, the number of teachers $n$
Output: student model $\mathcal{S}$
randomly initialize student $\mathcal{S}$ and teachers $\mathcal{T}_{1:n}$
while not converge do
    randomly divide $\mathcal{D}$ into $n+1$ subsets $(\mathcal{D}_1, \mathcal{D}_2, ..., \mathcal{D}_{n+1})$
    for $t = 1$ to $n+1$ do
        for $i = 1$ to $n$ do
            train $\mathcal{T}_i$ on $\mathcal{D}_{\mathcal{O}(i,t)}$
        train $\mathcal{S}$ on $\mathcal{D}_t$ according to Equation 6
    for $i = 1$ to $n$ do $\mathcal{T}_i \leftarrow \mathcal{S}$
return student model $\mathcal{S}$
```

To overcome this limitation, we follow the underlying idea of two-way knowledge transfer where the knowledge is also transferred from the student to teachers (Zhang et al., 2018; Lan et al., 2018). We use a simple reinitialization method to achieve the two-way knowledge transfer. At the end of each epoch, we reinitialize teacher models with the parameters of the student model:

$$\mathcal{T}_i \leftarrow \mathcal{S}, \quad i \in \{1, 2, ..., n\}. \quad (7)$$

Through the reinitialization, the student and teachers are exactly the same at the beginning of each epoch. In this way, both the student and teachers are iteratively improved so the student performance is no longer limited by the fixed ability of teachers. We summarize the training process of COKD in Algorithm 1.

6 Experiments

6.1 Setup

To evaluate the performance of COKD, we conduct experiments on multiple machine translation tasks. For low-resource translation where the problem of imbalanced training is severe, we run experiments on WMT17 English-Turkish (En-Tr, 207K sentence pairs), IWSLT15 English-Vietnamese (En-Vi, 133K sentence pairs), and TED bilingual dataset. We also evaluate the high-resource performance of COKD on WMT14 English-German (En-De, 4.5M sentence pairs). For WMT17 En-Tr and IWSLT15 En-Vi, we use case-sensitive SacreBLEU (Post, 2018) to report reproducible BLEU scores. For TED bilingual dataset, following Xu et al. (2021), we report the tokenized BLEU. For WMT14 En-De translation, we report the tokenized BLEU (Papineni et al., 2002) with compound split.

For WMT17 En-Tr, we use *newstest2016* as the validation set and *newstest2017* as the test set. We learn a joint BPE model (Sennrich et al., 2016) with 16K operations. For IWSLT15 En-Vi, we use the pre-processed data used in Luong and Manning (2015)[2]. For TED bilingual dataset, we use the pre-processed data used in Xu et al. (2021)[3]. For WMT14 En-De, the validation set is *newstest2013* and the test set is *newstest2014*. We learn a joint BPE model with 32K operations.

In the main experiments, we set the number of teachers n to 1 and the hyperparameter α to 0.95. We implemented our approach based on the base version of Transformer (Vaswani et al., 2017). Following Wei et al. (2019), we increase the dropout rate to 0.2 on WMT17 En-Tr and IWSLT15 En-Vi. For TED bilingual dataset, we further increase the dropout rate of Transformer baseline to 0.3. All models are optimized with Adam (Kingma and Ba, 2014) with the optimizer settings in Vaswani et al. (2017). The batch size is 32K for all translation tasks. For inference, we average the last 5 checkpoints and use beam search with beam size 5. The checkpoint interval is 1000 for low-resource tasks and 5000 for WMT14 En-De.

6.2 Main Results

We first conduct experiments on the two low-resource datasets WMT17 En-Tr and IWSLT15 En-Vi and the high-resource dataset WMT14 En-De to evaluate the capability of our method. We compare our method with knowledge distillation methods and deep mutual learning (Zhang et al., 2018), and also report the results of Online Distillation from Checkpoints (ODC) (Wei et al., 2019) for comparison. The results are listed in Table 2.

Models	En-Tr	En-Vi	En-De
Transformer*	12.20	28.56	–
ODC*	12.92	29.47	–
Transformer	13.42	29.08	27.45
Word-KD	13.66	29.54	27.76
Seq-KD	13.91	29.69	27.84
Mutual	13.72	29.83	27.81
COKD	**16.66**	**31.95**	**28.26**

Table 2: BLEU scores on three translation tasks. * means results reported in Wei et al. (2019). Word-KD means word-level knowledge distillation, and Seq-KD means sequence-level knowledge distillation. Mutual means our reimplementation of deep mutual learning (Zhang et al., 2018).

Low-Resource First, we focus on the results on the two low-resource datasets where the problem of imbalanced training is severe. Since we have applied the checkpoint averaging technique on the baseline system, our baseline is very competitive and outperforms the baseline of Wei et al. (2019). We refer readers to Appendix D for results without checkpoint averaging. Knowledge distillation techniques and deep mutual learning bring some improvements to the baseline, but the improvements are relatively weak. In comparison, COKD substantially improves the baseline performance by about 3 BLEU scores, demonstrating the effectiveness of COKD on low-resource translation tasks.

High-Resource On the high-resource dataset WMT14 En-De, COKD still outperforms the baseline and knowledge distillation methods. The improvement of COKD is relatively small compared to the low-resource setting, which can be explained from the perspective of imbalanced training. As illustrated in Figure 1, high-resource datasets like WMT14 En-De is less affected by the problem of imbalanced training, so the alleviation of this problem may not bring strong improvements on high-resource datasets.

TED Bilingual Dataset We further conduct experiments on TED bilingual dataset to confirm the effectiveness of COKD on low-resource translation tasks. We evaluate COKD on both En-X and X-En directions and report the results in Table 3. The performance of COKD is still very impressive, which improves the baseline by 1.59 BLEU on average in the En-X direction, and improves the baseline by 2.15 BLEU on average in the En-X direction.

6.3 Ablation Study

In this section, we study the effect of complementary teachers and teacher reinitialization in COKD. We remove each of them respectively and report

their performance in Table 4. By removing complementary teachers, we do not split the dataset and assign random data order to teachers, which leads to obvious performance degradtion. We also notice that a large part of improvement comes from the reinitialization, suggesting the importance of two-way knowledge transfer where both the student and teachers are iteratively improved.

6.4 Hyperparameters

There are two hyperparameters in COKD: the number of teachers n and the loss weight α, whose default settings are $n = 1$, $\alpha = 0.95$ in the main experiments. In this section, we conduct experiments on WMT17 En-Tr to show the effect of the two hyperparameters.

The number of teachers We change the number of teachers n from 1 to 5 to evaluate the effect of n in COKD and report the BLEU score and training time in Table 5. We find that using more teachers does not necessarily lead to better performance, suggesting that the main improvement is not due to the ensemble of multiple teachers. Large n may slightly outperform the $n = 1$ setting but comes with a larger training cost. Therefore, we recommend the $n = 1$ setting in practical applications. Though the training cost is still larger, it is acceptable on low-resource datasets considering the strong performance improvement.

Hyperparameter α We set the hyperparameter α to $0.75, 0.9, 0.95, 0.98, 1$ respectively. The corresponding BLEU scores are listed in Table 6. We can see that the model performance is sensitive to the hyperparameter α. Generally, the model prefers large α, where a slightly smaller α may significantly degrade the model performance. We explain this phenomenon as the imbalance of complementary knowledge and new knowledge. The distillation loss carries the complementary knowledge and the cross-entropy loss carries the new knowledge, so an appropriate α should balance the two kinds of knowledge. Considering that the distillation loss is only a little biased to the complementary knowledge, α should be much larger than 0.5, otherwise it cannot keep the balance. We empirically recommend the $\alpha = 0.95$ setting, which also shows good performance on other datasets.

6.5 COKD Alleviates Imbalanced Training

In this section, we evaluate the effectiveness of COKD in alleviating the problem of imbalanced training. We take the final model of COKD and measure the correlation between batch-id and loss in the last epoch. We conduct experiments on the WMT17 En-Tr dataset where the problem of imbalanced training is severe. As Figure 2 shows, the downward trend of loss is successfully alleviated by COKD, and the correlation coefficient is improved from -0.64 to -0.16.

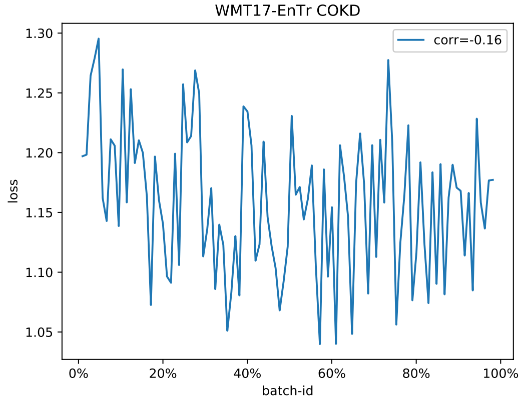

Figure 2: The loss curve of COKD on the last epoch.

7 Conclusion

In this paper, we observe that catastrophic forgetting will cause imbalanced training, which is severe in low-resource machine translation and will affect the translation quality. We rethink the checkpoint averaging technique and explain its success from the perspective of imbalanced training. We further propose Complementary Online Knowledge Distillation (COKD), which successfully alleviates the imbalanced training problem and achieves substantial improvements in translation quality.

A Configurations for Classification Tasks

In this section, we describe the configurations of classification tasks in detail. For the two image classification tasks CIFAR-10 and CIFAR-100, our implementation is based on the source code released by Chen et al. (2020)[4]. We use the ResNet-32 network (He et al., 2016). For preprocessing, we normalized all images by channel means and standard deviations. We use stochastic gradient descent with Nesterov momentum for optimization and set the initial learning rate to 0.1, momentum to 0.9. We set the mini-batch size to 128 and weight decay to 5×10-4. The learning rate is divided by 10 at 150 and 225 of the total 300 training epochs for these two datasets.

For the text classification task AG-News, our implementation is based on an open-source NLP benchmark[5]. We use the VDCNN network (Conneau et al., 2017) with depth 29. We use stochastic gradient descent with momentum for optimization and set the initial learning rate to 0.01, momentum to 0.9. We train the model for 100 epochs and multiply the learning rate by 0.9 every 15 steps. We set the mini-batch size to 128.

B Simulation of Low-Resource WMT14 En-De

We randomly select 100K sentences from the WMT14 En-De dataset for the training to simulate the low-resource scenario. Figure 3 shows that the loss curve is downward and has a large negative correlation coefficient -0.63. Comparing with the whole dataset result, it confirms the conclusion that low-resource translation suffers more from imbalanced training.

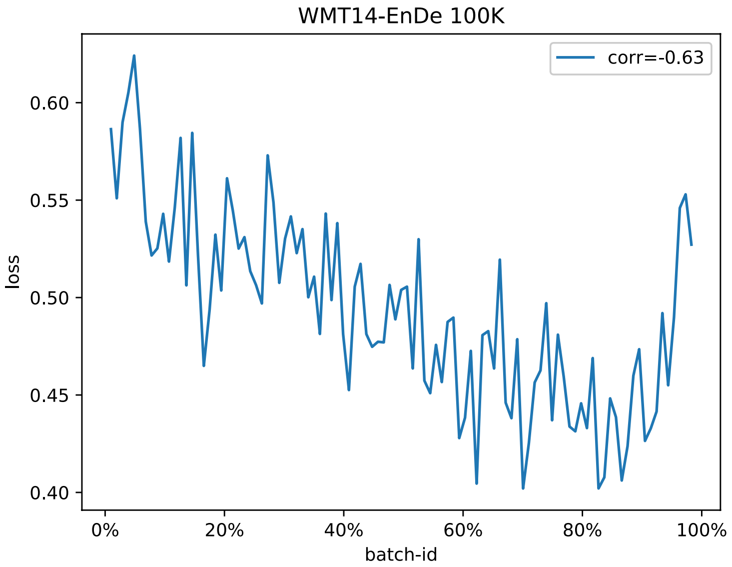

Figure 3: Relationship between the batch-id and loss on the simulated low-resource scenario of WMT14 En-De.

C Case Analysis of Checkpoint Averaging

In this section, we give a case analysis to show that checkpoint averaging may bring new imbalance and degrade the model performance. We conduct experiments on the validation set of WMT17 En-Tr translation. We set the checkpoint interval to 0.1 epoch, so 10 checkpoints are saved in the last training epoch. We average these 10 checkpoints and illustrate the relationship between the batch-id and loss in Figure 4.

Different from the previous imbalance, Figure 4 shows an upward trend with a large positive correlation coefficient of 0.81. The BLEU score of the averaged model is 12.71, which is even lower than the BLEU of a single checkpoint. Intuitively, this is because earlier samples are recently exposed to many

[5] https://github.com/ArdalanM/nlp-benchmarks

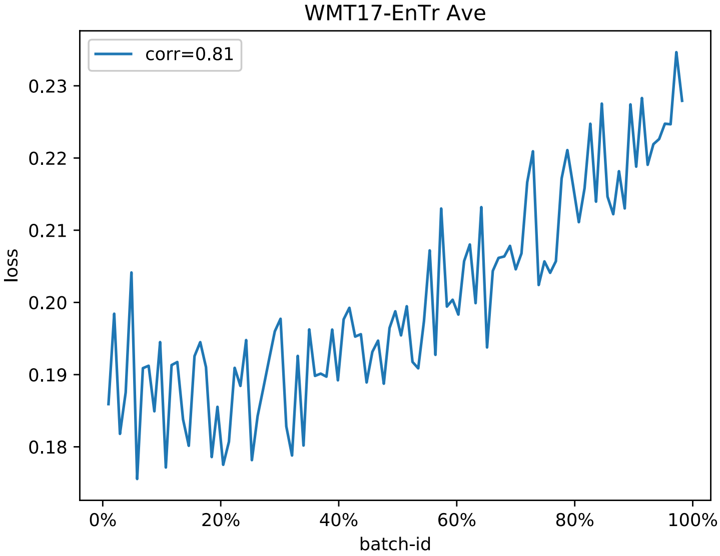

Figure 4: Relationship between the batch-id and loss on WMT17 En-Tr.

checkpoints, while the latter samples are only exposed to the last few checkpoints. The underlying cause is the small interval of checkpoints. As the checkpoint interval is small, the i.i.d. assumption does not hold, so checkpoint averaging cannot eliminate the imbalance and may bring a new imbalance.

D Performance without Checkpoint Averaging

In the main experiments, we still apply the checkpoint averaging technique during inference to alleviate the imbalanced training problem. Here we report the performance without checkpoint averaging in Table 7.

Models	**En-Tr** Best	Ave	Δ	**En-Vi** Best	Ave	Δ	**En-De** Best	Ave	Δ
Transformer	12.79	13.42	+0.63	28.52	29.08	+0.56	27.29	27.45	+0.16
Word-KD	13.25	13.66	+0.41	29.09	29.54	+0.45	27.64	27.76	+0.12
Seq-KD	13.37	13.91	+0.54	29.26	29.69	+0.43	27.65	27.84	+0.19
Mutual	13.13	13.72	+0.59	29.35	29.83	+0.48	27.59	27.81	+0.22
COKD	16.61	16.66	+0.05	31.86	31.95	+0.09	28.18	28.26	+0.08

Table 7: BLEU scores on three translation dateset. **Best** and **Ave** represent the best and average checkpoint performance, respectively.

We can see that the performance of COKD only decreases a little after removing checkpoint averaging, indicating that COKD itself can successfully alleviate the problem of imbalanced training. In contrast, the performance gap between Best and Ave is larger on other NMT Systems, suggesting that the problem of imbalanced training is severe and cannot be simply mitigated by other techniques like knowledge distillation and mutual learning.

E Fine-Tuning with Lower Learning Rate

When the training is finished, we can manually reduce the learning rate to fine-tune the model, which also improves the model accuracy in some situations. The common explanation is that fine-tuning can help to converge the optimization process and reduce the loss function. Here we analyze fine-tuning from another perspective and find that it can also alleviate the imbalanced training problem.

Intuitively, if the learning rate is very low, the model will not be much biased towards recent training samples, which should reduce the imbalance. We conduct experiments on WMT17 En-Tr to confirm our hypothesis. We reduce the learning rate from the base setting of $7 \cdot 10^{-4}$ to $1 \cdot 10^{-5}$ to fine-tune the model and draw the loss curve in Figure 5. From both the correlation coefficient and loss curve, we can see that the imbalance is greatly reduced by fine-tuning. Regrading the BLEU score, the BLEU score after fine-tuning is only 0.25 higher than the baseline, which is much smaller than the improvement of checkpoint averaging. We speculate that it is due to some drawbacks of fine-tuning. For example, fine-tuning with a low learning rate has a risk of overfitting the dataset, which may influence its performance on low-resource datasets.

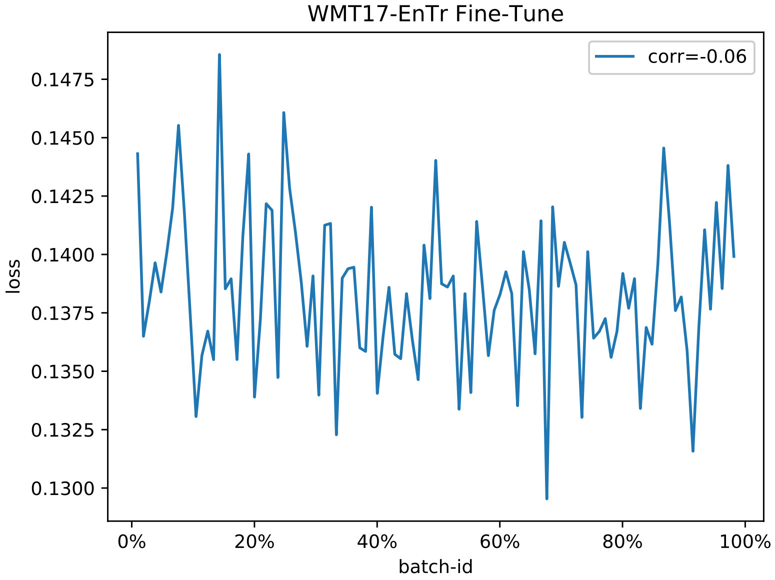

Figure 5: Relationship between the batch-id and loss on WMT17 En-Tr.

Metaphors in Pre-Trained Language Models: Probing and Generalization Across Datasets and Languages

Abstract

Human languages are full of metaphorical expressions. Metaphors help people understand the world by connecting new concepts and domains to more familiar ones. Large pre-trained language models (PLMs) are therefore assumed to encode metaphorical knowledge useful for NLP systems. In this paper, we investigate this hypothesis for PLMs, by probing metaphoricity information in their encodings, and by measuring the cross-lingual and cross-dataset generalization of this information. We present studies in multiple metaphor detection datasets and in four languages (i.e., English, Spanish, Russian, and Farsi). Our extensive experiments suggest that contextual representations in PLMs do encode metaphorical knowledge, and mostly in their middle layers. The knowledge is transferable between languages and datasets, especially when the annotation is consistent across training and testing sets. Our findings give helpful insights for both cognitive and NLP scientists.

1 Introduction

Pre-trained language models (PLMs) (Peters et al., 2018; Devlin et al., 2019), are now used in almost all NLP applications, e.g., machine translation (Li et al., 2021), question answering (Zhang et al., 2020), dialogue systems (Ni et al., 2021), and sentiment analysis (Minaee et al., 2020). They have sometimes been referred to as "foundation models" (Bommasani et al., 2021) due to their significant impact on research and industry.

Metaphors are important aspects of human languages. In conceptual metaphor theory (CMT) (Lakoff and Johnson, 2008), metaphor is defined as a cognitive phenomenon associating two different concepts or domains. This phenomenon is built in cognition and expressed in language. The creativity and problem solving (i.e., generalization to new problems) depend on the analogies and metaphors a cognitive system, like our brain, relies on. Modeling metaphors is therefore essential in building human-like computational systems that can relate emerging concepts to the more familiar ones.

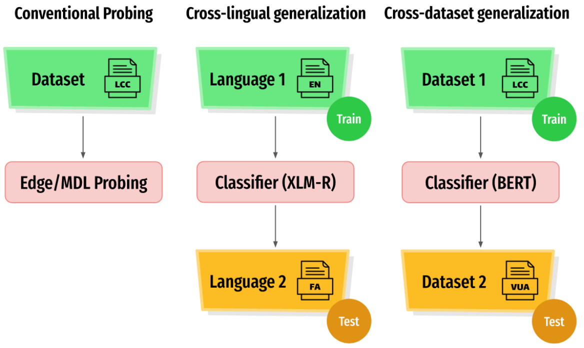

Figure 1: An illustration of our probing and generalization scenarios for metaphorical knowledge.

So far, there has been no comprehensive analysis of whether and how PLMs represent metaphorical information. We intuitively assume that PLMs must encode some information about metaphors due to their great performance in metaphor detection and other language processing tasks. Confirming that experimentally is a question that we address here. Specifically, we aim to know *whether generalizable metaphorical knowledge is encoded in PLM representations or not*. The outline of our work is presented in Figure 1.

We first do *probing* experiments to answer questions such as: (i) with which accuracies and extractablities do different PLMs encode metaphorical knowledge? (ii) how deep is the metaphorical knowledge encoded in PLM multi-layer representations? We take two probing methods, edge probing (Tenney et al., 2019b) and minimum description length (Voita and Titov, 2020), and apply them to four metaphor detection datasets, namely LCC (Mohler et al., 2016), TroFi (Birke and Sarkar, 2006), VUA pos, and VUA Verbs (Steen, 2010).

[⋆] Equal contribution.

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 2037 - 2050
May 22-27, 2022

To better estimate the *generalization* of metaphorical knowledge in PLMs, we design two setups in which testing comes from a different distribution than training data: cross-lingual and cross-dataset metaphor detection. Each setup can reveal important information on whether or not the metaphorical knowledge is encoded consistently in PLMs. Four languages (English, Farsi, Russian and Spanish) and four datasets (LCC, TroFi, VUA pos, and VUA Verbs) are considered in these generalization experiments.

In summary, this paper makes the following contributions:

- For the first time, and through careful probing analysis, we confirm that PLMs do encode metaphorical knowledge.
- We show that metaphorical knowledge is encoded better in the middle layers of PLMs.
- We evaluate the generalization of metaphorical knowledge in PLMs across four languages and four dataset sources, and find out that there is considerable transferability for the pairs with consistent data annotation even if they are in different languages. [1]

2 Related Work

Metaphor detection using PLMs. The metaphor detection task (Mason, 2004; Birke and Sarkar, 2007; Shutova et al., 2013) is a good fit for analyzing the metaphorical knowledge. Using PLMs for metaphor detection has been common in recent years, setting new state-of-the-art results, indicating implicitly that PLMs represent metaphorical information. Choi et al. (2021) introduce a new architecture that integrates metaphor detection theories with BERT. They use the definitions as well as example usages of words jointly with PLM representations. Similarly, Song et al. (2021) presents a new perspective on metaphor detection task by framing it as relation classification, focusing on the verbs. These approaches beat the earlier work of using PLMs (Su et al., 2020; Chen et al., 2020; Gong et al., 2020), RNN-based (Wu et al., 2018; Mao et al., 2019) and feature-based approaches (Turney et al., 2011; Shutova et al., 2016). Note that our goal is not to compete with these models, but to probe and analyze the relevant knowledge in PLMs.

Tsvetkov et al. (2014) present **cross-lingual metaphor detection** models using linguistic features and word embeddings. Bilingual dictionaries map different languages. Their datasets are quite small (1̃000 training and 2̃00 testing examples), making them unsuitable for a robust evaluation. However, this paper still remains as the only cross-lingual evaluation of metaphor detection, to the best of our knowledge. Here, using multilingual PLMs, we perform zero-shot cross-lingual transfer for metaphor detection. Our goal is to test if PLMs represent metaphorical knowledge transferable across languages.

Probing methods in NLP. Probing is an analytical tool used for assessing linguistic knowledge in language representations. In probing, the information richness of the representations is inspected by the quality of a supervised model in predicting linguistic properties based only on the representations (Köhn, 2015; Gupta et al., 2015; Yaghoobzadeh and Schütze, 2016; Conneau et al., 2018; Tenney et al., 2019b,a; Yaghoobzadeh et al., 2019; Hewitt and Manning, 2019; Zhao et al., 2020; Belinkov, 2022). Here, we apply probing to perform our study on whether metaphorical knowledge is present in PLM representations, and whether that is generalizable across languages and datasets.

A popular probing method introduced by Tenney et al. (2019b) is *edge probing* (Figure 2). They propose a suite of span-level tasks, including POS tagging and coreference resolution. Despite the widespread use of edge probing and other conventional probes, the question of whether the probing classifier is learning the task itself rather than identifying the linguistic knowledge raises concerns.

An Information-theoretic view can solve this issue (Voita and Titov, 2020) by reformulating probing as a data transmission problem. They consider the effort needed to extract linguistic knowledge in addition to the final quality of the probe, showing that this approach is more informative and robust than normal probing methods. We employ both edge and MDL probing in this work.

Probing multilingual PLMs. The application of probing methods in NLP is extended to multilingual PLMs as well (Pires et al., 2019; Eichler et al., 2019; Ravishankar et al., 2019a,b; Choenni and Shutova, 2020). Choenni and Shutova (2020) introduce probing tasks for typological features of multiple languages in multilingual PLMs. Ravis-

---

[1] Our implementation is available at `https://github.com/EhsanAghazadeh/Metaphors_in_PLMs`

hankar et al. (2019a,b) extend the probing tasks of Conneau et al. (2018), to a few other languages. Pires et al. (2019) study the generalization of multilingual-BERT across languages when performing cross-lingual downstream tasks. Here, as part of our study, we probe the generalization of metaphorical knowledge in XLM-R (Conneau et al., 2020), a notable multilingual PLM.

Out-of-distribution generalization. There has been no earlier work on studying or evaluating out-of-distribution generalization in metaphor detection. This generalization refers to scenarios where testing and training sets come from different distributions (Duchi and Namkoong, 2018; Hendrycks et al., 2021, 2020). Here, we have scenarios where testing and training data are in different languages or domains / datasets. These are challenging evaluation scenarios for the generalization of encoded information (metaphoricity in our case).

3 Inspecting Metaphorical Knowledge in PLMs

Metaphors are used frequently in our everyday language to convey our thoughts more clearly. There are related theories in linguistics and cognitive science. Following linguistic theories, metaphoricity is mostly annotated using metaphor identification procedure (MIP). MIP identifies a word in a given context as a metaphor if it has a basic or literal meaning that contrasts with its context words. Based on conceptual metaphor theory (CMT) (Lakoff and Johnson, 2008), one target domain (e.g., ARGUMENT) is explained using a source domain (e.g., WAR). The source domain is usually more concrete or physical, while the target is more abstract. Relating these two theories, metaphors are expressed in language connecting two contrasting domains. For example, in "We won the argument", the domain of ARGUMENT is linked to the domain of WAR by using the word "won". The word "won" is a "metaphor" here since its primary domain contrasts with its contextual domain. The same word "won" in a sentence like "The Allies won the war" refers to its literal meaning and therefore is not a metaphor. The task of metaphor detection is defined to do this classification of "literal" and "metaphor".

Accordingly, when designing a metaphor detection system, to figure out if a token is a metaphor in a particular context, we assume following a process like: (i) finding if the token has multiple meanings in different domains, including a more basic, concrete, or body-related meaning. For example, "fight", "win" and "mother" satisfy this condition. (ii) finding if the source domain of the token contrasts with the target domain. Here the contrast is important and finding the exact domains might not be necessary. The source domain, in which its literal / basic meaning resides, is a non-contextual attribute, while the target domain is mainly found using the contextual clues (WAR and ARGUMENT for "won" in the above example).

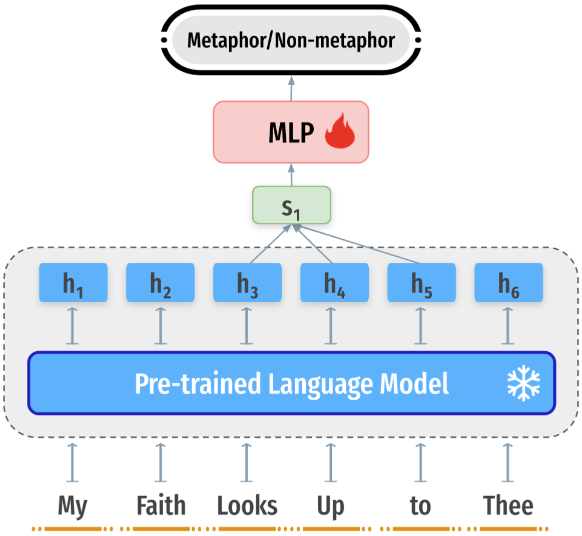

Figure 2: Probing architecture for metaphors employed in edge probing and MDL probing.

Here, we use the metaphor detection datasets annotated based on these theories and analyze the PLM representations to see if they encode metaphorical knowledge and if the encoding is generalizable. To do so, we first probe PLMs for their metaphorical information, generally and also across layers. This gives us intuition on how well metaphoricity is encoded and how local or contextual that is. Then, we test if the knowledge of metaphor detection can be transferred across languages and if multilingual PLMs capture that. Finally, the generalization of metaphorical knowledge across datasets is examined to see if the theories and annotations followed by different datasets are consistent, and if PLMs learn generalizable knowledge rather than dataset artifacts.

3.1 Probing

Here, we aim to answer general questions about metaphors in PLMs: do PLMs encode metaphorical information and, if so, how it is distributed in their layers. We do not attempt to achieve the best metaphor detection results but to analyze layers of PLMs to test if they contain the necessary information to perform this task. In trying to answer this question, we apply probing methods, discussed as follows, to focus on the representation itself by freezing the PLM parameters and training classifiers on top.

We hypothesize that metaphorical information does exist in PLM layers and more in the middle layers. As we discussed earlier, metaphor detection depends on contrast prediction between source and target domains of a token. We assume that this prediction is made mainly based on the initial layers of PLM representations of either the token itself or its context or both. In higher layers of PLMs, the representations are dominated by contextual information, making it hard to retrieve the source domain, and so, reasoning about the contrast of the source and target domains becomes difficult.

Methods We employ edge probing (Tenney et al., 2019b) and MDL (Voita and Titov, 2020). Edge probing consists of a classifier in which word representations obtained from PLMs are fed as inputs after projecting to 256-dimensional vectors first. The quality of the classifier illustrates how well the representations encode a specific linguistic knowledge. This method is designed for span-level tasks, i.e., the classifier can only access the representations of a limited part of the input sentence specified in the dataset. Edge probing has two pooler sections for making fixed-sized vectors; one pools representations across the words in the span and the other pools representations across the layers.

The Minimum Description Length (MDL) probing is based on information theory and combines the quality of the classifier and the amount of effort needed to achieve this quality.

Voita and Titov (2020) propose two methods for computing MDL: "*variational coding*" and "*online coding*." The former computes the complexity of the classifier with a Bayesian model. In the latter, the classifier is trained gradually on different portions of the dataset, and the code length will be the sum of the cross-entropies, each for a data portion. Voita and Titov (2020) show that the two methods' results are consistent with each other. Accordingly, we opted for the "*online coding*" method since it is more straightforward in implementation. Since the code length is related to the size of the dataset N, we report the "*compression*", which is equal to 1 for a random classifier and larger for better models, and is defined as: $compression = \frac{N \cdot \log_2(K)}{\text{MDL}}$ See extra details in Voita and Titov (2020).

3.2 Generalization

To see if PLMs encode generalizable metaphorical knowledge, we evaluate them in settings where testing and training data are in different distributions. We explore transferability analysis across languages and datasets as two sources of distribution. We explain each in the following sections.

3.2.1 Cross-lingual

Multilingual encoders project the representations in multiple languages into a shared space so that semantically similar words and sentences across languages end up close to each other. If we use a multilingual PLM model, and our classifier shows that representations in language S are informative about metaphoricity, what happens if we apply this classifier to the representations in language T? We hypothesize that if the representation is rich in both languages, the annotation of metaphor is consistent, and the concept of metaphor is transferable across languages, then the classifier would be able to predict metaphoricity in language T from what it learns in S.

When testing cross-lingual generalization, the linguistic and cultural differences of metaphoricity are important as well. We assume that metaphors are conceptualized in a similar process across languages, and metaphor detection is defined consistently. The lexicalization is, of course, different, but that is something that multilingual PLMs are supposed to handle to some extent.

3.2.2 Cross-dataset

When training and testing on the same distribution, any learning model often uses heuristics and annotation biases. The consequence is the recurring overestimation of the capabilities of PLMs in doing hard tasks. This might be the case for our probing experiments as well. Therefore, another generalization dimension we consider is cross-dataset transfer, i.e., training on dataset S and testing on dataset T. S and T could be annotated by different people with possibly different goals in mind, and their raw sentences could come from different domains. However, they must be annotated for the same task of metaphor detection.

In our case, the four datasets discussed more in §4.1 differ in their distribution of the candidate

VUA Verbs	He **[finds]**$_1$ it hard to communicate with people , not least his separated parents .→ 1 He finds it hard to **[communicate]**$_1$ with people , not least his separated parents . → 0
VUA POS	They picked up power from a **[spider]**$_1$'s web of unsightly overhead wires . → 1 They picked up power from a spider 's web of unsightly overhead **[wires]**$_1$. → 0
TroFi	" Locals **[absorbed]**$_1$ a lot of losses , " said Mr. Sandor of Drexel → nonliteral Vitamins could be passed right out of the body without being **[absorbed]**$_1$ → literal
LCC	Lawful gun ownership is not a **[disease]**$_1$. → 3.0 But the Supreme Court says it's not a way to **[hurt]**$_1$ the Second Amendment → 2.0 Is he angry that gun rights **[progress]**$_1$ has been done without him? → 1.0 I mean the 2nd amendment **[suggests]**$_1$ a level playing field for all of us. → 0.0

Table 1: Examples of sentences, spans, and target labels for each probing dataset.

dataset	POS	Sizes
LCC (en)	ALL	28,096 / 4,014 / 8,028
LCC (fa)	ALL	12,238 / 1,802 / 3,604
LCC (es)	ALL	12,238 / 2,236 / 4,474
LCC (ru)	ALL	12,238 / 1,748 / 3,498
TroFi	V	3,838 / 548 / 1,096
VUA Verbs	V	9,176 / 1,310 / 2,622
VUA POS	ALL	21,036 / 3,006 / 6,010

Table 2: Statistics of the datasets. We label-balance each to have 50% metaphor. Number of instances for train / dev / test sets and the types of POS are given as well. N: Noun, V: Verb, ALL: Noun, Verb, Adjective, Adverb.

POS types (e.g., TroFi is only verbs, but LCC is not). Further, the annotation process is different as each follows its own guidelines. However, the essential task of metaphor detection, i.e., distinguishing metaphor and literal usages, is the same for all. Therefore, we expect some transferability across datasets but with differences aligned with their mismatches.

4 Experimental Setup and Results

4.1 Datasets and Setup

Datasets We use four metaphor detection datasets in our study. The annotations of LCC (Mohler et al., 2016) are done mostly on web crawled data as well as news corpora. It provides metaphoricity scores including 0 as no , 2 as conventional, and 3 as clear metaphor.[2] We use the examples with score 0 as literal, and others as metaphor.

TroFi dataset (Birke and Sarkar, 2006) consists of metaphoric and literal usages of 51 English verbs from WSJ. VUA (Steen, 2010) corpus consists of words in the academic, fiction, and news subdomains of the British National Corpus (BNC). The authors published two versions: VUA POS and VUA Verbs.

LCC contains annotations in four languages: English, Russian, Spanish, and Farsi. The other three datasets, TroFi, VUA Verbs and VUA POS, are in English only. We have label-balanced all the datasets to get a more straightforward interpretation of results (the accuracy of a fair-coin random baseline is 50% in all cases) and have split the datasets to train / dev / test sets with ratios of 0.7 / 0.1 / 0.2.

The statistics of the datasets are shown in Table 2. Example sentences with the corresponding annotations can be seen in Table 1.

Setup In implementing the edge probe, we use batch size = 32 and learning rate = 5e-5 and train for five epochs in all experiments. For the MDL probe, the same structure of edge probing is employed. We apply a logarithm to the base two instead of the natural logarithm in cross-entropy loss to have all the obtained code lengths in bits (see extra details in Voita and Titov 2020). Our experiments are done using the GPUs provided by Google Colab free and pro.

4.2 Probing Results

Here, BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), and ELECTRA (Clark et al., 2020) represent our PLMs. Due to our resource limitations, we conduct all experiments on the *base* version of the models (12 layers, 768 hidden size, 110M parameters) implemented in HuggingFace's Transfomers (Wolf et al., 2020). We employ edge probing for evaluating overall metaphorical knowl-

---

[2] 1 is weak metaphor and as Mohler et al. (2016) describe metaphors with $0.5 \leq score < 1.5$ as unclear, we ignore it.

Dataset	Baseline Acc.	 Comp.	BERT Acc.	 Comp.	RoBERTa Acc.	 Comp.	ELECTRA Acc.	 Comp.
LCC (en)	74.86	1.05_2	88.25	1.85_6	88.06	1.96_5	**89.30**	**2.05_5**
TroFi	67.34	1.01_4	**68.58**	1.07_4	68.46	**1.09_6**	68.07	1.08_3
VUA POS	65.92	1.03_0	80.32	1.43_5	81.72	1.48_6	**83.03**	**1.51_4**
VUA Verbs	65.97	1.04_9	78.29	1.28_9	78.88	**1.34_5**	**79.96**	1.31_4

Table 3: Edge probing accuracy results for various metaphoricity datasets in BERT, RoBERTa, and ELECTRA. Baseline is a randomly initialized BERT. The edge probing results are the average of three runs. The compression result is the best across layers, and the subscript denotes the best layer.

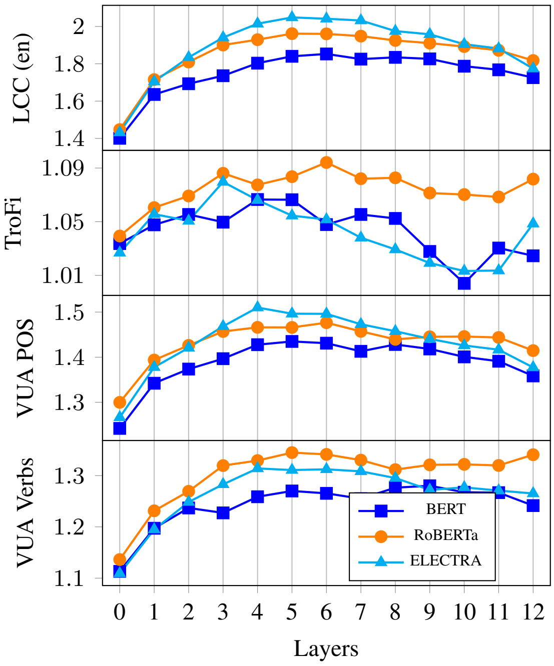

Figure 3: MDL compression across layers of three PLMs in four metaphor detection datasets. Higher number means better quality and extractability.

edge in our selected PLMs, and MDL for the layer-wise comparisons. MDL is shown to be more effective for layer-wise probing (Fayyaz et al., 2021).

Table 3 shows the edge probing accuracy and MDL probing compression results for our three PLMs. Accordingly, RoBERTa and ELECTRA are shown to encode metaphorical knowledge better than BERT on both metrics. This is consistent with their better performance on various tasks, acquired by having better pre-training objectives and / or enjoying more extensive pre-training data. The higher probing quality of ELECTRA's representations, is also consistent with Fayyaz et al. (2021) results on various linguistic knowledge tasks, including dependency labeling, named entity recognition, semantic role labeling, and coreference resolution.

MDL probing compression across layers is demonstrated in Figure 3. We see the numbers increase mostly at the first 3 to 6 layers, depending on the dataset, but it decreases afterwards[3]. In other words, metaphorical information is more concentrated in the middle layers, where the representations are relatively contextualized but not as much as higher layers. To put this in perspective, we can consider Tenney et al. (2019a) and Fayyaz et al. (2021) where the best layers for various linguistic knowledge tasks in BERT are within 4 and 9. This shows that metaphor detection in PLM representations can be resolved earlier than some basic linguistic tasks.

In §3.1, we elaborated a hypothesis that the process of detecting metaphors is not very deep since what it needs to do is mainly contrast prediction between source and target domains, and the deep layers do not represent the source domain well. Our reported probing results confirm that metaphor detection is not deep in PLM layers. To further evaluate our reasoning, we probe the domain knowledge in PLM representations across layers. We employ LCC's annotation of source and target domains, and run a similar MDL probing on different PLMs but for domain prediction. The obtained results, shown in Figure A.1 in appendix, demonstrate that the source domain information is represented in the initial layers (2-6), confirming that the source domain is dominated by other information in higher layers. On the other hand, target domain information generally increases across layers. Therefore, the middle layers can be the best place for contrasting source and target domains.

---

[3] For RoBERTa and in the case of TroFi and VUA Verbs, we see exceptional increases in the last layers.

		Train Lang			
		en	es	fa	ru
Test Lang	en	**85.14** (65.37)	79.31 (52.71)	77.59 (50.22)	80.51 (52.40)
	es	79.40 (53.17)	**84.59** (66.09)	76.70 (50.32)	79.68 (53.32)
	fa	75.70 (50.07)	75.29 (52.65)	**81.04** (65.91)	77.14 (50.36)
	ru	83.92 (53.25)	80.54 (51.48)	76.61 (51.05)	**88.36** (67.98)

Table 4: Cross-lingual metaphor detection accuracies after five epochs of training for XLM-R and (its random version). For each test language, we bold its in-distribution (e.g., en → en), and underline the best out-of-distribution (e.g., ru → en) numbers.

4.3 Generalization Experiments

As our PLMs, we use XLM-R (Conneau et al., 2020) for cross-lingual and BERT for cross-dataset experiments. To compare the cross-lingual and cross-dataset transferability, in §4.3.3, we employ the same setup, including using XLM-R as PLM for both. The results in §4.3.1 and 4.3.2 are not comparable. We apply the same edge probing architecture as in the probing experiments. We sometimes refer to both language and dataset as *distribution*.

We run two experiments for each case of a source distribution S and a target distribution T: one with the PLM and one with a randomized version of the PLM where weights are set to random values. Randomly initialized Transformers with the same architecture as PLMs are common baselines in the community. The difference between the two gives evidence about the helpfulness of the encoded knowledge gained during pre-training in doing the task. When $S = T$, this effect is measured for in-distribution and when $S \neq T$, for out-of-distribution generalization. Comparing results of in-distribution (e.g., training and testing on English data) and out-of-distribution (e.g., training on Spanish and testing on English) setups demonstrates how generalizable the metaphorical knowledge in PLM is and how consistent the annotations are.

4.3.1 Cross-lingual

The four LCC datasets corresponding to four languages are used here. We subsample from the datasets to have the same number of examples in the training sets, i.e., 12,238 which is the size of the Russian training set. The results are shown in Table 4. The random baseline is acquired using a randomly initialized XLM-R.

We observe that XLM-R significantly outperforms the random, confirming that metaphorical knowledge learned during the pre-training is transferable across languages. This considerable transferability can be attributed to the ability of XLM-R to build language-universal representations useful for metaphoricity transfer. Moreover, the innate similarities of metaphors in distinct languages can contribute to higher transferability, despite the lexicalization differences. E.g., analogizing a concept to a tool (en) occurs the same way in other languages like instrumento (es), ابزار (fa) and инструмент (ru). Finally, the constraints of the dataset producers in, for instance, keeping the languages in relatively similar target and source domains, could be influential. (See Figures A.2 and A.3).

An interesting observation is that training on Russian shows the best out-of-distribution results when testing on other languages. We analyze this further. First, we observe that LCC(ru) has almost the closest target domain distribution to all other languages (See Table A.2 in Appendix).

Second, the reported results can also be influenced by the amount of data from each of these languages in the pre-training data of XLM-R. Russian has the second largest size after English (Conneau et al., 2020). Finally, for English, the higher-resource language with closer target domain distribution, we find out that there are considerable number of examples in the LCC(en) related to "GUNS" and "CONTROL_OF_GUNS". These domains are not covered in other LCC datasets (See Figure A.3 in Appendix).

4.3.2 Cross-dataset

Similar to the cross-lingual evaluations, here we have four datasets used as sources and targets. We set the train size of each to the minimum of all, i.e., 3,838. For each pair, we run two experiments: one with randomized and one with pre-trained BERT as our PLM. Results are shown in Table 5.

		Train Dataset			
		LCC(en)	TroFi	VUA POS	VUA Verbs
Test Dataset	LCC(en)	**84.26** (54.93)	62.04 (50.05)	70.35 (50.69)	70.37 (50.14)
	TroFi	59.49 (50.58)	**68.73** (64.96)	55.38 (49.45)	59.67 (53.68)
	VUA POS	62.23 (51.47)	55.29 (50.47)	**76.86** (56.01)	71.6 (53.47)
	VUA Verbs	60.20 (50.88)	54.55 (51.73)	72.6 (56.01)	**75.21** (60.03)

Table 5: Cross-dataset edge probing accuracy results on BERT is shown in pairs: pre-trained model and, in the parenthesis, the randomly initialized model. We set the training size to the minimum among datasets, i.e., TroFi. For each test dataset, we bold its in-distribution (e.g., VUA Verbs → VUA Verbs), and underline the best out-of-distribution (e.g., VUA POS → VUA Verbs) numbers.

PLM is much better than random in all out-of-distribution cases, suggesting the presence of generalizable metaphorical information. As expected, VUA Verbs and POS achieve the best results when mutually tested, because, apart from the POS, they have the same distribution. VUA datasets and LCC(en) show good transferability, but the gap with in-distribution results is still considerable (>13% absolute). VUA Verbs is the best source for TroFi, likely because of the POS match between them. Overall, apart from the two VUA datasets, the gap between in- and out-of-distribution performance is large.

The random PLM accuracies range from about 54%-64% and 50%-56% for in- and out-of-distribution cases. We hypothesize that this drop in the out-of-distribution is related to the annotation biases, which a randomly initialized classifier can leverage better when testing and training sets are from the same distribution. When the sets have different distributions, the biases do not transfer well.

4.3.3 Comparing cross-dataset and cross-lingual

LCC(en)	LCC(es)	LCC(fa)	LCC(ru)
82.31	78.02	77.3	78.04
TroFi	VUA POS	VUA Verbs	
60.54	68.61	67.15	

Table 6: Comparing cross-dataset and cross-lingual scenarios using the same model (XLM-R), training size, testing set, i.e., LCC(en), and different training sources.

As additional transferability analysis, we compare cross-lingual and cross-dataset results, by using XLM-R and evaluating different training sources on LCC(en) test set. We make the size of each train set to be the same (3,838). The results are shown in Table 6, where the first and second rows belong to cross-lingual and cross-dataset, respectively. To base our results, we include the in-distribution result of training on LCC(en), i.e., 82.31%.

Clearly, there is a substantial gap between cross-lingual and cross-dataset accuracies. The annotation guideline is consistent in the LCC language datasets, while for the cross-dataset settings, we have datasets that differ in many aspects, including annotation procedure and definitions, covered part-of-speeches (e.g., Trofi and VUA Verbs vs. LCC and VUA POS) and sentence lengths (LCC: 25.9, VUA: 19.4, Trofi: 28.3).

5 Discussion and Conclusion

Metaphors are important in human cognition, and if we seek to build cognitively inspired or plausible language understanding systems, we need to work more on their best integration in the future. Therefore, any work in this regard is impactful.

Our probing experiments showed that PLMs do in fact represent the information necessary to do the task of metaphor detection. We assume this information is related to metaphorical knowledge learned during pre-training. Further, the layer-wise analysis confirmed our hypothesis that middle layers are more informative.

Even though our probing experiments did show that metaphorical knowledge is present in PLMs, it was still unclear if this knowledge is generalizable beyond the training data. So, to probe the probe and evaluate generalization, we ran cross-lingual and cross-dataset experiments. Our results showed that the transferability across languages works quite well for the four languages in LCC annotation. However, when the definitions and annotations were inconsistent across different datasets, the cross-dataset results were not satisfactory.

Overall, we conclude that metaphorical knowledge does exist in PLM representations and in middle layers mainly, and it is transferable if the annotation is consistent across training and testing data. We will explore more the cross-lingual transfer of metaphors and the impact of cross-cultural similarities in the future. Also, the application of metaphorical knowledge for text generation is something important that we will address.

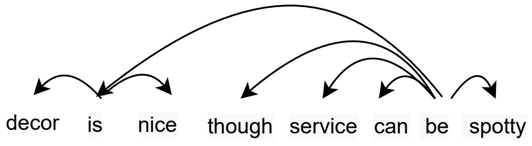
Abstract

Dependency trees have been intensively used with graph neural networks for aspect-based sentiment classification. Though being effective, such methods rely on external dependency parsers, which can be unavailable for low-resource languages or perform worse in low-resource domains. In addition, dependency trees are also not optimized for aspect-based sentiment classification. In this paper, we propose an aspect-specific and language-agnostic discrete latent opinion tree model as an alternative structure to explicit dependency trees. To ease the learning of complicated structured latent variables, we build a connection between aspect-to-context attention scores and syntactic distances, inducing trees from the attention scores. Results on six English benchmarks, one Chinese dataset and one Korean dataset show that our model can achieve competitive performance and interpretability.

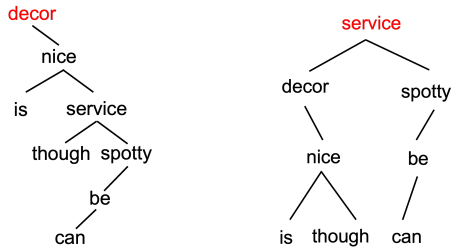
1 Introduction

Aspect-based sentiment classification (ABSA) is the task of recognizing the sentiment polarities of specific aspect categories or aspect terms in a given sentence (Jiang et al., 2011; Dong et al., 2014; Wang et al., 2016; Tang et al., 2016; Li et al., 2018; Du et al., 2019; Sun et al., 2019a; Seoh et al., 2021; Xiao et al., 2021). Different from document-level sentiment analysis, different aspect terms in the same document can bear different sentiment polarities. For example, given a restaurant review "**decor** is nice though **service** can be spotty", the corresponding sentiment labels of "decor" and "service" are positive and negative, respectively.

How to locate the corresponding opinion contexts for each aspect term is a key challenge for ABSA. To this end, recent efforts leverage dependency trees (Zhang et al., 2019; Sun et al., 2019a; Wang et al., 2020). Syntactic dependencies have been shown to better capture the interaction between the aspect and the opinion contexts (Huang et al., 2020; Tang et al., 2020). For example, in Figure1(a), using syntactic relations, we can find that the corresponding opinion words for "decor" and "service" are "nice" and "spotty", respectively.



(a) dependency tree.



(b) Induced tree for "decor". (c) Induced tree for "service".

Figure 1: A dependency tree of the input sentence "**decor** is nice though **service** can be spotty" and two induced trees of two aspects in this sentence.

Despite its effectiveness, dependency syntax has the following limitations. First, dependency parsers can be unavailable for low-resource languages or perform worse in low-resource domains (Duong et al., 2015; Rotman and Reichart, 2019; Vania et al., 2019; Kurniawan et al., 2021). Second, dependency trees are also not *optimized* for aspect-based sentiment classification. Previous studies transform dependency trees to aspect-specific forms by hand-crafted rules (Dong et al., 2014; Nguyen and Shirai, 2015; Wang et al., 2020) to improve the aspect sentiment classification performance. However, the tree structure is adjusted mainly by the node hierarchy, without optimizing dependency relations for ABSA.

In this paper, we explore a simple method to induce a discrete opinion tree structure automatically for each aspect. Two examples are shown in Figure 1. In particular, given a target and a sentence,

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics

our algorithm induces a tree structure recursively according to a set of attention scores, calculated using a neural layer on top of BERT representation of the sentence (Devlin et al., 2019). Starting with the root node, the algorithm builds a tree by selecting one child node on each side of a current node and recursively continue the partition process to obtain a binarized and lexicalized tree structure. The resulting tree serves as the input structure and is fed into graph convolutional networks (Kipf and Welling, 2017) for learning the sentiment classifier. We study policy-based reinforcement learning (Williams, 1992) to train the tree inducer. One challenge is that the generated policy can be easily remembered by the BERT encoder, which leads to insufficient explorations (Shi et al., 2019). To alleviate this issue, we propose a set of regularizers to help BERT-based policy generations.

Although our method is conceptually simple and straightforward for the inference stage, we show that it has a deep theoretic grounding. In particular, the attention based tree induction parsers trained using the policy network can be viewed as a simplified version to a standard latent tree structured VAE model (Kingma and Welling, 2014; Yin et al., 2018), where the KL divergence between the prior and the posterior tree probabilities is approximated by attention-based syntactic distance measures (Shen et al., 2018a).

Experiments on six English benchmarks, a Chinese hotel review dataset and a Korean automotive review dataset show the effectiveness of our proposed models. The discrete structure also makes it easy to interpret the classification results. In addition, our algorithm is faster, smaller and more accurate than a full variational latent tree variable model. To our knowledge, we are the first to learn aspect-specific discrete opinion tree structures with BERT. We make our code publicly available at `https://github.com/CCSoleil/dotGCN`.

2 Model

Figure 2 shows the architecture of our proposed model. Given an input sentence x and a specific aspect term a, we induce an opinion tree t according to a recognition network $Q_\phi(t|x,a)$, where ϕ is the set of network parameters. We apply multi-layered graph convolutional networks (GCNs) over the BERT output vectors to model the structural relations in the opinion tree and extract aspect-specific features. Finally, we use an attention-based classifier to learn the sentiment classifier $P_\theta(y|x,a,t)$, where θ is the set of parameters.

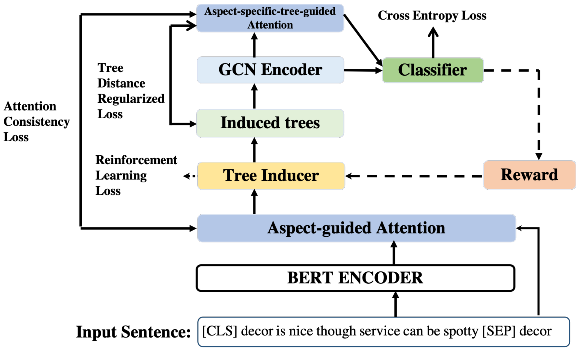

Figure 2: The model architecture.

To train the model, RL is used for $Q_\phi(t|x,a)$ (Section 2.3) and standard backpropagation is used for training $P_\theta(y|x,a,t)$ (Section 2.2).

2.1 Opinion Tree Based Classifier

Opinion Tree Denote the input sentence as $x = w_1 w_2 \dots w_n$ and the aspect as $a = w_b w_{b+1} \dots w_e$. $[b,e]$ is a continuous span of $[1,n]$. w_i is the i-th word. As shown in Figure 1, the opinion tree for a is a binarized tree. Each node contains a word span and at most two children. a is placed at the root node. Except for the root node, [1] each node contains only one word. An in-order traversal over t can recover the original sentence. Ideally, the nodes near the root node should contain the corresponding opinion words, such as "nice" for "decor" and "spotty" for "service".

Algorithm 1 shows the process of building an opinion tree t for a that conforms to the above conditions using a node score function $\mathbf{v}$, where $\mathbf{v}_i$ indicates the informative score of the i-th word contributing to the sentiment polarity y of a. $\mathbf{v}_i^j$ is the corresponding scores of words in the span $[i,j]$. We first make the aspect span $[b,e]$ as the root node and then build its left and right children from the spans $[1,b-1]$ and $[e+1,n]$, respectively. To build the left or right subtree, we first select the element with the largest score in the span as the root node of the subtrees and then recursively use the *build_tree* call for the corresponding span partitions.

Calculating v Following Song et al. (2019), we feed the inputs "[CLS] w_1 w_2 $\dots w_n$ [SEP] w_b $w_{b+1} \dots w_e$" to BERT[2] to obtain the aspect-specific sentence representation $\mathbf{H}$, and then calculate a set

---

[1] A case study in Appendix shows an example of a root node containing multiple words "grilled alaskan king salmon".

[2] To obtain word-level representations by BERT, we average the output vectors of the corresponding subword tokens.

```
Input: The scores $\mathbf{v}_1^n$, the aspect span $[b, e]$;
//build the root node ;
root ← new TreeNode;
root.words = $w_b w_{b+1} \dots w_e$; //$w_i$ is the $i$-th word.
root.left = build_tree ($\mathbf{v}_1^{b-1}$, 1, b-1);
root.right = build_tree($\mathbf{v}_{e+1}^n$, e+1, n);
build_tree($\mathbf{v}_i^j$, $i$, $j$):
    if $i > j$: return None;
    node ← new TreeNode;
    $k \leftarrow \arg\max_{k' \in [i,j]} \mathbf{v}_{k'}$;
    node.words = $w_k$;
    node.left = build_tree($\mathbf{v}_i^{k-1}$, $i$, $k-1$);
    node.right = build_tree($\mathbf{v}_{k+1}^j$, $k+1$, $j$);
    return node;
Output: $root$;
```

Algorithm 1: Aspect-specific construction algorithm given a scoring function $\mathbf{v}$.

of attention scores of the aspect words,

$$\mathbf{v}^p = \mathbf{u}_p \sigma(\mathbf{W}_p \mathbf{H} + \mathbf{W}_{a,p} \mathbf{h}_a),\ \mathbf{s}^p = \text{softmax}(\mathbf{v}^p), \quad (1)$$

where $\mathbf{u}_p$, $\mathbf{W}_p$ and $\mathbf{W}_{a,p}$ are model parameters, σ is the ReLU activation function, $\mathbf{h}_a$ is the aspect representation by sum pooling from $\mathbf{H}_b \mathbf{H}_{b+1} \dots \mathbf{H}_e$. ϕ in $Q_\phi(t|x, a)$ contains the model parameters of BERT, $\mathbf{u}_p$, $\mathbf{W}_p$ and $\mathbf{W}_{a,p}$.

Graph Representation Given t and $\mathbf{H}$, we use GCNs to learn the representation vectors for each word. We convert t to an undirected graph G. Specifically, we take each word as a node in G and design the adjacency matrix $\mathbf{A} \in \mathbb{R}^{n \times n}$ of G by considering four types of edges. First, we include self loops for each word. Second, we fully connect each word within the aspect term. Third, for the child node w_j of the root node, we link w_j to each word in a. Last, we consider edges in t between single word nodes except the root node. Formally, $\mathbf{A}$ is given by

$$\mathbf{A}_{i,j} = \begin{cases} 1 & \text{if } i = j, \ \ \text{(self-loops)} \\ 1 & \text{if } i \in (b, e) \text{ and } j \in (b, e), \ \ \text{(aspect words)} \\ 1 & \text{if } i \in [b, e] \text{ and } a \text{ is the parent node of } w_j \\ 1 & \text{if } w_i \text{ is the parent or a child node of } w_j \\ 0 & \text{otherwise.} \end{cases} \quad (2)$$

$\mathbf{A}$ is ensured to be symmetric by Eq 2.

We then use GCNs to capture the structured relations between word pairs, given the adjacency matrix $\mathbf{A}$ between nodes and the representation matrix of the $(l-1)$-th layer $\mathbf{H}^{l-1} \in \mathbb{R}^{n \times d}$, the l-th layer representation $\mathbf{H}^l$ given by a GCN is,

$$\mathbf{H}^l = f(\mathbf{A}\mathbf{H}^{l-1}\mathbf{W}^l + \mathbf{b}^l), \quad (3)$$

where f is an activation function (i.e., ReLU), $\mathbf{W}^l \in \mathbb{R}^{d \times d}$ and $\mathbf{b}^l \in \mathbb{R}^d$ are the model parameters for the l-th layer. The input to the first GCN layer $\mathbf{H}^0$ is $\mathbf{H}$ given by the sentence encoder.

Target Aspect Representation We consider both the representation vector of the "[CLS]" token ($\mathbf{H}^0_{cls}$) and the aspect vectors given by the last GCN layer ($\mathbf{H}^N_b, \mathbf{H}^N_{b+1} \dots, \mathbf{H}^N_e$) as the aspect-specific representation vector to query the input sentence representation $\mathbf{H}^0$. The final aspect-specific feature representation $\mathbf{c}$ over the input sentence representation is given by an attention layer,

$$\alpha_t = (\mathbf{H}^0_t)^T (\mathbf{H}^0_{cls} + \sum_{i=b}^{e} \mathbf{H}^N_i), \boldsymbol{\alpha} = \text{softmax}(\boldsymbol{\alpha}),\ \mathbf{c} = \boldsymbol{\alpha}\mathbf{H}^0, \quad (4)$$

where α_t is the attention scores of a to w_t, $\boldsymbol{\alpha}$ is the normalized scores and $\mathbf{c}$ is the final feature.

Output layers use $\mathbf{c}$ for computing the sentiment polarity scores. The final sentiment distribution is given by a softmax classifier,

$$\mathbf{p} = \text{softmax}(\mathbf{W}_c \mathbf{c} + \mathbf{b}_c), \quad (5)$$

where $\mathbf{W}_c$ and $\mathbf{b}_c$ are model parameters and $\mathbf{p}$ is the predicted distribution.

2.2 Training the Sentiment Classifier

Cross Entropy Loss The classifier is trained by maximizing the log-likelihood of the training samples. Formally, the objective is to minimize

$$\mathcal{L}_{\text{sup}} = -\sum_{i=1}^{|D|} \sum_{a \in x_i} \log \mathbf{p}_{i,y_a}, \quad (6)$$

where $|D|$ is the size of training data, y_a is the sentiment label of a in the i-th example x_i and $\mathbf{p}_{i,y_a}$ is the classification probability for a, which is given by Eq 5. The set of model parameters θ in $P_\theta(y|x, a, t)$ includes GCN blocks and the classifier parameters in Eq 5.

Tree Distance Regularized Loss Following Pouran Ben Veyseh et al. (2020), we introduce a syntax constraint to regularize the attention weights. Ideally, the words near to the root node should receive high attention weights. Given an opinion tree t, we compute the tree distance d_i for each word i using the length of the shortest path to the root. Given the distances and the attention scores $\boldsymbol{\alpha}$, we use the KL divergence to encourage the aspect term to attend the contexts with shorter distances.

$$\begin{aligned} \mathbf{td} &= \text{softmax}([-d_1, \dots, -d_i, \dots, -d_n]) \\ \mathcal{L}_{td} &= \text{KL}(\mathbf{td}, \boldsymbol{\alpha}), \end{aligned} \quad (7)$$

where td_i is the normalized tree distance and KL is the Kullback-Leibler (KL) divergence.

Backpropagation During training, we replace the argmax operator in Algorithm 1 with stochastic sampling to explore more discrete structures. Since the tree sampling process is a discrete decision making procedure, it is non-differentiable. The gradient can be propagated from $\mathcal{L}_{\text{sup}}$ in Eq 6 to t and θ, but can not be further propagated from t to ϕ. Therefore, we use the policy gradient given by REINFORCE (Williams, 1992) to optimize ϕ of the policy network (Section 2.3).

2.3 Training the Tree Inducer

Suppose that the reward function for a latent tree t is R_t, the goal of reinforcement learning is to minimize the negative expected reward function,

$$\mathcal{L}_{\text{rl}} = -\mathbb{E}_{Q_\phi(t|x,a)} R_t \tag{8}$$

For each t, we use the sentiment log-likelihood $\log P_\theta(y|x,t,a)$ as R_t. Using REINFORCE, the gradient of L_{rl} with respect to ϕ is,

$$\frac{\partial \mathcal{L}_{\text{rl}}}{\partial \phi} = -\mathbb{E}_{Q_\phi(t|x,a)}[R_t \frac{\partial \log Q_\phi(t|x,a)}{\partial \phi}] \tag{9}$$

$\log Q_\phi(t|x,a)$ is the log-likelihood of the generated sample t, which can be decomposed to a sum of log-likelihood at each tree-building step. According to Algorithm 1, each call of *build_tree*$(\mathbf{v}_i^j, i, j)$ involves selecting an action k from the span $[i,j]$ given the scores $\mathbf{v}_m^n$. The action space contains $j-i+1$ actions. The log-likelihood of this action is given by,

$$\log \pi_k = \log \frac{\exp(\mathbf{v}_k)}{\sum_{l=i}^{j} \exp(\mathbf{v}_l)}, \quad i \le k \le j. \tag{10}$$

In particular, we use $\mathbf{v}^p$ in Eq 1 as the score function $\mathbf{v}$. Enumerating all possible trees to calculate the expectation term in Eq 9 is intractable, and we use a Monte Carlo method (Rubinstein and Kroese, 2016), approximating the training objective by taking M samples,

$$\begin{aligned} &\mathbb{E}_{Q_\phi(t|x,a)}[R_t \frac{\partial \log Q_\phi(t|x,a)}{\partial \phi}] \\ &\approx \frac{1}{M} \sum_{i=1}^{M} R_{t_i} \frac{\partial \log Q_\phi(t_i|x,a)}{\partial \phi}. \end{aligned} \tag{11}$$

Attention Consistency Loss Instead of solely relying on the reinforced gradient to train the policy network, we also apply an attention consistency loss to directly supervise the policy network. Note that there are two attention scores in our model. The first is the attention score $\mathbf{s}^p$ defined in Eq 1, which is trained by the reinforcement learning algorithm. The second is the attention score $\boldsymbol{\alpha}$ defined in Eq 4 for extracting useful context features for the aspect-specific classifier. $\boldsymbol{\alpha}$ is trained via end-to-end back propagation. Intuitively, words that receive the largest attention scores should be effective opinion words of the target aspect. Therefore, it should be put closer to the root node by the policy network. To this end, we enforce a consistent regularization between the two attention scores so that polarity oriented attention $\boldsymbol{\alpha}$ can be directly used to supervise the scoring policy $\mathbf{s}^p$. Formally, $\mathcal{L}_{att}$ is given by,

$$\mathcal{L}_{att} = \text{KL}(\boldsymbol{\alpha}.\text{detach}(), \mathbf{s}^p), \tag{12}$$

where *detach* is a stop gradient operator.

Overall Loss Finally, the overall loss is given by

$$\mathcal{L} = \mathcal{L}_{sup} + \lambda_{rl}\mathcal{L}_{rl} + \lambda_{att}\mathcal{L}_{att} + \lambda_{td}\mathcal{L}_{td}, \tag{13}$$

where $\mathcal{L}_{sup}$ is the supervised loss, $\mathcal{L}_{rl}$ is the reinforcement learning loss, $\mathcal{L}_{att}$ is a novel attention consistency loss and $\mathcal{L}_{td}$ is a loss to guide the attention score distributions by tree constraints. λ_{rl}, λ_{att} andλ_{td} are hyper-parameters.

3 A Variational Inference Perspective

Interestingly, $\mathcal{L}_{sup}$, $\mathcal{L}_{rl}$ and $\mathcal{L}_{att}$ can be unified in a theoretic framework using variational inference (Kingma and Welling, 2014). We show in this section, that our method can be viewed as a stronger extension to a latent tree VAE model.

3.1 Variational Latent Tree Model

To model $P_\theta(y|x,a)$, we introduce a latent discrete structured variable t. Formally, the training objective is to minimize the negative log-likelihood,

$$\mathcal{L}_{\text{MLE}} = -\log P(y|x,a,\theta) = -\log \sum_t P_\theta(y,t|x,a), \tag{14}$$

Eq 14 calculates log-of-sum over all possible trees t, which is exponential. Eq 14 can be approximated by the evidence lower bound (ELBO) using variational parameters ϕ (Kingma and Welling, 2014; Yin et al., 2018),

$$\begin{aligned} \mathcal{L}_{\text{ELBO}} = &-\mathbb{E}_{q_\phi(t|x,y,a)}[\log P_\theta(y|x,a,t)] \\ &+ \text{KL}\Big(q_\phi(t|x,y,a), p_\theta(t|x,a)\Big), \end{aligned} \tag{15}$$

where $p_\theta(t|x,a)$ is the prior distribution for generating latent trees, $q_\phi(t|x,y,a)$ is the corresponding posterior distribution, $\log P_\theta(y|x,a,t)$ is the log-likelihood function by assuming that the latent tree t is already known, and $\mathbb{E}_{q_\phi(t|x,y,a)}[\log P_\theta(y|x,a,t)]$ is the expected log-likelihood function over $q_\phi(t|x,y,a)$ by considering all the potential trees. The KL term acts as a regularizer to force the matching of the prior and the posterior distributions. During training, $q_\phi(t|x,y,a)$ is used to induce the tree. For inference, $p_\theta(t|x,a)$ is used since y is still unknown.

In practice, a scale hyper-parameter β can be used to control the behaviour of the KL term (Bowman et al., 2016b),

$$\begin{aligned}\mathcal{L}_{\text{ELBO}} = &- \mathbb{E}_{q_\phi(t|x,y,a)}[\log P_\theta(y|x,a,t)] \\ &+ \beta \text{KL}\Big(q_\phi(t|x,y,a)||p_\theta(t|x,a)\Big).\end{aligned} \tag{16}$$

The first term is an **expectation term** and the second term is a **KL term**. Eq 16 is a standard VAE model for the ABSA task, which, however, has not been discussed in the research literature. It can be trained using the tree entropy (Kim et al., 2019b) and neural mutual information estimation (Fang et al., 2019). However, both are slow because they both need to consider a large batch of tree samples. To model $q_\phi(t|x,y,a)$, we instead calculate a score function $\mathbf{s}^q$ for the posterior by a MLP layer similar to Eq 1,

$$\mathbf{s}^q = \text{softmax}\Big(\mathbf{u}_q \sigma(\mathbf{W}_q \mathbf{H}' + \mathbf{W}_{a,q} \mathbf{h}'_a)\Big), \tag{17}$$

where $\mathbf{u}_q$, $\mathbf{W}_q$ and $\mathbf{W}_{a,q}$ are parameters, $\mathbf{H}'$ and $\mathbf{h}'_a$ are the posterior sentence and aspect representations respectively given y. To ensure that y can guide the encoder, we feed the input sequence together with y to BERT by using "[CLS] w_1 w_2 $\dots w_n$ [SEP] w_f w_{f+1} $\dots w_e$ y" to obtain $\mathbf{H}'$.

3.2 Correlation with Our Model

Our method can be regarded as a novel simplification to the above model, which can be shown by correlating the expectation term and the KL term defined in Eq 16 with the attention scores in Eq 1 and Eq 4, respectively. In particular, we consider converting t into a special type of tree distance, namely the aspect-to-context attention scores. Then we delegate the probability distribution over structured tree samples to a set of attention scores. Intuitively, if the attention scores are similar, the generated trees should be highly similar.

Approximate Expectation Term Considering the gradient of the first expectation term with respect to ϕ is,

$$\begin{aligned}&\frac{\partial \mathbb{E}_{q_\phi(t|x,y,a)}[\log P_\theta(y|x,a,t)]}{\partial \phi} \\ &= \mathbb{E}_{q_\phi(t|x,y,a)}[\log P_\theta(y|x,a,t)\frac{\partial \log q_\phi(t|x,y,a)}{\partial \phi}].\end{aligned} \tag{18}$$

Assuming that the posterior $q_\phi(t|x,y,a)$ is approximate to $Q_\phi(t|x,a)$ given by the recognition network, Eq 18 is equivalent to $\mathcal{L}_{\text{rl}}$ in Eq 11.

Approximate KL Term The KL term resembles $\mathcal{L}_{att}$ in Eq 12 for $\beta = \lambda_{att}$, namely $\text{KL}\Big(q_\phi(t|x,y,a)||p_\theta(t|x,a)\Big) \approx \text{KL}(\boldsymbol{\alpha}, \mathbf{s}^p)$. First, we delegate the probability distribution over tree samples to a set of attention scores. In particular, we use $\mathbf{s}^p$ and $\mathbf{s}^q$ as the proxies for $p_\theta(t|x,a)$ and $q_\phi(t|x,y,a)$, respectively. This is equivalent to say that the posterior scores $\mathbf{s}^q$ and the prior score $\mathbf{s}^p$ are fed to Algorithm 1 to derive the corresponding trees during training. Second, since both $\mathbf{s}^q$ and the attention score $\boldsymbol{\alpha}$ in Eq 4 are directly supervised by the output label y, we can safely assume that $\mathbf{s}^q \approx \boldsymbol{\alpha}$. Then the KL term $\text{KL}(\mathbf{s}^q, \mathbf{s}^p)$ in Eq 16 becomes $\text{KL}(\boldsymbol{\alpha}, \mathbf{s}^p)$, which is the attention-based regularization loss defined in Eq 12.

4 Experiments

We perform experiments on eight aspect-based sentiment analysis benchmarks, including six English datasets, one Chinese dataset, and one Korean datase. The data statistics is shown in Appendix A.3. We use Stanza (Qi et al., 2020) as the external parser to produce dependency parses for comparing with dependency tree based models, reporting accuracy (Acc.) and macro-f1 (F1) scores for each model. More details are presented in Appendix A.1.

MAMS Jiang et al. (2019) provide a recent challenge dataset with 4,297 sentences and 11,186 aspects. We take it as the main dataset because it is a large-scale multi-aspect dataset with more aspects in each sentence compared to the other datasets. MAMS-small is a small version of MAMS.

Chinese hotel reviews dataset Liu et al. (2020) provide manually annotated 6,339 targets and 2,071 items for multi-target sentiment analysis.

Korean automotive comments dataset Hyun et al. (2020) provide a dataset with 30,032 comment-aspect pairs in Korean.

SemEval datasets We use five SemEval datasets, including twitter posts (`Twitter`) from Dong et al. (2014), laptop comments (`Laptop`) provided

by Pontiki et al. (2014), restaurant reviews of SemEval 2014 task 4 (`Rest14`; Pontiki et al. 2014), SemEval 2015 task 12 (`Rest15`; Pontiki et al. 2015) and SemEval 2016 task 5 (`Rest16`; Pontiki et al. 2016). These datasets are pre-processed following Tang et al. (2016) and Zhang et al. (2019).

4.1 Baselines

We denote our model as `dotGCN` (**d**iscrete **o**pinion **t**ree GCN), making comparisons with BERT-based models, including models without using trees and dependency tree based models. In addition, the variational inference baseline (Section 3.1) is denoted as **viGCN**. Baselines are (1) **BERT-SPC** is a simple baseline by fine-tuning the vector of "[CLS]" of BERT from Jiang et al. (2019); (2) **AEN**. Song et al. (2019) use an attentional encoder with BERT; (3) **CapsNet**. Jiang et al. (2019) combine capsule network with BERT; (4) **Hard-Span**. Hu et al. (2019) use RL to determine aspect-specific opinion spans; (5) **depGCN**. Zhang et al. (2019) applies aspect-specific GCNs over dependency trees; (6) **RGAT**. Wang et al. (2020) use relational graph attention networks over aspect-centered dependency trees to incorporate the dependency edge type information; (7) **SAGAT**. Huang et al. (2020) use graph attention network and BERT, exploring both syntax and semantic information in the sequence; (8) **DGEDT**. Tang et al. (2020) jointly consider BERT outputs and dependency tree based representations by a bidirectional GCN. (9) **kumaGCN**. Chen et al. (2020) combine the dependency trees and latent graphs induced by self-attention neural networks;

4.2 Development Results

We perform development experiments using MAMS since this is the largest dataset and the examples are more challenging compared to the other datasets. We implement three baselines, including BERT-SPC, depGCN and kumaGCN. For fair comparison, we also combine depGCN and kumaGCN with the syntax regularization loss in Eq 7 by calculating syntactic distances on the input dependency trees with respect to the aspect terms.

Table 1 shows the results on MAMS validation-set. BERT-SPC achieves 84.08 accuracy and 83.52 F1. Surprisingly, the dependency tree based models cannot outperform BERT-SPC, which verifies the limitation of using cross-domain dependency parsers for this task. kumaGCN outperforms depGCN due to its ability to include an implicit latent graph. Adding the syntax regularization loss generally improves the model performance of syntax-based models. In particular, kumaGCN + $\mathcal{L}_{\text{td}}$ is on par with BERT-SPC.

viGCN outperforms kumaGCN + $\mathcal{L}_{\text{td}}$ and depGCN + $\mathcal{L}_{\text{td}}$, which shows the potential of structured latent tree models. Our dotGCN model achieves 84.53 accuracy and 83.97 F1, outperforming all the baselines by a large margin, which empirically shows the induced discrete opinion tree is promising to this task. Compared to viGCN, our model gives better scores. In addition, our model converges nearly 1.8 times faster (0.66h/epoch v.s. 1.25h/epoch) than viGCN. dotGCN does not have to calculate the true posterior distribution over structured tree samples and thus largely reduce computation overhead.

Ablation Study Table 1 shows ablation studies on MAMS validation set by removing three proposed loss items during training, namely $\mathcal{L}_{\text{td}}$, $\mathcal{L}_{\text{rl}}$ and $\mathcal{L}_{\text{att}}$. We can observe that the model performance degrades after removing either one of them. Removing the syntax regularization loss $\mathcal{L}_{\text{td}}$ slightly hurts the performance. Without using the attention consistency loss $\mathcal{L}_{\text{att}}$, the model falls behind BERT-SPC, which suggests the importance of our proposed attention consistency regularizations. Excluding the reinforcement learning loss leads to the

biggest performance drop (Acc: $84.53 \rightarrow 83.48$) among the three settings. This shows that the reinforcement learning component plays a central role in the full model.

4.3 Main Results

MAMS Table 2 shows the results of dotGCN and the baselines from Jiang et al. (2019) on the MAMS test set. We implement BERT-SPC, denoted as BERT-SPC*, which outperforms the BERT-SPC model of Jiang et al. (2019). Compared to baselines (BERT-SPC, CapsNet, CapsNet-DR and BERT-SPC*) without using dependency trees, dotGCN gives significantly better results ($p < 0.01$). For fair comparison with dependency tree based models, we also implement depGCN+$\mathcal{L}_{\text{td}}^*$ and kumaGCN+$\mathcal{L}_{\text{td}}^*$. depGCN+$\mathcal{L}_{\text{td}}^*$ achieves 84.36 accuracy and 83.88 F1 on the MAMS test set. kumaGCN+$\mathcal{L}_{\text{td}}^*$ gives similar results with 84.37 accuracy and 83.83 F1. Our dotGCN outperforms all the baselines, giving 84.95 accuracy and 84.44 F1. In terms of the averaged accuracy of F1 scores on MAMS and MAMS-small, dotGCN is significantly better than depGCN and kumaGCN ($p < 0.05$). The results demonstrate that the induced aspect-specific discrete opinion trees are promising to handle multi-aspect sentiment tasks.

Multilingual The results[3] on the Chinese hotel review dataset are shown in Table 2. dotGCN outperforms the baseline BERT-SPC* by 0.72 accuracy points and 0.61 F1, respectively. The result shows that our model can be generalized across languages without relying on language-specific parsers. On the Korean dataset, we obtain 5.20 accuracy and 11.61 F1 improvements compared to the LCF-BERT (Zeng et al., 2019), which is the best BERT-based model. These results show that our model can be well generalized to multiple languages and may potentially benefits low-resource languages for this task.

Model	Laptops	Restaurants
BERT-SPC	74.57	82.66
Soft-Span	74.92	82.68
Hard-Span	74.10	83.91
dotGCN	**76.65**	**84.11**

Table 4: Comparisons with span-based RL.

SemEval Table 3 shows the results of our model on the SemEval datasets. First, tree based graph neural network models are generally better than BERT-SPC. On the five datasets, which are relatively small, our model still achieves competitive performances in terms of the averaged F1 and accuracy scores as shown in Table 3. In particular, our model in general outperforms depGCN and depGCN + $\mathcal{L}_{\text{td}}^*$ on four out of five datasets, which verifies that the reinforced discrete opinion trees can be promising structured representations compared to auto-parsed dependency trees.

We also compare our models with span-based reinforcement learning models (Hard-Span; Hu et al. (2019)) on the dataset of laptops and restaurants preprocessed by Tay et al. (2018). As shown in Table 4, our model outperforms Hard-Span by 2.55 accuracy points on laptops[4]. On restaurants, our model achieves a comparable result to Hard-Span. It shows that the opinion tree is a better representation compared to an opinion span.

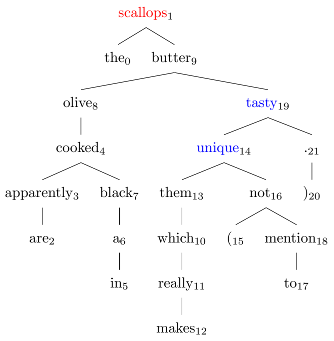
4.4 Case Study

Figure 3a and Figure 3b show the induced tree and dependency parse for the aspect term “scallops”, respectively. The opinion words “unique” and “tasty”

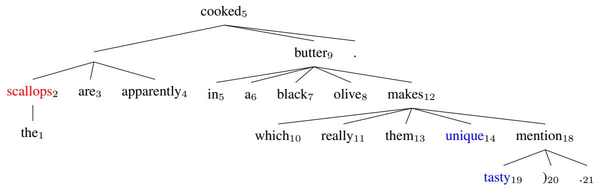
---

[3] Since the Hotel dataset is based on Chinese characters, there are no annotated words. To avoid character-level dependency parsing, we omit them in Table 2 for consistency.

[4] Since the code of span-based RL methods is not publicly available, we do not include a significant test here.



(a) An induced tree for long-term dependencies.



(b) The corresponding dependency tree by Stanza.

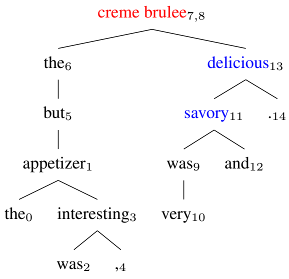
Figure 3: Tree examples. *red*: aspect, *blue*: opinions, *number*: word index. The sentence is "the **scallops** are apparently cooked in a black olive butter which really makes them unique (not to mention tasty) ."

are far away from the aspect (more than 10 words) in the dependency tree. In the induced tree by dotGCN, the opinion word "tasty" and "unique" are 2 and 3 depths from the aspect "scallops" respectively, which shows that dotGCN can potentially handle complex interactions among aspects and opinion contexts. In addition, the tree induced by dotGCN is binarized, and the root node can contain multiple words as shown in Figure 4a.

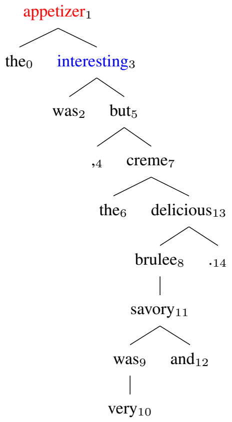
Figure 4a and Figure 4b show the induced trees for two aspect terms with different sentiment polarities. For "creme brulee", the policy network assigns high weights to both "delicious" and "savory". Interestingly, it assigns a higher weight to "delicious" than "savory", though "savory" is closer to its aspect term than "delicious". For "appetizer", the word "interesting" receives higher attention scores than the other two sentiment words. These results show that dotGCN is able to distinguish different sentiment contexts for different aspect terms in the same sentence.

4.5 Analysis

Distances between Aspect Terms and Opinion Words Figure 5 shows the distances between aspect terms and opinion words. We use the annotated opinion words of Rest16 provided by Fan et al. (2019) to compare our induced trees and dependency trees. The distances calculated over the original sequences are also included. We can observe



(a) An induced tree for "creme brulee".



(b) An induced tree for "appetizer".

Figure 4: Tree examples. The sentence is "the **appetizer** was interesting , but the **creme brulee** was very savory and delicious ."

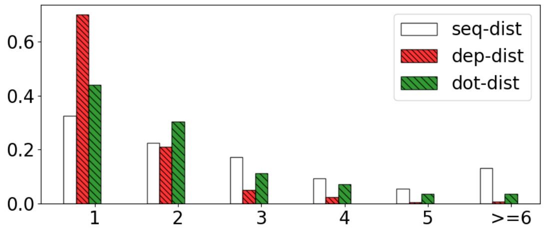


Figure 5: Distances between aspect terms and opinion words. *seq*: sequential structure; *dep*: dependency tree, *dot* denotes our discrete opinion tree.

that the distance distribution over the sequences is relatively flat compared to that over tree structures. For the two tree structures, nearly 90% of opinion words are within 3 depths from the aspect terms. The distance distribution of our induced trees is similar to that of the dependency trees, which empirically demonstrates that induced discrete trees are able to capture the interactions between aspect terms and opinions. By treating dependency trees as gold standard, our tree inducer obtains 35.4% unlabeled attachment scores (UAS), which shows the induced trees are significantly different from the dependency trees although both can connect opinion words with aspect terms.

Low frequent aspects Table 5 shows the classifi-

Frequency	depGCN+$\mathcal{L}^*_{td}$	dotGCN
0	81.96	**83.53** (+1.57)
1	74.63	74.63
>=2	85.60	86.29

Table 5: Classification accuracy of test set with respect to the frequency of aspects in training set using MAMS.

cation accuracy of the MAMS test set with respect to the aspect frequency. For aspect terms which appear in the training corpus, both methods give similar results. However, for unseen aspects, dotGCN gives better results than depGCN. This is potentially due to the severe parsing errors for the low-frequent aspects. dotGCN does not depend on external parsers and thus can circumvent this problem. It empirically suggests that the induced tree structures have strong robustness for capturing the aspect-opinion interactions compared to depGCN.

5 Related Work

Tree Induction for ABSA There has been much work on unsupervised discrete induction (Bowman et al., 2016a; Shen et al., 2018b; Kim et al., 2019b,a; Jin et al., 2019; Cao et al., 2020; Yang et al., 2021; Dai et al., 2021), which aims to obtain general constituent trees without explicit syntax annotations and task-dependent supervised signals. We focus on learning task-specific tree-structures for ABSA, where the tree is fully binarized and lexicalized. Choi et al. (2018) propose Gumbel Tree-LSTM for learning task-specific tree for semantic compositions. Similarly, Maillard et al. (2019) propose an unsupervised chart parser for jointly learning sentence embeddings and syntax. However, they focus on sentence-level tasks and do not consider aspect information.

Aspect-level Sentiment Classification Much recent work has explored neural attention mechanism to this task (Tang et al., 2016; Ma et al., 2017; Li et al., 2018; Liang et al., 2019). Among tree-based methods, Zhang et al. (2019) and Sun et al. (2019b) encode dependency tree using GCN for aspect-level sentiment analysis; Zhao et al. (2019) use GCN to model fully connected graphs between aspect terms; Wang et al. (2020) use relational graph attention networks to incorporate the dependency edge type information, and construct aspect-specific graph structures; Barnes et al. (2021) attempt to directly predict dependency-based sentiment graphs. Tang et al. (2020) use duel-transformer structure to enhance the dependency graph for this task. Our work is similar in that we also consider the structure dependencies, but different in that we rely on automatically induced tree structures instead of external parses. Chen et al. (2020) propose to induce aspect-specific latent graph by sampling from self-attention-based Hard Kumaraswamy distributions (Bastings et al.). However, to achieve competitive performance, their method still requires a combination of external dependency parse trees and the induced latent graphs.

Sun et al. (2019a) and Xu et al. (2019) constructed aspect related auxiliary sentences as inputs to BERT (Devlin et al., 2019) for strong contextual encoders. Xu et al. (2019) proposed BERT-based post training for enhancing domain-specific contextual representations for aspect sentiment analysis. Our work shares a similar feature extraction approach, but differently we focus on inducing latent trees for ABSA.

6 Conclusion

We proposed a method to induce aspect-specific discrete opinion trees for aspect-based sentiment analysis, obtaining trees by viewing aspect-to-context attention scores as syntactic distances. The attention scores are trained using both RL and a novel attention-based regularization. Our model empirically achieves competitive performance compared with dependency tree based models, while being independent of parsers. We also provide a theoretic view of our method using variational inference.

A Appendix

A.1 Settings

Our codes are implemented based on the PyTorch Transformers library (Wolf et al., 2020). We use *bert-based-uncased*[5] for English, *bert-base-chinese*[6] for Chinese, *bert-base-multilingual-uncased*[7] for Korean. We tune the hyper-parameters on the MAMS dataset. We select the best model according to the accuracy scores on the development set. For each model, we train it 10 epochs with the Adam optimizer (Kingma and Ba, 2014). The initial learning rate for fine-tuning BERT parameters is $2e^{-5}$ and the weight decay is $1e^{-5}$. The number of GCN layers is 2 by following Zhang et al. (2019). The hidden size of the MLP layer in Eq 1 is 256. For the policy network training, we generate $M = 3$ trees. $\lambda_{rl} = \lambda_{att} = \lambda_{sd} = 0.1$. For the variational inference model, $\beta = 0.05$. We try five options for these hyper-parameters ($\lambda_{rl}, \lambda_{att}, \lambda_{sd}$) including 0, 0.01, 0.05, 0.1 and 0.2. We report accuracy (Acc.) and macro-f1 (F1) scores for each model. For the other settings about neural network architectures and reinforcement learning, we follow Zhang et al. (2019) and Shi et al. (2019), respectively.

We run our models using a single GPU Card (TitanXP 1080ti or Titan XP 2080 or V100). Each training epoch for MAMS taskes about 40 mins.

A.2 Statistics of Tay et al. (2018)'s dataset

We compare our discrete opinion tree RL model with span-based RL model on a dataset preprocessed by Tay et al. (2018). Table 6 shows the statistics.

Abstract

Thanks to the strong representation power of neural encoders, neural chart-based parsers have achieved highly competitive performance by using local features. Recently, it has been shown that non-local features in CRF structures lead to improvements. In this paper, we investigate injecting non-local features into the training process of a local span-based parser, by predicting constituent n-gram non-local patterns and ensuring consistency between non-local patterns and local constituents. Results show that our simple method gives better results than the self-attentive parser on both PTB and CTB. Besides, our method achieves state-of-the-art BERT-based performance on PTB (95.92 F1) and strong performance on CTB (92.31 F1). Our parser also achieves better or competitive performance in multilingual and zero-shot cross-domain settings compared with the baseline.

1 Introduction

Constituency parsing is a fundamental task in natural language processing, which provides useful information for downstream tasks such as machine translation (Wang et al., 2018), natural language inference (Chen et al., 2017), text summarization (Xu and Durrett, 2019). Over the recent years, with advance in deep learning and pre-training, neural chart-based constituency parsers (Stern et al., 2017a; Kitaev and Klein, 2018) have achieved highly competitive results on benchmarks like Penn Treebank (PTB) and Penn Chinese Treebank (CTB) by solely using local span prediction.

The above methods take the contextualized representation (e.g., BERT) of a text span as input, and use a local classifier network to calculate the scores of the span being a syntactic constituent, together with its constituent label. For testing, the output layer uses a non-parametric dynamic programming algorithm (e.g., CKY) to find the highest-scoring tree. Without explicitly modeling structured dependencies between different constituents, the methods give competitive results compared to non-local discrete parsers (Stern et al., 2017a; Kitaev and Klein, 2018). One possible explanation for their strong performance is that the powerful neural encoders are capable of capturing implicit output correlation of the tree structure (Stern et al., 2017a; Gaddy et al., 2018; Teng and Zhang, 2018).

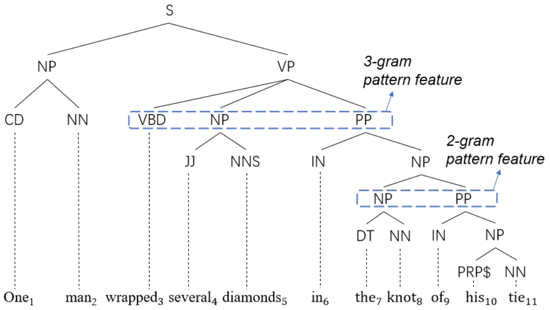

Figure 1: An example of the non-local n-gram *pattern* features: the 3-gram pattern $(3, 11, \{$`VBD NP PP`$\})$ is composed of two constituent nodes and one part-of-speech node; the 2-gram pattern $(7, 11, \{$`NP PP`$\})$ is composed of two constituent nodes.

Recent work has shown that modeling non-local output dependencies can benefit neural structured prediction tasks, such as NER (Ma and Hovy, 2016), CCG supertagging (Cui and Zhang, 2019) and dependency parsing (Zhang et al., 2020a). Thus, an interesting research question is whether injecting non-local tree structure features is also beneficial to neural chart-based constituency parsing. To this end, we introduce two auxiliary training objectives. The first is *Pattern Prediction*. As shown in Figure 1, we define *pattern* as the n-gram constituents sharing the same parent.[1] We ask the model to predict the pattern based on its span representation, which directly injects the non-local

constituent tree structure to the encoder.

To allow stronger interaction between non-local patterns and local constituents, we further propose a *Consistency* loss, which regularizes the co-occurrence between constituents and patterns by collecting corpus-level statistics. In particular, we count whether the constituents can be a sub-tree of the pattern based on the training set. For instance, both `NNS` and `NP` are legal to occur as sub-trees of the 3-gram pattern {`VBD` `NP` `PP`} in Figure 1, while `S` or `ADJP` cannot be contained within this pattern based on grammar rules. Similarly, for the 2-gram pattern {`NP` `PP`} highlighted in Figure 1, both `IN` and `NP` are consistent constituents, but `JJ` is not. The *Consistency* loss can be considered as injecting prior linguistic knowledge to our model, which forces the encoder to understand the grammar rules. Non-local dependencies among the constituents that share the same pattern are thus explicitly modeled. We denote our model as Injecting **N**on-local **F**eatures for neural **C**hart-based parsers (NFC).

We conduct experiments on both PTB and CTB. Equipped with BERT, NFC achieves 95.92 F1 on PTB test set, which is the best reported performance for BERT-based single-model parsers. For Chinese constituency parsing, NFC achieves highly competitive results (92.31 F1) on CTB, outperforming the baseline self-attentive parser (91.98 F1) and a 0-th order neural CRF parser (92.27 F1) (Zhang et al., 2020b). To further test the generalization ability, we annotate a multi-domain test set in English, including dialogue, forum, law, literature and review domains. Experiments demonstrate that NFC is robust in zero-shot cross-domain settings. Finally, NFC also performs competitively with other languages using the SPMRL 2013/2014 shared tasks, establishing the best reported results on three rich resource languages. We release our code and models at `https://github.com/RingoS/nfc-parser`.

2 Related Work

Constituency Parsing. There are mainly two lines of approaches for constituency parsing. Transition-based methods process the input words sequentially and construct the output constituency tree incrementally by predicting a series of local transition actions (Zhang and Clark, 2009; Cross and Huang, 2016; Liu and Zhang, 2017). For these methods, the sequence of transition actions make traversal over a constituent tree. Although transition-based methods directly model partial tree structures, their local decision nature may lead to error propagation (Goldberg and Nivre, 2013) and worse performance compared with methods that model long-term dependencies (McDonald and Nivre, 2011; Zhang and Nivre, 2012). Similar to transition-based methods, NFC also directly models partial tree structures. The difference is that we inject tree structure information using two additional loss functions. Thus, our integration of non-local constituent features is implicit in the encoder, rather than explicit in the decoding process. While the relative effectiveness is empirical, it could potentially alleviate error propagation.

Chart-based methods score each span independently and perform global search over all possible trees to find the highest-score tree given a sentence. Durrett and Klein (2015) represented nonlinear features to a traditional CRF parser computed with a feed-forward neural network. Stern et al. (2017b) first used LSTM to represent span features. Kitaev and Klein (2018) adopted a self-attentive encoder instead of the LSTM encoder to boost parser performance. Mrini et al. (2020) proposed label attention layers to replace self-attention layers. Zhou and Zhao (2019) integrated constituency and dependency structures into head-driven phrase structure grammar. Tian et al. (2020) used span attention to produce span representation to replace the subtraction of the hidden states at the span boundaries. Despite their success, above work mainly focuses on how to better encode features over the input sentence. In contrast, we take the encoder of Kitaev and Klein (2018) intact, being the first to explore new ways to introduce non-local training signal into the local neural chart-based parsers.

Modeling Label Dependency. There is a line of work focusing on modeling non-local output dependencies. Zhang and Zhang (2010) used a Bayesian network to encode the label dependency in multi-label learning. For neural sequence labeling, Zhou and Xu (2015) and Ma and Hovy (2016) built a CRF layer on top of neural encoders to capture label transition patterns. Pislar and Rei (2020) introduced a sentence-level constraint to encourage the model to generate coherent NER predictions. Cui and Zhang (2019) investigated label attention network to model the label dependency by producing label distribution in sequence labeling tasks. Gui et al. (2020) proposed a two-stage label decoding framework based on Bayesian network to model long-term label dependencies. For syntactic parsing, Zhang et al. (2020b) demonstrated that structured Tree CRF can boost parsing performance over graph-based dependency parser. Our work is in line with these in the sense that we consider non-local structure information for neural structure prediction. To our knowledge, we are the first to inject sub-tree structure into neural chart-based encoders for constituency parsing.

3 Baseline

Our baseline is adopted from the parsing model of Kitaev and Klein (2018) and Kitaev et al. (2019). Given a sentence $X = \{x_1, ..., x_n\}$, its corresponding constituency parse tree T is composed by a set of labeled spans

$$T = \{(i_t, j_t, l_t^{\mathrm{c}})\}|_{t=1}^{|T|} \tag{1}$$

where i_t and j_t represent the t-th constituent span's fencepost positions and l_t^{c} represents the constituent label. The model assigns a score $s(T)$ to tree T, which can be decomposed as

$$s(T) = \sum_{(i,j,l)\in T} s(i, j, l^{\mathrm{c}}) \tag{2}$$

Following Kitaev et al. (2019), we use BERT with a self-attentive encoder as the scoring function $s(i, j, \cdot)$, and a chart decoder to perform a global-optimal search over all possible trees to find the highest-scoring tree given the sentence. In particular, given an input sentence $X = \{x_1, ..., x_n\}$, a list of hidden representations $\mathbf{H}_1^n = \{\mathbf{h}_1, \mathbf{h}_2, \ldots, \mathbf{h}_n\}$ is produced by the encoder, where $\mathbf{h}_i$ is a hidden representation of the input token x_i. Following previous work, the representation of a span (i, j) is constructed by:

$$\mathbf{v}_{i,j} = \mathbf{h}_j - \mathbf{h}_i \tag{3}$$

Finally, $\mathbf{v}_{i,j}$ is fed into an MLP to produce real-valued scores $s(i, j, \cdot)$ for all constituency labels:

$$s(i, j, \cdot) = \mathbf{W}_2^{\mathrm{c}}\text{ReLU}(\mathbf{W}_1^{\mathrm{c}}\mathbf{v}_{i,j} + \mathbf{b}_1^{\mathrm{c}}) + \mathbf{b}_2^{\mathrm{c}} \tag{4}$$

where $\mathbf{W}_1^{\mathrm{c}}$, $\mathbf{W}_2^{\mathrm{c}}$, $\mathbf{b}_1^{\mathrm{c}}$ and $\mathbf{b}_2^{\mathrm{c}}$ are trainable parameters, $\mathbf{W}_2^{\mathrm{c}} \in \mathbb{R}^{|H|\times|L^{\mathrm{c}}|}$ can be considered as the constituency label embedding matrix (Cui and Zhang, 2019), where each column in $\mathbf{W}_2^{\mathrm{c}}$ corresponds to the embedding of a particular constituent label. $|H|$ represents the hidden dimension and $|L^{\mathrm{c}}|$ is the size of the constituency label set.

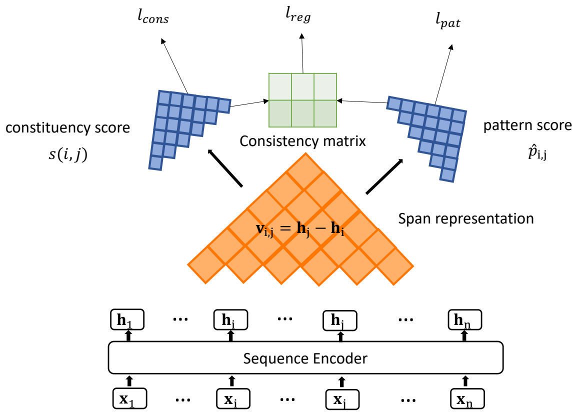

Figure 2: The three training objectives in NFC.

Training. The model is trained to satisfy the margin-based constraints

$$s(T^*) \geq s(T) + \Delta(T, T^*) \tag{5}$$

where T^* denotes the gold parse tree, and Δ is Hamming loss. The hinge loss can be written as

$$\mathcal{L}_{\text{cons}} = \max\left(0, \max_{T\neq T^*}[s(T) + \Delta(T, T^*)] - s(T^*)\right) \tag{6}$$

During inference time, the most-optimal tree

$$\hat{T} = \operatorname*{argmax}_T s(T) \tag{7}$$

is obtained using a CKY-like algorithm.

4 Additional Training Objectives

We propose two auxiliary training objectives to inject non-local features into the encoder, which rely only on the annotations in the constituency treebank, but not external resources.

4.1 Instance-level Pattern Loss

We define n-gram constituents, which shares the same parent node, as a pattern. We use a triplet $(i^{\mathrm{p}}, j^{\mathrm{p}}, l^{\mathrm{p}})$ to denote a pattern span beginning from the i^{p}-th word and ending at j^{p}-th word. l^{p} is the corresponding pattern label. Given a constituency parse tree in Figure 1, $(3, 11, \{$`VBD NP PP`$\})$ is a 3-gram pattern.

Similar to Eq 4, an MLP is used for transforming span representations to pattern prediction probabilities:

$$\hat{p}_{i,j} = \text{Softmax}\left(\mathbf{W}_2^{\mathrm{p}}\text{ReLU}(\mathbf{W}_1^{\mathrm{p}}\mathbf{v}_{i,j} + \mathbf{b}_1^{\mathrm{p}}) + \mathbf{b}_2^{\mathrm{p}}\right) \tag{8}$$

where $\mathbf{W}_1^{\mathrm{p}}$, $\mathbf{W}_2^{\mathrm{p}}$, $\mathbf{b}_1^{\mathrm{p}}$ and $\mathbf{b}_2^{\mathrm{p}}$ are trainable parameters, $\mathbf{W}_2^{\mathrm{p}} \in \mathbb{R}^{|H|\times|L^{\mathrm{p}}|}$ can be considered as the pattern label embedding matrix, where each column in $\mathbf{W}_2^p$ corresponds to the embedding of a particular pattern label. $|L^{\mathrm{p}}|$ represents the size of the pattern label set. For each instance, the cross-entropy loss between the predicted patterns and the gold patterns are calculated as

$$\mathcal{L}_{pat} = -\sum_{i=1}^{n}\sum_{j=1}^{n} p_{i,j} \log \hat{p}_{i,j} \tag{9}$$

We use the span-level cross-entropy loss for patterns (Eq 9) instead of the margin loss in Eq 6, because our pattern-prediction objective aims to augment span representations via greedily classifying each pattern span, rather than to reconstruct the constituency parse tree through dynamic programming.

4.2 Corpus-level Consistency Loss

Constituency scores and pattern probabilities are produced based on a shared span representation; however, the two are subsequently separately predicted. Therefore, although the span representations contain both constituent and pattern information, the dependencies between constituent and pattern predictions are not explicitly modeled. Intuitively, constituents are distributed non-uniformly in patterns, and such correlation can be obtained in the corpus-level statistic. We propose a consistency loss, which explicitly models the non-local dependencies among constituents that belong to the same pattern. As mentioned in the introduction, we regard all constituent spans within a pattern span as being consistent with the pattern span. Take 2-gram patterns for example, which represents two neighboring subtrees covering a text span. The constituents that belong to the two subtrees, including the top constituent and internal sub constituents, are considered as being consistent. We consider only the constituent labels but not their corresponding span locations for this task.

This loss can be understood first at the instance level. In particular, if a constituent span $(i_t, j_t, l_t^{\mathrm{c}})$ is a subtree of a pattern span $(i_{t'}, j_{t'}, l_{t'}^{\mathrm{p}})$, i.e. $i_t >= i_{t'}$ and $j_t <= j_{t'}$, where $l_t^{\mathrm{c}} = L^{\mathrm{c}}[a]$ (the a-th constituent label in L^{c}) and $l_{t'}^{\mathrm{p}} = L^{\mathrm{p}}[b]$ (the b-th pattern label in L^p), we define $L^{\mathrm{c}}[a]$ and $L^{\mathrm{p}}[b]$ to be *consistent* (denoted as $y_{a,b} = 1$). Otherwise we consider it to be *non-consistent* (denoted as $y_{a,b} = 0$). This yields a consistency matrix $\mathbf{Y} \in \mathbb{R}^{|L^c| \times |L^{\mathrm{p}}|}$ for each instance. The gold consistency matrix $\mathbf{Y}$ provides information regarding non-local dependencies among constituents and patterns.

An intuitive method to predict the consistency matrix $\mathbf{Y}$ is to make use of the constituency label embedding matrix $\mathbf{W}_2^{\mathrm{p}}$ (see Eq 4 for definition), the pattern label embedding matrix $\mathbf{W}_2^{\mathrm{c}}$ (see Eq 8 for definition) and the span representations $\mathbf{V}$ (see Eq 3 for definition):

$$\hat{\mathbf{Y}} = \mathrm{Sigmoid}\big((\mathbf{W}_2^{\mathrm{c}\top}\mathbf{U}_1\mathbf{V})(\mathbf{V}^{\top}\mathbf{U}_2\mathbf{W}_2^{\mathrm{p}})\big) \tag{10}$$

where $\mathbf{U}_1, \mathbf{U}_2 \in \mathbb{R}^{|H| \times |H|}$ are trainable parameters.

Intuitively, the left term, $\mathbf{W}_2^{\mathrm{c}\top}\mathbf{U}_1\mathbf{V}$, integrates the representations of the pattern span and all possible constituent label embeddings. The second term, $\mathbf{V}^{\top}\mathbf{U}_2\mathbf{W}_2^{\mathrm{p}}$, integrates features of the span and all pattern embeddings. Each binary element in the resulting $\hat{\mathbf{Y}} \in \mathbb{R}^{|L^c| \times |L^p|}$ denotes whether a particular constituent label is consistent with a particular pattern in the given span context. Eq 10 can be predicted on the instance-level for ensuring consistency between patterns and constituent. However, this naive method is difficult for training, and computationally infeasible, because the span representation matrix $\mathbf{V} \in \mathbb{R}^{|H| \times n^2}$ is composed of n^2 span representations $\mathbf{v}_{i,j} \in \mathbb{R}^{|H|}$ and the asymptotic complexity is:

$$O\Big((|L^{\mathrm{p}}| + |L^{\mathrm{c}}|)(|H|^2 + n^2|H|) + |L^{\mathrm{p}}||L^{\mathrm{c}}|n^2\Big) \tag{11}$$

for a single training instance.

We instead use a corpus-level constraint on the non-local dependencies among constituents and patterns. In this way, Eq 10 is reduced to be independent of individual span representations:

$$\hat{\mathbf{Y}} = \mathrm{Sigmoid}\big(\mathbf{W}_2^{\mathrm{c}}\mathbf{U}\mathbf{W}_2^{\mathrm{p}\top}\big) \tag{12}$$

where $\mathbf{U} \in \mathbb{R}^{|H| \times |H|}$ is trainable.

This trick decreases the asymptotic complexity to $O(|L^{\mathrm{c}}||H|^2 + |L^{\mathrm{p}}||L^{\mathrm{c}}||H|)$. The cross-entropy loss between the predicted consistency matrix and gold consistency labels is used to optimize the model:

$$\mathcal{L}_{reg} = -\sum_{a=1}^{|L^{\mathrm{c}}|}\sum_{b=1}^{|L^{\mathrm{p}}|} y_{a,b} \log \hat{y}_{a,b} \tag{13}$$

The corpus-level constraint can be considered as a prior linguistic knowledge statistic from the treebank, which forces the encoder to understand the grammar rules.

Table 1: Dataset statistics. # - number of sentences.

4.3 Training

Given a constituency tree, we minimize the sum of the three objectives to optimize the parser:

$$\mathcal{L} = \mathcal{L}_{cons} + \mathcal{L}_{pat} + \mathcal{L}_{reg} \tag{14}$$

4.4 Computational Cost

The number of training parameters increased by NFC is $\mathbf{W}_1^{\mathrm{p}} \in \mathbb{R}^{|H|\times|H|}$, $\mathbf{W}_2^{\mathrm{p}} \in \mathbb{R}^{|H|\times|L^p|}$, $\mathbf{b}_1^{\mathrm{p}} \in \mathbb{R}^{|H|}$ and $\mathbf{b}_2^{\mathrm{p}} \in \mathbb{R}^{|L^p|}$ in Eq 8 and $\mathbf{U} \in \mathbb{R}^{|H|\times|H|}$ in Eq 12. Taking training model on PTB as an example, NFC adds less than 0.7M parameters to 342M parameters baseline model (Kitaev and Klein, 2018) based on BERT-large-uncased during training. NFC is identical to our baseline self-attentive parser (Kitaev and Klein, 2018) during inference.

5 Experiments

We empirically compare NFC with the baseline parser in different settings, including in-domain, cross-domain and multilingual benchmarks.

5.1 Dataset

Table 1 shows the detailed statistic of our datasets.

In-domain. We conduct experiments on both English and Chinese, using the Penn Treebank (Marcus et al., 1993) as our English dataset, with standard splits of section 02-21 for training, section 22 for development and section 23 for testing. For Chinese, we split the Penn Chinese Treebank (CTB) 5.1 (Xue et al., 2005), taking articles 001-270 and 440-1151 as training set, articles 301-325 as development set and articles 271-300 as test set.

Cross-domain. To test the robustness of our methods across difference domains, we further annotate five test set in dialogue, forum, law, literature and review domains. For the dialogue domain, we randomly sample dialogue utterances from Wizard of Wikipedia (Dinan et al., 2019), which is a chit-chat dialogue benchmark produced by humans. For the forum domain, we use users' communication records from Reddit, crawled and released by Völske et al. (2017). For the law domain, we sample text from European Court of Human Rights Database (Stiansen and Voeten, 2019), which includes detailing judicial decision patterns. For the literature domain, we download literary fictions from Project Gutenberg[2]. For the review domain, we use plain text across a variety of product genres, released by SNAP Amazon Review Dataset (He and McAuley, 2016). After obtaining the plain text, we ask annotators whose majors are linguistics to annotate constituency parse tree by following the PTB guideline. We name our dataset as **Multi**-domain **C**onstituency **Tree**bank (MCTB). More details of the dataset are documented in Yang et al. (2022).

Multi-lingual. For the multilingual testing, we select three rich resource language from the SPMRL 2013-2014 shared task (Seddah et al., 2013): French, German and Korean, which include at least 10,000 training instances, and three low-resource language: Hungarian, Basque and Polish.

5.2 Setup

Our code is based on the open-sourced code of Kitaev and Klein (2018)[3]. The training process gets terminated if no improvement on development F1 is obtained in the last 60 epochs. We evaluate the models which have the best F1 on the development set. For fair comparison, all reported results and baselines are augmented with BERT. We adopt `BERT-large-uncased` for English, `BERT-base` for Chinese and `BERT-multi-lingual-uncased` for other languages. Most of our hyper-parameters are adopted from Kitaev and Klein (2018) and Fried et al. (2019). For scales of the two additional losses, we set the scale of pattern loss to 1.0 and the scale of consistency loss to 5.0 for all experiments.

To reduce the model size, we filter out those non-

local pattern features that appear less than 5 times in the PTB training set and those that account for less than 0.5% of all pattern occurrences in the CTB training set. The out-of-vocabulary patterns are set as $<$ `UNK` $>$. This results in moderate pattern vocabulary sizes of 841 for PTB and 514 for CTB. For evaluation on PTB, CTB and cross-domain dataset, we use the EVALB script for evaluation. For the SPMRL datasets, we follow the same setup in EVALB as Kitaev and Klein (2018).

5.3 In-domain Experiments

We report the performance of our method on the test sets of PTB and CTB in Table 2 and 3, respectively. Compared with the baseline parser (Kitaev and Klein, 2018), our method obtains an absolute improvement of 0.20% F1 on PTB (p<0.01) and 0.33% F1 on CTB (p<0.01), which verifies the effectiveness of injecting non-local features into neural local span-based constituency parsers. Note that the proposed method adds less than 0.7M parameters to the 342M parameter baseline model using BERT-large.

The parser trained with both the pattern loss (Section 4.1) and consistency loss (Section 4.2) outperforms the one trained only with pattern loss by 0.14% F1 (p<0.01). This suggests that the constraints between constituents and non-local pattern features are crucial for injecting non-local features into local span-based parsers. One possible explanation for the improvement is that the constraints may bridge the gap between local and non-local supervision signals, since these two are originally separately predicted while merely sharing the same encoder in the training phase.

We further compare our method with the recent state-of-the-art parsers on PTB and CTB. Liu and Zhang (2017) propose an in-order transition-based constituency parser. Kitaev and Klein (2018) use self-attentive layers instead of LSTM layers to boost performance. Zhou and Zhao (2019) jointly optimize constituency parsing and dependency parsing objectives using head-driven phrase structure grammar. Mrini et al. (2020) extend Zhou and Zhao (2019) by introducing label attention layers. Zhang et al. (2020b) integrate a CRF layer to a chart-based parser for structural training (without non-local features). Tian et al. (2020) use span attention for better span representation.

Compared with these methods, the proposed method achieves an F1 of 95.92%, which exceeds previous best numbers for BERT-based single-model parsers on the PTB test set. We further compare experiments for five runs, and find that NFC significantly outperforms Kitaev and Klein (2018) (p<0.01). The test score of 92.31% F1 on CTB significantly outperforms the result (91.98% F1) of the baseline (p<0.01). Compared with the CRF parser of Zhang et al. (2020b), our method gives better scores without global normalization in training. This shows the effectiveness of integrating non-local information during training using our simple regularization. The result is highly competitive with the current best result (Mrini et al., 2020), which is obtained by using external dependency parsing data.

Table 5: Multilingual Experiment results on SPMRL test-sets. † indicates our reproduced baselines.

5.4 Cross-domain Experiments

We compare the generalization of our methods with baselines in Table 4. In particular, all the parsers are trained on PTB training and validated on PTB development, and are tested on cross-domain test in the zero-shot setting. As shown in the table, our model achieves 5 best-reported results among 6 cross-domain test sets with an averaged F1 score of 89.85%, outperforming our baseline parser by 2.97% points. This shows that structure information is useful for improving cross-domain performance, which is consistent with findings from previous work (Fried et al., 2019).

To better understand the benefit of pattern features, we calculate Pearson correlation of n-gram pattern distributions between the PTB training set and various test sets in Figure 3. First, we find that the correlation between the PTB training set and the PTB test set is close to 1.0, which verifies the effectiveness of the corpus-level pattern knowledge during inference. Second, the 3-gram pattern correlation of all domains exceeds 0.75, demonstrating that n-gram pattern knowledge is robust across domains, which supports the strong performance of NFC in the zero-shot cross-domain setting. Third, pattern correlation decreases significantly as n increases, which suggests that transferable non-local information is limited to a certain window size of n-gram constituents.

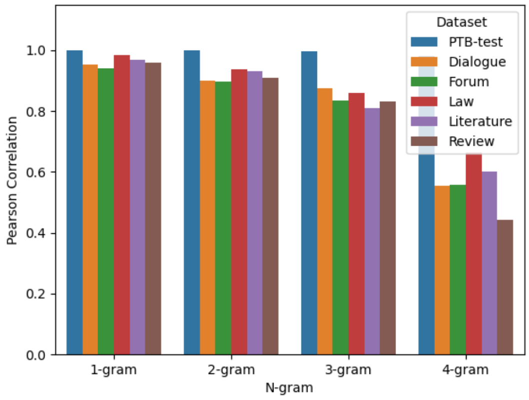

Figure 3: Pearson correlation of n-gram pattern distribution between PTB training set and different test set.

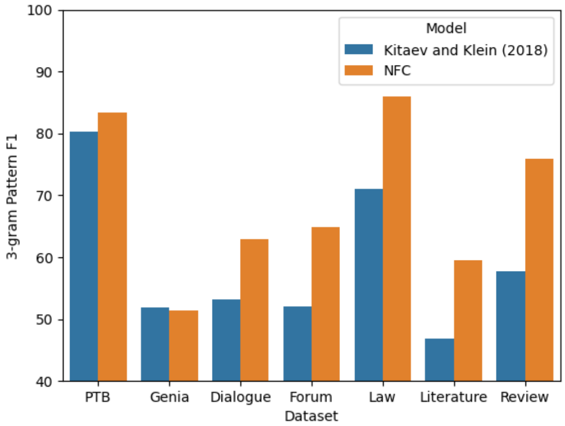
5.5 Multilingual Experiments

We compare NFC with Kitaev and Klein (2018) and Nguyen et al. (2020) on SPMRL. The results are shown in Table 5. Nguyen et al. (2020) use pointer network to predict a sequence of pointing decisions for constituency parsing. As can be seen, Nguyen et al. (2020) do not show obvious advantages over Kitaev and Klein (2018). NFC outperforms these two methods on three rich resource languages. For example, NFC achieves 89.07% F1 on Korean, outperforming Kitaev and Klein (2018) by 0.27% F1, suggesting that NFC is generally effective across languages. However, NFC does not give better results compared with Kitaev and Klein (2018) on low-resource languages. One possible explanation is that it is difficult to obtain prior linguistic knowledge from corpus-level statistics by using a relatively small number of instances.

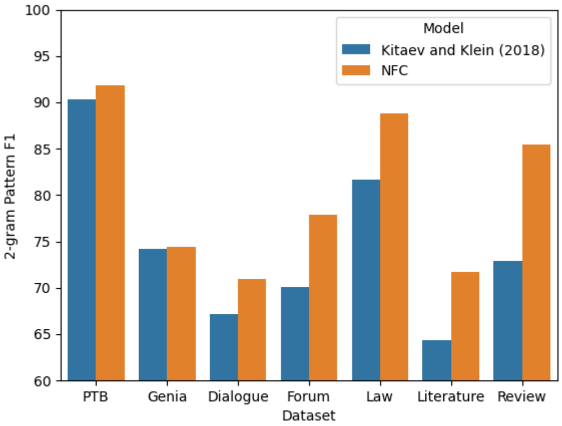
6 Analysis

6.1 n-gram Pattern Level Performance

Figure 4 shows the pattern-level F1 before and after introducing the two auxiliary training objectives. In particular, we calculate the pattern-level F1 by calculating the F1 score for patterns based



(a) F1 scores measured by 3-gram pattern.



(b) F1 scores measured by 2-gram pattern.

Figure 4: Pattern-level F1 on different English datasets. Noted that we train NFC based on 3-gram pattern in English. There is no direct supervision signal for 2-gram pattern.

on the constituency trees predicted by CKY decoding. Although our baseline parser with BERT achieves 95.76% F1 scores on PTB, the pattern-level F1 is 80.28% measured by 3-gram. When testing on the dialogue domain, the result is reduced to only 57.47% F1, which indicates that even a strong neural encoder still has difficulties capturing constituent dependency from the input sequence alone. After introducing the pattern and consistency losses, NFC significantly outperforms the baseline parser measured by 3-gram pattern F1. Though there is no direct supervision signal for 2-gram pattern, NFC also gives better results on pattern F1 of 2-gram, which are subsumed by 3-gram patterns. This suggests that NFC can effectively represent sub-tree structures.

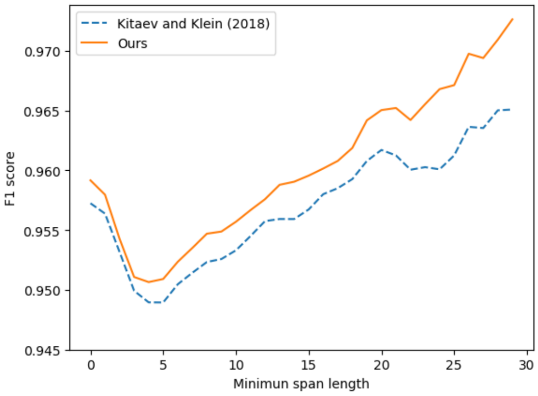


Figure 5: F1 scores versus minimum constituent span length on PTB test set. Note that constituent spans shorter than 30 accounts for approximately 98.5% of all for the PTB test set.

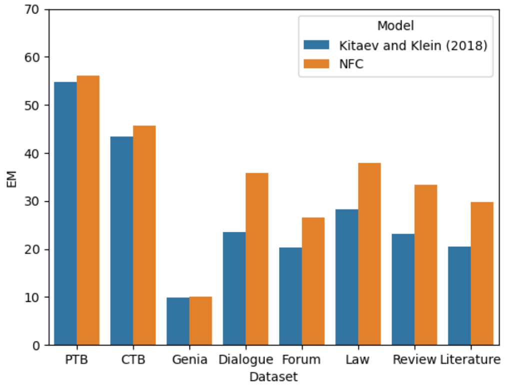

Figure 6: Exact matching (EM) score across different domains. EM indicates the percentage of sentences whose predicted trees are entirely correct.

6.2 F1 against Span Length

We compare the performance of the baseline and our method on constituent spans with different word lengths. Figure 5 shows the trends of F1 scores on the PTB test set as the minimum constituent span length increases. Our method shows a minor improvement at the beginning, but the gap becomes more evident when the minimum span length increases, demonstrating its advantage in capturing more sophisticated constituency label dependency.

6.3 Exact Match

Exact match score represents the percentage of sentences whose predicted trees are entirely the same as the golden trees. Producing exactly matched trees could improve user experiences in practical scenarios and benefit downstream applications on other tasks (Petrov and Klein, 2007; Kummerfeld et al., 2012). We compare exact match scores of

NFC with that of the baseline parser. As shown in Figure 6, NFC achieves large improvements in exact match score for all domains. For instance, NFC gets 33.40% exact match score in the review domain, outperforming the baseline by 10.2% points. We assume that this results from the fact that NFC successfully ensures the output tree structure by modeling non-local correlation.

6.4 Model Efficiency

As mentioned in Section 4.4, NFC only introduces a few training parameters to the baseline model (Kitaev and Klein, 2018). For PTB, NFC takes about 19 hours to train with a single RTX 2080Ti, while the baseline takes about 13 hours. For CTB, the approximate training time is 12 hours for NFC and 7 hours for the baseline. Our inference time is the same as that of the baseline parser, since no further computational operations are added to the inference phase. Both take around 11 seconds to parse the PTB section 23 (2416 sentences, an average of 23.5 tokens per sentence).

7 Conclusion

We investigated graph-based constituency parsing with non-local features – both in the sense that features are not restricted to one constituent, and in the sense that they are not restricted to each training instance. Experimental results verify the effectiveness of injecting non-local features to neural chart-based constituency parsing. Equipped with pre-trained BERT, our method achieves 95.92% F1 on PTB and 92.31% F1 on CTB. We further demonstrated that the proposed method gives better or competitive results in multilingual and zero-shot cross-domain settings.

We appreciate the insightful comments from the anonymous reviewers. We thank Zhiyang Teng for the insightful discussions. We gratefully acknowledge funding from the National Natural Science Foundation of China (NSFC No.61976180).

Ethical Considerations

As mentioned in Section 5.1, we collected the raw data from free and publicly available sources that have no copyright or privacy issues. We recruited our annotators from the linguistics departments of local universities through public advertisement with a specified pay rate. All of our annotators are senior undergraduate students or graduate students in linguistic majors who took this annotation as a part-time job. We manually shuffled the data so that all batches of to-be-annotated data have similar lengths on average. An annotator could annotate around 25 instances per hour. We pay them 50 CNY an hour. The local minimum salary in the year 2021 is 22 CNY per hour for part-time jobs.

Our annotated data only involves factual information (i.e., syntactic annotation), but not opinions, attitudes or beliefs. Therefore, the annotation job does not belong to human subject research; and IRB approval is not required.

Abstract

In this paper, we firstly empirically find that existing models struggle to handle hard mentions due to their insufficient contexts, which consequently limits their overall typing performance. To this end, we propose to exploit sibling mentions for enhancing the mention representations. Specifically, we present two different metrics for sibling selection and employ an attentive graph neural network to aggregate information from sibling mentions. The proposed graph model is scalable in that unseen test mentions are allowed to be added as new nodes for inference. Exhaustive experiments demonstrate the effectiveness of our sibling learning strategy, where our model outperforms ten strong baselines. Moreover, our experiments indeed prove the superiority of sibling mentions in helping clarify the types for hard mentions.

1 Introduction

Fine-Grained Entity Typing (FGET) aims to assign one or more fine-grained types to an entity mention given its context. For instance, the mention *Steve Jobs* should be classified as *Person* and *Entrepreneur* under the context "Steve Jobs cofounded Apple ...". Many tasks have witnessed the importance of FGET, such as relation extraction (Jiang et al., 2020b; Chu et al., 2020; Jiang et al., 2020a; Cheng et al., 2021), entity linking (Onoe and Durrett, 2020), and other tasks (Jiang et al., 2020c; Zhang et al., 2020b; Liu et al., 2021b).

It is challenging to learn effective representations for contextualized mentions[1] in many information extraction tasks (Gao et al., 2022), especially in FGET, since the representations are required to well distinguish fine-grained types with similar but different semantics. Noticeable efforts have been made to learn type-aware representations for mentions (Ren et al., 2016; Xin et al., 2018; Choi et al., 2018; Zhang et al., 2018; Lin and Ji, 2019; Abhishek et al., 2017; Xu and Barbosa, 2018; Ali et al., 2020; Chen et al., 2021) and significant progress has been achieved. However, as supported by our empirical experiments, existing SOTA models perform poorly on a certain number of "*hard*" mentions, leading to limited overall performance. The main reasons are the following challenges. First, the structure of some contexts surrounding the hard mentions are inherently too complex to extract informative features for identifying entity types. Second, the contexts of some hard mentions are ambiguous and thus it is insufficient to handle these mentions by learning from their contexts only.

In this paper, we show that representation learning of such hard mentions can be well handled by learning informative knowledge from their *sibling mentions*. Sibling mentions refer to the mentions that *potentially share the same or semantically similar types* (e.g., *country* and *nation*) with the target mention. We illustrate how sibling mentions assist classifying hard mentions in Figure 1. Intuitively, the context of the target mention *Sharp* is ambiguous and insufficient for inferring the ground-truth types (i.e., *organization*, *company*, and *tech company*), since both a *person* and a *company* can "sign a deal with Qualcomm". Fortunately, the sibling mentions provide rich information that works as an important supplement for the target mention *Sharp*. By aggregating the supplementary information from siblings, it is promising to learn effective representations with less ambiguity for hard target mentions.

Sibling mentions

Figure 1: Illustration of the proposed sibling enhanced heterogeneous graph model.

To utilize sibling mentions, we model FGET as a heterogeneous graph learning problem. The graph is composed of two kinds of nodes, namely the mentions and the types. Besides, there are three kinds of edges connecting the nodes as shown in the left part of Figure 1, which represent the *sibling* relationship between mentions, the *hierarchical* relationship between types, and the *isLabel* relationship between mentions and types, respectively. The sibling relationship is considered as the most important part in our graph. For detecting it, we propose two similarity metrics, based on which we design an effective sibling selection algorithm. Upon the constructed nodes and edges, we employ an attentive graph neural module to learn their representations. Particularly, the representations of mention nodes are enriched by aggregating the information from their sibling and type neighbors. It is also noteworthy that, during inference stage, our graph model is scalable to include the unseen test mentions as new nodes and connect them with their existing sibling mention nodes in the graph to derive reliable representations for predictions.

Extensive experiments are conducted to verify the effectiveness of our model. Our experimental results demonstrate that our model outperforms several strong baselines on the standard test sets with a large margin. Moreover, our model is indeed able to well handle hard mentions with the help from sibling mentions.

We summarize our contributions as follows:

- We are the first to point out a bottleneck issue suffered by existing SOTA models, i.e., they perform poorly on a certain number of hard mentions, and we quantitatively analyze its influence on typing accuracy via measuring hard mentions by entropy.
- We are the first to exploit sibling information for mention representation learning in FGET. We design two effective metrics for sibling detection and propose a scalable graph model to take advantages of sibling mentions.

2 Methodology Overview

Given a mention m and the type set $\mathcal{Y}$, an FGET model needs to predict the correct types Y_m ($Y_m \subset \mathcal{Y}$) for m based on its context.

In this paper, mention representations are learned and refined with the help of sibling mentions and ground-truth types. To achieve it, we propose a heterogeneous graph model enhanced by sibling mentions for FGET, as illustrated in Figure 1. First, a mention-type graph $\mathcal{G}$ is constructed from training samples (Sec 3). Then, the features for mentions and types are learned by an attentive graph neural module upon $\mathcal{G}$ (Sec 4).

During inference stage (Sec 5), we add test mentions into graph $\mathcal{G}$ by connecting them to their sibling mentions in the training set. By aggregating sibling information, the representations of test mentions are generated and used for type prediction.

3 Graph Construction

3.1 Graph Definition

Consider graph $\mathcal{G} = (\mathcal{V}_m, \mathcal{V}_y, \mathcal{E}_m, \mathcal{E}_y, \mathcal{E}_{m,y})$, where $\mathcal{V}_m$ and $\mathcal{V}_y$ are the set of mention nodes and type nodes, respectively. $\mathcal{E}_m$ is the set of edges between the target mentions and their sibling mentions, while $\mathcal{E}_y$ is the set of edges between types. $\mathcal{E}_{m,y}$ denotes the edges connecting the target mentions and the ground-truth types. $\mathcal{E}_m$, $\mathcal{E}_y$ and $\mathcal{E}_{m,y}$ are obtained as follows:

$$\begin{aligned}\mathcal{E}_m = &\{(m_i, m_j) | m_i, m_j \in \mathcal{V}_m,\\ &isSib(m_i, m_j) = 1\}\end{aligned} \tag{1}$$

$$\mathcal{E}_y = \{(y_i, y_j) | y_i, y_j \in \mathcal{V}_y, isA(y_i, y_j) = 1\} \tag{2}$$

$$\begin{aligned}\mathcal{E}_{m,y} =&\{(m_i, y_j)|m_i \in \mathcal{V}_m,\ y_j \in \mathcal{V}_y,\\ &isLabel(m_i, y_j) = 1\}\end{aligned} \tag{3}$$

where $isA(y_i, y_j) = 1$ indicates y_j is the parent or child type of y_i in the type hierarchy [2], and $isLabel(m_i, y_j) = 1$ means mention m_i is labeled with the type y_j in the training set. Since type hierarchy and the ground-truth types of mentions are available in the training set, $\mathcal{V}_m$, $\mathcal{V}_y$, $\mathcal{E}_y$ and $\mathcal{E}_{m,y}$ can be easily derived. $isSib(m_i, m_j) = 1$ means m_j is the sibling mention of m_i, which will be discussed in Sec 3.2.

3.2 Sibling Selection

The key to construct $\mathcal{E}_m$ is to define $isSib(m_i, m_j)$, i.e., the criterion for judging whether m_j is the sibling of m_i. We design two metrics to detect the sibling relationships between mentions, named (unsupervised) *word distribution-based* and (supervised) *typing distribution-based* metrics.

Word distribution-based metric The basic assumption for this metric is that mentions sharing more contextual words tend to have more similar ground-truth types. We use TF-IDF to encode mentions as sparse feature vectors. Then the sibling similarity between any two mentions is measured by the cosine similarity of their vectors.

Typing distribution-based metric In this metric, we first derive the prior score distributions over the type set $\mathcal{Y}$ for all the mentions in the dataset from an extra base model (Lin and Ji, 2019) trained on the same dataset. Then the sibling mentions are selected by their cosine similarities to the target mention based on the score distributions.

Sibling mention selection Given one of the metrics above, we obtain the sibling mentions according to Algorithm 1. Note that for each target mention $m_i \in \mathcal{V}_m$, we first select a subset $\mathcal{V}'_m$ from $\mathcal{V}_m$ and only calculate the similarities between m_i and the mentions $m_j \in \mathcal{V}'_m$. The contexts of mentions from $\mathcal{V}'_m$ share at least one word with that of the target mention and $|\mathcal{V}'_m| \ll |\mathcal{V}_m|$, which greatly reduces time complexity. Then, based on the similarity scores, we choose the top-K most similar mentions $\mathcal{V}'_{m,K}$ as the siblings for m_i and let $isSib(m_i, m_j) = 1$ for each $m_j \in \mathcal{V}'_{m,K}$. Be aware that, by definition, the sibling relationship is directed, i.e., $isSib(m_j, m_i) = 1$ does not ensure $isSib(m_i, m_j) = 1$ holds.

Algorithm 1: Sibling mention selection

```
Input : the set of mention nodes $\mathcal{V}_m$
for $m_i, m_j \in \mathcal{V}_m$ do
    $isSib(m_i, m_j) \leftarrow 0$
end
for $m_i \in \mathcal{V}_m$ do
    ▷ select a candidate set $\mathcal{V}'_m$ from $\mathcal{V}_m$
    for $m_j \in \mathcal{V}'_m$ do
        ▷ compute similarity $sim(m_i, m_j)$
    end
    ▷ select the top-$K$ similar mentions $\mathcal{V}'_{m,K}$ from $\mathcal{V}'_m$
    for $m_j \in \mathcal{V}'_{m,K}$ do
        $isSib(m_i, m_j) \leftarrow 1$
    end
end
```

4 Graph-based Typing Model

4.1 Attentive Graph Neural Module

We employs graph neural networks (GNNs) with L layers (Velickovic et al., 2018; Xu et al., 2019) to aggregate the information of sibling mentions and types for learning mention representations. At the first layer of $\mathcal{G}$, the embedding of each type $y_i \in \mathcal{Y}$ (denoted by $\boldsymbol{y}_i^{(1)} \in \mathbb{R}^{d_r}$) is randomly initialized. In contrast, to capture the rich features from contexts, the initial embeddings for mentions are derived by a parameterized mention encoder $g(\cdot)$, i.e., $\boldsymbol{m}_i^{(1)} = g(m_i; \theta_{\mathrm{M}}) \in \mathbb{R}^{d_r}$ (details in Sec 4.2). Given the initial mention and type embeddings (i.e., $\boldsymbol{m}_i^{(1)}$ and $\boldsymbol{y}_i^{(1)}$), the graph module iteratively updates them to obtain $\boldsymbol{m}_i^{(l+1)}$ and $\boldsymbol{y}_i^{(l+1)}$.

Update of $\boldsymbol{y}_i^{(l+1)}$ In the l-th ($l = 1, ..., L-1$) layer, the updating formula for type embedding $\boldsymbol{y}_i^{(l+1)} \in \mathbb{R}^{d_r}$ is:

$$\boldsymbol{y}_i^{(l+1)} = f_0\Bigg(\sum_{y_k \in \mathcal{Y}_{y_i}} \alpha_{i,k}^{(l)} f_1(\boldsymbol{y}_k^{(l)}) + f_1(\boldsymbol{y}_i^{(l)})\Bigg), \tag{4}$$

where f_0 and f_1 are linear layers with *ReLU* activation. $\mathcal{Y}_{y_i}$ denotes the type neighbors for y_i in graph $\mathcal{G}$, which are the parent or child types of y_i in the type hierarchy. $\alpha_{i,k}^{(l)}$ is the attention weight from type y_i to y_k defined as

$$\alpha_{i,k}^{(l)} = \begin{cases} \sigma\big(\boldsymbol{y}_i^{(l)\top} \boldsymbol{W}_1^{(l)} \boldsymbol{y}_k^{(l)}\big), & y_k \text{ is a child type;} \\ \sigma\big(\boldsymbol{y}_k^{(l)\top} \boldsymbol{W}_1^{(l)} \boldsymbol{y}_i^{(l)}\big), & y_k \text{ is a parent type,} \end{cases} \tag{5}$$

---

[2] The edges between y_i and its parent or child type y_j are directed, as detailed in Eq.(5)

$\boldsymbol{W}_1^{(l)} \in \mathbb{R}^{d_r \times d_r}$ is the weight matrix to model the parent-child relationship. Note that Eq.(4) does not involve mention embeddings and only focuses on learning the hierarchical structure of types. The interaction between types and mentions will be modeled by Eq.(6) during the update process of mention embeddings.

Update of $\boldsymbol{m}_i^{(l+1)}$ The updating formula for the mention embedding $\boldsymbol{m}_i^{(l+1)} \in \mathbb{R}^{d_r}$ is:

$$\boldsymbol{m}_i^{(l+1)} = f_2\left(\sum_{m_j \in \mathcal{M}_{m_i}} \mu_{i,j}^{(l)} f_3(\boldsymbol{m}_j^{(l)}) + \sum_{y_k \in \mathcal{Y}_{m_i}} \nu_{i,k}^{(l)} f_4(\boldsymbol{y}_k^{(l)}) \right), \tag{6}$$

where $\mathcal{M}_{m_i}$ and $\mathcal{Y}_{m_i}$ are the sibling and type neighbors[3] of m_i in graph $\mathcal{G}$. $\mu_{i,j}^{(l)}$ and $\nu_{i,k}^{(l)}$ are the attention weights from m_i to mention m_j and type y_k in the l-th layer, respectively. Specifically,

$$\begin{aligned} \mu_{i,j}^{(l)} &= \sigma\big(\boldsymbol{m}_i^{(l)\top} \boldsymbol{W}_2^{(l)} \boldsymbol{m}_j^{(l)}\big), \\ \nu_{i,k}^{(l)} &= \sigma\big(\boldsymbol{m}_i^{(l)\top} \boldsymbol{W}_3^{(l)} \boldsymbol{y}_k^{(l)}\big), \end{aligned} \tag{7}$$

$\boldsymbol{W}_2^{(l)}, \boldsymbol{W}_3^{(l)} \in \mathbb{R}^{d_r \times d_r}$ are learnable parameters. f_2, f_3, f_4 are linear layers with *ReLU* activation.

Here, we use the attention mechanism to distinguish informative neighbors. Besides, the update process of target mentions involves both the sibling and type neighbors, whose representations are also updated at the same. In this way, the learned representations for both mentions and types are more consistent and thus more reliable for prediction.

4.2 Mention Encoder $g(m_i; \theta_{\mathrm{M}})$

The mention encoder uses the backbone from Lin and Ji (2019). Given a mention, we first encode the mention span and the surrounding context as the weighted sum of their ELMo (Peters et al., 2018) word representations respectively. Then, the unified feature vector for the mention is derived by concatenating both representations.

4.3 Type Prediction

Given a mention m_i, the predicted score distribution $\boldsymbol{p}_i \in \mathbb{R}^{|\mathcal{Y}|}$ over the type set $\mathcal{Y}$ is computed as:

$$\boldsymbol{p}_i = \sigma\big(\boldsymbol{Y}^{(L)} \boldsymbol{W}_4 \boldsymbol{m}_i^{(L)} + \boldsymbol{W}_5 \boldsymbol{m}_i^{(L)}\big), \tag{8}$$

where $\boldsymbol{Y}^{(L)} = \left[\boldsymbol{y}_1^{(L)}, \boldsymbol{y}_2^{(L)}, ..., \boldsymbol{y}_{|\mathcal{Y}|}^{(L)}\right] \in \mathbb{R}^{|\mathcal{Y}| \times d_r}$, $\boldsymbol{y}_i^{(L)}$ and $\boldsymbol{m}_i^{(L)}$ are the type and mention embeddings in the L-th layer in GNN. $\boldsymbol{W}_4 \in \mathbb{R}^{d_r \times d_r}$ and $\boldsymbol{W}_5 \in \mathbb{R}^{|\mathcal{Y}| \times d_r}$ are learnable parameters. $\boldsymbol{p}_i[k]$ (the k-th element in $\boldsymbol{p}_i$) denotes the predicted probability for type y_k.

4.4 Loss Function

The loss over m_i is computed as:

$$\ell_i = -\sum_{k=1}^{|\mathcal{Y}|} \left(\delta_k^i \log \boldsymbol{p}_i[k] + (1-\delta_k^i) \log(1-\boldsymbol{p}_i[k])\right) \tag{9}$$

where $\delta_k^i \in \{0, 1\}$ indicates whether y_k is the ground-truth type of m_i in the training set. The overall loss is the average over all the mentions, i.e., $\mathcal{L} = \frac{1}{|\mathcal{V}_m|} \sum_i \ell_i$.

4.5 Dropout of $\mathcal{Y}_{m_i}$

The representation $\boldsymbol{m}_i^{(L)}$ incorporates the information from ground-truth type neighbors (Eq.(6)). However, it is then used for predicting the ground-truth types in turn (Eq.(8)). The setting that $\mathcal{Y}_{m_i}$ contains *all* the ground-truth types will inevitably degenerate the model to just focus on the type neighbors while totally ignore the mention neighbors. To overcome this, each neighboring type in $\mathcal{Y}_{m_i}$ is randomly discarded with a certain probability γ. In this way, the prediction of discarded type will force the model to learn from the sibling mentions rather than directly from type neighbors.

5 Scalable Testing

In the following, we describe the prediction process for test mentions.

Step 1: Given a batch of n test mentions, we first obtain their sibling mentions. To be specific, for each test mention m_t, we select a candidate set $\mathcal{V}_m^{'}$ from the training mentions $\mathcal{V}_m$. Then, the cosine similarity is computed between m_t and each m_i in $\mathcal{V}_m^{'}$, based on which the top K mentions are selected as siblings (see Sec 3.2).

Step 2: We add the test mentions as nodes into the mention-type graph $\mathcal{G}$, where the test mentions are connected to their sibling mentions selected at Step 1. Note that, in the new graph, test mentions have no type neighbors since their ground-truth types are not available. Besides, there is no edge between any two test mentions in the new graph.

Step 3: Following Eq.(6), the representations of test mentions $\{m_t\}$ are updated by aggregating the embeddings for their sibling mentions. Note that $\mathcal{Y}_{m_t}$ is empty, so no information from the ground-truth types are involved. Through layers of updates, the final representations $\{\boldsymbol{m}_t^{(L)}\}$ are obtained.

---

[3] We define that $\mathcal{M}_{m_i}$ contains m_i itself, thus the self-connections are taken into account during graph learning.

Step 4: Based on the mention embedding $\boldsymbol{m}_t^{(L)}$ and the type embeddings $\boldsymbol{Y}^{(L)}$, we predict the type score distribution for m_t by Eq.(8).

We conclude that, (1) *our graph module is scalable* to add arbitrary number of unseen test mentions as new nodes to the existing graph to derive their representations. By contrast, many popular graph settings (Kipf and Welling, 2017; Velickovic et al., 2018; Wang et al., 2019) fail to extend to new nodes. (2) Since the embeddings for sibling mentions have been well learnt during training, the only need is to compute the embeddings for test mentions for prediction, which are derived simultaneously during graph inference with high efficiency.

6 Experiments

6.1 Datasets

We evaluate the proposed model on two widely-used datasets: OntoNotes and BBN.

OntoNotes The original OntoNotes dataset is annotated by distant supervision (Gillick et al., 2014). The training, development and test samples in OntoNotes are about 251K, 2K and 9K, respectively. We also conduct experiments on the augmented version[4] (Choi et al., 2018) with 793K training samples[5]. The above two versions share the same test set and development set, as well as the same type set of size 89.

BBN Different from OntoNotes, BBN is manually annotated (Weischedel and Brunstein, 2005). The training, development and test set contain about 84K, 2K and 14K samples respectively, and the type set contains 47 type in total.

6.2 Experimental Setup

Our model is implemented based on the PyTorch Geometric package (Fey and Lenssen, 2019). In the main experiments (Sec 6.4), we obtain the sibling mentions according to the typing distribution-based metric described in Sec 3.2. We conduct hyper-parameter search on the development set and the optimal settings are presented in Appendix A.

Following the previous works (Ling and Weld, 2012; Ren et al., 2016; Chen et al., 2019), we report the performance in terms of strict accuracy (Acc), macro-average F1 score (Ma-F1) and micro-average F1 score (Mi-F1). To guarantee the reliability, we repeat the experiment three times under each setting, and report the average results.

6.3 Baselines

We compare our proposed model with several state-of-the-art FGET models: (1) AFET (Ren et al., 2016); (2) AAA (Abhishek et al., 2017); (3) NFETC (Xu and Barbosa, 2018); (4) NEURAL (Shimaoka et al., 2017); (5) ACT (Zhang et al., 2018); (6) Lin and Ji (2019); (7) Chen et al. (2020); (8) LABELGCN (Xiong et al., 2019); (9) Choi et al. (2018); (10) Ali et al. (2020). Note that Lin and Ji (2019) is considered as an important baseline in our experiments and is marked with ★ in Table 1-3, since we use it as the base model to derive the prior typing distributions for sibling selection (Sec 3.2).

6.4 Results and Analysis

Table 1, 2 and 3 illustrate the experimental results on the original and the augmented OntoNotes, as well as the BBN dataset.

Analysis The results demonstrate that learning from sibling mentions helps our model outperform most baselines across the benchmarks. The detailed analysis is presented as follows:

(1) We select sibling mentions according to the typing distribution from Lin and Ji (2019). We observe that, after aggregating sibling information through the attentive graph neural module (Sec 4.1), our model significantly outperforms Lin and Ji (2019) on both the original OntoNotes and the BBN dataset. When trained on the augmented OntoNotes of the same size, our model increases the accuracy score by more than 5% over Lin and Ji (2019)★. Compared with Lin and Ji (2019)* which utilizes the full 3M augmented OntoNotes for training, our model still maintains a comparable performance and even improves the accuracy score by about 2%.

(2) Many previous works have demonstrated the effectiveness of modeling type hierarchy for entity typing (Ren et al., 2016; Xu and Barbosa, 2018; Xiong et al., 2019; Chen et al., 2020). As a comparison, our model also considers the hierarchical information of types and incorporates it in a natural way (Sec 4.1). From the results, we conclude that learning jointly from type hierarchy and sibling mentions can remarkably improve the typing performance.

(3) The attention mechanism plays an important role in our graph module and some of the baselines (Ren et al., 2016; Abhishek et al., 2017; Xu and

---

[4] http://nlp.cs.washington.edu/entity_type

[5] We use the open-sourced version, which is a subset of the dataset reported in Choi et al. (2018).

Barbosa, 2018). It not only helps identify the informative features from neighbors but also helps alleviate noise from the training data constructed by distant supervision (e.g., OntoNotes). The results reveal that our graph-based solution is more effective than the existing solutions.

6.5 Ablation Studies

6.5.1 Effect of the sibling selection metrics

In Sec 3.2, we propose two similarity metrics to discover sibling relationships in graph $\mathcal{G}$, and abbreviate them as: "Word-based" and "Typing-based" metrics. Here, we provide two additional metrics for more detailed analysis: the "Gold typing-based" and the "Random-based" metrics, which are two extreme variations of the typing-based metrics. Under the gold typing-based metric, the siblings are selected by the gold typing distribution, where each dimension is 0 or 1 according to the ground-truth types of the mention. In this way, candidate mentions that share more ground-truth types with the target mention will have larger cosine similarity and thus be chosen as the siblings with a higher probability. On the contrary, under the random-based metric, siblings are selected at random. Since the type set is large, the siblings are more likely to be irrelevant with the target mention and may contain much noise.

Measuring sibling quality Intuitively, different similarity metrics will affect the quality of siblings. To quantify this effect, we measure the sibling quality for the test mentions $\mathcal{V}'$ in the original OntoNotes and define the metrics as follows.

For each mention $m_i \in \mathcal{V}'$, denote its ground-truth types as $\mathcal{Y}_{m_i}$ and sibling mentions in graph $\mathcal{G}$ (defined in Sec 3.1) as $\mathcal{M}_{m_i}$. Further, for $\mathcal{M}_{m_i}$, we denote their ground-truth types as $\mathcal{Y}_{\mathcal{M}_i}$, i.e.,

$$\mathcal{Y}_{\mathcal{M}_i} = \bigcup_{m_j \in \mathcal{M}_{m_i} \setminus \{m_i\}} \mathcal{Y}_{m_j}. \tag{10}$$

Similar to the definitions of Precision, Recall and F1, we define *Purity, Coverage* and *Quality* to measure the sibling quality of $\mathcal{V}'$:

$$\begin{aligned}
\text{Purity} &= \frac{1}{|\mathcal{V}'|} \sum_{m_i \in \mathcal{V}'} = \frac{|\mathcal{Y}_{m_i} \cap \mathcal{Y}_{\mathcal{M}_i}|}{|\mathcal{Y}_{\mathcal{M}_i}|} \\
\text{Coverage} &= \frac{1}{|\mathcal{V}'|} \sum_{m_i \in \mathcal{V}'} \frac{|\mathcal{Y}_{m_i} \cap \mathcal{Y}_{\mathcal{M}_i}|}{|\mathcal{Y}_{m_i}|} \\
\text{Quality} &= \frac{2 * \text{Coverage} * \text{Purity}}{\text{Coverage} + \text{Purity}}
\end{aligned} \tag{11}$$

Results The results are presented in Table 4. In general, the model performance is closely related to the sibling quality. Besides, the typing-based metric performs better than the word-based metric. This indicates that the the continuous type-level probability distribution is more reliable for sibling selection than the discrete word-level distribution. The scores from the gold typing-based and the random-based metrics reveal the upper bound and the lower bound of the scores for the typing-based metric. On the one hand, the quality of the siblings selected by the gold typing-based metric is much higher than those by other methods, with the Coverage up to 97.6%. Meanwhile, its corresponding model also outperforms the other three by a large margin. Note that the typing performance in this scenario is limited by the annotation

Metrics	Purity	Coverage	Quality	Macro P	Macro R	Macro F1	Micro P	Micro R	Micro F1
Random-based	9.6	71.3	16.9	65.1	56.4	60.1	65.1	43.5	52.2
Word-based	12.2	75.6	21.0	82.7	69.7	75.3	82.1	60.4	69.7
Typing-based	13.1	82.3	22.5	83.3	71.4	76.5	83.3	61.9	71.0
Gold typing-based	21.8	97.6	35.7	96.1	80.0	86.9	94.9	69.2	80.0

Table 4: Comparison among different sibling selection metrics. Note that the sibling quality scores of "Gold typing-based" do not reach 1, since the sibling mentions are only selected from a subset $\mathcal{V}'_m$ (see Sec 3.2) for time efficiency, which are not guaranteed to have exactly the same ground-truth types with the target mention.

K	Purity	Coverage	Quality	Macro P	Macro R	Macro F1	Micro P	Micro R	Micro F1
0	-	-	-	81.6	68.9	74.4	80.8	60.1	68.9
5	13.1	82.3	22.5	83.3	71.4	76.5	83.3	61.9	71.0
10	10.4	89.5	18.6	82.8	70.2	75.4	81.9	60.5	69.5
15	7.9	94.4	14.5	81.3	68.5	73.8	78.6	61.3	68.8

Table 5: Effect of the sibling size K on sibling quality and typing performance over the original OntoNotes dataset.

quality to some extent. Since OntoNotes is annotated by distant-supervision, the scores for the gold typing-based metric could not reach higher due to the label noise of the siblings. On the other hand, a distinct drop of the scores is observed with the random-based metric. This is reasonable since the randomly selected siblings contain much noisy information, which is helpless and even harmful for typing of the target mention. It can be concluded from the above observations that there is still much room to improve the sibling quality as well as the typing performance of the sibling-enhanced model.

6.5.2 Effect of sibling size K

The model performance is sensitive to the size of selected sibling mentions for a target mention in the graph $\mathcal{G}$. Denote the sibling size as K, following the default hyper-parameter settings, we train our model on the original OntoNotes under different $K \in \{0, 5, 10, 15\}$ using the typing-based sibling selection metric. The corresponding sibling quality and model performance are reported in Table 5. We observe that the best scores are obtained with the top 5 sibling mentions. When $K = 0$, the graph only contains the self-connections from the target mentions to themselves. Without the additional information from siblings, the Macro F1 score decreases by 2.1%, which indicates the effectiveness of sibling mentions for improving the typing performance of our model. When $K \neq 0$, the Coverage score goes up while the Purity and Quality scores go down as K ranges from 5 to 15. Meanwhile, the typing performance decreases as K increases. It suggests that, for OntoNotes, a properly smaller sibling size is a trade-off choice for the model to use siblings with higher quality and thus achieve better typing performance.

6.5.3 Effect of dropout probability γ

We randomly discard some type neighbors with a dropout probability γ during training (Sec 4.5), which forces the model to learn from the sibling mentions other than the ground-truth types. Table 6 shows the results under different values of γ on the original OntoNotes dataset. Generally, the model achieves better performance with larger γ. This indicates discarding a large proportion of ground-truth types is beneficial for learning from sibling mentions. Besides, it also narrows the difference between training and test settings where the test mentions do not have ground-truth types as neighbors. The best performance is achieved when γ equals around 0.7. However, dropping all the type neighbors (i.e., $\gamma = 1$) will block the interaction between the type and mention representations in the graph, which may slightly damage the performance.

γ	Macro P	Macro R	Macro F1	Micro P	Micro R	Micro F1
0.0	83.1	70.7	76.1	82.1	62.2	70.7
0.3	83.0	70.9	76.1	81.7	62.3	70.7
0.5	83.0	71.3	76.4	81.6	63.0	71.1
0.7	83.3	71.4	76.5	83.3	61.9	71.0
1.0	82.7	71.4	76.3	80.6	63.0	70.8

Table 6: Effect of γ on the performance over the original OntoNotes dataset.

6.6 How sibling mentions work in FGET

6.6.1 Quantifying the hard mentions

To select sibling mentions, we first derive the prior typing distribution from the base model (Lin and Ji, 2019) as described in Sec 3.2. During experiments, we observe that the contextual information for some mentions are insufficient or too complex, which makes the base model confused on these mentions. Entropy measures the uncertainty of a probability distribution. Thus, we quantify the difficulty of mentions by the entropy of their corresponding prior typing distributions and define the mentions with the top-500 highest entropy values as *hard mentions*, which account for about 5% of the *whole mentions*. Table 7 compares the performance of our model and the base model on both the whole mentions and the hard mentions from the test dataset of the original OntoNotes. we see that both models perform worse on the hard mentions than on the whole mentions. Besides, except for the superiority of our model regarding the Acc, Ma-F1 and Mi-F1 scores, it also achieves a lower entropy value than the base model especially on the hard mentions. This indicates the information from siblings makes the output type distributions more concentrated and therefore increases the confidence for model predictions.

Mention	Model	Ep	Acc	Ma-F1	Mi-F1
whole mentions	Ours	2.1	59.2	76.5	71.0
	Base	2.4	55.4	73.8	68.4
hard mentions	Ours	2.5	57.2	73.6	66.6
	Base	3.3	51.0	65.3	58.9

Table 7: Results on the whole mentions and hard mentions of the original OntoNotes. *Base* denotes the base model from Lin and Ji (2019). *Ep* is short for Entropy.

6.6.2 Case Study

To further provide an intuitive understanding about how our model benefits from sibling mentions, we present an example in Table 8. As expected, the retrieved siblings based on the metric defined in Sec 3.2 share similar ground-truth types with the target mention. This verifies the effectiveness of our sibling selection algorithm. Moreover, we observe that the siblings even help predict the correct but out-of-gold-set types for the target mention in this case. Although the annotated types for the target mention [*GM officials*] only contains */person* in the test set. The sibling mentions still provide a strong evidence for our model to also predict */person/title* as a possible type for the target mention.

Target mention: [*GM officials*] told workers late last week of the following moves: production of full-sized vans will be consolidated into a single plant in Flint, Mich.
Ground-truth: */person*
Prediction from our model: */person, /person/title*

Sibling 1: "It's been a steadily improving relationship.", says the [*president*].
Ground-truth: */person, /person/title*

Sibling 2: Apart from those two actions, Mr.Sikes and the three other [*commissioners*] said they expect to reexamine how AT&T is regulated since competition has increased.
Ground-truth: */person, /person/title*

Sibling 3: HUD Secretary [*Jack Kemp*] backed an unsuccessful effort to strike such language last week, but received little support from the White House $\cdots$
Ground-truth: */person, /person/artist, /person/artist/actor, /person/artist/author, /person/political_figure*

Table 8: An example to illustrate the relationship between the target mention and the sibling mentions from the Original OntoNotes.

7 Related Work

FGET is an important task for the downstream NLP tasks and many efforts have been make in improving its performance (Zhang et al., 2020a; Liu et al., 2021a). Early works in FGET (Ling and Weld, 2012; Shimaoka et al., 2016) mainly focus on feature extraction for mentions, which do not consider label noise introduced by distant supervision (Gillick et al., 2014; Choi et al., 2018; Li et al., 2020). Recent years have witnessed an increasing number of researchers being dedicated to data denoising. A popular solution (Ren et al., 2016; Abhishek et al., 2017; Xu and Barbosa, 2018; Ali et al., 2020) is to design loss functions for the clean and noisy parts of the training data separately. Nevertheless, Zhang et al. (2020c) proposes an automatic relabeling framework to estimate the pseudo-truth label distribution of each sample, which treats the noisy and clean data uniformly. Besides, Chen et al. (2019) groups mentions of the same type into a compact cluster to improve the robustness of the model. Ali et al. (2020) refines noisy representations by corpus-level contextual clues. Onoe and Durrett (2019) introduces two additional models to delete the samples that are too noisy to be useful, and repair noisy labels for the retained examples. In addition, there are some notable work which tries to build FGET with limited resources (Qian et al., 2021).

Modeling the type hierarchy is another important topic in FGET. Prior solutions (Shimaoka et al., 2017) introduce a one-hot matrix to encode the hierarchy. Xu and Barbosa (2018) proposes a hierarchy-aware loss function. Recently, graph-based methods have been proven to be powerful in many NLP tasks (Kipf and Welling, 2017; Liang et al., 2021; Xu et al., 2019; Liang et al., 2022). Using graphs to model the type hierarchy in FGET is a natural idea. Jin et al. (2019) models the potential type correlations for in-knowledge-base entities via hierarchical multi graph convolutional networks (GCNs). Further, Xiong et al. (2019) extends GCNs to a vast number of free-form types. Chen et al. (2020) designs a multi-level learning-to-rank loss to leverage hierarchical information. Recently, Onoe et al. (2021) models the mention and type representations in a box space instead of the traditional vector space.

8 Conclusion

In this paper, we firstly point out that SOTA typing models suffer from a bottleneck issue, i.e., they perform poorly on a certain number of hard mentions, which leads to their limited overall performance. To this end, we propose to exploit sibling information for mention representation learning and define two metrics for detecting sibling relationship between mentions. Further, we model sibling learning as a graph learning problem. Our model is scalable in that, once trained, it can generate sibling-aware representations for previously unseen mentions efficiently during inference stage. Extensive experiments show that the proposed model indeed handles hard mentions well and thereby yields better overall performance than SOTA baseline models.

Abstract

The goal of the cross-lingual summarization (CLS) is to convert a document in one language (*e.g.*, English) to a summary in another one (*e.g.*, Chinese). Essentially, the CLS task is the combination of machine translation (MT) and monolingual summarization (MS), and thus there exists the hierarchical relationship between MT&MS and CLS. Existing studies on CLS mainly focus on utilizing pipeline methods or jointly training an end-to-end model through an auxiliary MT or MS objective. However, it is very challenging for the model to directly conduct CLS as it requires both the abilities to translate and summarize. To address this issue, we propose a hierarchical model for the CLS task, based on the conditional variational auto-encoder. The hierarchical model contains two kinds of latent variables at the local and global levels, respectively. At the local level, there are two latent variables, one for translation and the other for summarization. As for the global level, there is another latent variable for cross-lingual summarization conditioned on the two local-level variables. Experiments on two language directions (English⇔Chinese) verify the effectiveness and superiority of the proposed approach. In addition, we show that our model is able to generate better cross-lingual summaries than comparison models in the few-shot setting.

1 Introduction

The cross-lingual summarization (CLS) aims to summarize a document in source language (*e.g.*, English) into a different language (*e.g.*, Chinese), which can be seen as a combination of machine translation (MT) and monolingual summarization (MS) to some extent (Orăsan and Chiorean, 2008; Zhu et al., 2019). The CLS can help people effectively master the core points of an article in a foreign language. Under the background of globalization, it becomes more important and is now coming into widespread use in real life.

Many researches have been devoted to dealing with this task. To our knowledge, they mainly fall into two categories, *i.e.*, pipeline and end-to-end learning methods. (*i*) The first category is pipeline-based, adopting either translation-summarization (Leuski et al., 2003; Ouyang et al., 2019) or summarization-translation (Wan et al., 2010; Orăsan and Chiorean, 2008) paradigm. Although being intuitive and straightforward, they generally suffer from error propagation problem. (*ii*) The second category aims to train an end-to-end model for CLS (Zhu et al., 2019, 2020). For instance, Zhu et al. (2020) focus on using a pre-constructed probabilistic bilingual lexicon to improve the CLS model. Furthermore, some researches resort to multi-task learning (Takase and Okazaki, 2020; Bai et al., 2021a; Zhu et al., 2019; Cao et al., 2020a,b). Zhu et al. (2019) separately introduce MT and MS to improve CLS. Cao et al. (2020a,b) design several additional training objectives (*e.g.*, MS, back-translation, and reconstruction) to enhance the CLS model. And Xu et al. (2020) utilize a mixed-lingual pre-training method with several auxiliary tasks for CLS.

As pointed out by Cao et al. (2020a), it is challenging for the model to directly conduct CLS as it requires both the abilities to translate and summarize. Although some methods have used the related tasks (*e.g.*, MT and MS) to help the CLS, the hierarchical relationship between MT&MS and CLS are not well modeled, which can explicitly enhance the CLS task. Apparently, how to effectively model the hierarchical relationship to exploit MT and MS is one of the core issues, especially when the CLS data are limited.[1] In many other related NLP tasks (Park et al., 2018; Serban et al., 2017;

---

[1] Generally, it is difficult to acquire the CLS dataset (Zhu et al., 2020; Ayana et al., 2018; Duan et al., 2019).

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 2088 - 2099
May 22-27, 2022

Shen et al., 2019, 2021), the Conditional Variational Auto-Encoder (CVAE) (Sohn et al., 2015) has shown its superiority in learning hierarchical structure with hierarchical latent variables, which is often leveraged to capture the semantic connection between the utterance and the corresponding context of conversations. Inspired by these work, we attempt to adapt CVAE to model the hierarchical relationship between MT&MS and CLS.

Therefore, we propose a Variational Hierarchical Model to exploit translation and summarization simultaneously, named VHM, for CLS task in an end-to-end framework. VHM employs hierarchical latent variables based on CVAE to learn the hierarchical relationship between MT&MS and CLS. Specifically, the VHM contains two kinds of latent variables at the local and global levels, respectively. Firstly, we introduce two local variables for translation and summarization, respectively. The two local variables are constrained to reconstruct the translation and source-language summary. Then, we use the global variable to explicitly exploit the two local variables for better CLS, which is constrained to reconstruct the target-language summary. This makes sure the global variable captures its relationship with the two local variables without any loss, preventing error propagation. For inference, we use the local and global variables to assist the cross-lingual summarization process.

We validate our proposed training framework on the datasets of different language pairs (Zhu et al., 2019): Zh2EnSum (Chinese⇒English) and En2ZhSum (English⇒Chinese). Experiments show that our model achieves consistent improvements on two language directions in terms of both automatic metrics and human evaluation, demonstrating its effectiveness and generalizability. Few-shot evaluation further suggests that the local and global variables enable our model to generate a satisfactory cross-lingual summaries compared to existing related methods.

Our main contributions are as follows[2]:

- We are the first that builds a variational hierarchical model via conditional variational auto-encoders that introduce a global variable to combine the local ones for translation and summarization at the same time for CLS.
- Our model gains consistent and significant performance and remarkably outperforms the most previous state-of-the-art methods after using mBART (Liu et al., 2020).
- Under the few-shot setting, our model still achieves better performance than existing approaches. Particularly, the fewer the data are, the greater the improvement we gain.

2 Background

Machine Translation (MT). Given an input sequence in the source language $X_{mt}=\{x_i\}_{i=1}^{|X_{mt}|}$, the goal of the neural MT model is to produce its translation in the target language $Y_{mt}=\{y_i\}_{i=1}^{|Y_{mt}|}$. The conditional distribution of the model is:

$$p_\theta(Y_{mt}|X_{mt}) = \prod_{t=1}^{|Y_{mt}|} p_\theta(y_t|X_{mt}, y_{1:t-1}),$$

where θ are model parameters and $y_{1:t-1}$ is the partial translation.

Monolingual Summarization (MS). Given an input article in the source language $X_{ms}^{src}=\{x_i^{src}\}_{i=1}^{|X_{ms}^{src}|}$ and the corresponding summarization in the same language $X_{ms}^{tgt}=\{x_i^{tgt}\}_{i=1}^{|X_{ms}^{tgt}|}$, the monolingual summarization is formalized as:

$$p_\theta(X_{ms}^{tgt}|X_{ms}^{src}) = \prod_{t=1}^{|X_{ms}^{tgt}|} p_\theta(x_t^{tgt}|X_{ms}^{src}, x_{1:t-1}^{tgt}).$$

Cross-Lingual Summarization (CLS). In CLS, we aim to learn a model that can generate a summary in the target language $Y_{cls}=\{y_i\}_{i=1}^{|Y_{cls}|}$ for a given article in the source language $X_{cls}=\{x_i\}_{i=1}^{|X_{cls}|}$. Formally, it is as follows:

$$p_\theta(Y_{cls}|X_{cls}) = \prod_{t=1}^{|Y_{cls}|} p_\theta(y_t|X_{cls}, y_{1:t-1}).$$

Conditional Variational Auto-Encoder (CVAE). The CVAE (Sohn et al., 2015) consists of one prior network and one recognition (posterior) network, where the latter takes charge of guiding the learning of prior network via Kullback–Leibler (KL) divergence (Kingma and Welling, 2013). For example, the variational neural MT model (Zhang et al., 2016a; Su et al., 2018a; McCarthy et al., 2020; Su et al., 2018c), which introduces a random latent variable $\mathbf{z}$ into the neural MT conditional distribution:

$$p_\theta(Y_{mt}|X_{mt}) = \int_{\mathbf{z}} p_\theta(Y_{mt}|X_{mt}, \mathbf{z}) \cdot p_\theta(\mathbf{z}|X_{mt}) d\mathbf{z}. \tag{1}$$

Given a source sentence X, a latent variable $\mathbf{z}$ is

---

[2] The code is publicly available at: `https://github.com/XL2248/VHM`

firstly sampled by the prior network from the encoder, and then the target sentence is generated by the decoder: $Y_{mt} \sim p_\theta(Y_{mt}|X_{mt}, \mathbf{z})$, where $\mathbf{z} \sim p_\theta(\mathbf{z}|X_{mt})$.

As it is hard to marginalize Eq. 1, the CVAE training objective is a variational lower bound of the conditional log-likelihood:

$$\begin{aligned}\mathcal{L}(\theta, \phi; X_{mt}, Y_{mt}) &= -\mathrm{KL}(q_\phi(\mathbf{z}'|X_{mt}, Y_{mt})\|p_\theta(\mathbf{z}|X_{mt})) \\ &\quad + \mathbb{E}_{q_\phi(\mathbf{z}'|X_{mt}, Y_{mt})}[\log p_\theta(Y_{mt}|\mathbf{z}, X_{mt})] \\ &\leq \log p(Y_{mt}|X_{mt}),\end{aligned}$$

where ϕ are parameters of the CVAE.

3 Methodology

Fig. 1 demonstrates an overview of our model, consisting of four components: *encoder*, *variational hierarchical modules*, *decoder*, *training and inference*. Specifically, we aim to explicitly exploit the MT and MS for CLS simultaneously. Therefore, we firstly use the *encoder* (§ 3.1) to prepare the representation for the *variational hierarchical module* (§ 3.2), which aims to learn the two local variables for the global variable in CLS. Then, we introduce the global variable into the *decoder* (§ 3.3). Finally, we elaborate the process of our *training and inference* (§ 3.4).

3.1 Encoder

Our model is based on transformer (Vaswani et al., 2017) framework. As shown in Fig. 1, the encoder takes six types of inputs, $\{X_{mt}, X^{src}_{ms}, X_{cls}, Y_{mt}, X^{tgt}_{ms}, Y_{cls}\}$, among which Y_{mt}, X^{tgt}_{ms}, and Y_{cls} are only for training recognition networks. Taking X_{mt} for example, the encoder maps the input X_{mt} into a sequence of continuous representations whose size varies with respect to the source sequence length. Specifically, the encoder consists of N_e stacked layers and each layer includes two sub-layers:[3] a multi-head self-attention (SelfAtt) sub-layer and a position-wise feed-forward network (FFN) sub-layer:

$$\begin{aligned}\mathbf{s}^\ell_e &= \mathrm{SelfAtt}(\mathbf{h}^{\ell-1}_e) + \mathbf{h}^{\ell-1}_e, \\ \mathbf{h}^\ell_e &= \mathrm{FFN}(\mathbf{s}^\ell_e) + \mathbf{s}^\ell_e,\end{aligned}$$

where $\mathbf{h}^\ell_e$ denotes the state of the ℓ-th encoder layer and $\mathbf{h}^0_e$ denotes the initialized embedding.

Through the encoder, we prepare the representations of $\{X_{mt}, X^{src}_{ms}, X_{cls}\}$ for training prior networks, encoder and decoder. Taking X_{mt} for example, we follow Zhang et al. (2016a) and apply *mean-pooling* over the output $\mathbf{h}^{N_e,X_{mt}}_e$ of the N_e-th encoder layer:

$$\mathbf{h}_{X_{mt}} = \frac{1}{|X_{mt}|}\sum_{i=1}^{|X_{mt}|}(\mathbf{h}^{N_e,X_{mt}}_{e,i}).$$

Similarly, we obtain $\mathbf{h}_{X^{src}_{ms}}$ and $\mathbf{h}_{X_{cls}}$.

For training recognition networks, we obtain the representations of $\{Y_{mt}, X^{tgt}_{ms}, Y_{cls}\}$, taking Y_{mt} for example, and calculate it as follows:

$$\mathbf{h}_{Y_{mt}} = \frac{1}{|Y_{mt}|}\sum_{i=1}^{|Y_{mt}|}(\mathbf{h}^{N_e,Y_{mt}}_{e,i}).$$

Similarly, we obtain $\mathbf{h}_{X^{tgt}_{ms}}$ and $\mathbf{h}_{Y_{cls}}$.

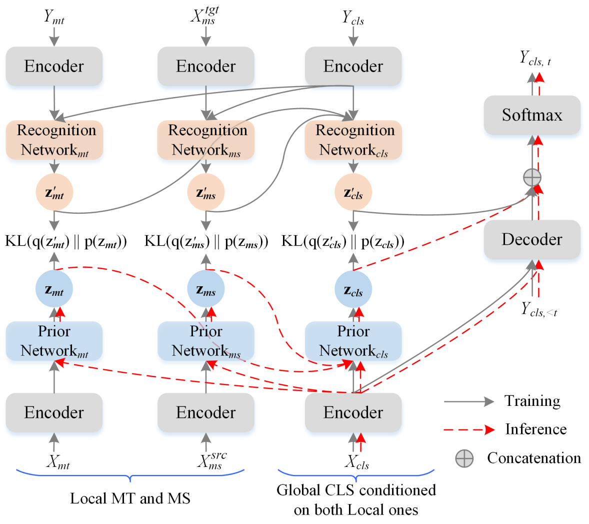

Figure 1: Overview of the proposed VHM framework. The local variables $\mathbf{z}_{mt}$, $\mathbf{z}_{ms}$ are tailored for translation and summarization, respectively. Then the global one $\mathbf{z}_{cls}$ is for cross-lingual summarization, where the $\mathbf{z}_{cls}$ not only conditions on the input but also $\mathbf{z}_{mt}$ and $\mathbf{z}_{ms}$. The solid grey lines indicate training process responsible for generating $\{\mathbf{z}'_{mt}, \mathbf{z}'_{ms}, \mathbf{z}'_{cls}\}$ from the corresponding posterior distribution predicted by recognition networks, which guide the learning of prior networks. The dashed red lines indicate inference process for generating $\{\mathbf{z}_{mt}, \mathbf{z}_{ms}, \mathbf{z}_{cls}\}$ from the corresponding prior distributions predicted by prior networks. The encoder is shared by all tasks with a bilingual vocabulary.

3.2 Variational Hierarchical Modules

Firstly, we design two local latent variational modules to learn the translation distribution in MT pairs and summarization distribution in MS pairs, respectively. Then, conditioned on them, we introduce a global latent variational module to explicitly exploit them.

---

[3] The layer normalization is omitted for simplicity and you may refer to (Vaswani et al., 2017) for more details.

3.2.1 Local: Translation and Summarization

Translation. To capture the translation of the paired sentences, we introduce a local variable $\mathbf{z}_{mt}$ that is responsible for generating the target information. Inspired by Wang and Wan (2019), we use isotropic Gaussian distribution as the prior distribution of $\mathbf{z}_{mt}$: $p_\theta(\mathbf{z}_{mt}|X_{mt}) \sim \mathcal{N}(\boldsymbol{\mu}_{mt}, \boldsymbol{\sigma}^2_{mt}\mathbf{I})$, where $\mathbf{I}$ denotes the identity matrix and we have

$$\begin{aligned}\boldsymbol{\mu}_{mt} &= \mathrm{MLP}^{mt}_\theta(\mathbf{h}_{X_{mt}}),\\ \boldsymbol{\sigma}_{mt} &= \mathrm{Softplus}(\mathrm{MLP}^{mt}_\theta(\mathbf{h}_{X_{mt}})),\end{aligned} \tag{2}$$

where $\mathrm{MLP}(\cdot)$ and $\mathrm{Softplus}(\cdot)$ are multi-layer perceptron and approximation of ReLU function, respectively.

At training, the posterior distribution conditions on both source input and the target reference, which provides translation information. Therefore, the prior network can learn a tailored translation distribution by approaching the recognition network via KL divergence (Kingma and Welling, 2013): $q_\phi(\mathbf{z}'_{mt}|X_{mt}, Y_{mt}) \sim \mathcal{N}(\boldsymbol{\mu}'_{mt}, \boldsymbol{\sigma}'^2_{mt}\mathbf{I})$, where $\boldsymbol{\mu}'_{mt}$ and $\boldsymbol{\sigma}'_{mt}$ are calculated as:

$$\begin{aligned}\boldsymbol{\mu}'_{mt} &= \mathrm{MLP}^{mt}_\phi(\mathbf{h}_{X_{mt}}; \mathbf{h}_{Y_{mt}}),\\ \boldsymbol{\sigma}'_{mt} &= \mathrm{Softplus}(\mathrm{MLP}^{mt}_\phi(\mathbf{h}_{X_{mt}}; \mathbf{h}_{Y_{mt}})),\end{aligned} \tag{3}$$

where $(\cdot;\cdot)$ indicates concatenation operation.

Summarization. To capture the summarization in MS pairs, we introduce another local variable $\mathbf{z}_{ms}$, which takes charge of generating the source-language summary. Similar to $\mathbf{z}_{mt}$, we define its prior distribution as: $p_\theta(\mathbf{z}_{ms}|X^{src}_{ms}) \sim \mathcal{N}(\boldsymbol{\mu}_{ms}, \boldsymbol{\sigma}^2_{ms}\mathbf{I})$, where $\boldsymbol{\mu}_{ms}$ and $\boldsymbol{\sigma}_{ms}$ are calculated as:

$$\begin{aligned}\boldsymbol{\mu}_{ms} &= \mathrm{MLP}^{ms}_\theta(\mathbf{h}_{X^{src}_{ms}}),\\ \boldsymbol{\sigma}_{ms} &= \mathrm{Softplus}(\mathrm{MLP}^{ms}_\theta(\mathbf{h}_{X^{src}_{ms}})).\end{aligned} \tag{4}$$

At training, the posterior distribution conditions on both the source input and the source-language summary that contains the summarization clue, and thus is responsible for guiding the learning of the prior distribution. Specifically, we define the posterior distribution as: $q_\phi(\mathbf{z}'_{ms}|X^{src}_{ms}, X^{tgt}_{ms}) \sim \mathcal{N}(\boldsymbol{\mu}'_{ms}, \boldsymbol{\sigma}'^2_{ms}\mathbf{I})$, where $\boldsymbol{\mu}'_{ms}$ and $\boldsymbol{\sigma}'_{ms}$ are calculated as:

$$\begin{aligned}\boldsymbol{\mu}'_{ms} &= \mathrm{MLP}^{ms}_\phi(\mathbf{h}_{X^{src}_{ms}}; \mathbf{h}_{X^{tgt}_{ms}}),\\ \boldsymbol{\sigma}'_{ms} &= \mathrm{Softplus}(\mathrm{MLP}^{ms}_\phi(\mathbf{h}_{X^{src}_{ms}}; \mathbf{h}_{X^{tgt}_{ms}})).\end{aligned} \tag{5}$$

3.2.2 Global: CLS

After obtaining $\mathbf{z}_{mt}$ and $\mathbf{z}_{ms}$, we introduce the global variable $\mathbf{z}_{cls}$ that aims to generate a target-language summary, where the $\mathbf{z}_{cls}$ can simultaneously exploit the local variables for CLS. Specifically, we firstly encode the source input X_{cls} and condition on both two local variables $\mathbf{z}_{mt}$ and $\mathbf{z}_{ms}$, and then sample $\mathbf{z}_{cls}$. We define its prior distribution as: $p_\theta(\mathbf{z}_{cls}|X_{cls}, \mathbf{z}_{mt}, \mathbf{z}_{ms}) \sim \mathcal{N}(\boldsymbol{\mu}_{cls}, \boldsymbol{\sigma}^2_{cls}\mathbf{I})$, where $\boldsymbol{\mu}_{cls}$ and $\boldsymbol{\sigma}_{cls}$ are calculated as:

$$\begin{aligned}\boldsymbol{\mu}_{cls} &= \mathrm{MLP}^{cls}_\theta(\mathbf{h}_{X_{cls}}; \mathbf{z}_{mt}; \mathbf{z}_{ms}),\\ \boldsymbol{\sigma}_{cls} &= \mathrm{Softplus}(\mathrm{MLP}^{cls}_\theta(\mathbf{h}_{X_{cls}}; \mathbf{z}_{mt}; \mathbf{z}_{ms})).\end{aligned} \tag{6}$$

At training, the posterior distribution conditions on the local variables, the CLS input, and the cross-lingual summary that contains combination information of translation and summarization. Therefore, the posterior distribution can teach the prior distribution. Specifically, we define the posterior distribution as: $q_\phi(\mathbf{z}'_{cls}|X_{cls}, \mathbf{z}_{mt}, \mathbf{z}_{ms}, Y_{cls}) \sim \mathcal{N}(\boldsymbol{\mu}'_{cls}, \boldsymbol{\sigma}'^2_{cls}\mathbf{I})$, where $\boldsymbol{\mu}'_{cls}$ and $\boldsymbol{\sigma}'_{cls}$ are calculated as:

$$\begin{aligned}\boldsymbol{\mu}'_{cls} &= \mathrm{MLP}^{cls}_\phi(\mathbf{h}_{X_{cls}}; \mathbf{z}_{mt}; \mathbf{z}_{ms}; \mathbf{h}_{Y_{cls}}),\\ \boldsymbol{\sigma}'_{cls} &= \mathrm{Softplus}(\mathrm{MLP}^{cls}_\phi(\mathbf{h}_{X_{cls}}; \mathbf{z}_{mt}; \mathbf{z}_{ms}; \mathbf{h}_{Y_{cls}})).\end{aligned} \tag{7}$$

3.3 Decoder

The decoder adopts a similar structure to the encoder, and each of N_d decoder layers includes an additional cross-attention sub-layer ($\mathrm{CrossAtt}$):

$$\begin{aligned}\mathbf{s}^\ell_d &= \mathrm{SelfAtt}(\mathbf{h}^{\ell-1}_d) + \mathbf{h}^{\ell-1}_d,\\ \mathbf{c}^\ell_d &= \mathrm{CrossAtt}(\mathbf{s}^\ell_d, \mathbf{h}^{N_e}_e) + \mathbf{s}^\ell_d,\\ \mathbf{h}^\ell_d &= \mathrm{FFN}(\mathbf{c}^\ell_d) + \mathbf{c}^\ell_d,\end{aligned}$$

where $\mathbf{h}^\ell_d$ denotes the state of the ℓ-th decoder layer.

As shown in Fig. 1, we firstly obtain the local two variables either from the posterior distribution predicted by recognition networks (training process as the solid grey lines) or from prior distribution predicted by prior networks (inference process as the dashed red lines). Then, conditioned on the local two variables, we generate the global variable ($\mathbf{z}'_{cls}$/$\mathbf{z}_{cls}$) via posterior (training) or prior (inference) network. Finally, we incorporate $\mathbf{z}^{(\prime)}_{cls}$[4] into the state of the top layer of the decoder with a projection layer:

$$\mathbf{o}_t = \mathrm{Tanh}(\mathbf{W}_p[\mathbf{h}^{N_d}_{d,t}; \mathbf{z}^{(\prime)}_{cls}] + \mathbf{b}_p), \tag{8}$$

where $\mathbf{W}_p$ and $\mathbf{b}_p$ are training parameters, $\mathbf{h}^{N_d}_{d,t}$ is the hidden state at time-step t of the N_d-th decoder layer. Then, $\mathbf{o}_t$ is fed into a linear transformation and softmax layer to predict the probability distri-

---

[4] Here, we use $\mathbf{z}'_{cls}$ when training and $\mathbf{z}_{cls}$ during inference, as similar to Eq. 8.

bution of the next target token:

$$\mathbf{p}_t = \mathrm{Softmax}(\mathbf{W}_o \mathbf{o}_t + \mathbf{b}_o),$$

where $\mathbf{W}_o$ and $\mathbf{b}_o$ are training parameters.

3.4 Training and Inference

The model is trained to maximize the conditional log-likelihood, due to the intractable marginal likelihood, which is converted to the following variational lower bound that needs to be maximized in the training process:

$$\begin{aligned}
&\mathcal{J}(\theta, \phi; X_{cls}, X_{mt}, X_{ms}^{src}, Y_{cls}, Y_{mt}, X_{ms}^{tgt}) = \\
&- \mathrm{KL}(q_\phi(\mathbf{z}'_{mt}|X_{mt}, Y_{mt}) \| p_\theta(\mathbf{z}_{mt}|X_{mt})) \\
&- \mathrm{KL}(q_\phi(\mathbf{z}'_{ms}|X_{ms}^{src}, X_{ms}^{tgt}) \| p_\theta(\mathbf{z}_{ms}|X_{ms}^{src})) \\
&- \mathrm{KL}(q_\phi(\mathbf{z}'_{cls}|X_{cls}, \mathbf{z}_{mt}, \mathbf{z}_{ms}, Y_{cls}) \| p_\theta(\mathbf{z}_{cls}|X_{cls}, \mathbf{z}_{mt}, \mathbf{z}_{ms})) \\
&+ \mathbb{E}_{q_\phi}[\log p_\theta(Y_{mt}|X_{mt}, \mathbf{z}_{mt})] \\
&+ \mathbb{E}_{q_\phi}[\log p_\theta(X_{ms}^{tgt}|X_{ms}^{src}, \mathbf{z}_{ms})] \\
&+ \mathbb{E}_{q_\phi}[\log p_\theta(Y_{cls}|X_{cls}, \mathbf{z}_{cls}, \mathbf{z}_{mt}, \mathbf{z}_{ms})],
\end{aligned}$$

where the variational lower bound includes the reconstruction terms and KL divergence terms based on three hierarchical variables. We use the reparameterization trick (Kingma and Welling, 2013) to estimate the gradients of the prior and recognition networks (Zhao et al., 2017).

During inference, firstly, the prior networks of MT and MS generate the local variables. Then, conditioned on them, the global variable is produced by prior network of CLS. Finally, only the global variable is fed into the decoder, which corresponds to red dashed arrows in Fig. 1.

4 Experiments

4.1 Datasets and Metrics

Datasets. We evaluate the proposed approach on Zh2EnSum and En2ZhSum datasets released by (Zhu et al., 2019).[5] The Zh2EnSum and En2ZhSum are originally from (Hu et al., 2015) and (Hermann et al., 2015; Zhu et al., 2018), respectively. Both the Chinese-to-English and English-to-Chinese test sets are manually corrected. The involved training data in our experiments are listed in Tab. 1.

Zh2EnSum. It is a Chinese-to-English summarization dataset, which has 1,699,713 Chinese short texts (104 Chinese characters on average) paired with Chinese (18 Chinese characters on average) and English short summaries (14 tokens on average). The dataset is split into 1,693,713 training pairs, 3,000 validation pairs, and 3,000 test pairs.

Zh2EnSum	D1	CLS	Zh2EnSum	1,693,713
	D2	MS	LCSTS	1,693,713
	D3	MT	LDC	2.08M
En2ZhSum	D4	CLS	En2ZhSum	364,687
	D5	MS	ENSUM	364,687
	D3	MT	LDC	2.08M

Table 1: Involved training data. LCSTS (Hu et al., 2015) is a Chinese summarization dataset. LDC corpora includes LDC2000T50, LDC2002L27, LDC2002T01, LDC2002E18, LDC2003E07, LDC2003E14, LDC2003T17, and LDC2004T07. ENSUM consists of CNN/Dailymail (Hermann et al., 2015) and MSMO (Zhu et al., 2018).

Models	Zh2EnSum

Table 3: Model details. Size (M): number of trainable parameters; Train (S) denotes how many seconds required for each model to train the 100-batch cross-lingual summarization task of the same batch size (3072). Data: Training Data, as listed in Tab. 1.

The involved training data used in multi-task learning, model size, training time, are listed in Tab. 2.

En2ZhSum. It is an English-to-Chinese summarization dataset, which has 370,687 English documents (755 tokens on average) paired with multi-sentence English (55 tokens on average) and Chinese summaries (96 Chinese characters on average). The dataset is split into 364,687 training pairs, 3,000 validation pairs, and 3,000 test pairs. The involved training data used in multi-task learning, model size, training time, are listed in Tab. 3.

Metrics. Following Zhu et al. (2020), 1) we evaluate all models with the standard ROUGE metric (Lin, 2004), reporting the F1 scores for ROUGE-1, ROUGE-2, and ROUGE-L. All ROUGE scores

Table 4: ROUGE F1 scores (%) and MoverScore scores (%) on Zh2EnSum test set, and ROUGE F1 scores (%) on En2ZhSum test set. RG and MVS refer to ROUGE and MoverScore, respectively. The “*” denotes results by running their released code. The “NA” indicates no such result in the original paper. “$\dagger$” and “$\dagger\dagger$” indicate that statistically significant better (M11 vs. M4 and M14 vs. M12) with t-test $p < 0.05$ and $p < 0.01$, respectively. “VHM + mBART” means that we use mBART weights as model initialization of our VHM.

are reported by the 95% confidence interval measured by the official script;[6] 2) we also evaluate the quality of English summaries in Zh2EnSum with MoverScore (Zhao et al., 2019).

4.2 Implementation Details

In this paper, we train all models using standard transformer (Vaswani et al., 2017) in *Base* setting. For other hyper-parameters, we mainly follow the setting described in Zhu et al. (2019, 2020) for fair comparison. For more details, please refer to Appendix A.

4.3 Comparison Models

Pipeline Models. TETran (Zhu et al., 2019). It first translates the original article into the target language by Google Translator[7] and then summarizes the translated text via LexRank (Erkan and Radev, 2004). TLTran (Zhu et al., 2019). It first summarizes the original article via a transformer-based monolingual summarization model and then translates the summary into the target language by Google Translator.

End-to-End Models. TNCLS (Zhu et al., 2019). It directly uses the de-facto transformer (Vaswani et al., 2017) to train an end-to-end CLS system. ATS-A (Zhu et al., 2020).[8] It is an efficient model to attend the pre-constructed probabilistic bilingual lexicon to enhance the CLS. MS-CLS (Zhu et al., 2019). It simultaneously performs summarization generation for both CLS and MS tasks and calculates the total losses. MT-CLS (Zhu et al., 2019).[9] It alternatively trains CLS and MT tasks. MS-CLS-Rec (Cao et al., 2020a). It jointly trains MS and CLS systems with a reconstruction loss to mutually map the source and target representations. mBART (Liu et al., 2020). We use mBART ($mbart.cc25$) as model initialization to fine-tune the CLS task. MLPT (Mixed-Lingual Pretraining) (Xu et al., 2020). It applies mixed-lingual pretraining that leverages six related tasks, covering both cross-lingual tasks such as translation and monolingual tasks like masked language models. MT-MS-CLS. It is our strong baseline, which is implemented by alternatively training CLS, MT, and MS. Here, we keep the dataset used for MT and MS consistent with Zhu et al. (2019) for fair comparison.

4.4 Main Results

Overall, we separate the models into three parts in Tab. 4: the pipeline, end-to-end, and multi-task

---

[6] The parameter for ROUGE script here is “-c 95 -r 1000 -n 2 -a”

[7] `https://translate.google.com/`

[8] `https://github.com/ZNLP/ATSum`

[9] `https://github.com/ZNLP/NCLS-Corpora`

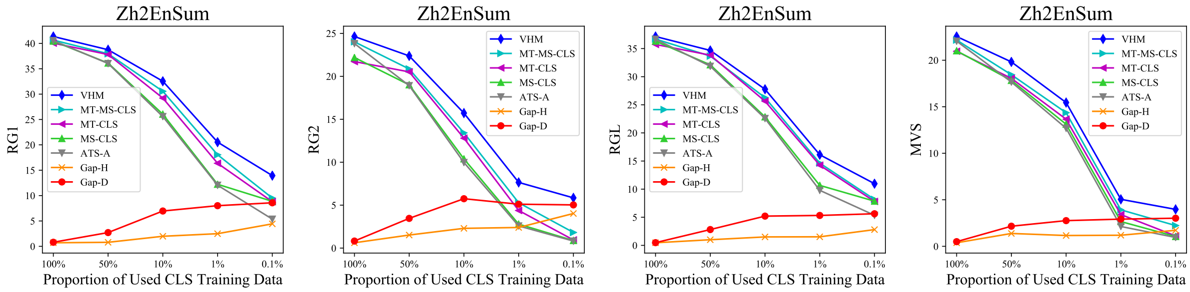

Figure 2: ROUGE F1 scores (%) and MoverScore scores (%) on Zh2EnSum test set in few-shot setting. **x%** means that the **x%** CLS training dataset is used, *e.g.*, **0.1%** represents that **0.1%** training dataset (about 1.7k instances) is used for training. The performance "Gap-H" (orange line) between "VHM" and "MT-MS-CLS" grows steadily with the decreasing of used CLS training data, which is similar to the performance "Gap-D" (red line) between "VHM" and "ATS-A".

settings. In each part, we show the results of existing studies and our re-implemented baselines and our approach, *i.e.*, the VHM, on Zh2EnSum and En2ZhSum test sets.

Results on Zh2EnSum. Compared against the pipeline and end-to-end methods, VHM substantially outperforms all of them (*e.g.*, the previous best model "ATS-A") by a large margin with 0.68/0.52/0.18/0.4↑ scores on RG1/RG2/RGL/MVS, respectively. Under the multi-task setting, compared to the existing best model "MS-CLS-Rec", our VHM also consistently boosts the performance in three metrics (*i.e.*, 0.39↑, 1.44↑, and 0.19↑ ROUGE scores on RG1/RG2/RGL, respectively), showing its effectiveness. Our VHM also significantly surpasses our strong baseline "MT-MS-CLS" by 0.71/0.62/0.46/0.38↑ scores on RG1/RG2/RGL/MVS, respectively, demonstrating the superiority of our model again.

After using mBART as model initialization, our VHM achieves the state-of-the-art results on all metrics.

Results on En2ZhSum. Compared against the pipeline, end-to-end and multi-task methods, our VHM presents remarkable ROUGE improvements over the existing best model "ATS-A" by a large margin, about 0.51/0.86/0.23↑ ROUGE gains on RG1/RG2/RGL, respectively. These results suggest that VHM consistently performs well in different language directions.

Our approach still notably surpasses our strong baseline "MT-MS-CLS" in terms of all metrics, which shows the generalizability and superiority of our model again.

4.5 Few-Shot Results

Due to the difficulty of acquiring the cross-lingual summarization dataset (Zhu et al., 2019), we conduct such experiments to investigate the model performance when the CLS training dataset is limited, *i.e.*, few-shot experiments. Specifically, we randomly choose 0.1%, 1%, 10%, and 50% CLS training datasets to conduct experiments. The results are shown in Fig. 2 and Fig. 3.

Results on Zh2EnSum. Fig. 2 shows that VHM significantly surpasses all comparison models under each setting. Particularly, under the 0.1% setting, our model still achieves best performances than all baselines, suggesting that our variational hierarchical model works well in the few-shot setting as well. Besides, we find that the performance gap between comparison models and VHM is growing when the used CLS training data become fewer. It is because relatively larger proportion of translation and summarization data are used, the influence from MT and MS becomes greater, effectively strengthening the CLS model. Particularly, the performance "Gap-H" between MT-MS-CLS and VHM is also growing, where both models utilize the same data. This shows that the hierarchical relationship between MT&MS and CLS makes substantial contributions to the VHM model in terms of four metrics. Consequently, our VHM achieves a comparably stable performance.

Results on En2ZhSum. From Fig. 3, we observe the similar findings on Zh2EnSum. This shows that VHM significantly outperforms all comparison models under each setting, showing the generalizability and superiority of our model again in the few-shot setting.

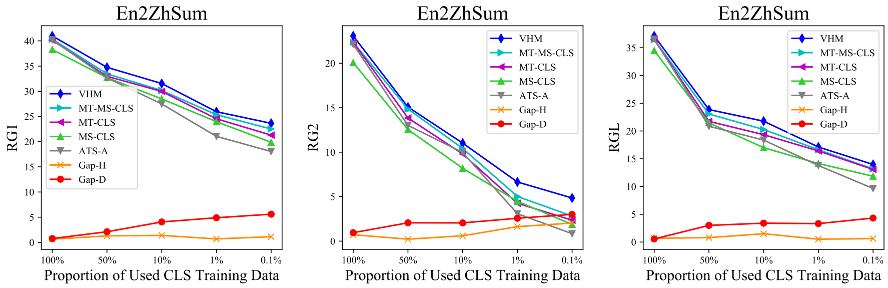

Figure 3: Rouge F1 scores (%) on the test set when using different CLS training data. The performance "Gap-H" (orange line) between "VHM" and "MT-MS-CLS" grows steadily with the decreasing of used CLS training data on ROUGE-2, which is similar to the performance "Gap-D" (red line) between "VHM" and "ATS-A".

#	**Models**	**Zh2EnSum**	**En2ZhSum**
		RG1/RG2/RGL/MVS	RG1/RG2/RGL

1	– $\mathbf{z}_{mt}$	40.75/23.47/36.48/22.18	40.35/22.48/36.55
2	– $\mathbf{z}_{ms}$	40.69/23.34/36.35/22.12	40.57/22.79/36.71
3	– $\mathbf{z}_{mt}$&$\mathbf{z}_{ms}$	40.45/22.97/36.03/22.36	39.98/21.91/36.33
4	– $\mathbf{z}_{cls}$	39.77/22.41/34.87/21.62	39.76/21.69/35.99
5	– hierarchy	40.47/22.64/34.96/21.78	39.67/21.79/35.87

Table 5: Ablation results (in the full setting). Row 1 denotes that we remove the local variable $\mathbf{z}_{mt}$, and sample $\mathbf{z}_{cls}$ from the source input and another local variable $\mathbf{z}_{ms}$, similarly for row 2. Row 3 denotes that we remove both local variables $\mathbf{z}_{mt}$ and $\mathbf{z}_{ms}$ and sample $\mathbf{z}_{cls}$ only from the source input. Row 4 means that we remove the global variable $\mathbf{z}_{cls}$ and directly attend the local variables $\mathbf{z}_{mt}$ and $\mathbf{z}_{ms}$ in Eq. 8. Row 5 represents that we keep three latent variables but remove the hierarchical relation between $\mathbf{z}_{cls}$ and $\mathbf{z}_{mt}$&$\mathbf{z}_{ms}$.

5 Analysis

5.1 Ablation Study

We conduct ablation studies to investigate how well the local and global variables of our VHM works. When removing variables listed in Tab. 5, we have the following findings.

(1) Rows 1∼3 vs. row 0 shows that the model performs worse, especially when removing the two local ones (row 3), due to missing the explicit translation or summarization or both information provided by the local variables, which is important to CLS. Besides, row 3 indicates that directly attending to $\mathbf{z}_{cls}$ leads to poor performances, showing the necessity of the hierarchical structure, *i.e.*, using the global variable to exploit the local ones.

(2) Rows 4∼5 vs. row 0 shows that directly attending the local translation and summarization cannot achieve good results due to lacking of the global combination of them, showing that it is very necessary for designing the variational hierarchical model, *i.e.*, using a global variable to well exploit and combine the local ones.

5.2 Human Evaluation

Following Zhu et al. (2019, 2020), we conduct human evaluation on 25 random samples from each of the Zh2EnSum and En2ZhSum test set. We compare the summaries generated by our methods (MT-MS-CLS and VHM) with the summaries generated by ATS-A, MS-CLS, and MT-CLS in the full setting and few-shot setting (0.1%), respectively. We invite three graduate students to compare the generated summaries with human-corrected references, and assess each summary from three independent perspectives:

1. How **informative** (*i.e.*, IF) the summary is?
2. How **concise** (*i.e.*, CC) the summary is?
3. How **fluent**, grammatical (*i.e.*, FL) the summary is?

Each property is assessed with a score from 1 (worst) to 5 (best). The average results are presented in Tab. 6 and Tab. 7.

Tab. 6 shows the results in the full setting. We find that our VHM outperforms all comparison models from three aspects in both language directions, which further demonstrates the effectiveness and superiority of our model.

Tab. 7 shows the results in the few-shot setting, where only 0.1% CLS training data are used in all models. We find that our VHM still performs best than all other models from three perspectives in both datasets, suggesting its generalizability and effectiveness again under different settings.

the pipeline methods (Leuski et al., 2003; Ouyang et al., 2019; Orăsan and Chiorean, 2008; Wan et al., 2010; Wan, 2011; Yao et al., 2015; Zhang et al., 2016b), *i.e.*, translation and then summarization or summarization and then translation. Due to the difficulty of acquiring cross-lingual summarization dataset, some previous researches focus on constructing datasets (Ladhak et al., 2020; Scialom et al., 2020; Yela-Bello et al., 2021; Zhu et al., 2019; Hasan et al., 2021; Perez-Beltrachini and Lapata, 2021; Varab and Schluter, 2021), mixed-lingual pre-training (Xu et al., 2020), knowledge distillation (Nguyen and Tuan, 2021), contrastive learning (Wang et al., 2021) or zero-shot approaches (Ayana et al., 2018; Duan et al., 2019; Dou et al., 2020), *i.e.*, using machine translation (MT) or monolingual summarization (MS) or both to train the CLS system. Among them, Zhu et al. (2019) propose to use roundtrip translation strategy to obtain large-scale CLS datasets and then present two multi-task learning methods for CLS. Based on this dataset, Zhu et al. (2020) leverage an end-to-end model to attend the pre-constructed probabilistic bilingual lexicon to improve CLS. To further enhance CLS, some studies resort to shared decoder (Bai et al., 2021a), more pseudo training data (Takase and Okazaki, 2020), or more related task training (Cao et al., 2020b,a; Bai et al., 2021b). Wang et al. (2022) concentrate on building a benchmark dataset for CLS on dialogue field. Different from them, we propose a variational hierarchical model that introduces a global variable to simultaneously exploit and combine the local translation variable in MT pairs and local summarization variable in MS pais for CLS, achieving better results.

Conditional Variational Auto-Encoder. CVAE has verified its superiority in many fields (Sohn et al., 2015; Liang et al., 2021a; Zhang et al., 2016a; Su et al., 2018b). For instance, in dialogue, Shen et al. (2019), Park et al. (2018) and Serban et al. (2017) extend CVAE to capture the semantic connection between the utterance and the corresponding context with hierarchical latent variables. Although the CVAE has been widely used in NLP tasks, its adaption and utilization to cross-lingual summarization for modeling hierarchical relationship are non-trivial, and to the best of our knowledge, has never been investigated before in CLS.

Multi-Task Learning. Conventional multi-task learning (MTL) (Caruana, 1997), which trains the model on multiple related tasks to promote the representation learning and generalization performance, has been successfully used in NLP fields (Collobert and Weston, 2008; Deng et al., 2013; Liang et al., 2021d,c,b). In the CLS, conventional MTL has been explored to incorporate additional training data (MS, MT) into models (Zhu et al., 2019; Takase and Okazaki, 2020; Cao et al., 2020a). In this work, we instead focus on how to connect the relation between the auxiliary tasks at training to make the most of them for better CLS.

7 Conclusion

In this paper, we propose to enhance the CLS model by simultaneously exploiting MT and MS. Given the hierarchical relationship between MT&MS and CLS, we propose a variational hierarchical model to explicitly exploit and combine them in CLS process. Experiments on Zh2EnSum and En2ZhSum show that our model significantly improves the quality of cross-lingual summaries in terms of automatic metrics and human evaluations. Particularly, our model in the few-shot setting still works better, suggesting its superiority and generalizability.

Appendix

A Implementation Details

In this paper, we train all models using standard transformer (Vaswani et al., 2017) in *Base* setting. For other hyper-parameters, we mainly follow the setting described in (Zhu et al., 2019, 2020) for fair comparison. Specifically, the segmentation granularity is "subword to subword" for Zh2EnSum, and "word to word" for En2ZhSum. All the parameters are initialized via Xavier initialization method (Glorot and Bengio, 2010). We train our models using standard transformer (Vaswani et al., 2017) in *Base* setting, which contains a 6-layer encoder (*i.e.*, N_e) and a 6-layer decoder (*i.e.*, N_d) with 512-dimensional hidden representations. And all latent variables have a dimension of 128. Each mini-batch contains a set of document-summary pairs with roughly 4,096 source and 4,096 target tokens. We apply Adam optimizer (Kingma and Ba, 2015) with β_1 = 0.9, β_2 = 0.998. Following Zhu et al. (2019), we train each task for about 800,000 iterations in all multi-task models (reaching convergence). To alleviate the degeneration problem of the variational framework, we apply KL annealing. The KL multiplier λ gradually increases from 0 to 1 over 400, 000 steps. All our methods without mBART as model initialization are trained and tested on a single NVIDIA Tesla V100 GPU. We use 8 NVIDIA Tesla V100 GPU to train our models when using mBART as model initialization, where the number of token on each GPU is set to 2,048 and the training step is set to 400, 000.

During inference, we use beam search with a beam size 4 and length penalty 0.6.

On the Robustness of Question Rewriting Systems to Questions of Varying Hardness

Abstract

In conversational question answering (CQA), the task of question rewriting (QR) in context aims to rewrite a context-dependent question into an equivalent self-contained question that gives the same answer. In this paper, we are interested in the robustness of a QR system to questions varying in rewriting hardness or difficulty. Since there is a lack of questions classified based on their rewriting hardness, we first propose a heuristic method to automatically classify questions into subsets of varying hardness, by measuring the discrepancy between a question and its rewrite. To find out what makes questions hard or easy for rewriting, we then conduct a human evaluation to annotate the rewriting hardness of questions. Finally, to enhance the robustness of QR systems to questions of varying hardness, we propose a novel learning framework for QR that first trains a QR model independently on each subset of questions of a certain level of hardness, then combines these QR models as one joint model for inference. Experimental results on two datasets show that our framework improves the overall performance compared to the baselines[1].

1 Introduction

In conversational question answering (CQA) (Choi et al., 2018; Reddy et al., 2019), several sequential questions need to be answered one by one given a relevant article. To answer a question in CQA, we need to understand the historical context of the question. For example, to answer the question "*When did he begin writing these pieces?*", we need to know what *he* refers to in the conversation context. In our work, we address question-in-context rewriting (QR), which aims to rewrite a context-dependent question into an equivalent self-contained question in CQA, e.g., replacing *he* in the above example with its referent from the context. The task is formulated as a text generation task that generates the rewrite of a question given the original question and its conversation context (Elgohary et al., 2019).

Topic words: Benigno Aquino III; Senate (2007 - 10)
$\mathbf{q_1}$: What changes did he make while in the Senate?
$\mathbf{a_1}$: I don't know.
$\mathbf{q_2}$: When was *he* elected?
→ $\mathbf{q'_2}$: When was *Benigno Aquino III* elected to Senate?
$\mathbf{a_2}$: May 15, 2007
$\mathbf{q_3}$: Was he a republican or democrat?
$\mathbf{a_3}$: Genuine Opposition (GO), a coalition comprising a number of parties, including Aquino's own Liberal Party, ...
$\mathbf{q_4}$: Are there any other interesting aspects about this article?
→ $\mathbf{q'_4}$: Are there any other interesting aspects about Benigno Aquino III article *aside from political affiliation or when Benigno was elected?*
$\mathbf{a_4}$: Aquino was endorsed by the pentecostal Jesus Is Lord Church.

Table 1: One dialogue example from Elgohary et al. (2019) including questions ($\mathbf{q_i}$) and answers ($\mathbf{a_i}$) and certain rewrites ($\mathbf{q'_i}$) of the questions.

We are interested in how robust a QR system is to questions with different rewriting hardness (or difficulty). As we can see from the examples in Table 1, rewriting the question $\mathbf{q_2}$ requires only replacing the pronoun *he* by its referent, which usually appears in the conversation context, and the model can identify the referent by *attention* (Luong et al., 2015). However, for the question $\mathbf{q_4}$, to find the missing *aside from* clause, the model needs to understand the entire conversation since the question asks about other interesting aspects about the article related to the topic of the entire conversation. Understanding the whole context will be challenging for the model. Can a QR model still work well when rewriting the hard questions?

In section 6.3, our first study is on evaluating the performance of a QR model under questions varying in hardness. One issue in this process is

that there is a lack of classified questions in different rewriting hardness. Though we can rely on human labor to annotate the questions, it is expensive and not scalable. Instead, we propose a simple yet effective heuristic method to classify the questions automatically. We measure the *discrepancy* between a question and its rewrite, where the larger the discrepancy, the more difficult to rewrite the question. The intuition is that if a question is very dissimilar to its rewrite, more information has to be filled into the rewrite, which means the question is harder to rewrite. We specifically use the BLEU score to measure the discrepancy, and lower scores mean larger discrepancies. Using this method, we then split the questions into three subsets: hard, medium, and easy, and evaluate the baseline systems using these subsets.

In order to verify the classified subsets and find out what makes questions different in rewriting difficulty, in section 6.3.2, we further evaluate the question characteristics in hard, medium, and easy subsets through human evaluation. We first manually summarize the commonly used rules for rewriting questions from the training set, and then annotate the questions using the labels of summarized rewriting rules, followed by counting the number of these rewriting rules used in these subsets.

Finally, to enhance the robustness of a QR model to questions varying in difficulties, we propose a novel learning framework in section 5, where we first separately train a QR model on each hard, medium, and easy subset, and then combine these models into a joint model for inference. Training one sole model on each subset is to let the model better learn domain-specific information to deal with one specific type of questions (hard/medium/easy). By combining the models together, we have a joint model capable of rewriting questions differing in rewriting hardness. Specially, we introduce adapters (Houlsby et al., 2019) to reduce parameters when building private models and we present sequence-level adapter fusion and distillation (SLAF and SLAD) to effectively combine the private models into a joint model.

Our contributions in this paper include:

- We are the *first* to study the robustness of a QR system to questions with varying levels of rewriting hardness;
- We propose an effective method to identify questions of different rewriting hardness;
- We manually annotate questions sampled from the subsets with summarized rewriting rules for validity and address what makes questions hard or easy for rewriting;
- We propose a novel QR framework by taking into account the rewriting hardness.

We have the following observations in our paper:

- The baseline systems perform much worse on the hard subset but perform well on the easy subset;
- We find that easy questions usually only require *replacing pronouns* but hard questions involve more complex operations like *expanding special Wh* questions*;
- Experiments show that our QR learning framework enhances the rewriting performance compared to the baselines.

2 Related Work

Elgohary et al. (2019) created the QR dataset which rewrites a subset of the questions from QuAC (Choi et al., 2018). Based on this dataset, some recent work has studied this task and formulates QR as a text generation task with an encoder-decoder architecture (Elgohary et al., 2019; Kumar and Joshi, 2016; Vakulenko et al., 2020; Li et al., 2019; Lin et al., 2020a).

The difficulty of answering a question given a relevant document has been studied in the question answering community (Dua et al., 2019; Wolfson et al., 2020). Sugawara et al. (2018) examine 12 reading comprehension datasets and determine what makes a question more easily answered. Perez et al. (2020); Min et al. (2019); Talmor and Berant (2018); Dong et al. (2017) study how to make a hard question more easily answered. However, there is no work to date that studies whether rewriting difficulties exist in QR and how to measure the difficulties. Some other work is similar to QR but focuses on other tasks such as dialogue tracking (Rastogi et al., 2019; Su et al., 2019; Liu et al., 2020) and information retrieval (Voskarides et al., 2020; Lin et al., 2020b; Liu et al., 2019).

Varying rewriting difficulties can result in multiple underlying data distributions in the QR training data. The shared-private framework has been studied to learn from training data with multiple distributions (Zhang et al., 2018; Liu et al., 2017). One issue of the shared-private framework is parameter inefficiency when building private models We use adapter tuning (Rebuffi et al., 2018, 2017) to build the private models. Adapter tuning was recently proposed for adapting a pre-trained language model, e.g., BERT (Devlin et al., 2019), to downstream tasks (Pfeiffer et al., 2020a,c; Houlsby et al., 2019), and its effectiveness has been verified by previous work (Bapna and Firat, 2019; Pfeiffer et al., 2020b; Wang et al., 2020; He et al., 2021). We are the first to apply it to reduce model parameters in the shared-private framework. How to combine the knowledge stored in multiple adapters is also important. Pfeiffer et al. (2020a) propose adapter fusion to build an ensemble of adapters in multi-task learning. We propose sequence-level adapter fusion in our work.

3 Question-in-Context Rewriting

Question-in-context rewriting (QR) aims to generate a self-contained rewrite from a context-dependent question in CQA. Given a conversational dialogue $\mathcal{H}$ with sequential question and answer pairs $\{\mathbf{q}_1, \mathbf{a}_1, \cdots, \mathbf{q}_n, \mathbf{a}_n\}$, for a question $\mathbf{q}_i$ from $\mathcal{H}$ with its history $\mathbf{h}_i = \{\mathbf{q}_1, \mathbf{a}_1, \cdots, \mathbf{q}_{i-1}, \mathbf{a}_{i-1}\}$, we generate its rewrite $\mathbf{q}'_i$. We define the labeled dataset $\mathcal{D} = \{\mathbf{q}_i, \mathbf{h}_i, \mathbf{q}'_i\}_{i=1}^{|\mathcal{D}|}$ which is a set of tuples of question $\mathbf{q}$, history $\mathbf{h}$, and rewrite $\mathbf{q}'$. Following previous work (Elgohary et al., 2019), we model QR in an encoder-decoder framework, by estimating the parameterized conditional distribution for the output $\mathbf{q}'$ given the input question $\mathbf{q}$ and history $\mathbf{h}$. For $(\mathbf{q}, \mathbf{h}, \mathbf{q}') \in \mathcal{D}$, we minimize the following loss function parameterized by θ:

$$\begin{aligned}\mathcal{L}_{NLL}^{\theta} &= -\log P(\mathbf{q}'|\mathbf{q}, \mathbf{h}; \theta) \\ &= -\sum_{t=1}^{T_{\mathbf{q}'}} \sum_{k=1}^{|V|} \mathbb{1}\{q'_t = k\} \log P(q'_t = k|\mathbf{q}'_{<t}, \mathbf{q}, \mathbf{h}; \theta)\end{aligned} \tag{1}$$

in which $T_{\mathbf{q}'}$ is the length of $\mathbf{q}'$ and $|V|$ is the vocabulary size. Following Elgohary et al. (2019), $\mathbf{q}$ and $\mathbf{h}$ are concatenated into one sequence as the input. All previous turns of the history information are combined for learning. The choice of the encoder-decoder framework can be LSTM (Elgohary et al., 2019), transformer (Vakulenko et al., 2020), or pre-trained language models (Lin et al., 2020a). In our work, we build our model based on the pre-trained language model BART (Lewis et al., 2020).

4 Difficulty of Question Rewriting

The difficulty of rewriting a question varies across questions. We propose a simple yet effective heuristic to formulate rewriting difficulty as the discrepancy between a question and its rewrite. To generate a self-contained rewrite, we need to identify relevant information from the conversation context to incorporate it into the original question. We observe that if the discrepancy is large, we need to identify more missing information from the conversation context which makes the rewriting task more difficult.

In this work, we use BLEU score to measure the discrepancy. BLEU has been widely used to measure how similar two sentences are (Papineni et al., 2002). Given a question $\mathbf{q}$ and its rewrite $\mathbf{q}'$, we define the difficulty score z for rewriting $\mathbf{q}$ as:

$$\mathrm{z} = BLEU(\mathbf{q}, \mathbf{q}') \tag{2}$$

where the rewrite $\mathbf{q}'$ is the reference and $\mathrm{z} \in [0, 1]$. A low z score indicates a larger discrepancy between $\mathbf{q}$ and $\mathbf{q}'$, making it more difficult to rewrite $\mathbf{q}$ into $\mathbf{q}'$. Besides BLEU, we also study the effectiveness of ROUGE, lengths of $\mathbf{q}$ and $\mathbf{q}'$, and $|\mathbf{q}|/|\mathbf{q}'|$ in §6.5 to measure rewriting difficulty.

5 Difficulty-Aware QR with Adapters

Previous work on QR learns to rewrite questions with only one shared model (Elgohary et al., 2019), which cannot adequately model all questions with different rewriting difficulties. Instead of using only one shared model, we propose a novel method to classify a question into several classes by measuring its rewriting difficulty (§5.1), learn a private model for each class (§5.2), and finally combine the private models for inference (§5.3). Different questions with varying rewriting difficulties result in multiple data distributions in the training set. By dividing the training data into several classes with varying rewriting difficulties, we can better learn the data distributions with the help of private models (Zhang et al., 2018).

5.1 Question Classification

We compute the difficulty score z of each question in the dataset. We set score intervals and group the questions with difficulty scores within the same interval together. Specifically, we divide the original dataset $\mathcal{D}$ into m classes: $\{\mathcal{D}_1, \mathcal{D}_2, \cdots, \mathcal{D}_m\}$. Setting m to a large number (e.g., the number of training samples) can more accurately model the

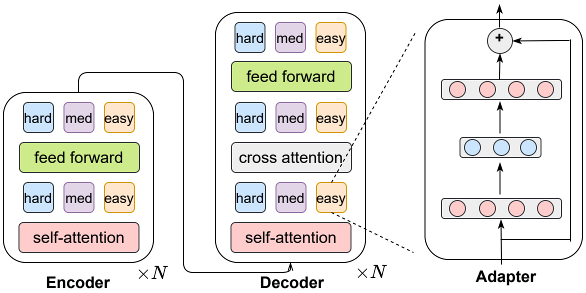

Figure 1: Illustration of our model architecture. Class-private adapters are added into the transformer. The original PLM weights are shared across all private models. N is the number of transformers in the encoder and decoder.

data distribution of the training data, but at the expense of data sparsity in each class such that a private model cannot be adequately trained.

5.2 Learning Private Models

After dividing the questions into m classes, we learn a private model for each class. By training on each class of data, the private model can better learn the domain-specific information. The common way to use a pre-trained language model (PLM) such as BART is to fine-tune the model on the downstream task. However, doing so will require m times the number of PLM parameters to build all private models, where m is the number of classes. This results in a large number of parameters, leading to inefficiency.

To reduce the number of model parameters in learning the private models, we introduce adapters into the PLM. Adapters are light-weight neural networks and are plugged into the PLM. When adapting the PLM to downstream tasks, we only need to update the parameters of the adapters but keep the original parameters of the PLM frozen and shared among all private models. Where to place the adapters in the neural architecture will affect the efficacy of adapters. As shown in Figure 1, for each transformer layer in the encoder, we add the adapters after the self-attention layer and feed-forward layer. We further add the adapters after the cross-attention layer in the decoder. Though our model is built on BART, our proposed placement of adapters can also be used in other PLMs, such as T5 (Raffel et al., 2020).

In Figure 1, the adapter is a module with a stack of two linear layers following Houlsby et al. (2019). Formally, given an input hidden vector $\mathbf{x}$ from the previous layer, we compute the output hidden vector $\mathbf{x}'$ of the adapter as:

$$\mathbf{x}' = f_2(\tanh(f_1(\mathbf{x}))) + \mathbf{x} \qquad (3)$$

where $f_1(\cdot)$ is the down-scale linear layer and $f_2(\cdot)$ is the up-scale linear layer. The hidden vector size is smaller than the dimension of the input vector. Learning a private model for one class only introduces $5 \times N$ adapters, where N is the number of layers in the encoder and decoder. The original parameters of the PLM are shared by all adapters, so the number of parameters required when building the private models can be much reduced.

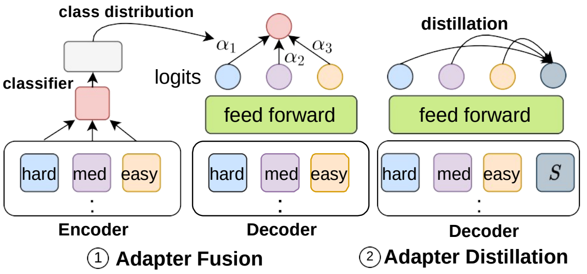

Figure 2: Illustration of our sequence-level adapter fusion and distillation.

5.3 Model Ensemble

After learning the private models for all classes, at test time, we present the question to the corresponding private model to generate its rewrite if we know which class this question belongs to. However, it is not possible to determine the difficulty score by calculating the BLEU score between the question and its rewrite since there is no gold-standard rewrite for the question at test time. As such, we need to combine the private models into one model for inference. In this work, we propose two methods to combine the private models, as explained below.

Sequence-level Adapter Fusion (SLAF). After dividing the training set into m classes based on the difficulty scores, we assign a difficulty label to each class to obtain a set of class labels $\{l_1, l_2, \cdots, l_m\}$. We introduce a classifier to learn to predict the difficulty label l, given a question $\mathbf{q}$ and its conversation history $\mathbf{h}$. As shown in Figure 2, during inference, we obtain the logistic output from each private model. The classifier generates the class distribution to combine the logistic outputs for sequence generation.

By assigning a difficulty label to each question, we obtain the dataset $\mathcal{D}' = \{\mathbf{q}_i, \mathbf{h}_i, \mathbf{q}'_i, l_i\}_{i=1}^{|\mathcal{D}'|}$. For each training sample $(\mathbf{q}, \mathbf{h}, \mathbf{q}', l) \in \mathcal{D}'$, we minimize the following loss function:

$$\mathcal{L}_{NLL}^{\theta_c} = -\log \mathrm{softmax}\Big(\sum_{i=1}^{m} \alpha_i f_i(\mathbf{q},\mathbf{h};\theta_i)\Big) - \log P(l|\mathbf{q},\mathbf{h};\theta_c) \qquad (4)$$

where f_i is the ith private model, α_i is the class weight of the ith private model, and θ_c is the parameter of the classifier. We jointly estimate the conditional distribution for sequence generation and the distribution for classification. In this process, the private models are frozen and not updated. We combine the vectors out of the private models to calculate the vector f_c as the input for the classifier:

$$f_c = \frac{1}{m}\sum_{i=1}^{m} f_{encoder}^{i}(\mathbf{q},\mathbf{h};\theta_i) \qquad (5)$$

where $f_{encoder}^{i}$ is the encoder of the ith private model. For each private model, we average the token embeddings from the last layer of the encoder.

Sequence-level Adapter Distillation (SLAD). SLAF provides a way to combine the private models, but it is time-consuming during inference since it requires each private model to compute its logistic output before combination. Another drawback is that the domain classifier in SLAF cannot generate the best class distributions at test time, causing non-optimal rewriting results by SLAF. As shown in Figure 2, to speed up inference and better combine the private models, we distill the private models into one shared model. We expect the student model S (modeled by adapters) to be able to generate questions with different rewriting difficulties. For each training sample $(\mathbf{q},\mathbf{h},\mathbf{q}',l) \in \mathcal{D}'$, we define the knowledge distillation loss function as follows:

$$\mathcal{L}_{KD}^{\theta_S} = -\sum_{t=1}^{T_{\mathbf{q}'}}\sum_{k=1}^{|V|} P^{(l)}\{q'_t = k|\mathbf{q}'_{<t},\mathbf{q},\mathbf{h};\theta^{(l)}\} \times \log P(q'_t = k|\mathbf{q}'_{<t},\mathbf{q},\mathbf{h};\theta_S) \qquad (6)$$

in which we approximate the output distribution of the teacher private model l parameterized by $\theta^{(l)}$ with the student model parameterized by θ_S. We learn the student model with the following function:

$$\mathcal{L}_{distill}^{\theta_S} = (1-\gamma)\cdot\mathcal{L}_{KD}^{\theta_S} + \gamma\cdot\mathcal{L}_{NLL}^{\theta_S} \qquad (7)$$

where $\mathcal{L}_{NLL}^{\theta_S}$ is the same loss function in Eq. 1, and γ is a hyper-parameter. The private models are fixed in the distillation process. Since we directly distill the knowledge of the private models into a shared model without the soft weights generated by the domain classifier from SLAF, SLAD can better combine the private models and achieve better rewriting performance.

	Train	Valid	Test	All

6 Experiments

6.1 Dataset

We conduct our experiments on CANARD (Elgohary et al., 2019) and QRECC (Anantha et al., 2021), which are designed for the task of question rewriting in CQA. CANARD was created from QuAC (Choi et al., 2018), by rewriting a subset of the questions by humans. The dataset consists of tuples of question, conversation history, and rewrite. QRECC answers conversational questions within large-scale web pages. Detailed data splits for the two datasets are shown in Table 2. We divide the questions into hard, medium, and easy classes, and the statistics are presented in Table 3.

6.2 Setup

Model Settings. We build our models on the pretrained language model of BART (Lewis et al., 2020). Specifically, we use BART-base to initialize our models. There are 6 transformer layers for the encoder and decoder in BART-base. For our

Model $\diagdown$ $\mathcal{D}$	Hard	Medium	Easy	Mean
LSTM-S	26.29	50.79	79.41	49.81
Fine-tune-S	39.38	53.70	66.33	53.14
Adapter-S	39.20	53.14	65.97	52.77

Table 4: BLEU scores (in %) on hard, medium, and easy classes from CANARD, based on the shared model. Fine-tune-S and Adapter-S are based on BART-base.

	Rewriting Rules	Examples
1	replace pronoun, e.g., he/his/she/her/they/their/it/its...	when was ***he*** born ? → when was ***Corbin Bleu*** born ?
2	add prepositional phrase	what happened in 1998 ? → what happened ***to Debra Marshall, Manager of Jeff Jarrett*** in 1998 ?
3	explain *else* context for questions with the forms, e.g., else/other/as well	Was there ***any other*** views he had in regards to them ? → ***Other than Peter Tatchell condemned the Soviet Union's invasions of Czechoslovakia***, was there any other views Peter Tatchell had in regards to Soviet Union ?
4	extend the nominal phrase, e.g., name/entity	Who wrote the ***song*** ? → Who wrote the ***'03 Bonnie & Clyde song*** ?
5	expand the special Wh* questions, e.g., why?/what happened/which	***Which*** of the show is the biggest ? → ***Which espisode of The Oprah Winfrey Show*** is the biggest?
6	add completed sentences after that/this	What was the aftermath of ***that*** ? → What was the aftermath of ***Robert Kennedy was chosen by McCarthy as a counsel for ...*** ?
7	other options	

Table 5: The commonly used rewriting rules for QR in CANARD.

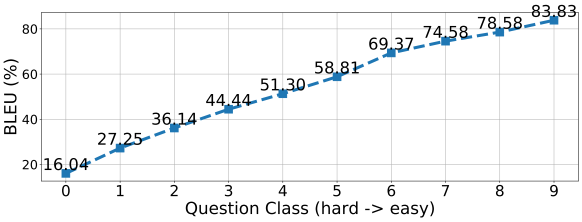

Figure 3: 10-class BLEU scores on CANARD with LSTM-S.

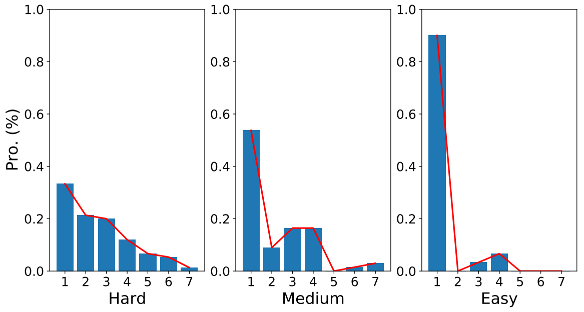

Figure 4: The distributions of rewriting rules on hard, medium, and easy subsets in CANARD.

adapter, we map the dimension of the input hidden vector from 768 to 384 which is re-mapped to 768 for the output vector. The hidden vector size for adapter tuning is the default value of 384. Based on BART-base, we need a total of $6 \times 2 + 6 \times 3 = 30$ adapters for each private model. We set γ to 0.5 in Eq. 7 for CANARD and 0.9 for QReCC. α from Eq. 4 is set to 2 for both CANARD and QReCC. When fine-tuning BART, we set the learning rate to 1e-5, and for adapter tuning, the learning rate is 1e-4 (both values are tuned from {1e-4, 1e-5}). We use the validation set to keep the best model based on the BLEU score. We implement our models with HuggingFace (Wolf et al., 2019) and keep the other default training settings. In CANARD, about 20% of the questions can be rewritten by replacing pronouns with their referents, so we carry out pronoun replacement first for the questions (if any) before using BLEU scores to measure rewriting difficulties. More details are given in Appendix A.

Baselines. We compare to the following baselines. **S** denotes training only one shared model with all the training data, which is commonly used in previous work (Elgohary et al., 2019; Lin et al., 2020a). By adapting BART, **P-hard**, **P-medium**, and **P-easy** are the baselines that train private models on the hard, medium, and easy classes respectively, using fine-tuning or adapter-tuning. Assuming that rewriting difficulty labels are accessible for questions at test time (i.e., the oracle setting), **Mix-gold** processes a question by the corresponding private model using the difficulty label. **SLAF** and **SLAD** denote sequence-level adapter fusion and adapter distillation respectively for combining the private models of P-hard, P-medium, and P-easy. **SLAF-uni.** combines the private models with uniform distributions. **SLAF-pred** predicts the class label for the input and then chooses the corresponding private model for generation. **LSTM-S** trains one model using an LSTM-based Seq2Seq model with copy mechanism (See et al., 2017) which was used in Elgohary et al. (2019).

Evaluation Metric. Following Elgohary et al. (2019), we use BLEU[2] to obtain the results on hard, medium, and easy classes, and the three results are

---

[2] https://github.com/mjpost/sacrebleu

averaged to obtain the mean result.

6.3 Robustness Evaluation

6.3.1 Rewriting Difficulty

We first study rewriting difficulties across different questions. Table 4 shows the results on hard, medium, and easy classes on CANARD. **Each class vs. Overall**: Comparing to the overall results, the rewriting performances of hard questions drop substantially, but are much higher on the easy class. **LSTM-S vs. BART-S**: By comparing LSTM-S to tuning on BART, LSTM-S achieves higher performance on the easy class but much worse performance on hard and medium classes. This is probably because for easy questions, the model only needs to copy some words from the context and LSTM-S has an explicit copy mechanism to achieve this goal but not BART. Since BART learns a more complex model than LSTM-S, it can better deal with harder questions.

We further divide the test set into ten classes in Figure 3, where the interval $[0, 1]$ is equally divided into ten sub-intervals of size 0.1. We find that when z gets smaller, rewriting performance degrades, indicating an increase in rewriting difficulty.

6.3.2 Human Evaluation

The above evaluation results show that our method can effectively divide the questions into subsets with different rewriting difficulties. Here, we conduct a human evaluation to evaluate the question characteristics on these subsets for validity and see what makes the questions hard or easy to rewrite.

Question Annotation. To find out what makes the questions different, we first summarize the commonly used rewriting rules, which describe the operations of translating a question into its rewrite. 6 rules are summarized from the training set of CANARD and presented in Table 5. Different rules account for different rewriting hardness for QR systems. For example, the rule of *replace pronoun* is very simple since it only requires the model to determine the pronoun to replace. However, rules 5 and 6 shown in the table will be much harder because the model needs to understand the conversational history well, and the information to be filled in is substantial.

Then we randomly select 50 examples from each subset (hard, medium, and easy) from the test set and annotate what rules in Table 5 are used for each example. One question may have multiple rewriting rules. More details are in Appendix B.

Model ╲ $\mathcal{D}$	**Hard**	**Medium**	**Easy**	**Mean**

Mix-gold	40.91	56.15	74.00	57.02
Tuning BART-base with adapters				
S	$39.20_{0.52}$	$53.14_{0.11}$	$65.97_{0.12}$	$52.77_{0.16}$
P-hard	$41.33_{0.27}$	$46.39_{0.46}$	$55.24_{0.93}$	$47.66_{0.51}$
P-medium	$34.41_{0.19}$	$54.68_{0.31}$	$62.98_{0.14}$	$50.69_{0.11}$
P-easy	$27.42_{0.26}$	$55.55_{0.16}$	$73.63_{0.18}$	$52.20_{0.12}$
SLAF-uni.	$34.05_{0.09}$	$55.88_{0.65}$	$67.27_{0.09}$	$52.40_{0.23}$
SLAF-pred	$32.96_{0.26}$	$55.62_{0.38}$	$70.83_{0.21}$	$53.14_{0.12}$
SLAF	$34.55_{0.05}$	$56.05_{0.32}$	$69.05_{0.15}$	$^{*}53.22_{0.17}$
SLAD	$38.26_{0.39}$	$54.22_{0.10}$	$67.57_{0.30}$	$^{*}53.35_{0.17}$
Mix-gold	$41.33_{0.27}$	$54.68_{0.31}$	$73.63_{0.18}$	$56.55_{0.12}$

Table 6: The test results (mean and standard deviation) on CANARD. We run 3 times for adapter tuning. $*$ indicates statistically significant improvement over S and SLAF-uni. ($p < 0.05$).

Results. We sum the number of each rewriting rule in each subset and show the distributions of rewriting rules for each subset in Figure 4. The three distributions are quite different. We find that:

- the easy subset mainly uses rule 1 for rewriting questions;
- for medium and hard subsets, other rules are used, such as rules 2, 3, and 4 which are more complex than rule 1;
- the hard class uses more rules 2, 3, 5, and 6 compared to the medium class, which demonstrates that the hard class is more difficult than the medium class.

Discussion. By knowing the characteristics of each class of questions, we can optimize the model architecture of private models accordingly. For hard questions, we can add some rules to deal with *Wh** questions. For easy questions, LSTM-based models seem to be good enough as Table 4 indicates. In this work, we have shown that the questions vary in rewriting difficulties and to improve the overall rewriting performance, we focus on the ensemble method to combine the private models. We leave optimizing the model architecture to future work.

6.4 Question Rewriting

We report our results on question rewriting based on CANARD and QRECC. From the results in Tables 6 and 7, we first show the results of each class, then the mean performances are displayed. **Mix-gold, SLAF, SLAD vs. S**: (**a**) Mix-gold, SLAF,

Table 7: The test results (mean and standard deviation) on QRECC. We run 3 times for adapter tuning. $*$ indicates statistically significant improvement over S, SLAF-uni., and SLAF-pred ($p < 0.05$).

and SLAD are consistently better than S, which demonstrates the effectiveness of learning private models to model multiple underlying distributions. (**b**) From the results on each class, SLAF and SLAD can substantially enhance the performance on medium and easy classes compared to S. (**c**) SLAD is more effective than SLAF and SLAD is more efficient during inference. (**d**) We find Mix-gold to be better than SLAF and SLAD, since Mix-gold is an oracle model that uses the correct difficulty label to select the private model for inference.

We find that by learning a private model for each class, the performance on the corresponding class can be consistently improved, which explains why Mix-gold, SLAF, and SLAD can outperform S. We also find that the sole private model cannot improve the overall rewriting performance of the three classes, but SLAF and SLAD can outperform S after model ensemble, which demonstrates the necessity of combining the private models.

Model Ensemble. One question is whether the improvements of SLAF and SLAD simply come from combing multiple models and whether applying only one private model selected by the predicted class label is better. As shown in Tables 6 and 7, we find SLAF-uni. performs worse than SLAF and SLAD, which demonstrates that the benefits of SLAF and SLAD are not simply because of the model ensemble, but class estimation also helps (In SLAD, class estimation lies in using gold class labels of questions for knowledge distillation during training). SLAF-pred can be regarded as an ensemble method since it uses multiple private models during inference. Compared to SLAF, SLAF-pred uses one-hot class weights to combine the private models. However, SLAF-pred performs worse than SLAF, and the reason could be that classifying the question into the corresponding class is nontrivial, wrong predictions will have much worse rewriting results as the results of P-hard, -medium, -easy on other classes indicate.

Table 8: Results of measuring rewriting difficulty on CANARD.

6.5 Further Analysis

Analysis of Rewriting Difficulty Measures. In our work, we use BLEU to measure the discrepancy between a question and its rewrite. We further experiment with other methods to assess their effectiveness for difficulty measurement. CANARD is evaluated here. As shown in Table 8, we first use the length of a question ($|q|$), its rewrite ($|q'|$), and their ratio ($|q|/|q'|$) to calculate a difficulty score. After re-ranking the questions with a difficulty score, we divide the ranked questions equally into three classes. Interestingly, we find that $|q|$ works well. After analysis, we find that rewriting short questions requires finding much missing information, which makes short questions hard questions. The $|q|/|q'|$ metric is not very useful, since $|q|/|q'|$ can only measure the discrepancy in question lengths, but does not necessarily measure their semantic difference. $|q'|$ does not work for difficulty measurement. Not surprisingly, the ROUGE score is also useful in measuring discrepancy just like BLEU.

Analysis of Learning Data Distribution. Tables 6 and 7 show that learning private models can enhance performance on each class. We further divide the data into eleven classes ($z \in [0, 0.1]$, $(0.1, 0.2], \cdots, (0.9, 1), 1$) and learn a private model for each class. We build the private models using LSTM-S, in which we first train a shared model on the full training data, then fine-tune the shared model on each class to obtain the private models. Table 9 shows the BLEU scores where the score in the (i, j) entry is obtained by training on class

	0	1	2	3	4	5	6	7	8	9	10

Table 9: BLEU scores for different classes on CANARD. The rows are the private models and the columns are the classes.

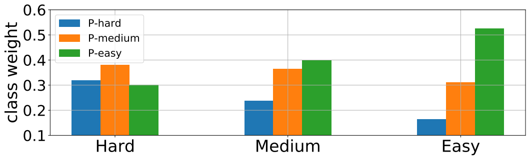

Figure 5: Class weights for different classes on CANARD.

i and testing on class j. On the whole, learning private models can enhance the performance of the corresponding class. With these private models, we can better model the data distributions, but how to combine a large number of private models is a challenge, since it is hard to train a classifier to correctly predict so many class labels, which will have some negative effects on the model ensemble.

Analysis of SLAF & SLAD. We plot the class distributions of hard, medium, and easy classes in Figure 5. We find that in the hard class, the class weights are almost equally distributed among the private models, which means that the hard questions are difficult for classification. This result explains why SLAF performs worse than S for hard questions in Tables 6 and 7. We further study the contribution of distillation in SLAD. In Figure 6, on the whole, when γ increases, the contribution of distillation decreases, and the performance drops, indicating that distillation is important for SLAD.

Case Study. We further show generated rewriting samples of various methods on CANARD in Appendix C.

7 Conclusion

In this work, we study the robustness of a QR system to questions varying in rewriting hardness. We use a simple yet effective heuristic to measure the rewriting difficulty. We further propose a novel method to deal with varying rewriting difficulties. Tested on CANARD and QReCC, we show the effectiveness of our methods.

A Experimental Setup

We use HuggingFace (Wolf et al., 2019) to implement our model. We follow the training script from `https://github.com/huggingface/transformers/tree/master/examples/seq2seq` to train the model. Models are trained for 10 epochs. Batch size is selected from {10, 16, 32}. Learning rate is selected from {1e-5, 1e-4}. We train 10 epochs for CANARD and 8 epochs for QReCC. The best model based on the BLEU score on the validation set is kept. The beam width for beam search is the default value of 4.

For our QR framework, we first train a private model for each class. For model ensemble, the weights of the private models are frozen without updating. On QReCC, to build the private models, on each class of data, we fine-tune the shared model which is trained on all the training data, since we find that this can enhance the final performance, but on CANARD, we do not see the improvement. The learning rate of fine-tuning in this process is 1e-5.

To pre-process the dataset, we only tokenize the sentences. And we append the question and its history context with "|||".

In CANARD, about 20% of the questions can be rewritten by replacing pronouns with their referents, so we carry out pronoun replacement first for the questions (if any) before using BLEU scores to measure rewriting difficulties.

B Human Assessment for Rewriting Rules

We first ask one annotator to summarize some common rewriting rules by looking at the training set of CANARD (Elgohary et al., 2019). When accessing the rewriting rules used for each question, the second annotator will rely on the summarized rewriting rules for annotation. For each class, we randomly select 50 questions from the test set for annotation.

Case Study. Table 10 shows some annotated results from the hard, medium, and easy classes.

C Case Study of Generated Rewrites

We further show some cases of generated rewrites from various methods (S, Mix-gold, SLAF, and SLAD). We use adapter tuning to build these models. Tables 11, 12, and 13 show the generated rewrites on hard, medium, and easy classes respectively.

👐 `OpenHands`: Making Sign Language Recognition Accessible with Pose-based Pretrained Models across Languages

Prem Selvaraj[*1], **Gokul NC**[*1,2], **Pratyush Kumar**[1,2,3], **Mitesh Khapra**[1,2]

Abstract

AI technologies for Natural Languages have made tremendous progress recently. However, commensurate progress has not been made on Sign Languages, in particular, in recognizing signs as individual words or as complete sentences. We introduce 👐 `OpenHands`[1], a library where we take four key ideas from the NLP community for low-resource languages and apply them to sign languages for word-level recognition. First, we propose using pose extracted through pretrained models as the standard modality of data in this work to reduce training time and enable efficient inference, and we release standardized pose datasets for different existing sign language datasets. Second, we train and release checkpoints of 4 pose-based isolated sign language recognition models across 6 languages (American, Argentinian, Chinese, Greek, Indian, and Turkish), providing baselines and ready checkpoints for deployment. Third, to address the lack of labelled data, we propose self-supervised pretraining on unlabelled data. We curate and release the largest pose-based pretraining dataset on Indian Sign Language (Indian-SL). Fourth, we compare different pretraining strategies and for the first time establish that pretraining is effective for sign language recognition by demonstrating (a) improved fine-tuning performance especially in low-resource settings, and (b) high crosslingual transfer from Indian-SL to few other sign languages. We open-source all models and datasets in 👐 `OpenHands` with a hope that it makes research in sign languages reproducible and more accessible.

1 Introduction

According to the World Federation of the Deaf, there are approximately 72 million Deaf people worldwide. More than 80% of them live in developing countries. Collectively, they use more than 300 different sign languages varying across different nations (UN, 2021). Loss of hearing severely limits the ability of the Deaf to communicate and thereby adversely impacts their quality of life. In the current increasingly digital world, systems to ease digital communication between Deaf and hearing people are important accessibility aids. AI has a crucial role to play in enabling this accessibility with automated tools for Sign Language Recognition (SLR). Specifically, transcription of sign language as complete sentences is referred to as Continuous Sign Language Recognition (CSLR), while recognition of individual signs is referred to as Isolated Sign Language Recognition (ISLR). There have been various efforts to build datasets and models for ISLR and CLSR tasks (Adaloglou et al., 2021; Koller, 2020). But these results are often concentrated on a few sign languages (such as the American Sign Language) and are reported across different research communities with few standardized baselines. When compared against text- and speech-based NLP research, the progress in AI research for sign languages is significantly lagging. This lag has been recently brought to notice of the wider NLP community (Yin et al., 2021).

For most sign languages across the world, the amount of labelled data is very low and hence they can be considered *low-resource languages*. In the NLP literature, many successful templates have been proposed for such low-resource languages. In this work, we adopt and combine many of these ideas from NLP to sign language research. We implement these ideas and release several datasets and models in an open-source library 👐 `OpenHands` with the following key contributions:

1. Standardizing on pose as the modality: We consider using pose-extractor as an encoder, which processes raw RGB videos and extracts the frame-wise coordinates for few keypoints. Pose-extractors are useful across sign languages and also other

---

[*] Equal contribution.

tasks such as action recognition (Yan et al., 2018; Liu et al., 2020), and can be trained to high accuracy. Further, as we report, pose as a modality makes both training and inference for SLR tasks efficient. We release pose-based versions of existing datasets for 5 sign languages: American, Argentinian, Greek, Indian, and Turkish.

2. Standardized comparison of models across languages: The progress in NLP has been earmarked by the release of standard datasets, including multilingual datasets like XGLUE (Liang et al., 2020), on which various models are compared. As a step towards such standardization for ISLR, we train 4 different models spanning sequence models (LSTM and Transformer) and graph-based models (ST-GCN and SL-GCN) on 7 different datasets across 6 sign languages mentioned in Table 1, and compare them against models proposed in the literature. We release all 28 trained models along with scripts for efficient deployment which demonstrably achieve real-time performance on CPUs and GPUs.

3. Corpus for self-supervised training: A defining success in NLP has been the use of self-supervised training, for instance masked-language modelling (Devlin et al., 2018), on large corpora of natural language text. To apply this idea to SLR, we need similarly large corpora of sign language data. To this end, we curate 1,129 hours of video data on Indian Sign Language. We pre-process these videos with a custom pipeline and extract keypoints for all frames. We release this corpus which is the first such large-scale sign language corpus for self-supervised training.

4. Effectiveness of self-supervised training: Self-supervised training has been demonstrated to be effective for NLP: Pretrained models require small amounts of fine-tuning data (Devlin et al., 2018; Baevski et al., 2020) and multilingual pretraining allows crosslingual generalization (Hu et al., 2020b). To apply this for SLR, we evaluate multiple strategies for self-supervised pretraining of ISLR models and identify those that are effective. With the identified pretraining strategies, we demonstrate the significance of pretraining by showing improved fine-tuning performance, especially in very low-resource settings and also show high crosslingual transfer from Indian SL to other sign languages. This is the first and successful attempt that establishes the effectiveness of self-supervised learning in SLR. We release the pretrained model and the fine-tuned models for 4 different sign languages.

Through these datasets, models, and experiments we make several observations. First, in comparing standardized models across different sign languages, we find that graph-based models working on pose modality define state-of-the-art results on most sign languages. RNN-based models lag on accuracy but are significantly faster and thus appropriate for constrained devices. Second, we establish that self-supervised pretraining helps as it improves on equivalent models trained from scratch on labelled ISLR data. The performance gap is particularly high if the labelled data contains fewer samples per label, i.e., for the many sign languages which have limited resources the value of self-supervised pretraining is particularly high. Third, we establish that self-supervision in one sign language (Indian SL) can be crosslingually transferred to improve SLR on other sign languages (American, Chinese, and Argentinian). This is particularly encouraging for the long tail of over 300 sign languages that are used across the globe. Fourth, we establish that for real-time applications, pose-based modality is preferable over other modalities such as RGB, use of depth sensors, etc. due to reduced infrastructure requirements (only camera), and higher efficiency in self-supervised pretraining, fine-tuning on ISLR, and inference. We believe such standardization can help accelerate dataset collection and model benchmarking. Fifth, we observe that the trained checkpoints of the pose-based models can be directly integrated with pose estimation models to create a pipeline that can provide real-time inference even on CPUs. Such a pipeline can enable the deployment of these models in real-time video conferencing tools, perhaps even on smartphones.

As mentioned all datasets and models are released with permissible licenses in 👐 `OpenHands` with the intention to make SLR research more accessible and standardized. We hope that others contribute datasets and models to the library, especially representing the diversity of sign languages used across the globe.

The rest of the paper is organized as follows. In section 2 we present a brief overview of the existing work. In section 3 we describe our efforts in standardizing datasets and models across six different sign languages. In section 4 we explain our pretraining corpus and strategies for self-supervised learning and detail results that establish its effectiveness. In section 5 we describe in brief the functionalities of the 👐 `OpenHands` library. In section 6, we summarize our work and also list potential follow-up work.

2 Background and Related Work

Significant progress has been made in Isolated Sign Language Recognition (ISLR) due to the release of datasets (Li et al., 2020; Sincan and Keles, 2020; Chai et al., 2014; Huang et al., 2019) and recent deep learning architectures (Adaloglou et al., 2021). This section reviews this work, with a focus on pose-based models.

2.1 Sign Language

A sign language (SL) is the visual language used by the Deaf and hard-of-hearing (DHH) individuals (and also by those who comunnicate with them), which involves usage of various bodily actions, like hand gestures and facial expressions, called signs to communicate. A sequence of signs constitutes a phrase or sentence in a SL. The signs can be transcribed into sign-words of any specific spoken language usually written completely in capital letters. Each such sign-word is technically called as a gloss and is the standardized basic atomic token of an SL transcript (Schembri and Crasborn, 2010). It is be noted that there is not (always) one-to-one relationships between glosses and spoken language words.

The task of converting each visual sign communicated by a signer into a gloss is called isolated sign language recognition (ISLR). The task of converting a continuous sequence of visual signs into serialized glosses is referred as continuous sign language recognition (CSLR). CSLR can either be modeled as an end-to-end task, or as a combination of sign language segmentation and ISLR. The task of converting signs into spoken language text is referred as sign language translation (SLT), which can again either be end-to-end or a combination of CLSR and gloss-sequence to spoken phrase converter.

In terms of real-world applications, eventhough CSLR is more practically useful than ISLR, it does not still undermine the value in studying and implementing ISLR. The applications of ISLR include building sign spotting systems (Albanie et al., 2020), building alignment networks (Albanie et al., 2021) to aid in building CSLR datasets (or evaluate CSLR output), building CSLR systems on top of an automatic SL segmentation model (Farag and Brock, 2019) which identifies the frame boundaries for signs in videos to divide them into approximate meaningful segments (glosses), etc.

Although SL content is predominantly recorded as RGB (color) videos, it can also be captured using various other modalities like depth maps or point cloud, finger gestures recorded using sensors, skeleton representation of the signer, etc. In this work, we focus on ISLR using pose-skeleton modality. A pose representation, extracted using pose estimation models, provides the spatial coordinates at which the joints (such as elbows and knees), called keypoints, are located in a field or video. This pose information can be represented as a connected graph with nodes representing keypoints and edges may be constructed across nodes to approximately represent the human skeleton.

2.2 Models for ISLR

Initial methods for SLR focused on hand gestures from either video frames (Reshna et al., 2020) or sensor data such as from smart gloves (Fels and Hinton, 1993). Given that such sensors are not commonplace and that body posture and face expressions are also of non-trivial importance for understanding signs (Hu et al., 2020a), convolutional network based models have been used for SLR (Rao et al., 2018).

ISLR can be considered as a multiclass classification task and generally accuracy metric is used the to evaluate the performance of the models. The ISLR task is related to the more widely studied action recognition task (Zhu et al., 2020). Like in action recognition task, highly accurate pose recognition models like OpenPose (Cao et al., 2018) and MediaPipe Holistic (Grishchenko and Bazarevsky, 2020) are being used for ISLR models (Li et al., 2020; Ko et al., 2018), where frame-wise keypoints are the inputs. Although RGB-based models may outperform pose-based models (Li et al., 2020) narrowly, pose-based models have far fewer parameters and are more efficient for deployment if used with very-fast pose estimation pipelines like MediaPipe BlazePose. In this work, we focus on lightweight pose-based ISLR which encode the pose frames and classify the pose using specific decoders. We briefly discuss the two broad types of such models: sequence-based and graph-based.

Sequence-based models process data sequentially along time either on one or both directions. Initially, RNNs were used for pose-based action recognition to learn from temporal features (Du et al., 2015; Zhang et al., 2017; Si et al., 2018). Specifically, sequence of pose frames are input to GRU or LSTM layers, and the output from the final timestep is used for classification. Transformer architectures with encoder-only models like BERT (Vaswani et al., 2017) have also been studied for pose-based ISLR models (De Coster et al., 2020). The input is a sequence of pose frames along with positional embeddings. A special [CLS] token is prepended to the sequence, whose final embedding is used for classification.

Graph convolution networks (Kipf and Welling, 2017), which are good at modeling graph data have been used for skeleton action recognition to achieve state-of-the-art results, by considering human skeleton sequences as spatio-temporal graphs (Cheng et al., 2020a; Liu et al., 2020). Spatial-Temporal GCN (ST-GCN) uses human body joint connections for spatial connections and temporal connections across frames to construct a 3d graph, which is processed by a combination of spatial graph convolutions and temporal convolutions to efficiently model the spatio-temporal data (Lin et al., 2020). Many architectural improvements have been proposed over ST-GCN for skeleton action recognition (Zhang et al., 2020; Shi et al., 2019b,a; Cheng et al., 2020b,a; Liu et al., 2020). MS-AAGCN (Shi et al., 2020) uses attention to adaptively learn the graph topology and also proposes STC-attention module to adaptively weight joints, frames and channels. Decoupled GCN (Cheng et al., 2020a) improves the capacity of ST-GCN without adding additional computations and also proposes attention guided drop mechanism called DropGraph as a regularization technique. Sign-Language GCN (SL-GCN) (Jiang et al., 2021) combines STC-attention with Decoupled-GCN and extends it to ISLR achieving state-of-the-art results.

2.3 Pretraining strategies

Although there are works which use an already trained classifier (on a large dataset) to finetune for smaller datasets and obtain state-of-the-art results in the latter (Albanie et al., 2020), there are currently no works which study the value of pretraining on openly available unlabelled data. On this front, we now survey three broad classes of self-supervised pretraining strategies that we reckon could be applied to SLR.

Masking-based pretraining: In NLP, masked language modelling is a pretraining technique where randomly masked tokens in the input are predicted. This approach has been explored for action recognition (Cheng et al., 2021), where certain frames are masked and a regression task estimates coordinates of keypoints. In addition, a direction loss is also proposed to classify the quadrant where the motion vector lies.

Contrastive-learning based: Contrastive learning is used to learn feature representations of the input to maximize the agreement between augmented views of the data (Gao et al., 2021; Linguo et al., 2021). For positive examples, different augmentations of the same data item are used, while for negative samples randomly-chosen data items usually from a few last training batches are used. A variant of contrastive loss called InfoNCE (van den Oord et al., 2018) is used to minimize the distance between positive samples.

Predictive Coding: Predictive Coding aims to learn data representation by continuously correcting its predictions about data in future timesteps given data in certain input timesteps. Specifically, the training objective is to pick the future timestep's representation from other negative samples which are usually picked from recent previous timesteps of the same video. Similar to contrastive learning, a loss function based on NCE is used (Mikolov et al., 2013; van den Oord et al., 2018). This technique was explored for action recognition in a model called Dense Predictive Coding (DPC) (Han et al., 2019). Instead of predicting at the frame-level, DPC introduces coarse-prediction at the scale of non-overlapping windows.

3 Standardized Pose-based ISLR Models across Sign Languages

In this section, we describe our efforts to curate standardized pose-based datasets across multiple sign languages and benchmark multiple ISLR models on them.

3.1 ISLR Datasets

Multiple datasets have been created for the ISLR task across sign languages. However, the amount of data significantly varies across different sign languages, with American and Chinese having the largest datasets currently. With a view to cover a diverse set of languages, we study 7 different

Dataset	Language	Vocab	Signers	Videos	Hrs	Data
AUTSL (Sincan and Keles, 2020)	Turkish	226	43	38,336	20.5	RGBD
CSL (Huang et al., 2019)	Chinese	500	50	125,000	108.84	RGBD
DEVISIGN (Chai et al., 2014)	Chinese	2000	30	24,000	21.87	RGBD
GSL (Adaloglou et al., 2021)	Greek	310	7	40,785	6.44	RGBD
INCLUDE (Sridhar et al., 2020)	Indian	263	7	4,287	3.57	RGB
LSA64 (Ronchetti et al., 2016)	Argentinian	64	10	3,200	1.90	RGB
WLASL (Li et al., 2020)	American	2000	119	21,083	14	RGB

Table 1: The diverse set of existing ISLR datasets which we study in this work through pose-based models

datasets across 6 sign languages as summarised in Table 1. For each of these datasets, we generate pose-based data using the Mediapipe pose-estimation pipeline (Grishchenko and Bazarevsky, 2020), which enables real-time inference in comparison with models such as OpenPose (Cao et al., 2018). Mediapipe, in our chosen Holistic mode, returns 3d coordinates for 75 keypoints (excluding the face mesh). Out of these, we select only 27 sparse 2d keypoints which convey maximum information, covering upper-body, hands and face. Thus, each input video is encoded into a vector of size $F \times K \times D$, where F is the number of frames in the video, K is the number of keypoints (27 in our case), and D is the number of coordinates (2 in our case). In addition, we perform several normalizations and augmentations explained in Section 5.

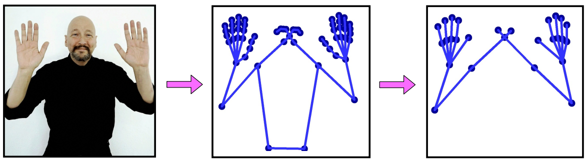

Figure 1: Illustration for RGB frame to pose keypoints conversion. The center skeleton shows the upper portion of the 75 keypoints returned by MediaPipe, from which we choose only 27 points as shown in right.

3.2 Standardized ISLR Models

On the 7 different datasets we consider, different existing ISLR models have been trained which are mentioned in Table 2 which produce their current state-of-the-art results. For INCLUDE dataset, an XGBoost model is used (Sridhar et al., 2020) with direct input as 135 pose-keypoints obtained using OpenPose. For AUTSL, SL-GCN is used (Jiang et al., 2021) with 27 chosen keypoints as input from HRNet pose estimation model. For GSL, the corresponding model (Parelli et al., 2020) is an attention-based encoder-decoder with 3D hand pose and 2D body pose as input. For WLASL, Temporal-GCN is used (Li et al., 2020) by passing 55 chosen keypoints from OpenPose. For LSA64, 33 chosen keypoints from OpenPose are used as input to an LSTM decoder (Konstantinidis et al., 2018). For DEVISIGN, RGB features are used (Yin et al., 2016) and the task is approached using a clustering-based classic technique called Iterative Reference Driven Metric Learning. For CSL dataset, an I3D CNN is used as encoder with input as RGBD frames and BiLSTM as decoder (Adaloglou et al., 2021). For DEVISIGN_L and CSL datasets, we report RGB model results in the table as there are no existing works using pose-based models.

The differences in the above models make it difficult to compare them on effectiveness, especially across diverse datasets. To enable standardized comparison of models, we train pose-based ISLR models on all datasets with similar training setups for consistent benchmarking. These models belong to two groups: sequence-based models and graph-based models. For sequence-based models we consider RNN and Transformer based architectures. For the **RNN model**, we use a 4-layered bidirectional LSTM of hidden layer dimension 128 which takes as input the framewise pose-representation of 27 keypoints with 2 coordinates each, i.e., a vector of 54 points per frame. We also use a temporal attention layer to weight the most effective frames for classification. For the **Transformer model**, we use a BERT-based architecture consisting of 5 Transformer-encoder layers with 6 attention heads and hidden dimension size 128, with a maximum sequence length of 256. For the graph-based models we consider ST-GCN (Yan et al., 2018) and SL-GCN (Jiang et al., 2021) models as discussed in section 2. For **ST-GCN model**, we use 10 spatio-

Dataset	State-of-the-art model		Model available in **OpenHands**			
	Model (Params)	**Accuracy**	**LSTM**	**BERT**	**ST-GCN**	**SL-GCN**

temporal GCN layers with the spatial dimension of the graph consisting of the 27 keypoints. For the **SL-GCN model**, we use again 10 SL-GCN blocks with the same graph structure and hyperparameters as the ST-GCN model.

3.3 Experimental Setup and Results

We train 4 models - LSTM, BERT, ST-GCN, and SL-GCN - for each of the 7 datasets. We use PyTorch Lightning to implement the data processing and training pipelines. We use Adam Optimizer to train all the models. We search for optimal hyperparameters using grid search to find the best hyperparams for each model on a standard dataset, and report the best configuration per model. For the LSTM model, we set the batch size as 32 and initial learning rate (LR) as $5e-3$, while for BERT, we set a batch size 64, and LR of $1e-4$. For ST-GCN and SL-GCN, we use a batch size of 32 and LR of 0.001. We train all our models on a NVIDIA Tesla V100 GPU. Also for all datasets, we only train on the train-sets given and we use valid-sets to do early stopping, whereas some works (like AUTSL) train on combination of train-set and val-set to report the final test accuracy. We run each experiment around 3 times, and report the best accuracy, eventhough we do not see significant difference in accuracies across the runs. All trained models and the training configurations are open-sourced in `OpenHands`.

Accuracy We report the obtained test-set accuracy of detecting individual signs, for each model against each dataset in Table 2. On all datasets, graph-based models report the state-of-the-art results using pose data. Except for AUTSL[2], on 6 of the 7 datasets, models we train improve upon the accuracy reported in the existing papers sometimes significantly (e.g., over 10% on GSL). These uniform results across a diverse set of SLs confirm that graph-based models on pose modality data define the SOTA.

In summary, the standardized benchmarking of multiple models in terms of accuracy on datasets and, measurements of latency on devices (explained in appendix) informs model selection. Making the trade-off between accuracy and latency, we use the ST-GCN model for the pretrained model we discuss later. Our choice is also informed by the cost of the training step: The more accurate SL-GCN model takes 4× longer to train than ST-GCN.

4 Self-Supervised Learning for ISLR

In this section, we describe our efforts in building the largest corpus for self-supervised pretraining and our experiments in different pretraining strategies.

4.1 Indian SL Corpus for Self-supervised pretraining

Channel	Hours	Domain
NewzHook	615	News
MBM Vadodara	225	News
ISH-News	145	News

Large text corpora such as BookCorpus,

---

[2] SOTA AUTSL model is trained on high quality pose data from HRNet model with more keypoints.

Wikipedia dumps, OSCAR, etc. have enabled pretraining of large language models. Although there are large amounts of raw sign language videos available on the internet, no existing work has studied how such large volumes of open unlabelled data can be collected and used for SLR tasks. To address this, we create a corpus of Indian SL data by curating videos, pre-process the videos, and release a standardized pose-based dataset compatible with the models discussed in the previous section.

We manually search for freely available major sources of Indian SL videos. We restrict our search to a single sign language so as to study the effect of pretraining on same language and crosslingual ISLR tasks. We sort the sources by the number of hours of videos and choose the top 5 sources for download. All of these 5 sources, as listed in Table 3 are YouTube channels, totalling over 1,500 hours before preprocessing.

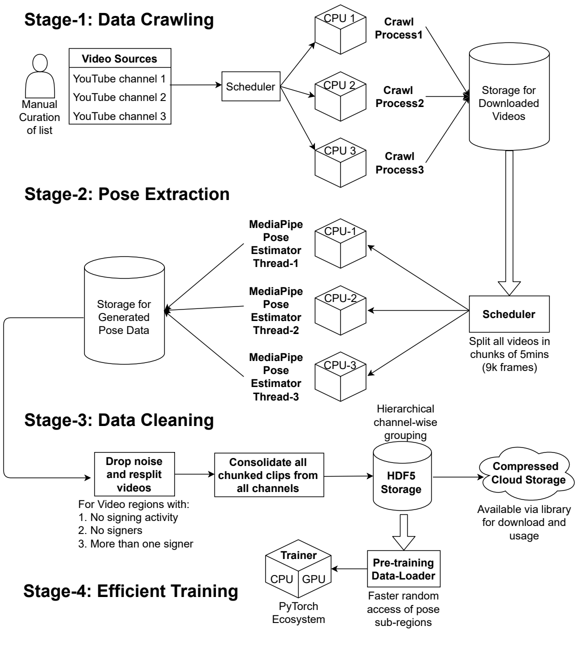

Figure 2: Pipeline used to collect and process Indian SL corpus for self-supervised pretraining

We pass these videos through a processing pipeline as described in Figure 2. We initially dump the pose data for all videos, then process them to remove those which are noisy or contain either no person or more than 1 person. This resulted in 1,129 hours of Indian SL data, as detailed source-wise in Table 3. This is significantly larger than all the training sets in the datasets we studied which is on average 177 hours. We pass these videos through MediaPipe to obtain pose information as described earlier, i.e., 75 keypoints per frame. The resultant Indian SL corpus has more than 100 million pose frames. We convert this to the HDF5 format to enable efficient random access, as is required for training. We open-source this corpus of about 250 GB which is available in 👐 `OpenHands`.

4.2 Pretraining Setup and Experiments

We explore the three major pretraining strategies as described in Section 2.3 and explain how and why certain self-supervised settings are effective for ISLR. We pretrain on randomly sampled consecutive input sequences of length 60-120 frames (approximating 2-4 secs with 30fps videos). After pretraining, we fine-tune the models on the respective ISLR dataset with an added classification head.

4.2.1 Masking-based pretraining

We follow the same hyperparameter settings as described in Motion-Transformer (Cheng et al., 2021), to pretrain a BERT-based model with random masking of 40% of the input frames. When using only the regression loss, we find that pretraining learns to reduce the loss as shown in appendix. However, when fine-tuned on the INCLUDE dataset, we see no major contribution of the pretrained model to increasing the accuracy as shown in Table 4. We posit that while pretraining was able to approximate interpolation for the masked frames based on the surrounding context, it did not learn higher-order features relevant across individual signs. We also experiment with different masking ratios (20% and 30%) as well as different length of random contiguous masking spans (randomly selected between 2-10), and obtain similar results.

4.2.2 Contrastive-learning based

Inspired from the work by Gao et al. (2021), we consider Shear, Scaling and Rotation augmentations to generate the 2 augmented copies of the input pose sequence and we pretrain the model and observe that it converges on reducing the InfoNCE loss (see appendix for plot). We then fine-tune on INCLUDE and again did not observe any gain over the baseline of training from scratch as seen in Table 4. To understand this, we analyzed the embeddings of data from the pretrained model and observed two facts: (a) Embeddings of different augmentations of a video clip are similar indicating successful pretraining, but (b) Embeddings of different videos from the INCLUDE dataset do not show any clustering based on the class (see visualization in appendix). Again, we posit that pretraining did not learn higher order semantics that could be helpful for ISLR.

4.2.3 Predictive-coding based

Our architecture is inspired from Dense Predictive Coding (Han et al., 2019), but using pose modality. The architecture is represented in Figure 3. The pose frames from a video clip will be partitioned into multiple non-overlapping windows with equal number of frames in each window. The encoder f takes each window of pose keypoints as input and embeds into the hidden space z. We use ST-GCN as the encoder. The ST-GCN encoder embeds each input window x_i, and the direct output is average pooled across the spatial and temporal dimensions to obtain the output embedding z_i for each window. The embeddings are then fed to a Gated Recurrent Unit (GRU) as a temporal sequence and the future timesteps $\hat{z}_i$ are predicted sequentially using the past timestep representations from GRU, with an affine transform layer ϕ. We use 4 windows of data as input to predict the embeddings of the next 3 windows, each window spanning 10 frames, which we empirically found to be the best setting. For pretraining, we used a batch size of 128 and for finetuning, we used a batch size of 64. For both pretraining and finetuning, we used Adam optimizer with an initial learning rate of 1e-3. The pretraining was done for 200k iterations on a NVIDIA V100 GPU, taking around 26 hours (on Microsoft platform's Azure NC6s_v3 machine).

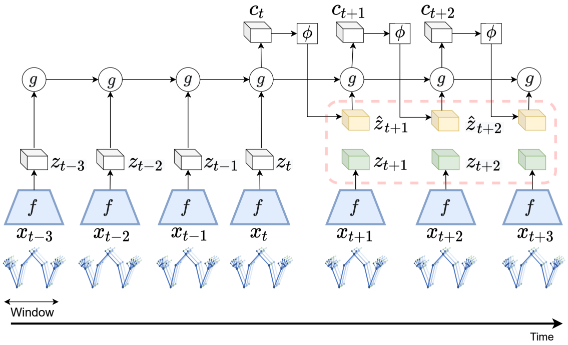

Figure 3: Model architecture for DPC pretraining

Upon fine-tuning on INCLUDE, DPC provides a significant improvement of 3.5% over the baseline. We include a plot comparing the validation accuracy between baseline and finetuned model in appendix. We posit that Sign Language DPC (SL-DPC) is successful, while previous methods were not, as it learns coarse-grained representations across multiple frames and thereby captures motion semantics of actions in SL.

To the best of our knowledge, this is the first comparison of pretraining strategies for SLR.

Training of ST-GCN	Accuracy
No pretraining + Fine-tune	91.2
Masked-based + Fine-tune	91.3
Contrastive learning + Fine-tune	90.8
Predictive-coding + Fine-tune	94.7

Table 4: Effectiveness of pretraining strategies as measured on ISLR accuracy on INCLUDE

4.3 Evaluation on low-resource and crosslingual settings

We demonstrated that DPC-based pretraining is effective. We now analyze the effectiveness of such pretraining in two constrained settings - (a) when fine-tuning datasets are small, and (b) when fine-tuning on sign languages different from the sign language used for pretraining. The former captures in-language generalization while the latter crosslingual generalization.

Dataset	Samples/class	STGCN	SLDPC
INCLUDE (Indian)	Full (Avg. 17)	91.2	94.7
	10	79.7	86.27
	5	45	57.35
	3	15.2	35.42
WLASL2k (American)	Full (Avg. 10)	21.4	27.4
	5	3.1	5.74
	3	1.6	2.78
DEVISign_L (Chinese)	Full (8)	55.8	59.5
	5	33.0	40.26
	3	8.46	18.65
LSA64 (Argentinian)	Full (50)	94.7	96.25
	5	64.7	75.32
	3	39.7	57.19

Table 5: Effectiveness of pretraining for in-language (first row) and crosslingual transfer (last three rows)

4.3.1 In-language generalization

The INCLUDE dataset contains an average of 17 samples per class. For this setting, we observed a gain of 3.5% with DPC-based pretraining over training from scratch. How does this performance boost change when we have fewer samples per class? We present results for 10, 5, and 3 samples per class in Table 5. We observe that as the number of labels decreases the performance boost due to pretraining is higher indicating effective in-language generalization.

4.3.2 Crosslingual transfer

Does the pretraining on Indian sign language provide a performance boost when fine-tuning on other sign languages? We study this for 3 different sign languages - American, Chinese, and Argentinian - and report results in Table 5. We see that crosslingual transfer is effective leading to gains of about 6%, 4%, and 2% on the three datasets, similar to the 3% gain on in-language accuracy. The increase in accuracy varies with datasets - For Argentianian and Indian datasets which already have 90+% accuracy, there are small improvements. However, WLASL which is scraped from web and has a lot more variations, sees a much higher improvement due to pretraining. Further, we also observe that these gains extend to low-resource settings of fewer labels per sign. For instance on Argentinian SL, with 3 labels, pretraining on Indian SL given an improvement of about 18% in accuracy. To the best of our knowledge this is the first successful demonstration of crosslingual transfer in ISLR.

In summary, we discussed different pretraining strategies and found that only SL-DPC learns semantically relevant higher-order features. With DPC-based pretraining we demonstrated both in-language and crosslingual transfer.

5 The 👐 `OpenHands` library

As mentioned in the main paper, we open-source all our contributions through the 👐 `OpenHands` library. This includes the pose-based datasets for 5 SLs, 4 ISLR models trained on 7 datasets, the pretraining corpus on Indian SL with over 1,100 hours of pose data, pretrained models on this corpus using self-supervised learning, and models fine-tuned for 4 different SLs on top of the pretrained model. We also provide scripts for efficient deployment using MediaPipe pose estimation and our trained ISLR models.

In addition, the library provides utilities that are helpful specifically for pose-based data. This includes methods to normalize keypoints by width and height of frames, to normalize all of the pose data to be in the same scale and reference coordinate system by using a constant feature of body as reference, and to fill missing keypoints. The library also includes utilities to create data augmentations such as *ShearTransform* to displace the joints in a random direction, *RotatationTransform* to simulate the viewpoint changes of the camera, *ScaleTransform* to simulate different scales of the pose data to account for relative zoomed-in or zoomed-out view of signers, *PoseRandomShift* to move a significant portion of the video by a time offset so as to make the ISLR models robust to inaccurate segmentation of real-time video, *UniformTemporalSubsample* to uniformly sample frames from the video instead of considering only the initial frames, in cases where the number of frames in a video clip exceeds a maximum limit, and *RandomTemporalSubsample* to sample a random fixed contiguous window of required size covering a maximum number of frames.

We encourage researchers to contribute datasets, models, and other utilities to make sign language research more accessible. All the aspects of the toolkit are well-documented online[3] for anyone to get started easily.

6 Conclusion

In this work, we make several contributions to make sign language research more accessible. We release pose-based datasets and 4 different ISLR models across 6 sign languages. This evaluation enabled us to identify graph-based methods such as ST-GCN as being accurate and efficient. We release the first large corpus of SL data for self-supervised pretraining. We evaluated different pretraining strategies and found DPC as being effective. We also show that pretraining is effective both for in-language and crosslingual transfer. All our models, datasets, training and deployment scripts are open-sourced in 👐 `OpenHands`.

Several directions for future work emerge such as evaluating alternative graph-based models, experimenting with varying sequence lengths of input data, efficiently sampling the data from the raw dataset for pretraining such that the samples are diverse enough, using better pose estimator models and more keypoints, and quantized inference for 2×-4× reduced latency. On the library front, we aim to release updated versions incorporating more SL datasets, better graph-based models, studying the performance on low FPS videos (like 2-4 FPS), effect of pretraining using other high-resource SL datasets, extending to CSLR, and improving deployment features.

APPENDIX

A Ethical considerations

All models trained in this work only use pose or skeletal data. Consequently all released datasets and models do not have any personally identifiable information (PII), thereby addressing privacy concerns of those who contributed to these datasets. Furthermore, such a standardization eliminates all visually distinguishing features of individuals like color, gender, ethnicity/race, etc., thereby overcoming any potential biases pertaining to sub-populations.

We address the licensing-related aspects of the datasets in the subsequent sub-sections.

A.1 Release of pose ISLR datasets

Our work builds on existing ISLR datasets across languages, by processing them to retain only pose data. Complying with the respective licenses of the datasets, we release our generated poses only for the openly available datasets with permissive licenses. Out of the 7 datasets we evaluate in the paper, we find that we can release the pose data for 5 of the datasets (AUTSL, WLASL, GSL, LSA64, and INCLUDE), covering 5 sign languages (respectively: Turkish, American, Greek, Argentinian and Indian). The other 2 datasets are CSL and DEVISIGN, belonging to Chinese sign language. The licenses of each original dataset is shown in Table 6.

Dataset	License
AUTSL	Permissive
CSL	Proprietary
DEVISIGN	Proprietary
GSL	Creative Commons 4.0
INCLUDE	MIT
LSA64	Creative Commons 4.0
WLASL	C-UDA

Table 6: Licenses of each ISLR dataset

We do not claim ownership over any of the original ISLR datasets, and release the pose data under the same licensing terms as the original datasets.

A.2 Release of raw pose data

We also open-source the pretraining dataset on Indian Sign Language (ISL) that we explained in Section 4.1. The detailed datasheet of this dataset, including motivation, composition, collection process, preprocessing, distribution, maintenance, and ethical considerations is included after the appendices.

B Inference Benchmarking

In this section, we explain how we achieve over 23fps real-time inference, by using MediaPipe Holistic for generating poses (as an ISLR encoder) and our pose-based models (as decoder) that recognizes the sign at any given window.

B.1 MediaPipe Inference

For pose-estimation, MediaPipe offers 3 variants of models: *heavy*, *full* and *lite* in decreasing order of accuracy but increasing order of inference-speed. The latency of these variants on Intel Xeon E5-2690 v4 CPU with a frame-size of 640x480 were 142.59ms, 55.28ms, and 35.37ms respectively per frame. For all training and testing in this work, we used the heavy model to get the best quality results.

For real-time inference, depending on one's CPU, either of the 3 variants can be used with the trained models, since all the 3 BlazePose models are trained on the same dataset to return same number of keypoints. Based on our experience, we prefer only *lite* or *full* variants depending on the CPU-type, and we find the *heavy* model only suitable if we employ frame-skipping and use decoder models that also work at a lower FPS (below 8fps).

B.2 ISLR Model Inference

Given that SLR is an interactive application, deployability atleast at 23 FPS without noticeable latency is essential. We thus study the latency of our models on various CPU configurations so as to target ubiquitous deployment. For each of the 4 models, we report the model size and latency measured on 4 different CPUs in Table 7. The LSTM model is an order of magnitude faster across all devices than the most accurate SL-GCN model, and is a good candidate when speed is essential at the cost of about 10% accuracy drop that we observed in Table 2. Amongst the graph-based methods, ST-GCN provides a good trade-off being about 2× faster than SL-GCN at the cost of only 3% lower average accuracy across datasets.

The benchmarking is done with a batch size of 1 with complete serial processing (without any data

Model →	**LSTM**	**Transformer**	**ST-GCN**	**SL-GCN**	**SLDPC**
Params →	1.6M	3.8M	2.3M	4.9M	4.0M
CPU	**Latency in milliseconds**				
Xeon E5-2690 v4 (2.60GHz)	08.05	30.64	23.02	52.8	47.60
AMD Ryzen 7 3750H (2.30GHz)	12.94	76.41	86.97	225.3	147.28
Xeon Platinum 8168 (2.70GHz)	05.38	23.76	51.64	112.66	112.52
Xeon E5-2673 v4 (2.30GHz)	09.03	43.69	99.39	201.31	188.43

Table 7: Number of parameters and average latency of different model architectures

loading parallelization). The latencies reported in the table corresponds to average inference time per video using the test set of the INCLUDE dataset, for both freshly trained models and pretrained sign language DPC (SLDPC) model.

Note that encoder (pose estimation) and decoder (classifier) are parallelized such that the former is a producer of skeletons for window of live frames, and the latter is a consumer which recognizes glosses.

C Additional notes on pretraining

In this section, we briefly present a few of the artifacts pertaining to the different configurations of the self-supervised training that we experiment.

C.1 Masking-based pretraining

Figure 4 shows the pretraining loss-plot for masked-language learning, to show that although the model converges, due to the reasons mentioned in the main paper, it does not learn useful representations for the downstream tasks.

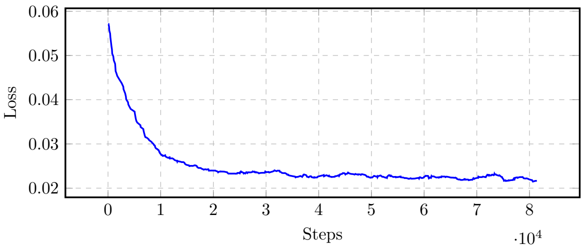

Figure 4: Loss curve for masked pretraining with regression loss

To explain this behaviour, we analyzed the input data as well as the outputs by the model. We find that the model was able to converge because learning to perform an approximate linear interpolation for the masked frames based on the surrounding context was sufficient reduce the loss significantly. However, we posit that such interpolation does not learn any high-level features. This is illustrated in Figure 5, where for each masking span length, we plot the sum of absolute differences between each consecutive masked frames F_i and F_{i-1}, for both predictions from the model as well as the actual frame keypoints. The numbers shown are averaged across all videos in the INCLUDE test set, in which the masking is done around the center region of each video. The plot shows that as masking length is increased, the gap between the predicted values and the actual values diverges indicating an inability to learn longer-range patterns that may be necessary to classify signs.

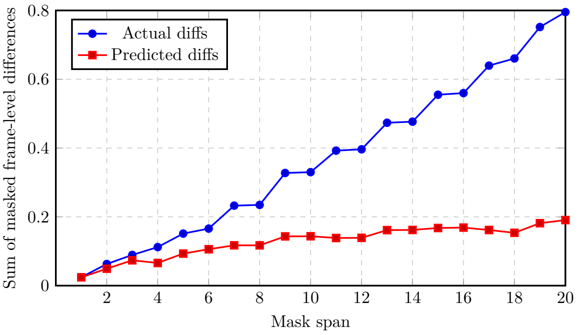

Figure 5: Differences in the output range of masked predictions of pretrained model and corresponding actual keypoints

We also experiment with pretraining using direction loss as explained in background, which essentially is an objective to classify which quadrant the motion vector for each frame will lie. We find that the pretraining does not converge. Upon checking the labels, we see that at the fine-grained level of each frames, the approximately discretized quadrant for each motion vector were seemingly almost random because of the slightly jittery predictions for each frame by the pose estimation model. Also, since the quadrant-type classification encodes only 4 directions, it fails to capture static motion (keypoints which do not move much temporally), which accounts for more than half of the total motion vectors. We thus posit that the direction classification targets are noisy and do not allow the pretraining loss to converge. Figure 6 shows the visualization of quadrants for a randomly-selected joint from a random video in the INCLUDE dataset, to visually verify how noisy the targets for direction loss are.

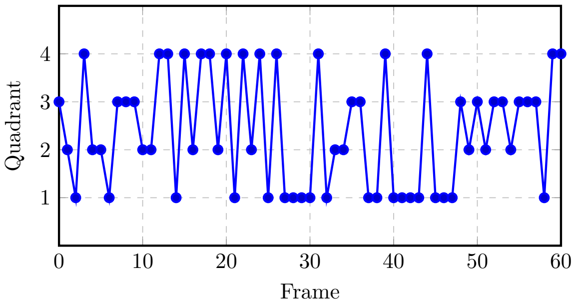

Figure 6: Sample visualization of direction labels for keypoint-15 from the frames of a random INCLUDE video (*Adjectives/4. sad/MVI_9720*)

C.2 Contrastive-learning based

The training setup for this experiment is: For pretraining, we used a batch size of 128 and for finetuning, we used a batch size of 64. For both pretraining and finetuning, we used Adam optimizer with an initial LR of 1e-3. To obtain negative samples, we use a Memory Bank to obtain the embeddings from samples of recent previous batches, which is essentially a FIFO queue of fixed size. We use Facebook's *MoCo codebase* to implement the setup, by plugging-in our ST-GCN as the encoder.

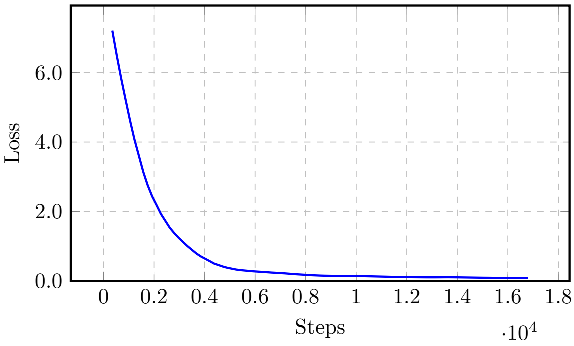

Figure 7: Loss curve for contrastive pretraining

Figure 7 shows the pretraining loss-plot for contrastive learning, to show that although the model converges, as explained in the main paper, the representations learnt do not signify any semantic relationships in the signs. To illustrate this, we take a standard subset of the INCLUDE dataset, called INCLUDE50 (containing 50 classes) and visualize the embeddings of all signs using PCA clustering. Note that each class is uniquely colored to identify if similar signs are grouped together. Figure 8 shows that the learnt embeddings do not discriminate the classes, suggesting that the embeddings may not be informative for the downstream sign recognition task.

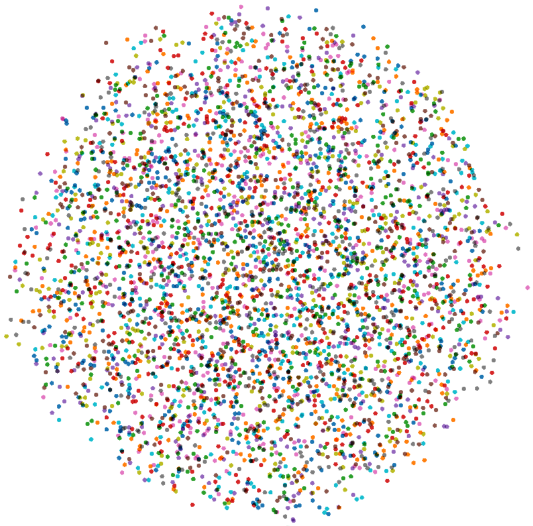

Figure 8: PCA visualization of INCLUDE50 embeddings obtained from Contrastive-Learning model

C.3 Predictive-coding based pretraining

The training setup for this experiment is: For pretraining, we used a batch size of 128 and for finetuning, we used a batch size of 64. For both pretraining and finetuning, we used Adam optimizer with a learning rate of 1e-3.

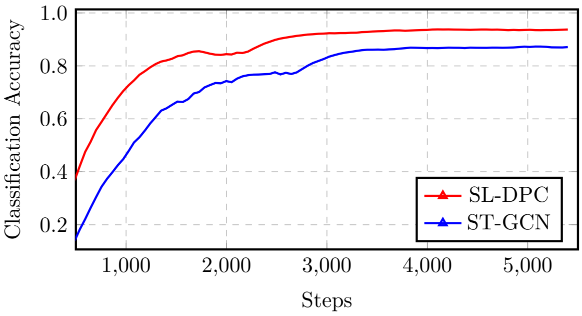

Figure 9: DPC Fine-tuning (orange) vs fresh training (light-green) validation accuracy plot

Figure 9 shows the performance gap between fine-tuning of a DPC pretrained model and an ST-GCN model being trained from scratch. This clearly demonstrates that self-supervised learning produces a significant boost in performance for downstream tasks.

D Sample usage snippets from 👐 **OpenHands** library

```
import omegaconf
from openhands.apis import ClassificationModel
from openhands.core import get_trainer

cfg = omegaconf.OmegaConf.load("path/to/config.yaml")
trainer = get_trainer(cfg)
model = ClassificationModel(cfg=cfg, trainer=trainer)
model.fit()
```

Datasheet for Raw Indian SL corpus

This is the detailed datasheet, including ethical considerations, of the unlabelled pretraining dataset proposed in Section 4.1.

Motivation For Datasheet Creation

Why was the datasheet created? (e.g., was there a specific task in mind? was there a specific gap that needed to be filled?)

There were no large-scale unlabelled datasets available for experimenting with self-supervised learning for sign languages, like we have for NLP, eg. bookcorpus (Zhu et al., 2015) and Common-Crawl (Abadji et al., 2022). Like in NLP, it is expected that such a dataset may help reduce the need for labelled dataset. This dataset was collected with a specific focus on Indian Sign Language (ISL) which has limited labelled resources.

Who created the dataset (e.g., which team, research group) and on behalf of which entity (e.g., company, institution, organization)?

The dataset was programatically created by crawling, cleaning, and preprocessing video data by the main authors of this paper, who are researchers at AI4Bharat group of IIT Madras.

Who funded the creation dataset?

The work was funded by Microsoft Philanthropies India through Microsoft AI4Accessibility program, via AI4Bharat.

Datasheet Composition

What are the instances?(that is, examples; e.g., documents, images, people, countries) Are there multiple types of instances? (e.g., movies, users, ratings; people, interactions between them; nodes, edges)

An instance in our dataset is a bundle of sequence of pose keypoints extracted from the videos of a specific source, in HDF5 format. The original videos are not part of the dataset.

How many instances are there in total (of each type, if appropriate)? The dataset consists of pose keypoints from 7 YouTube channels. Hence there are 7 instances in total.

What data does each instance consist of ? “Raw” data (e.g., unprocessed text or images)? Features/attributes?

Each instance contains the raw pose keypoints data (i.e., without any label data) extracted from the videos of a specific YouTube channel. The features extracted are obtained directly from MediaPipe Holistic tool (Grishchenko and Bazarevsky, 2020), which provides human skeletons for any given set of frames with a person. Our video sources are from news and educational domains. Around 87% of the total data is from 3 news channels. The Education domain channels are *National Institute of Open Schooling*, an intiative by Government of India and SIGN Library channel, an initiative to make educational content in Indian SL.

Is there a label or target associated with each instance? If so, please provide a description.

No, this is an unlabeled raw dataset used for self-supervised pretraining.

Is any information missing from individual instances? If so, please provide a description, explaining why this information is missing (e.g., because it was unavailable). This does not include intentionally removed information, but might include, e.g., redacted text.

We are releasing only the pose keypoints derived from the videos, and not the videos. For reproducibility, we also provide the YouTube video URLs of the corresponding pose keypoints.

Are relationships between individual instances made explicit (e.g., users’ movie ratings, social network links)? If so, please describe how these relationships are made explicit.

All instances are independent of each other and are not linked directly in anyway.

Are there recommended data splits (e.g., training, development/validation, testing)? If so, please provide a description of these splits, explaining the rationale behind them.

No. We recommend to use the entire raw data for pretraining purposes, and as a validation set to compare losses and perform early stopping, we recommend to use the open-sourced INCLUDE dataset (Sridhar et al., 2020). In case if a researcher wants to split the raw data to derive their own train-test split, we recommend them to use the data from "SIGN Library" source for test/development set and the remaining for training.

Are there any errors, sources of noise, or redundancies in the dataset? If so, please provide a

description.

We did our best to ensure there are no redundancies by crawling videos with unique video IDs and titles. There are no labels so there is no error due to labelling. One source of error could be inaccuracy in pose extraction by the MediaPipe library. We did not manually evaluate this accuracy across all datasets, but in manual checks we found MediaPipe to be highly accurate especially since most videos consist of one prominently featured signer with limited or no occlusion.

Is the dataset self-contained, or does it link to or otherwise rely on external resources (e.g., websites, tweets, other datasets)? If it links to or relies on external resources, a) are there guarantees that they will exist, and remain constant, over time; b) are there official archival versions of the complete dataset (i.e., including the external resources as they existed at the time the dataset was created); c) are there any restrictions (e.g., licenses, fees) associated with any of the external resources that might apply to a future user? Please provide descriptions of all external resources and any restrictions associated with them, as well as links or other access points, as appropriate.

The dataset we release is self-contained as used for pretraining in this work. As discussed, to recreate or process the original videos, we provide links to the original videos. However, as this data is hosted on YouTube with rights owned by the respective video creators, these videos may not be available indefinitely.

Collection Process

What mechanisms or procedures were used to collect the data (e.g., hardware apparatus or sensor, manual human curation, software program, software API)? How were these mechanisms or procedures validated?

The data collection pipeline is explained in Section 4 of the main paper. In summary, videos were automatically crawled from the web to collect openly available resources under permissible licenses. These videos were then processed with MediaPipe to obtain pose data as explained in the main paper.

How was the data associated with each instance acquired? Was the data directly observable (e.g., raw text, movie ratings), reported by subjects (e.g., survey responses), or indirectly inferred/derived from other data (e.g., part-of-speech tags, model-based guesses for age or language)? If data was reported by subjects or indirectly inferred/derived from other data, was the data validated/verified? If so, please describe how.

The (pose) data was derived from the crawled videos without any human intervention as stated above. The automatic validation/cleaning of the dataset is explained in the main paper's section 4.

If the dataset is a sample from a larger set, what was the sampling strategy (e.g., deterministic, probabilistic with specific sampling probabilities)?

We release all good quality data in the dataset after a very minimal cleaning process described in the main paper. There was no subjective sampling of the data.

Who was involved in the data collection process (e.g., students, crowdworkers, contractors) and how were they compensated (e.g., how much were crowdworkers paid)?

The code for the automatic crawling and cleaning processes were written by full-time researchers at AI4Bharat (authors of paper), with some help from a volunteer (a full-time student), who has been thanked in the acknowledgements section.

Over what timeframe was the data collected? Does this timeframe match the creation timeframe of the data associated with the instances (e.g., recent crawl of old news articles)? If not, please describe the timeframe in which the data associated with the instances was created.

The crawling was done in the month of June 2021 to include all the videos from the YouTube channels till then. It took over a month to crawl the videos.

Data Preprocessing

Was any preprocessing/cleaning/labeling of the data done (e.g., discretization or bucketing, tokenization, part-of-speech tagging, SIFT feature extraction, removal of instances, processing of missing values)? If so, please provide a description. If not, you may skip the remainder of the questions in this section.

The steps and pipeline used to create the dataset is explained in section 4 of the main paper. No further preprocessing is done before releasing. In addition, the augmentations and normalization performed for training different models are explained in the paper.

Dataset Distribution

How will the dataset be distributed? (e.g., tarball on website, API, GitHub; does the data have a DOI and is it archived redundantly?)

The dataset is released as zipped HDF5 files, one zip for each YouTube channel, and available via Zenodo hosting platform. The dataset has an DOI which is cited in the Acknowledgements section. A mirror link to the dataset can be availed on request (in-case the platform is down or other issues).

When will the dataset be released/first distributed? What license (if any) is it distributed under?

The dataset is released along with the camera-ready version of the paper submitted finally to the conference. It is licensed under the Creative Commons Attribution 4.0 International license.

Are there any copyrights on the data?

The original videos are the copyright of the respective YouTube channels, and are not released. We only release the pose data with no Personally Identifiable Information (PII).

Are there any fees or access/export restrictions?

No.

Dataset Maintenance

Who is supporting/hosting/maintaining the dataset?

The dataset is being hosted at Zenodo, an open-access repository to store and distribute scientific artifacts. The dataset is being maintained by AI4Bharat, a research lab in the CSE department of IIT Madras, India.

Will the dataset be updated? If so, how often and by whom?

If there are any errors found or if any required data is missing, we take responsibility to update/rectify the same.

How will updates be communicated? (e.g., mailing list, GitHub)

It would be conveyed via the changelogs in the GitHub repository.

If the dataset becomes obsolete how will this be communicated?

We do not expect this to happen. But in such a rare case, it will be notified in the GitHub repository as an important note.

Is there a repository to link to any/all papers/systems that use this dataset?

All research works that use our dataset are requested to cite this paper. If this is followed, by viewing the list of citations for this paper (for example on Google Scholar) one could track all papers/systems using the dataset.

If others want to extend/augment/build on this dataset, is there a mechanism for them to do so? If so, is there a process for tracking/assessing the quality of those contributions. What is the process for communicating/distributing these contributions to users?

We would greatly appreciate others adding to the dataset - hence the name of the hosting repository is 👐 `OpenHands`. Those intending to extend the dataset can contact us on our email addresses or on the Github repository. Quality of the extended dataset would be measured by performance of sign language recognition systems built with the dataset.

Legal and Ethical Considerations

Does the dataset contain data that might be considered confidential (e.g., data that is protected by legal privilege or by doctorpatient confidentiality, data that includes the content of individuals non-public communications)? If so, please provide a description.

No, the dataset does not contain any confidential or personal data.

Does the dataset contain data that, if viewed directly, might be offensive, insulting, threatening, or might otherwise cause anxiety? If so, please describe why

No, the dataset does not contain any offensive or inappropriate data. No audio/speech/image data is included in the data.

Does the dataset relate to people? If not, you may skip the remaining questions in this section.

Yes, but the dataset has only the skeleton information of signers without any PII.

Does the dataset identify any subpopulations (e.g., by age, gender)? If so, please describe how these subpopulations are identified and provide

a description of their respective distributions within the dataset.

No, it does not identify any subpopulations.

Is it possible to identify individuals (i.e., one or more natural persons), either directly or indirectly (i.e., in combination with other data) from the dataset? If so, please describe how.

No, it is not possible to identify the individuals behind the dataset, because the data released contains only the pose points of the signers.

Does the dataset contain data that might be considered sensitive in any way (e.g., data that reveals racial or ethnic origins, sexual orientations, religious beliefs, political opinions or union memberships, or locations; financial or health data; biometric or genetic data; forms of government identification, such as social security numbers; criminal history)? If so, please provide a description.

No, the dataset does not include any sensitive data.

Did you collect the data from the individuals in question directly, or obtain it via third parties or other sources (e.g., websites)?

We obtain it via publicly available YouTube channels released by the respective groups, and not from any individuals.

bert2BERT: Towards Reusable Pretrained Language Models

Abstract

In recent years, researchers tend to pre-train ever-larger language models to explore the upper limit of deep models. However, large language model pre-training costs intensive computational resources, and most of the models are trained from scratch without reusing the existing pre-trained models, which is wasteful. In this paper, we propose bert2BERT[1], which can effectively transfer the knowledge of an existing smaller pre-trained model to a large model through parameter initialization and significantly improve the pre-training efficiency of the large model. Specifically, we extend the previous *function-preserving* (Chen et al., 2016) method proposed in computer vision on the Transformer-based language model, and further improve it by proposing a novel method, *advanced knowledge* for the large model's initialization. In addition, a two-stage learning method is proposed to further accelerate the pre-training. We conduct extensive experiments on representative PLMs (e.g., BERT and GPT) and demonstrate that (1) our method can save a significant amount of training cost compared with baselines including learning from scratch, StackBERT (Gong et al., 2019) and MSLT (Yang et al., 2020); (2) our method is generic and applicable to different types of pre-trained models. In particular, bert2BERT saves about 45% and 47% computational cost of pre-training $\text{BERT}_{\text{BASE}}$ and GPT_{BASE} by reusing the models of almost their half sizes.

1 Introduction

Pre-trained language models (PLMs), such as BERT (Devlin et al., 2019), GPT (Radford et al., 2018, 2019; Brown et al., 2020), ELECTRA (Clark et al., 2020), XLNet (Yang et al., 2019) and RoBERTa (Liu et al., 2019), have achieved great success in natural language processing (NLP). However, the pre-training process of large PLMs can be extremely computationally expensive and produces huge carbon footprints. For example, GPT-3 uses 3.1E+6 GPU hours for training, at an estimated cost of $4.6 million[2], consuming a lot of computing resources. Therefore, how to reduce the training cost of PLM is of great importance to Green AI (Schwartz et al., 2020).

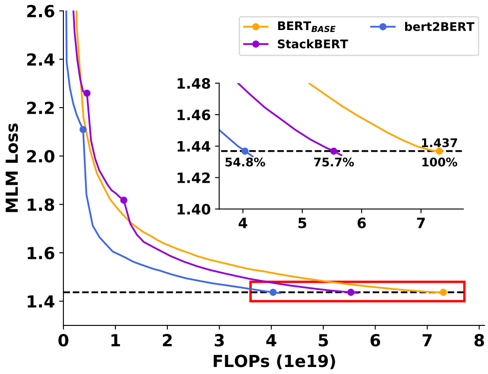

Figure 1: Loss curves of bert2BERT and baselines. StackBERT (Gong et al., 2019) is based on the progressive training setting. More details are shown in Table 2.

Recently, there is a trend of training extremely large models to explore the upper limits of PLMs. For example, large pre-trained models, including GPT-3 (Brown et al., 2020) (175B), PanGu-α (Zeng et al., 2021) (200B) and Switch Transformers (Fedus et al., 2021) (1571B), have been proved promising in language understanding and generation. However, these models are all pre-trained from scratch independently without utilizing the knowledge of smaller ones that have already been trained. On the other hand, our empirical studies show that the pre-trained models of different scales could share similar knowledge, for example in Figure 2, the attention patterns of the two PLMs with different sizes are similar.

To save the training cost of large models, we

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 2134 - 2148

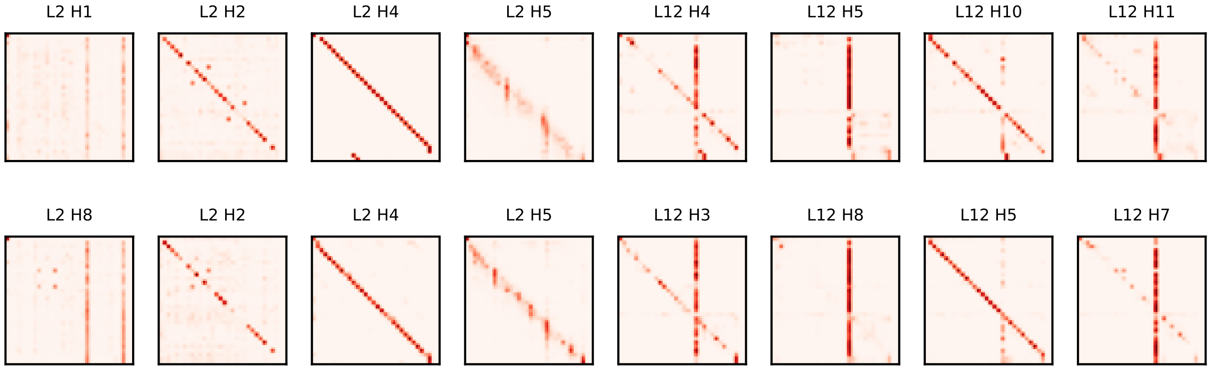

Figure 2: The comparisons of attention patterns between small and large PLMs. The upper ones are the attention patterns of $\text{BERT}_{\text{BASE}}$ model whose architecture is $\{L\text{=}12, D\text{=}768\}$, and the lower ones are the attention patterns of one small BERT model whose architecture is $\{L\text{=}12, D\text{=}512\}$. We find that there are a large number of similar attention patterns in the same layer of the two models, indicating the possibility of reusing parameters of trained small PLMs to speed up the pre-training of large PLMs. The attention maps of PLMs with different layers are also similar, which is visualized in previous work (Gong et al., 2019; Yang et al., 2020).

propose the bert2BERT method, which can efficiently transfer the learned knowledge of the smaller model to the large model. bert2BERT consists of two components: (1) For parameter initialization, we first extend the function preserving training (Chen et al., 2016) to PLMs by duplicating and stacking the parameters of the existing smaller PLM, which we call function-preserving initialization (FPI). FPI ensures that the initialized large model has almost the same behavior as the small model, so that the large model has a good starting point for later optimization. We also find that duplicating the weights of the upper layer to the current layer can further accelerate the convergence of the large model, which we call advanced knowledge initialization (AKI). Although the AKI somewhat violates the principle of function preserving, we find that empirically it also has a good starting point as shown in Table 1, which leads to a faster convergence rate and achieves higher training efficiency. (2) Secondly, a two-stage training strategy is further applied to the large model to accelerate the training process.

To demonstrate the superiority of our method, we conduct extensive experiments on two representative PLMs: BERT and GPT, with different source model sizes. The results show that: (1) our method can save a significant amount of computation in pre-training compared to the traditional way of learning from scratch and progressive stacking methods such as StackBERT (Gong et al., 2019) and MSLT (Yang et al., 2020); (2) our method is model-agnostic, which can be applied on a wide range of Transformer-based PLMs. One typical example is that, when using a small pre-trained model with half the size of $\text{BERT}_{\text{BASE}}$ for initialization, bert2BERT saves **45%** computation cost of the original $\text{BERT}_{\text{BASE}}$ pre-training.

In general, our contributions are summarized as follows: (1) We explore a new direction for the efficient pre-training by reusing the trained parameters of small models to initialize the large model; (2) We successfully extend function preserving method (Chen et al., 2016) on BERT and further propose advanced knowledge initialization, which can effectively transfer the knowledge of the trained small model to the big model and improve the pre-training efficiency; (3) The proposed method outperforms other training methods and achieves 45% computation reduction on $\text{BERT}_{\text{BASE}}$; (4) Our method is generic, effective for both the BERT and GPT models, and have great potential to become an energy-efficient solution for pre-training super large-scale language models.

2 Related Work

Efficient Pre-training in NLP. The efficiency of pre-training has been explored by previous work. Some works (Gong et al., 2019; Yang et al., 2020; Gu et al., 2021) propose progressive learning to accelerate the pre-training, which are motivated by the fact that different layers have some similar knowledge (e.g., attention patterns). They start pre-training a small model with fewer Transformer layers, and then iteratively expand the model by stacking the already trained layers on the top. Another line of work proposes to "back distill" the knowledge of the small models into large models, which is termed as knowledge inheritance (Qin et al., 2021). Some works focus on the data efficiency (Wu et al., 2021) and take notes for rare words during the pre-training process to help the model understand them when they occur next. ELECTRA (Clark et al., 2020) proposes a task of replaced token detection to predict whether each token in the input was replaced or not, which improves the pre-training efficiency. Our method is orthogonal to this kind of work and the combination of ELECTRA and bert2BERT could achieve better efficiency. In addition, there are several other orthogonal techniques for efficient pre-training: mixed-precision training (Shoeybi et al., 2019), large batch optimization (You et al., 2020), model architecture innovation (Lan et al., 2020), layer dropping technique (Zhang and He, 2020), etc.

Reusable Neural Network. Reusable neural network, a topic related to transfer learning (Pan and Yang, 2010), is introduced to accelerate the model training in computer vision. One classical work is Net2Net (Chen et al., 2016), which first proposes the concept of the function-preserving transformation to make neural networks reusable. However, Net2Net randomly selects the neurons to be split. To handle this problem, some works (Wu et al., 2019, 2020b; Wang et al., 2019b; Wu et al., 2020a) leverage a functional steepest descent idea to decide the optimal subset of neurons to be split. The pruning technique (Han et al., 2015) is also introduced for reusable neural networks (Feng and Panda, 2020). In this paper, we study the reusable pre-trained language model and propose a new method, bert2BERT, to accelerate the pre-training of BERT and GPT.

3 Preliminary

BERT consists of one embedding layer and multiple Transformer (Vaswani et al., 2017) layers.

3.1 Embedding Layer

The embedding layer first maps the tokens in a sentence into vectors with an embedding matrix $\boldsymbol{W}^E$. Then one normalization layer is employed to produce the initial hidden states $\boldsymbol{H}_0$.

3.2 Transformer Layer

The hidden states are iteratively processed by multiple Transformer layers as follows:

$$\boldsymbol{H}_l = \text{Transformer}_l(\boldsymbol{H}_{l-1}), l \in [1, L] \tag{1}$$

where L denotes the number of Transformer layers, each including a multi-head attention (MHA) and a feed-forward network (FFN).

MHA. It is composed of multiple parallel self-attention heads. The hidden states of the previous layer are fed into each head and then the outputs of all heads are summed to obtain the final output as follows:

$$\begin{aligned} \boldsymbol{Q}_i, \boldsymbol{K}_i, \boldsymbol{V}_i &= \boldsymbol{H}_{l-1}\boldsymbol{W}^Q_{l,i}, \boldsymbol{H}_{l-1}\boldsymbol{W}^K_{l,i}, \boldsymbol{H}_{l-1}\boldsymbol{W}^V_{l,i}, \\ \boldsymbol{H}^{\text{HEAD}}_{l,i} &= \text{softmax}(\frac{\boldsymbol{Q}_i\boldsymbol{K}_i^T}{\sqrt{d_k}})\boldsymbol{V}_i\boldsymbol{W}^O_{l,i}, \\ \text{MHA}(\boldsymbol{H}_{l-1}) &= \sum_{i=1}^{a} \boldsymbol{H}^{\text{HEAD}}_{l,i}, \\ \boldsymbol{H}^{\text{MHA}}_l &= \text{LayerNorm}(\boldsymbol{H}_{l-1} + \text{MHA}(\boldsymbol{H}_{l-1})). \end{aligned} \tag{2}$$

$\boldsymbol{H}_{l-1}$ is linearly projected to queries ($\boldsymbol{Q}_i$), keys ($\boldsymbol{K}_i$) and values ($\boldsymbol{V}_i$) using $\boldsymbol{W}^Q_{l,i}, \boldsymbol{W}^K_{l,i}, \boldsymbol{W}^V_{l,i}$ respectively. $\boldsymbol{H}^{\text{HEAD}}_{l,i}$ indicates the context-aware vector which is obtained by the scaled dot-product of queries and keys in the i-th attention head. a represents the number of self-attention heads. d_k is the head dimension acting as the scaling factor.

FFN. It consists of two linear layers and one GeLU activation function (Hendrycks and Gimpel, 2016), that is:

$$\begin{aligned} \boldsymbol{H}^{\text{FFN}}_l &= \text{GeLU}(\boldsymbol{H}^{\text{MHA}}_l\boldsymbol{W}^1_l + \boldsymbol{b}^1_l)\boldsymbol{W}^2_l + \boldsymbol{b}^2_l, \\ \boldsymbol{H}_l &= \text{LayerNorm}(\boldsymbol{H}^{\text{MHA}}_l + \boldsymbol{H}^{\text{FFN}}_l). \end{aligned} \tag{3}$$

Layer Normalization. Both the modules of MHA and FFN have one layer normalization (Ba et al., 2016) that stabilizes the dynamics of the hidden state in the Transformer. Formally, it is written as:

$$\text{LayerNorm}(\boldsymbol{H}) = (\frac{\boldsymbol{H} - \mu_{\boldsymbol{H}}}{\sigma_{\boldsymbol{H}}}) \odot \boldsymbol{W}^{LN} + \boldsymbol{b}^{LN}, \tag{4}$$

where $\odot$ means the element-wise multiplication. The statistics of $\mu_{\boldsymbol{H}}$ and $\sigma_{\boldsymbol{H}}$ are the mean and variance of hidden states $\boldsymbol{H}$ respectively.

4 Methodology

4.1 Problem Statement

We aim to accelerate the pre-training of target model $\mathcal{T}(L^t, D^t)$ by transferring the knowledge of an existing pre-trained source model $\mathcal{S}(L^s, D^s)$, where $L^{s|t}$ means the numbers of Transformer layer and $D^{s|t}$ means the model width (i.e., hidden size), satisfying $L^s \leq L^t$ and $D^s \leq D^t$. Formally, our problem is two-fold: (1) how to perform an effective parameter initialization for $\mathcal{T}$ by reusing the trained parameters of $\mathcal{S}$, and (2) how to efficiently train the initialized $\mathcal{T}$, so that $\mathcal{T}$ can have a faster convergence rate in pre-training.

4.2 Overview

Targeting the above problems, bert2BERT first initializes the target model $\mathcal{T}$ with the parameters of the existing model $\mathcal{S}$ by the width-wise expansion ($D^s \rightarrow D^t$) and depth-wise expansion ($L^s \rightarrow L^t$). Through this expansion, the knowledge contained in the parameters of the source model is directly transferred to the target model. Then we further pre-train the initialized target model with a two-stage pre-training method. The overall workflow is illustrated in Section 4.5.

Essentially, the width-wise expansion can be decomposed into expansions of parameter matrices (or vectors[3]). As illustrated in Figure 3, the matrix expansion enlarges $\boldsymbol{W} \in \mathbb{R}^{d^w_{\text{in}} * d^w_{\text{out}}}$ of $\mathcal{S}$ to $\boldsymbol{U} \in \mathbb{R}^{d^u_{\text{in}} * d^u_{\text{out}}}$ of $\mathcal{T}$ by two kinds of operations: in-dimension and out-dimension expansion.

In the following sections, we first introduce two strategies of width-wise expansion: function-preserving and advanced knowledge initialization. Then, we introduce the depth-wise expansion and detail the two-stage pre-training process.

4.3 Width-wise Expansion

For the paper clarity, we introduce two index mapping functions: g_{in} and g_{out}, where $g_{\text{in}}(i)$ means the i-th in-dimension of $\boldsymbol{U}$ reuses the $g_{\text{in}}(i)$-th in-dimension parameters of $\boldsymbol{W}$, $g_{\text{out}}(j)$ means the j-th out-dimension of $\boldsymbol{U}$ reuses the $g_{\text{out}}(j)$-th out-dimension parameters of $\boldsymbol{W}$. Both our two methods are defined with these two mapping functions. $\boldsymbol{W}_{(i,j)}$ means the parameter element, i and j refer to the i-th in-dimension index and j-th out-dimension index respectively. As shown in Figure 3, the i-th in-dimension parameters of $\boldsymbol{W}$ are the parameters of the i-th input neuron of $\boldsymbol{W}$ or the i-th column of $\boldsymbol{W}$.

4.3.1 Function Preserving Initialization

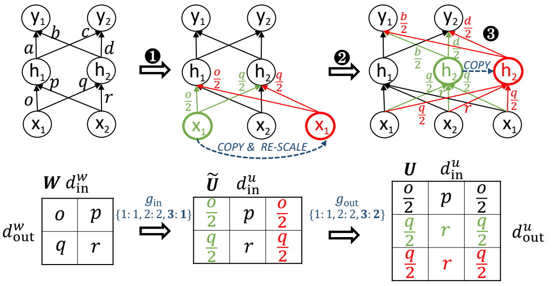

Figure 3: Overview of the function preserving initialization (FPI). Given the same input $\{x_1, x_2\}$, FPI ensures the initialized target model has the same output $\{y_1, y_2\}$ with the source model. The first and the second steps are expanding the in-dimension and out-dimension of the parameter matrix according to mapping functions g_{in} and g_{out} respectively. After we expand the matrix $\boldsymbol{W}$ into $\boldsymbol{U}$, we use the in-dimension expansion on the upper parameter matrix again to ensure the output $\{y_1, y_2\}$ same as the original one. From the view of neurons, FPI copies the corresponding input and output neurons to expand the neural network.

Function preserving initialization (FPI) (Chen et al., 2016) aims to make the initialized target model have the same function as the source model, which means that given the same input, the initialized target model has the same output as the source model. In this paper, we extend FPI on a different architecture, Transformer-based pre-trained language model. We give an example in Figure 3 to illustrate FPI. Formally, the mapping functions are defined as follows:

$$g_{\text{in}}(i) = \begin{cases} i & i \in [1, d^w_{\text{in}}] \\ f(\{1, 2, ..., d^w_{\text{in}}\}) & i \in (d^w_{\text{in}}, d^u_{\text{in}}], \end{cases} \quad (5)$$

$$g_{\text{out}}(j) = \begin{cases} j & j \in [1, d^w_{\text{out}}] \\ f(\{1, 2, ..., d^w_{\text{out}}\}) & j \in (d^w_{\text{out}}, d^u_{\text{out}}], \end{cases} \quad (6)$$

where $f(\cdot)$ is uniform sampling. We denote the weight expansion as $\boldsymbol{U} = \text{EXPN}(\boldsymbol{W}; g_{\text{in}}, g_{\text{out}})$, which includes in-dimension expansion (Eq. 7) and out-dimension expansion (Eq. 8):

$$C_{g_{\text{in}}(i)} = \sum_{i'=1}^{d^u_{\text{in}}} \mathbb{I}(g_{\text{in}}(i') = g_{\text{in}}(i)) \quad (7)$$
$$\widetilde{\boldsymbol{U}}_{(i,*)} = \frac{1}{C_{g_{\text{in}}(i)}} \boldsymbol{W}_{(g_{\text{in}}(i),*)},$$

$$\boldsymbol{U}_{(*,j)} = \widetilde{\boldsymbol{U}}_{(*,g_{\text{out}}(j))}, \quad (8)$$

where $\mathbb{I}(\cdot)$ is an indicator function, and $C_{g_{\text{in}}(i)}$ is the count of $g_{\text{in}}(i)$ in the values of $g_{\text{in}}(\cdot)$, which is used to re-scale the original parameters to keep the function preserving property.

Expansion for All Modules. We apply FPI for all modules of BERT via matrix expansion $\text{EXPN}(\cdot)$. Specifically, for the embedding matrix $\boldsymbol{W}^E$, we only conduct the out-dimension expansion:

$$\boldsymbol{U}^E_{(*,j)} = \boldsymbol{W}^E_{(*,g^e_{\text{out}}(j))}. \quad (9)$$

MHA module can be decomposed into multiple parallel self-attention heads and we conduct the head-wise expansion for this module, which means

---

[3] We omit the expansion of bias (vector) for simplicity. It follows a similar process as the matrix expansion.

increasing the number of attention heads. The head-wise expansion is formulated as:

$$\boldsymbol{U}^{Q|K|V|O} = \mathrm{EXPN}(\boldsymbol{W}^{Q|K|V|O}; g_{\text{in}}^{q|k|v|o}, g_{\text{out}}^{q|k|v|o}). \tag{10}$$

Specifically, the head-wise expansion means that we reuse the head group parameters to construct the new matrices. The i-th head group in l-th layer contains $\boldsymbol{W}_{l,i}^{Q}|\boldsymbol{W}_{l,i}^{K}|\boldsymbol{W}_{l,i}^{V}|\boldsymbol{W}_{l,i}^{O}$ in Eq. 2 and the out-dimension expansion for $\boldsymbol{W}_{l,i}^{Q}|\boldsymbol{W}_{l,i}^{K}|\boldsymbol{W}_{l,i}^{V}$ is:

$$g_{\text{out}}^{q|k|v}(j) = \begin{cases} j & j \in [1, a^s] \\ f(\{1, 2, ..., a^s\}) & j \in (a^s, a^t], \end{cases} \tag{11}$$

where j is the head index and $a^{s|t}$ mean the head numbers of source model and target model respectively. The module has three constraints: { $g_{\text{out}}^{e} = g_{\text{in}}^{q|k|v}$; $g_{\text{out}}^{q|k|v} = g_{\text{in}}^{o}$; $g_{\text{in}}^{q|k|v} = g_{\text{out}}^{o}$}, with the first two constraints for hidden dimension consistency (Wen et al., 2018; Chen et al., 2021) and the third one for residual connection (Eq. 2).

For the FFN module, we perform the expansion on the parameter matrices $\boldsymbol{W}^{1|2}$ (Eq. 3) as follows:

$$\boldsymbol{U}^{1|2} = \mathrm{EXPN}(\boldsymbol{W}^{1|2}; g_{\text{in}}^{1|2}, g_{\text{out}}^{1|2}). \tag{12}$$

Similar to the MHA module, the mapping functions of FFN also have three constraints: $\{g_{\text{out}}^{o} = g_{\text{in}}^{1}$; $g_{\text{out}}^{1} = g_{\text{in}}^{2}$; $g_{\text{in}}^{1} = g_{\text{out}}^{2}\}$.

For the layer normalization, we take the layer normalization of FFN as an example, its expansion is formulated as:

$$\boldsymbol{U}_j^{LN} = \boldsymbol{W}_{g_{\text{out}}^{2}(j)}^{LN}. \tag{13}$$

Note that in layer normalization (Eq. 4), the mean μ and variance σ are calculated based on the hidden representations $\boldsymbol{H}$. Thus, the expansion of this parameter inevitably induces a gap and prevents the target model from strictly following the function preserving principle. However, we empirically find that the gap is so small that it can hardly affect the initialization and convergence of the target model. Thus we ignore this discrepancy.

We have validated the effectiveness of the adapted FPI in different settings in Table 1. The results show that the initialized model $\mathcal{T}$ achieves almost the same loss as $\mathcal{S}$, demonstrating that FPI successfully retains the knowledge of the small model when performing parameter expansion.

4.3.2 Advanced Knowledge Initialization

To further improve the convergence rate of the pre-training target model, we propose the advanced knowledge initialization (AKI), which expands new matrices based on not only the parameters of the same layer but also the parameters of the upper layer in the source model. The intuition is based on previous findings (Jawahar et al., 2019; Clark et al., 2019) that adjacent Transformer layers have similar functionality, which ensures that it will not damage the knowledge contained in the parameters of the current layer. Moreover, the knowledge that comes from adjacent layers can break the symmetry (Chen et al., 2016) appeared in FPI, which has been demonstrated beneficial. We give an illustrative example in Figure 4 and formulate AKI as:

Method	$\mathcal{S}(12, 384)$	$\mathcal{S}(12, 512)$
Original	1.89	1.67
Rand	10.40	10.42
DirectCopy	9.05	6.45
FPI	**1.89**	**1.70**
AKI	2.08	1.96

Table 1: The comparison of MLM losses between FPI and baselines. “Original” refers to the MLM losses of source pre-trained models $\mathcal{S}$. “Rand” refers to the MLM losses of randomly initialized target models. “DirectCopy” refers to a naive method that directly copies the source model to the target model and the unfilled part is randomly initialized, “FPI” represents the function preserving method. We expand both models to the target model $\mathcal{T}(12, 768)$ and find that FPI can make the target model have similar losses with these trained source models. The loss gap between FPI and Original is brought by layer normalization. “AKI” represents the advanced knowledge initialization method.

$$\boldsymbol{U}^{l} = \mathrm{EXPN}(\boldsymbol{W}^{l}, \boldsymbol{W}^{l+1}; g_{\text{in}}^{l|l+1}, g_{\text{out}}^{l}). \tag{14}$$

Specifically, we first do the in-dimension expansion for $\boldsymbol{W}^{l|l+1}$. Here we take $\boldsymbol{W}^{l}$ as an example:

$$\begin{aligned} C_{g_{\text{in}}^{l}(i)} &= \sum_{i'=1}^{d_{\text{in}}^{u}} \mathbb{I}(g_{\text{in}}^{l}(i') = g_{\text{in}}^{l}(i)) \\ \widetilde{\boldsymbol{U}}_{(i,*)}^{l} &= \frac{1}{C_{g_{\text{in}}^{l}(i)}} \boldsymbol{W}_{(g_{\text{in}}^{l}(i),*)}^{l}. \end{aligned} \tag{15}$$

It is similar with Eq. 7. Then we stack the expanded matrices of $\widetilde{\boldsymbol{U}}^{l}$ and $\widetilde{\boldsymbol{U}}^{l+1}$ to construct the final matrix:

$$\boldsymbol{U}_{(*,j)}^{l} = \begin{cases} \widetilde{\boldsymbol{U}}_{(*,j)}^{l} & j \in [1, d_{\text{out}}^{w}] \\ \widetilde{\boldsymbol{U}}_{(*,g_{\text{out}}^{l}(j))}^{l+1} & j \in (d_{\text{out}}^{w}, d_{\text{out}}^{u}]. \end{cases} \tag{16}$$

We directly copy the expanded $\widetilde{\boldsymbol{U}}^{l}$ as the top part of the new matrix and place the sampled parameters from $\widetilde{\boldsymbol{U}}^{l+1}$ on the bottom of the new matrix.

We aggregate upper-layer information into a new matrix for two intuitions: (1) it breaks the FPI symmetry that hinders model convergence (Chen et al.,

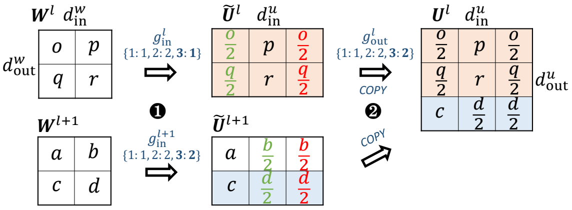

Figure 4: Overview of AKI. It first performs the in-dimension expansion on both the matrixes of current and upper layers. Then it uses the widened matrix of the current layer as the top part of the new matrix and samples the row of the widened matrix of the upper layer as the bottom part of the new matrix.

2016). For example, FPI makes the attention patterns in the same layer repeated, which is redundant and called symmetry; (2) upper-layer information can be used as similar but high-level knowledge to guide the model to converge faster. We display the attention patterns of the target model initialized by AKI in Appendix E and find that the target model can maintain the attention patterns of both current and upper layers very well.

Expansion for All Modules. For embedding matrix, we only do the out-dimension expansion as Eq. 9 in the FPI. Both the modules of MHA and FFN do the matrix expansion by following the defined operation in Eq. 15 and Eq. 16. The constraints of mapping functions follow the setting of FPI.

Empirically, we find that the AKI method outperforms FPI, while the performance is worse if we build a new matrix based on the matrix of the lower layer (or low-level knowledge). How to construct the optimal initialization for the target model with the parameters of different layers remains an open question and we leave it as future work.

For more details, we give a clear illustration of the FPI and AKI process in Appendix F.

4.4 Depth-wise Expansion

After the width-wise expansion, we obtain a widened model with the same width as the target model. To bridge the depth gap, we perform depth-wise expansion to increase model depth to the depth of the target model. We illustrate this process in Algorithm 1 and the main idea is to iteratively stack the widened model until its depth is equal to the target model (Gong et al., 2019).

4.5 Two-stage Pre-training

To further improve the pre-training efficiency of initialized target model, we propose a two-stage training method: (1) train sub-models with different layers in a random manner to make the complete model converge at a low cost. These sub-models are built with bottom Transformer layers of the initialized target model and share one classification layer. At each optimization step, we randomly sample one sub-model and only update its top Transformer layers and the shared classification layer. (2) After the sub-structure training, we further perform the traditional full-model training. The details of our method are displayed in Algorithm 2.

Algorithm 1 Target Model Initialization

```
Input: the target model $\mathcal{T}(L^t, D^t)$ and the source
    model $\mathcal{S}(L^s, D^s)$.
$\mathcal{T}_1(L^s, D^t) \leftarrow$ do AKI or FPI with $\mathcal{S}(L^s, D^s)$
$k \leftarrow \lfloor L^t / L^s \rfloor$
for $t = 2 \to k$ do
    $\mathcal{T}_t(L^s \cdot t, D^t) \leftarrow$ stack $\mathcal{T}_1$ on top of $\mathcal{T}_{t-1}$
end for
$\mathcal{T} \leftarrow$ stack top $L^t - L^s \cdot k$ layers of $\mathcal{T}_1$.
Output: the initialized model $\mathcal{T}(L^t, D^t)$
```

Algorithm 2 Two-stage Pre-training

```
Input: the initialized model $\mathcal{T}$, large-scale unsu-
    pervised dataset $\mathcal{D}$, the epoch number of sub-
    model training $E_b$ and the epoch number of
    whole training process $E$, the layer number $l_b$.
Construct sub-models and these models have
    the layer numbers of $\{l_b, 2 \cdot l_b, \ldots, L^t\}$.
for $e = 1 \to E_b$ do
    for $batch$ in $D$ do
        $\mathcal{T}' \leftarrow$ sample one sub-model.
        Perform forward and backward of $\mathcal{T}'$.
        Update only top $l_b$ layers of $\mathcal{T}'$.
    end for
end for
for $e = E_b \to E$ do
    for $batch$ in $D$ do
        Perform forward and backward of $\mathcal{T}$.
        Update whole model $\mathcal{T}$.
    end for
end for
Output: the pre-trained model $\mathcal{T}$
```

5 Experiment

5.1 Experimental Setup

Pre-training Details. We use the English Wikipedia and Toronto Book Corpus (Zhu et al., 2015) as the pre-training data. The settings of pre-training are: peak learning rate of 1e-4, warmup

Model	FLOPs ($\times$1e19)	Ratio (Saving)	Loss (MLM)	SQuADv1.1 (F1)	SST-2 (Acc)	MNLI (Acc)	MRPC (Acc)	CoLA (Mcc)	QNLI (Acc)	QQP (Acc)	STS-B (Acc)	Avg.

Table 2: Comparison between bert2BERT and baselines. We report mean (and standard deviation) performance over 3 runs on the dev set. bert2BERT means the combination of AKI and two-stage pre-training here. FPI and AKI mean that the function preserving initialization, advanced knowledge initialization respectively. † means the re-implemented results, where the $\text{BERT}_{\text{BASE}}$ and StackBERT achieve similar results with the original paper, and the MSLT result is different from the original paper may be due to the different training settings (e.g., in the original paper, it uses the LAMB optimizer (You et al., 2020) and only trains the corpus with a max sequence length of 128).

steps of 10k, training epochs of E=40, batch size of 512, sub-model training epochs of E_b=5, layer number of l_b=3. Unless otherwise noted, all methods including bert2BERT and baselines use the same pre-training settings for fair comparisons. In the settings of bert2BERT, the target model has a $\text{BERT}_{\text{BASE}}$ architecture of $\mathcal{T}(12, 768)$ and the source model has an architecture of $\mathcal{S}(12, 512)$.

Fine-tuning Details. For the evaluation, we use tasks from GLUE benchmark (Wang et al., 2019a) and SQuADv1.1 (Rajpurkar et al., 2016). We report F1 for SQuADv1.1, Matthews correlation coefficient (Mcc) for CoLA (Warstadt et al., 2019) and accuracy (Acc) for other tasks. For the GLUE tasks fine-tuning, we set the batch size to 32, choose the learning rate from {5e-6, 1e-5, 2e-5, 3e-5} and epochs from {4, 5, 10}. For the SQuADv1.1 fine-tuning, we set the batch size to 16, the learning rate to 3e-5, and the number of training epochs to 4. All results are the average of 3 runs on the dev set.

Baselines. We first introduce a naive bert2BERT baseline named DirectCopy, which directly copies the small model to the target model and randomly initializes the unfilled parameters. StackBERT (Gong et al., 2019) and MSLT (Yang et al., 2020) are also included as the baselines. Both of them are trained in a progressive manner. Following the original setting, for the StackBERT, we first train the 3-layer BERT for 5 epochs, stack it twice into a 6-layer BERT and then train it for 7 epochs. In the final step, we stack the 6-layer model into $\text{BERT}_{\text{BASE}}$ and further train it with 28 epochs. For MSLT, we first perform 4-stage training. In each stage, we add the top 3 layers of the model already trained to the top of the model and then pre-train the new model by partially updating the top 3 layers. Each stage of the partial training process has 8 epochs. Finally, we further perform 20 full-model training epochs[4] to achieve the same loss as $\text{BERT}_{\text{BASE}}$ trained from scratch. The baselines are trained using the same optimizer, training steps, and warmup steps as the bert2BERT.

5.2 Results and Analysis

We demonstrate the effectiveness of the proposed method on the SQuAD and GLUE benchmark. The results are shown in Table 2. We also represent the loss curves in Figure 1 and Appendix A. The results show that: (1) DirectCopy only saves 12.2% computational costs, which indicates this naive method of directly copying the trained parameters of the source model to the target model is not effective; (2) our proposed methods, FPI and AKI, achieve better performances than the baselines. Although AKI does not follow the function preserving, it has a bigger loss than FPI at the start of training, AKI achieves a faster convergence rate by using the advanced knowledge and breaking the symmetry; (3) by performing the two-stage pre-training on the target model initialized by AKI, we can save $\mathbf{45.2}\%$ computational costs. Note that the total parameters of the source model are half of those of the target model (54M vs. 110M). The loss of bert2BERT in Figure 1 is high at the stage of sub-model training because it represents the average loss of all sub-models. We also compare the attention patterns of the target models initialized by DirectCopy, FPI, and AKI. The attention patterns and their discussions are displayed in Appendix E.

---

[4] We have tried the same setting as the original paper with 8 epoch full-model running but it does not achieve the same loss with $\text{BERT}_{\text{BASE}}$ (1.511 vs. 1.437).

bert2BERT with Smaller Source Model. We also evaluate bert2BERT on different settings, where the source model $\mathcal{S}$(6, 512), $\mathcal{S}$(8, 512), $\mathcal{S}$(10, 512) are significantly smaller than the target model (35M | 42M | 48M vs. 110M). The results are shown in Table 3 and loss curves are displayed in Appendix B. We observe that DirectCopy for $\mathcal{S}$(6, 512) achieves no efficiency improvement over the original pre-training, which indicates that the significant size gap between the source and target model greatly reduces the benefit of DirectCopy methods. Compared with DirectCopy, our proposed method reduces the computation cost by 23.3%, which again demonstrates the effectiveness of bert2BERT. The results show that the smaller the size gap between the source model and target model, the greater the cost savings of bert2BERT. We also note that it is more challenging to speed up the target model with a small source model $\mathcal{S}$(6, 512). We encourage future work to explore to transfer the knowledge from smaller source models to improve the pre-training efficiency of the target model.

Settings	Model	FLOPs (× 1e19)	Ratio (Saving)	Loss (MLM)	Avg.
$\mathcal{S}$(6, 512)	DirectCopy	7.3	0%	1.440	89.1
	bert2BERT	5.6	23.3%	1.435	89.3
$\mathcal{S}$(8, 512)	bert2BERT	4.6	36.8%	1.435	89.2
$\mathcal{S}$(10, 512)	bert2BERT	4.2	42.7%	1.434	89.1

Table 3: bert2BERT with smaller source model. Avg means the average score of SST-2/MNLI/SQuADv1.1.

Effect of Sub-model Training Epochs. Our training procedure includes two stages: sub-model training and full-model training. Here, we study the effect of the number of sub-model training epochs by performing bert2BERT on the different settings of E_b={0, 5, 10, 20}. The results are presented in Table 4 and the loss curves are displayed in Appendix C. We observe that our method achieves the best efficiency when the epoch number is set to 5, while a larger or smaller epoch number will bring a negative impact.

Model	FLOPs (× 1e19)	Ratio (Saving)	Loss (MLM)	Avg.
bert2BERT : $\mathcal{S}(12, 512) \rightarrow \mathcal{T}(12, 768)$				
bert2BERT ($E_b = 0$)	4.5	38.4%	1.434	89.4
bert2BERT ($E_b = 5$)	**4.0**	**45.2%**	1.433	89.3
bert2BERT ($E_b = 10$)	4.1	43.9%	1.436	89.3
bert2BERT ($E_b = 20$)	5.4	25.4%	1.448	89.1

Table 4: Effect of sub-model training epochs. Avg means the average score of SST-2/MNLI/SQuADv1.1.

5.3 Application on GPT

Datasets. To demonstrate that our method is generic, following the BERT setting, we also use the English Wikipedia and Book Corpus in the GPT-training. For the evaluation, we use the datasets of WikiText-2, PTB, and WikiText103 and evaluate these models under the zero-shot setting without fine-tuning on the training set.

Implementation Details. We use the architecture of $\{L$=12, D=768$\}$ for the GPT target model, and pre-train it with the learning rate of 1e-4, training epochs of 20. For bert2BERT, we use the source model with an architecture of $\{L$=12, D=512$\}$, initialize the target model with AKI, and pre-train it by the full-model training (E_b=0).

Results and Analysis. We compare the original pre-training method and bert2BERT, the results are shown in Table 5 and Appendix D. We observe that the proposed method saves **47%** computation cost of GPT pre-training, exhibiting a similar trend to BERT pre-training. Although GPT and BERT have different architectures (e.g., post-LN and pre-LN (Xiong et al., 2020)) and are pre-trained with different tasks, bert2BERT saves a significant amount of training cost on both these two models, which shows that the proposed method is generic and is effective for different kinds of PLMs.

Model	FLOPs (× 1e19)	PTB (w/o FT)	WikiText-2 (w/o FT)	WikiText103 (w/o FT)
bert2BERT : $\mathcal{S}(12, 512) \rightarrow \mathcal{T}(12, 768)$				
GPT	4.9	133.8	47.0	53.5
bert2BERT	**2.6** (47% ↓)	132.1	47.9	53.0

Table 5: Experiments on GPT. We report the perplexity for these tasks. "w/o FT" means that the pre-trained model is directly evaluated on the test set without fine-tuning on the train set.

5.4 Application on T5

Datasets. To demonstrate that our method can be used to train larger models, we use the Baidu Wikipedia, Sougou Wikipedia, and Zhihu to train the T5 model (Raffel et al., 2020). For the evaluation, we use the dataset of the original Chinese natural language inference task (OCNLI) (Hu et al., 2020).

Implementation Details. Since the bert2BERT method is suitable for BERT and GPT, it can also be used for the T5 model, which consists of an encoder and a decoder. The target T5 model's architecture is $\{L_e$=12, L_d=12, D=1024, A=16$\}$, where

L_e and L_d means the numbers of encoder and decoder Transformer layers respectively, D means the hidden size, A means the number of attention heads. We pre-train it with the learning rate of 1e-4, batch size of 1024. For bert2BERT, we use the source model with an architecture of $\{L_e$=12, L_d=12, D=256, A=4$\}$, initialize the target model with FPI, and pre-train it by the full-model training (E_b=0). Note that the scale gap between the source model and the target model is over 10 times (31M vs. 360M), which is a challenging setting.

Results and Analysis. We compare the original pre-training method and bert2BERT method on the T5 model, the results are shown in Table 6. We observe that the proposed method saves at least 25% computation cost of T5 pre-training. It demonstrates the effectiveness of the method on larger models.

Model	FLOPs (× 1e20)	Loss (MLM)	OCNLI (Acc)
bert2BERT : $\mathcal{S}(12, 12, 256, 4) \rightarrow \mathcal{T}(12, 12, 1024, 16)$			
T5	1.6	1.90	72.03
bert2BERT	**1.2** (**25**% ↓)	1.90	72.75

Table 6: Experiments on the T5 model.

6 Conclusion and Future Work

This paper proposes an efficient pre-training method, bert2BERT, which reuses the parameters of the small trained model as the initialization parameters of the large model. We employ the proposed method in BERT and GPT under different settings of model sizes. The extensive results show that bert2BERT is generic to Transformer-based models and saves a significant amount of computation cost. Moreover, the detailed analysis shows that our techniques, function-preserving, advanced knowledge initialization, and two-stage pre-training, are all effective. In the future, we will apply bert2BERT on training super large-scale language models (e.g., use the 10B source model to train the 100B target model) and extends its scope to other PLMs such as ELECTRA and BART (Lewis et al., 2020).

A Ablation Study of bert2BERT

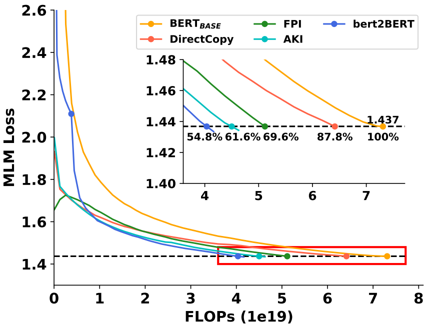

Figure 5: Ablation study of bert2BERT. bert2BERT means the combination of AKI and two-stage pre-training.

The ablation study of bert2BERT is displayed in Table 5. From the table, we observe that: (1) all the proposed methods is better than the original pre-training method and DirectCopy; (2) although AKI has a worse initialization than FPI, it achieves faster convergence rate than FPI; (3) the two-stage pre-training furthers reduce the cost from 61.6% to 54.8%; (4) the FPI curve has an upward trend at the beginning. We conjecture that it is due to the symmetry brought by FPI and the model needs some optimization time to break this symmetry.

B bert2BERT with smaller source model

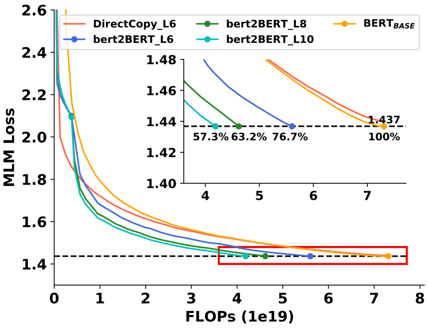

Figure 6: Loss curves of bert2BERT and baselines with smaller source models.

We test bert2BERT with different source models and the loss curves are represented in Figure 6.

C Effect of sub-model training epochs

We study the effect of sub-model training epochs on the pre-training efficiency. The loss curves are represented in Figure 7. Note that the setting $E_b = 20$ has not achieved the same loss (1.437) as the baseline BERT$_{\text{BASE}}$ in the 40 training epochs.

D Application on GPT

The loss curve of our method on GPT application is displayed in Figure 8.

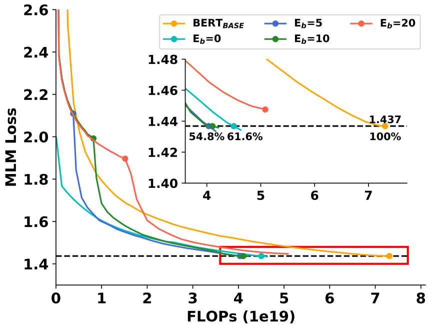

Figure 7: Loss curves of bert2BERT with different sub-model training epochs.

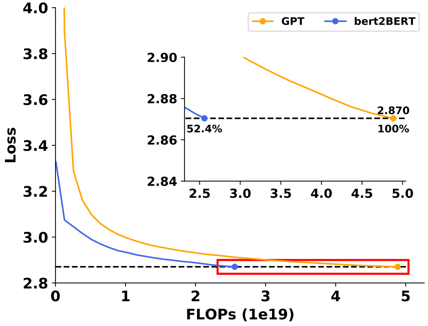

Figure 8: Pre-training loss curves of GPT.

E Comparisons of Attention Patterns

We take the source model $\mathcal{S}(4, 256)$ and target model $\mathcal{T}(4, 512)$ as an example to analyze the attention patterns of DirectCopy in Figure 10, FPI in Figure 11 and AKI in Figure 12.

We display the attention patterns of the source model $\mathcal{S}(4, 256)$ in Figure 9. Compared with the source model, we observe that the newly added attention patterns of DirectCopy are messy, and the randomly initialized parameters destroy the attention patterns of the source model. The proposed FPI method makes the new model have the same attention patterns as the source model, thus the knowledge of the source model is preserved. However, FPI always induces symmetrical attention patterns in the same layer. This symmetry will hinder the convergence. To handle this problem, we use AKI method to reuse the parameters of the upper layer (advanced knowledge) to break the symmetry, and meanwhile make the knowledge in the same layer richer. Through the AKI method, the attention patterns of the upper layer can be also maintained well in the target model. For example, as shown in Figure 12, the newly added attention patterns of the 1st layer in the target model are similar to the ones of the 2nd layer in the source model.

F Illustration of FPI and AKI process

We illustrate the process of FPI and AKI in Figure 13 and 14 respectively.

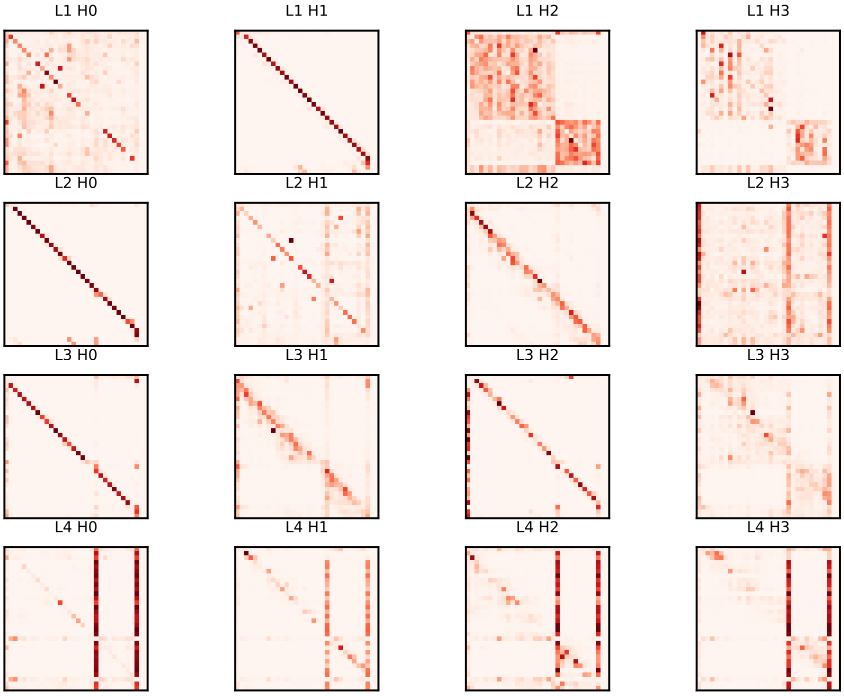

Figure 9: Attention patterns of the source model $\mathcal{S}(4, 256)$, which has 4 attention heads in each layer.

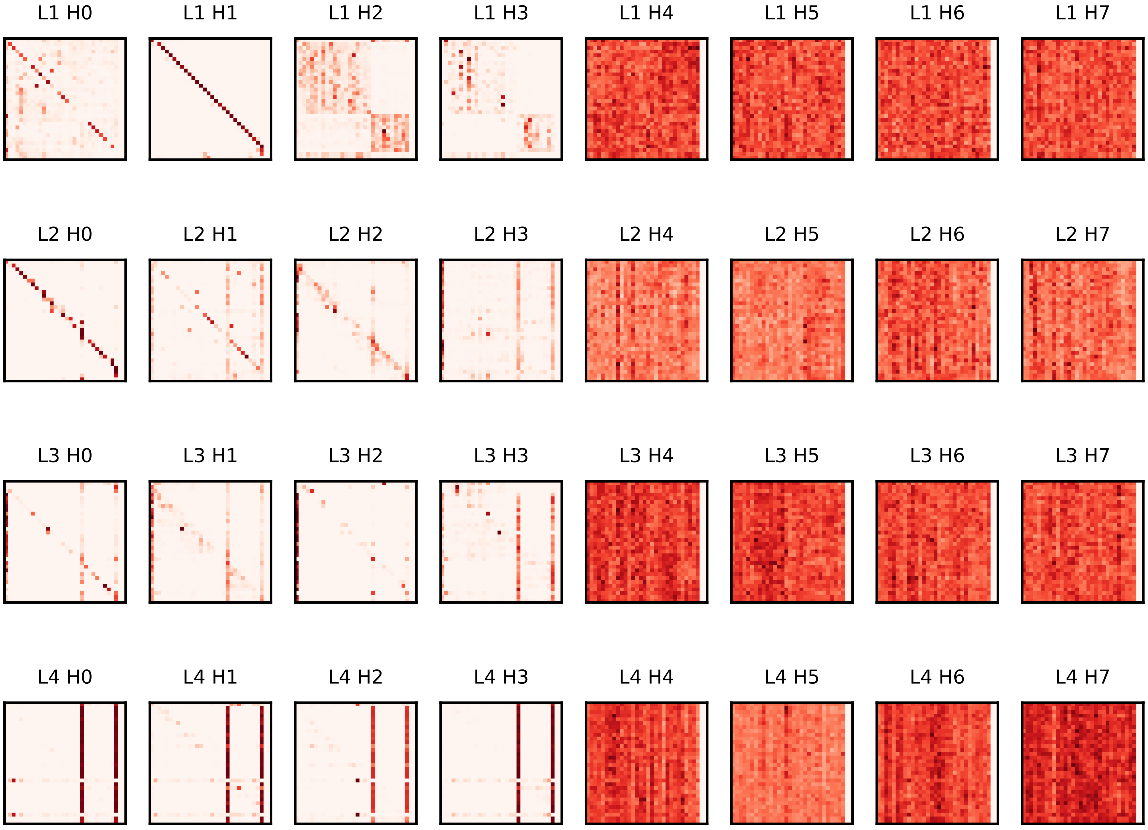

Figure 10: Attention patterns of the target model $\mathcal{T}(4, 512)$ based on the baseline DirectCopy method. The first 4 attention patterns (H0-H3) in each row correspond to the source model's attention patterns, and the last 4 attention patterns (H4-H7) are newly added.

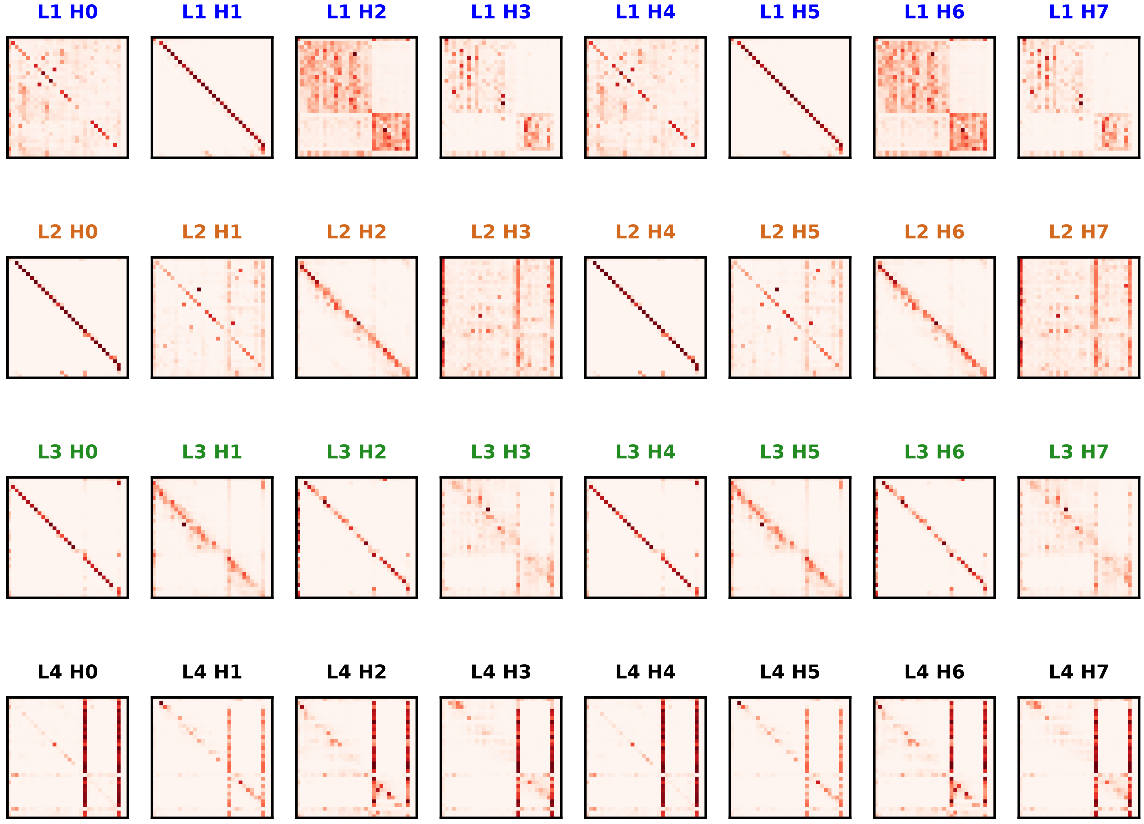

Figure 11: Attention patterns of the target model $\mathcal{T}(4, 512)$ based on our FPI method. The last 4 attention patterns (H4-H7) in each row are obtained by FPI expansion.

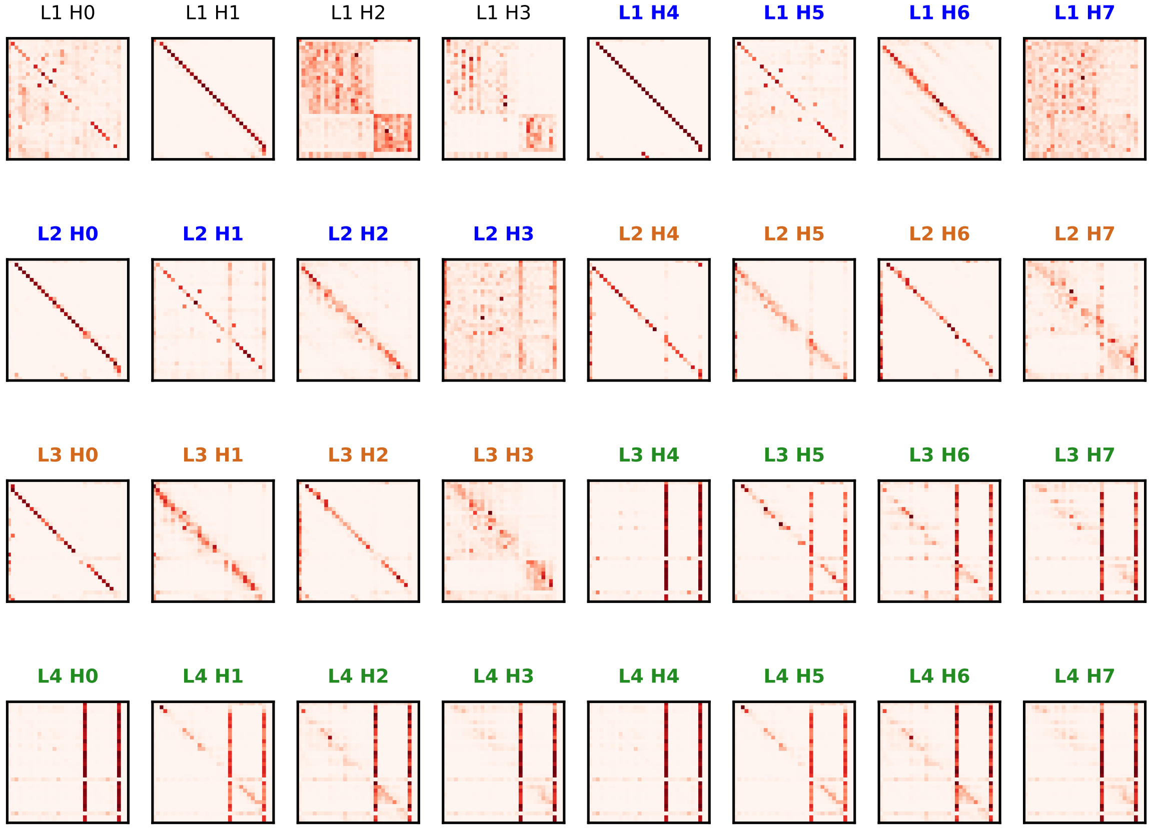

Figure 12: Attention patterns of the target model $\mathcal{T}(4, 512)$ based on our AKI method. The last 4 attention patterns (H4-H7) in each row are obtained by AKI expansion.

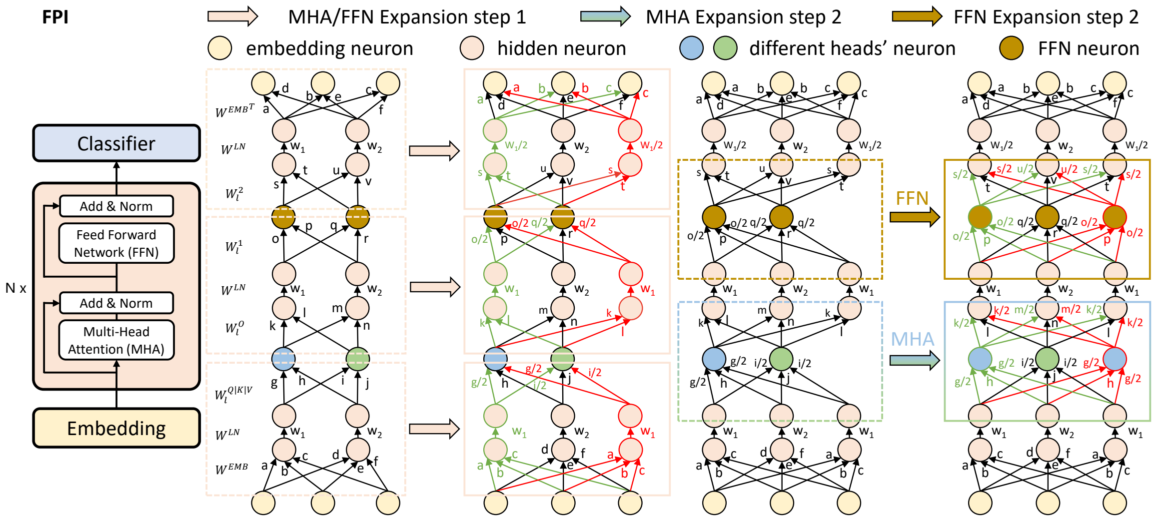

Figure 13: FPI process. We use the FPI method to widen the source model with a width of 2 into a target model with a width of 3. In the example, the source model and the target model have 2 and 3 attention heads respectively. And the head dimension is 1. To facilitate the illustration, we reduce the number of neurons in the FFN layer. We also note that since the MLM classifier of BERT is a transposition of the Embedding layer, they share a parameter matrix. Therefore, in step 1, we expand the MLM classifier by re-scaling the parameter values of the LN layer below the MLM classifier instead of following formula 7.

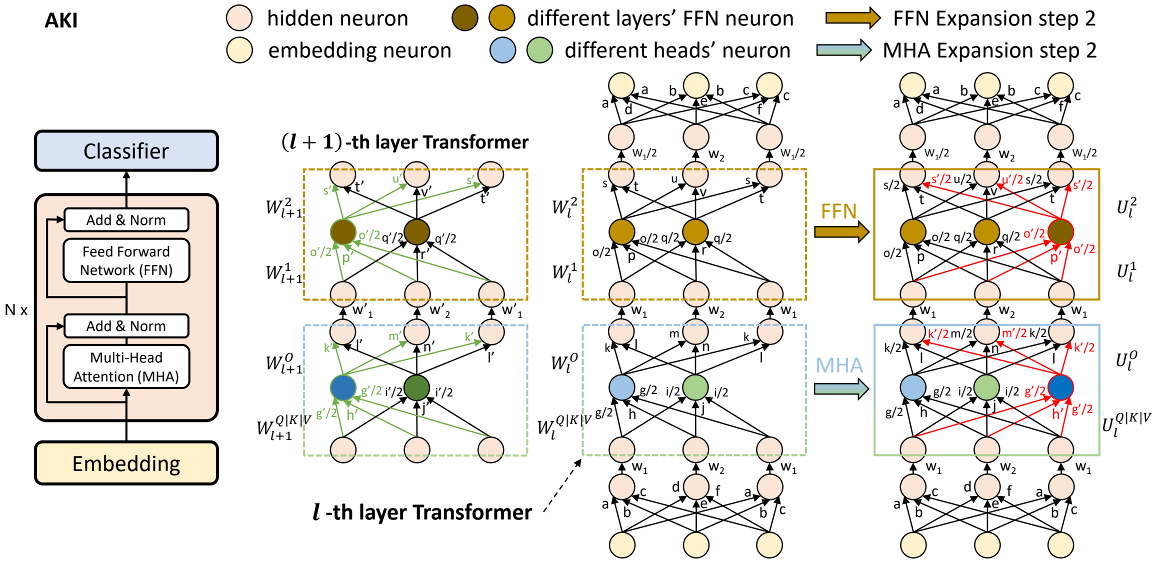

Figure 14: AKI process. We ignore its first step because it is the same as FPI's first step. The main difference between AKI and FPI is that in step 2, AKI copies some attention heads in MHA and some parameters in FFN of the $(l+1)$-th layer instead of only copying the l-th layer to construct the new l-th layer Transformer.

Vision-Language Pre-Training for Multimodal Aspect-Based Sentiment Analysis

`{ylin, jfyu, rxia}@njust.edu.cn`

Abstract

As an important task in sentiment analysis, Multimodal Aspect-Based Sentiment Analysis (MABSA) has attracted increasing attention in recent years. However, previous approaches either (i) use separately pre-trained visual and textual models, which ignore the cross-modal alignment or (ii) use vision-language models pre-trained with general pre-training tasks, which are inadequate to identify fine-grained aspects, opinions, and their alignments across modalities. To tackle these limitations, we propose a task-specific Vision-Language Pre-training framework for MABSA (VLP-MABSA), which is a unified multimodal encoder-decoder architecture for all the pre-training and downstream tasks. We further design three types of task-specific pre-training tasks from the language, vision, and multi-modal modalities, respectively. Experimental results show that our approach generally outperforms the state-of-the-art approaches on three MABSA subtasks. Further analysis demonstrates the effectiveness of each pre-training task. The source code is publicly released at `https://github.com/NUSTM/VLP-MABSA`.

1 Introduction

Recent years have witnessed increasing attention on the Multimodal Aspect-Based Sentiment Analysis (MABSA) task[1]. Previous research mostly focused on its two subtasks, including Multimodal Aspect Term Extraction (MATE) and Multimodal Aspect-oriented Sentiment Classification (MASC). Given a text-image pair as input, MATE aims to extract all the aspect terms mentioned in the text (Zhang et al., 2018; Lu et al., 2018; Wu et al., 2020a,b; Zhang et al., 2021a), whereas MASC aims to classify the sentiment towards each extracted aspect term (Xu et al., 2019; Yu and Jiang, 2019; Khan and Fu, 2021). As the two subtasks are closely related to each other, Ju et al. (2021) recently introduced the Joint Multimodal Aspect-Sentiment Analysis (JMASA) task, aiming to jointly extract the aspect terms and their corresponding sentiments. For example, given the text-image pair in Table. 1, the goal of JMASA is to identify all the aspect-sentiment pairs, i.e., (*Sergio Ramos*, *Positive*) and (*UCL*, *Neutral*).

Image	
Text	Sergio Ramos chosen as the best player of UCL final
Output	(Sergio Ramos, Positive) (UCL, Neutral)

Table 1: An example of the MABSA task

Most of the aforementioned studies to MABSA primarily focused on employing pre-trained unimodal models (e.g., BERT for text and ResNet for image) to obtain textual and visual features respectively. The separate pre-training of visual and textual features ignores the alignment between text and image. It is therefore crucial to perform vision-language pre-training to capture such cross-modal alignment. However, for the MABSA task, the studies on vision-language pre-training are still lacking.

To the best of our knowledge, there are very few studies focusing on vision-language pre-training for one of the MABSA subtasks, i.e., MATE (Sun et al., 2020, 2021). One major drawback of these studies is that they mainly employ general vision-language understanding tasks (e.g., text-image

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 2149 - 2159
May 22-27, 2022

matching and masked language modeling) to capture text-image alignments. Such general pre-training is inadequate to identify fine-grained aspects, opinions, and their alignments across the language and vision modalities. Therefore, it is important to design task-specific vision-language pre-training, to model aspects, opinions, and their alignments for the MABSA task.

To address this issue, in this paper, we propose a task-specific Vision-Language Pre-training framework for Multimodal Aspect-Based Sentiment Analysis. Specifically, inspired by the recent success of BART-based generative models in text-based ABSA (Yan et al., 2021), we first construct a generative multimodal architecture based on BART (Lewis et al., 2020), for both vision-language pre-training and the downstream MABSA tasks. We then propose three types of vision-language pre-training tasks, including Masked Language Modeling (MLM) and Textual Aspect-Opinion Extraction (AOE) from the language modality, Masked Region Modeling (MRM) and Visual Aspect-Opinion Generation (AOG) from the vision modality, and Multimodal Sentiment Prediction (MSP) across two modalities. Figure 1 illustrates the whole framework of our proposed pre-training approach. Compared with general pre-training methods, our task-specific pre-training approach incorporates multimodal aspect, opinion, and sentiment supervision, which guides pre-trained models to capture important objective and subjective information for the MABSA task.

To evaluate the effectiveness of our pre-training approach, we adopt MVSA-Multi, a widely-used Multimodal Twitter dataset for coarse-grained text-image sentiment analysis (Niu et al., 2016), as our pre-training dataset. We then employ several representative pre-trained models and rule-based methods to obtain the aspect and opinion supervision for our AOE and AOG tasks. As the dataset provides sentiment labels for each multimodal tweet, we adopt them as the supervision for our MSP task.

Our contributions in this work are as follows:

- We introduce a task-specific Vision-Language Pre-training framework for MABSA named VLP-MABSA, which is a unified multimodal encoder-decoder architecture for all the pre-training and downstream tasks.
- Apart from the general MLM and MRM tasks, we further introduce three task-specific pre-training tasks, including Textual Aspect-Opinion Extraction, Visual Aspect-Opinion Generation, and Multimodal Sentiment Prediction, to identify fine-grained aspect, opinions, and their cross-modal alignments.
- Experiments on three MABSA subtasks show that our pre-training approach generally obtains significant performance gains over the state-of-the-art methods. Further analysis on supervised and weakly-supervised settings demonstrates the effectiveness of each pre-training task.

2 Related Work

Vision-Language Pre-training. Inspired by the success of pre-trained language models like BERT (Devlin et al., 2019), many multimodal pre-training models have been proposed (Chen et al., 2020b; Yu et al., 2021; Zhang et al., 2021b) to perform many vision-language tasks which achieve fantastic success. Correspondingly, many general pre-training tasks are proposed, such as Masked Language Modeling (MLM), Masked Region Modeling (MRM) and Image-Text Matching (ITM) (Chen et al., 2020b; Yu et al., 2021). Besides, in order to make the pre-trained models better understand downstream tasks, researchers also design task-specific pre-training models for different downstream tasks (Hao et al., 2020; Xing et al., 2021). In our work, apart from the popular general pre-training tasks, we also design three kinds of task-specific pre-training tasks for the MABSA task.

Text-based Joint Aspect-Sentiment Analysis (JASA). JASA aims to extract aspect terms in the text and predict their sentiment polarities. Many approaches have been proposed including pipeline approaches (Zhang et al., 2015; Hu et al., 2019), multi-task learning approaches (He et al., 2019; Hu et al., 2019) and collapsed label-based approaches (Li et al., 2019; Hu et al., 2019; Chen et al., 2020a). Recently, Yan et al. (2021) proposed a unified generative framework which achieves highly competitive performance on several benchmark datasets for JASA.

Multimodal Sentiment Analysis. Multimodal Sentiment Analysis (MSA) in social media posts is an important direction of sentiment analysis. Many neural network approaches have been proposed to perform the coarse-grained MSA in the literature, which aim to detect the overall sentiment of each input social post (You et al., 2015, 2016; Luo et al., 2017; Xu et al., 2018; Yang et al., 2021b). Different

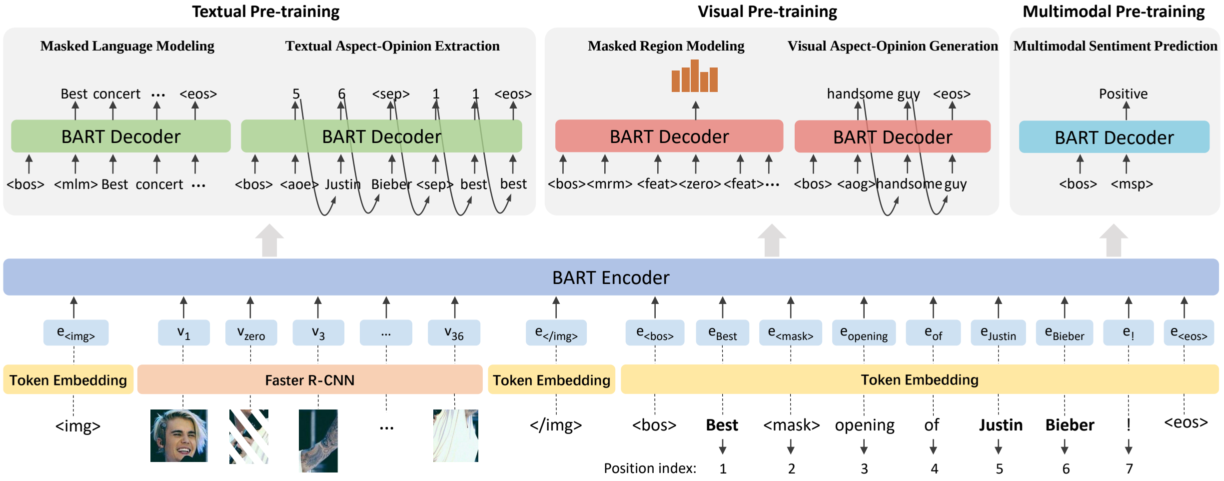

Figure 1: Overview of our Vision-Language Pre-Training framework for MABSA

from these studies, our work focuses on the fine-grained MABSA task, which aims to identify the sentiments towards all the aspects mentioned in each input social post.

Multimodal Aspect-Based Sentiment Analysis. As an important sentiment analysis task, many approaches have been approached to tackle the three subtasks of MABSA, including Multimodal Aspect Term Extraction (Zhang et al., 2018; Yu et al., 2020b; Wu et al., 2020a,b; Sun et al., 2020; Zhang et al., 2021a), Multimodal Aspect Sentiment Classification (Xu et al., 2019; Yu et al., 2020a; Yang et al., 2021a; Khan and Fu, 2021) and Joint Multimodal Aspect-Sentiment Analysis (Ju et al., 2021). In this work, we aim to propose a general pre-training framework to improve the performance of all the three subtasks.

3 Methodology

Figure 1 shows the overview of our model architecture. The backbone of our model is BART (Lewis et al., 2020), which is a denoising autoencoder for sequence-to-sequence models. We extend BART to encode both textual and visual inputs, and decode pre-training and downstream tasks from different modalities. In the following subsections, we first introduce our feature extractor, and then illustrate the encoder and decoder of our model, followed by describing the details of three types of pre-training tasks and downstream MABSA tasks.

3.1 Feature Extractor

Image Representation. Following many existing Vision-Language pre-training models (Chen et al., 2020b; Yu et al., 2021), we employ Faster R-CNN (Anderson et al., 2018) to extract visual features. Specifically, we adopt Faster R-CNN to extract all the candidate regions from an input image. We then only retain 36 regions with the highest confidence. Meanwhile, we also keep the semantic class distribution of each region, which will be used for the Masked Region Modeling task. For the retained regions, we use mean-pooled convolutional features processed by Faster R-CNN as our visual features. Let us use $R = \{r_1, ..., r_{36}\}$ to denote the visual features, where $r_i \in \mathbb{R}^{2048}$ refers to the visual feature of the i-th region. To be consistent with the text representation, we adopt a linear transformation layer to project visual features to d-dimensional vectors, denoted by $V \in \mathbb{R}^{d\times 36}$.

Text Representation. For text input, we first tokenize the text and then feed tokens to the embedding matrix. The embeddings of text tokens are used as text features. Let us use $E = \{e_1, ..., e_T\}$ to denote the token indexes of text inputs where T denotes the length of the input text, and $\mathbf{W} = \{\mathbf{w}_1, ..., \mathbf{w}_T\}$ to denote the embeddings of tokens.

3.2 BART-based Generative Framework

We employ a BART-based generative framework for both vision-language pre-training and downstream MABSA tasks.

Encoder. The encoder of our model is a multi-layer bidirectional Transformer. As shown in Figure 1, to distinguish inputs of different modalities, we follow Xing et al. (2021) by using $\langle \textit{img} \rangle$ and $\langle \textit{/img} \rangle$ to indicate the start and the end of visual features, and $\langle \textit{bos} \rangle$ and $\langle \textit{eos} \rangle$ to indicate the textual input. In the following part of the paper, we denote the concatenated multimodal input by X.

Decoder. The decoder of our model is also a multi-layer Transformer. The difference is that the

Sentiment	#Image-Text Pairs	#Aspects	#Opinions	#Words
Positive	11903	10593	22752	215044
Neutral	4107	3756	7567	74456
Negative	1500	1016	2956	25211

Table 2: The statistics of the MVSA-Multi Dataset. #Apects and #Opinions are the number of aspect terms and opinion terms we extract from the dataset by the rule-based methods introduced in Section 3.3.1.

decoder is unidirectional when generating outputs, while the encoder is bidirectional. Since all pre-training tasks share the same decoder, we insert two special tokens at the beginning of the inputs of the decoder to indicate different pre-training tasks. Following Yan et al. (2021), we insert a special token $\langle bos \rangle$ to indicate the beginning of generation, and then insert a task-specific special token to indicate the task type. Specifically, the special tokens for Masked Language Modeling, Textual Aspect-Opinion Extraction, Masked Region Modeling, Visual Aspect-Opinion Generation, and Multimodal Sentiment Prediction are $\langle bos \rangle \langle mlm \rangle$, $\langle bos \rangle \langle aoe \rangle$, $\langle bos \rangle \langle mrm \rangle$, $\langle bos \rangle \langle aog \rangle$, and $\langle bos \rangle \langle msp \rangle$, respectively.

3.3 Pre-training Tasks

The dataset we use for pre-training is MVSA-Multi (Niu et al., 2016), which is widely used in Multimodal Twitter Sentiment Analysis (Yadav and Vishwakarma, 2020; Yang et al., 2021b). This dataset provides image-text input pairs and coarse-grained sentiments of image-text pairs. Statistics of the dataset are given in Table 2.

With the dataset, we design three types of pre-training tasks, including textual, visual, and multi-modal pre-training as follows.

3.3.1 Textual Pre-training

Textual Pre-training contains two tasks: a general Masked Language Modeling task to build alignment between textual and visual features and a task-specific Textual Aspect-Opinion Extraction task to extract aspects and opinions from text.

Masked Language Modeling (MLM). In the MLM pre-training task, we use the same strategy as BERT (Devlin et al., 2019) by randomly masking the input text tokens with a probability of 15%. The goal of the MLM task is to generate the original text based on the image and the masked text, and thus the loss function of the MLM task is:

$$\mathcal{L}_{MLM} = -\mathbb{E}_{X \sim D} \sum_{i=1}^{T} \log P(e_i | e_{<i}, \tilde{X}), \quad (1)$$

where e_i and $\tilde{X}$ denote the i^{th} token of the input text and the masked multimodal input, respectively. T is the length of input text.

Textual Aspect-Opinion Extraction (AOE). The AOE task aims to extract aspect and opinion terms from the text. Since the MVSA-Multi dataset does not provide annotations for aspect and opinion terms, we resort to a pre-trained model for aspect extraction and a rule-based method for opinion extraction. Specifically, for aspect extraction, we employ the pre-trained model from a well-known Named Entity Recognition (NER) tool for tweets (Ritter et al., 2011) to perform NER on each tweet in the dataset, and regard the recognized entities as aspect terms. For opinion extraction, we utilize a widely-used sentiment lexicon named SentiWordNet (Esuli and Sebastiani, 2006) to obtain the dictionary of opinion words. Given each tweet, if its sub-sequences (i.e., words or phrases) match the words in the dictionary, we treat them as opinion terms. These extracted aspect and opinion terms are used as the supervision signal of our AOE task.

With the textual aspect-opinion supervision, we follow Yan et al. (2021) by formulating the AOE task as an index generation task. Given the input text as the source sequence, the goal is to generate a target index sequence which consists of the start and end indexes of all aspect and opinion terms. Let us use $Y = [a_1^s, a_1^e, ..., a_M^s, a_M^e, \langle sep \rangle, o_1^s, o_1^e, ..., o_N^s, o_N^e, \langle eos \rangle]$ to denote the target index sequence, where M and N are the number of aspect terms and opinion terms, a^s,a^e and o^s,o^e indicate the start and end indexes of an aspect term and an opinion term respectively, $\langle sep \rangle$ is used to separate aspect terms and opinion terms, and $\langle eos \rangle$ informs the end of extraction. For example, as shown in Figure 1, the extracted aspect and opinion terms are *Justin Bieber* and *best* respectively, and the target sequence is $Y = [5, 6, \langle sep \rangle, 1, 1, \langle eos \rangle]$. For y_t in the target sequence Y, it is either a position index or a special token (e.g., $\langle sep \rangle$). We use $C = [\langle sep \rangle, \langle eos \rangle]$ to denote the set of special tokens, and $\mathbf{C}^d$ as their embeddings.

We assume that $\mathbf{H}^e$ denotes the encoder output of the concatenated multimodal input, $\mathbf{H}_T^e$ denotes the textual part of $\mathbf{H}^e$, and $\mathbf{H}_V^e$ denotes the visual part of $\mathbf{H}^e$. The decoder takes the multimodal encoder output $\mathbf{H}^e$ and the previous decoder output $Y_{<t}$ as inputs, and predicts the token probability

distribution $P(y_t)$ as follows:

$$\mathbf{h}_t^d = \text{Decoder}(\mathbf{H}^e; Y_{<t}), \tag{2}$$

$$\bar{\mathbf{H}}_T^e = (\mathbf{W} + \mathbf{H}_T^e)/2, \tag{3}$$

$$P(y_t) = \text{Softmax}([\bar{\mathbf{H}}_T^e; \mathbf{C}^d]\mathbf{h}_t^d), \tag{4}$$

where $\mathbf{W}$ denotes the embeddings of input tokens. The loss function of the AOE task is as follows:

$$\mathcal{L}_{AOE} = -\mathbb{E}_{X\sim D} \sum_{t=1}^{O} \log P(y_t | Y_{<t}, X), \tag{5}$$

where $O = 2M + 2N + 2$ is the length of Y and X denotes the multimodal input.

3.3.2 Visual Pre-training

Visual Pre-training contains two tasks: a general Masked Region Modeling task and a task-specific Visual Aspect-Opinion Generation task to capture subjective and objective information in the image.

Masked Region Modeling (MRM). Following Xing et al. (2021), our MRM task aims to predict the semantic class distribution of the masked region. As shown in Figure 1, for the input of the encoder, we randomly mask image regions with a probability of 15%, which are replaced with zero vectors. For the input of the decoder, we first add two special tokens ⟨*bos*⟩⟨*mrm*⟩, and then represent each masked region with ⟨*zero*⟩ and each remaining region with ⟨*feat*⟩. After feeding the input to the decoder, an MLP classifier is stacked over the output of each ⟨*zero*⟩ to predict the semantic class distribution. Let us use $p(v_z)$ to denote the predicted class distribution of the z-th masked region, and $q(v_z)$ to denote the class distribution detected by Faster R-CNN. The loss function for MRM is to minimize the KL divergence of the two class distributions:

$$\mathcal{L}_{MRM} = \mathbb{E}_{X\sim D} \sum_{z=1}^{Z} D_{KL}(q(v_z)||p(v_z)), \tag{6}$$

where Z is the number of masked regions.

Visual Aspect-Opinion Generation (AOG). The AOG task aims to generate the aspect-opinion pair detected from the input image. In the field of Computer Vision, Borth et al. (2013) proposed to detect the visual sentiment concept, i.e., Adjective-Noun Pair (ANP) such as *smiling man* and *beautiful landscape* in the image. Since the nouns and adjectives of ANP respectively capture the fine-grained aspects and opinions in the image, we regard ANPs as visual aspect-opinion pairs. In order to detect the ANP of each input image, we adopt a pre-trained ANP detector DeepSentiBank[2] (Chen et al., 2014) to predict the class distribution over 2089 pre-defined ANPs. The ANP with the highest probability is selected as the supervision signal of our AOG task. For example, in Figure 1, the ANP detected from the input image is *handsome guy*, and we regard it as the supervision.

With the visual aspect-opinion supervision, we formulate the AOG task as a sequence generation task. Specifically, let us use $G = \{g_1, ..., g_{|G|}\}$ to denote the tokens of the target ANP and $|G|$ to denote the number of ANP tokens. The decoder then takes the multimodal encoder output $\mathbf{H}^e$ and the previous decoder output $G_{<i}$ as inputs, and predicts the token probability distribution $P(g_i)$:

$$\mathbf{h}_i^d = \text{Decoder}(\mathbf{H}^e; G_{<i}), \tag{7}$$

$$P(g_i) = \text{Softmax}(\mathbf{E}^T \mathbf{h}_i^d), \tag{8}$$

where $\mathbf{E}$ denotes the embedding matrix of all tokens in the vocabulary.

The loss function of the AOG task is:

$$\mathcal{L}_{AOG} = -\mathbb{E}_{X\sim D} \sum_{i=1}^{|G|} \log P(g_i | g_{<i}, X). \tag{9}$$

3.3.3 Multimodal Pre-training

Multimodal Pre-training has one task named Multimodal Sentiment Prediction (MSP). Different from the aforementioned pre-training tasks whose supervision signals only come from one modality, the supervision signals for MSP come from multimodality, which can enhance models to identify the subjective information in both language and vision and capture their rich alignments.

Multimodal Sentiment Prediction (MSP). As the MVSA-Multi dataset provides the coarse-grained sentiment labels for all the text-image pairs, we use the sentiment labels as supervision signals of our MSP task. Formally, we model the MSP task as a classification task, where we first feed the two special tokens ⟨*bos*⟩⟨*msp*⟩ to the decoder and then predict the sentiment distribution $P(s)$ as follows:

$$\mathbf{h}_{msp}^d = \text{Decoder}(\mathbf{H}^e; \mathbf{E}_{msp}), \tag{10}$$

$$P(s) = \text{Softmax}(\text{MLP}(\mathbf{h}_{msp}^d)), \tag{11}$$

where $\mathbf{E}_{msp}$ is the embeddings of two special tokens.

---

[2] https://github.com/stephen-pilli/DeepSentiBank

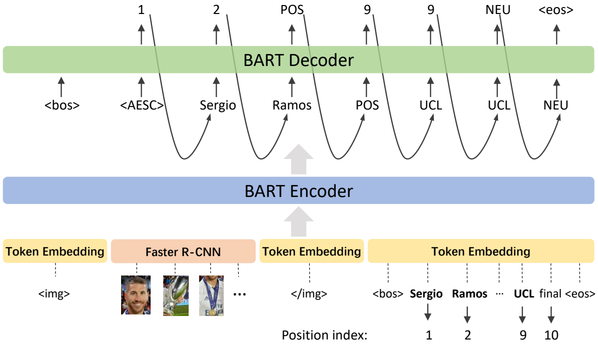

Figure 2: An example of downstream task JMASA. ⟨*AESC*⟩ informs the current task is JMASA.

We use the cross-entropy loss for the MSP task:

$$\mathcal{L}_{MSP} = -\mathbb{E}_{X\sim D} \log P(s|X), \qquad (12)$$

where s is the golden sentiment annotated in dataset.

3.3.4 Full Pre-training Loss

To optimize all the model parameters, we adopt the alternating optimization strategy to iteratively optimize our five pre-training tasks. The objective function is as follows:

$$\begin{aligned}\mathcal{L} =& \lambda_1\mathcal{L}_{MLM} + \lambda_2\mathcal{L}_{AOE} + \lambda_3\mathcal{L}_{MRM} + \\ & \lambda_4\mathcal{L}_{AOG} + \lambda_5\mathcal{L}_{MSP}\end{aligned} \qquad (13)$$

where λ_1, λ_2, λ_3, λ_4, and λ_5 are tradeoff hyper-parameters to control the contribution of each task.

3.4 Downstream Tasks

We consider all the three subtasks in MABSA as our downstream tasks, including Joint Multimodal Aspect-Sentiment Analysis (JMASA), Multimodal Aspect Term Extraction (MATE), and Multimodal Aspect-oriented Sentiment Classification (MASC). We model these downstream tasks based on the same BART-based generative framework in vision-language pre-training, so that the downstream task can benefit more from pre-training during the fine-tuning stage. Following Yan et al. (2021), we formulate the outputs of the three subtasks as follows:

- JMASA: $Y = [a_1^s, a_1^e, s_1, ..., a_i^s, a_i^e, s_i, ...]$,
- MATE: $Y = [a_1^s, a_1^e, ..., a_i^s, a_i^e, ...]$,
- MASC: $Y = [\underline{a_1^s}, \underline{a_1^e}, s_1, ..., \underline{a_i^s}, \underline{a_i^e}, s_i, ...]$,

where a_i^s, a_i^e, and s_i inform the start index, end index, and sentiment of an aspect term in the text. The underlined tokens are given during inference.

Table 3: The basic statistics of two TWITTER datasets.

Similar to the AOE task in Section 3.3.1, we formulate all the subtasks as index generation tasks, and use Eqn. (2) to Eqn. (4) to generate the token distribution. The difference is that the special token set is modified as $C = [\langle POS\rangle, \langle NEU\rangle, \langle NEG\rangle, \langle EOS\rangle]$ by adding the sentiment categories. Figure 2 shows an example for JMASA. Since the aspect-sentiment pairs are (*Sergio Ramos*, *Positive*) and (*UCL*, *Neutral*), its target sequence is $[1, 2, \langle POS\rangle, 9, 9, \langle NEU\rangle, \langle eos\rangle]$.

4 Experiment

4.1 Settings

Downstream datsets. We adopt two benchmark datasets annotated by Yu and Jiang (2019), namely TWITTER-2015 and TWITTER-2017 to evaluate our model. The statistics of the two datasets are shown in Table 3.

Implementation Details. We employ BART-base (Lewis et al., 2020) as our framework. Specifically, the encoder and decoder both have six layers and are initialized with BART-base parameters. We fix all the hyper-parameters after tuning them on the development set. The pre-training tasks were trained for 40 epochs and the downstream tasks were fine-tuned for 35 epochs. The batch sizes are set to 64 and 16, respectively. The learning rate is set to 5e-5. The hidden size of our model is set to 768, which is the same as BART. The tradeoff hyper-parameters λ_1, λ_2, λ_3, λ_4, and λ_5 are all set to 1. Note that for the subtask MASC, different from Ju et al. (2021) evaluating on the correctly predicted aspects, we provide all the golden aspects to the decoder of our framework during the inference stage and evaluate on all the aspects. We implement all the models with PyTorch, and run experiments on a RTX3090 GPU.

Evaluation Metrics. We evaluate our model over three subtasks of MABSA and adopt Micro-F1 score (F1), Precision (P) and Recall (R) as the evaluation metrics to measure the performance. For MASC, to fairly compare with other approaches,

we also use Accuracy (Acc).

4.2 Compared Systems

In this section, we introduce four types of compared systems for different tasks.

Approaches for Multimodal Aspect Term Extraction (MATE). 1) *RAN* (Wu et al., 2020a), which aligns text with object regions by a co-attention network. 2) *UMT* (Yu et al., 2020b), which uses Cross-Modal Transformer to fuse text and image representations for Multimodal Named Entity Recognition (MNER). 3) *OSCGA* (Wu et al., 2020b), another MNER approach using visual objects as image representations. 4) *RpBERT* (Sun et al., 2021), which uses a multitask training model for MNER and image-text relation detection.

Approaches for Multimodal Aspect Sentiment Classification (MASC). 1) *TomBERT* (Yu and Jiang, 2019), which tackles the MASC task by employing BERT to capture intra-modality dynamics. 2) *CapTrBERT* (Khan and Fu, 2021), which translates the image to a caption as an auxiliary sentence for sentiment classification.

Text-based approaches for Joint Aspect-Sentiment Analysis (JASA). 1) *SPAN* (Hu et al., 2019), which formulates the JASA task as a span prediction problem. 2) *D-GCN* (Chen et al., 2020a), which proposes a directional graph convolutional network to capture the correlation between words. 3) *BART* (Yan et al., 2021), which adapts the JASA task to BART by formulating it as an index generation problem.

Multimodal approaches for Joint Multimodal Aspect-Sentiment Analysis (JMASA). 1) *UMT+TomBERT* and *OSCGA+TomBERT*, which are simple pipeline approaches by combining methods for subtasks mentioned above. 2) *UMT-collapsed* (Yu et al., 2020b), *OSCGA-collapsed* (Wu et al., 2020b) and *RpBERT-collapsed* (Sun et al., 2021), which model the JMASA task with collapsed labels such as *B-POS* and *I-POS*. 3) *JML* (Ju et al., 2021), which is a multi-task learning approach proposed recently with the auxiliary cross-modal relation detection task.

4.3 Main Results

In this section, we analyze the results of different approaches on three subtasks of MABSA.

Results of JMASA. Table 4 shows the results of different methods for JMASA. As we can see from the table, *BART* achieves the best performance among text-based methods, and it even outperforms some multimodal methods, which proves the superiority of our base framework. For multimodal methods, *JML* achieves better performance than previous methods mainly due to its auxiliary task about relation detection between image and text. Among all the methods, *VLP-MABSA* which is the whole model with all the pre-training tasks consistently performs the best across two datasets. Specifically, it significantly outperforms the second best system *JML* with 2.5 and 2.0 absolute percentage points with respect to *F1* on TWITTER-2015 and TWITTER-2017, respectively. This mainly benefits from our task-specific pre-training tasks, which identify aspects and opinions as well as their alignments across the two modalities.

Results of MATE and MASC. Table 5 and Table 6 show the results of MATE and MASC, re-

		TWITTER-2015			TWITTER-2017

Table 7: The results of pre-training tasks on two benchmarks. We evaluate over three tasks JMASA, MATE, and MASC in terms of *F1*, *F1* and *Acc*, respectively. *T*, *V*, and *MM* denote the Textual, Visual, and Multimodal pre-training, respectively. Each row adds an extra pre-training task to the row above it.

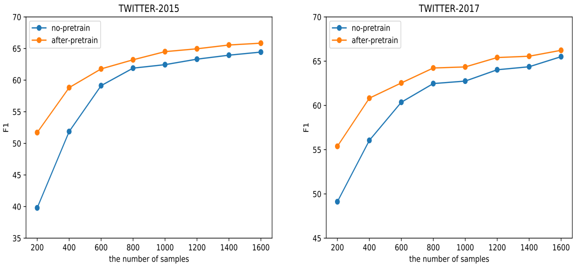

Figure 3: The effectiveness of pre-training when using different number of training samples for the downstream task. Y-axis refers to the **F1** score (%) of the JMASA task.

spectively. Similar to the trend on the JMASA subtask, we can clearly observe that our proposed approach *VLP-MABSA* generally achieves the best performance across the two datasets, except on the accuracy metric of TWITTER-2015. These observations further demonstrate the general effectiveness of our proposed pre-training approach.

4.4 In-depth Analysis of Pre-training Tasks

To explore the impact of each pre-training task, we perform a thorough ablation study over the full supervision setting which uses full training dataset and the weak supervision setting which only randomly chooses 200 training samples for fine-tuning.

Impact of Each Pre-training Task. As we can see from Table 7, the performance generally improves with respect to most metrics when adding more pre-training tasks.

To better analyze the effect of each pre-training task, we take the weak supervision experiments on TWITTER-2015 as an example. When only using MLM to pre-train our model, the performance only gets slight improvements. After adding the AOE task, the result of MATE gets a huge improvement of 9.44% on *F1*. This shows that the AOE task greatly enhances our model's ability to recognize the aspect terms. When adding the MRM task, the performance gets slight improvements again. This reflects that general pre-training tasks (e.g., MLM and MRM) are not adequate for our model to tackle downstream tasks which need the model to understand the subjective and objective information from image and text. When adding the AOG task, the performance over three subtasks gets a moderate improvement, which proves the effectiveness of the AOG task. Finally, adding the MSP task significantly boosts the performance, especially on the MASC task. This shows that the MSP task can enhance our model's understanding of sentiment across language and image modalities. By combining all the pre-training tasks, our full model generally achieves the best results over most of the subtasks whether in both full supervision and weak supervision settings.

Impact of pre-training when using different number of downstream training samples. To better understand the impact of pre-training, we compare the results with and without pre-training when adopting different number of samples for downstream training. We use the JMASA task as the example to observe the impact. As shown in Fig. 3, when the sample size is small, pre-training can bring a huge improvement. In contrast, when the sample size becomes larger, pre-training brings relatively small improvements. This further illustrates the robustness and the effectiveness of our pre-training approach, especially in low-resource scenarios.

4.5 Case Study

To further demonstrate the effectiveness of our approach, we present four test examples with predictions from different methods. The compared methods are *BART*, our framework using multimodal inputs without pre-training (denoted by *MM*), and our framework using multimodal inputs with full pre-training (denoted by *VLP*), respectively. As shown in Table 8, for example (a), both *BART* and *MM* extracted the wrong aspect term (i.e., *the Faithfull Pearl Jam*) and gave the incorrect sentiment prediction towards *Eddie*. For example (b), *BART* only extracted one aspect term *Madonna* while *MM* identified an additional aspect term *Demelza*. However, the sentiment towards *Madonna* was wrongly predicted by *MM*. For example (c), *BART* only

recognized part of the aspect term *Colombia* and *MM* wrongly predicted the sentiment towards *Miss Colombia* as *Neutral*. For example (d), both *BART* and *MM* failed to recognize the aspect term *D-League*. Among all the cases, our *VLP* model with full pre-training correctly extracted all the aspect terms and classified the sentiment , which shows the advantage of our generative framework and task-specific pre-training tasks.

5 Conclusion

In this paper, we proposed a task-specific Vision-Language Pre-training framework for Multimodal Aspect-Based Sentiment Analysis (VLP-MABSA). We further designed three kinds of pre-training tasks from the language, vision, and multi-modal modalities, respectively. Experimental results show that our proposed approach generally outperforms the state-of-the-art methods for three subtasks of MABSA. Our work is a first step towards a unified Vision-Language Pre-training framework for MABSA. In the future, we plan to apply our pre-training approach on a larger dataset and consider the relation between image and text in our pre-training framework. We hope this work can potentially bring new insights and perspectives to the research of MABSA.

"You might think about slightly revising the title": Identifying Hedges in Peer-tutoring Interactions

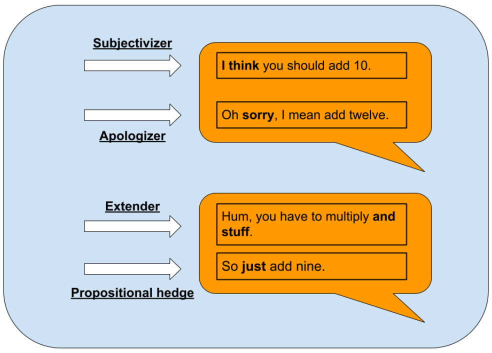
Abstract

Hedges play an important role in the management of conversational interaction. In peer-tutoring, they are notably used by tutors in dyads (pairs of interlocutors) experiencing low rapport to tone down the impact of instructions and negative feedback. Pursuing the objective of building a tutoring agent that manages rapport with students in order to improve learning, we used a multimodal peer-tutoring dataset to construct a computational framework for identifying hedges. We compared approaches relying on pre-trained resources with others that integrate insights from the social science literature. Our best performance involved a hybrid approach that outperforms the existing baseline while being easier to interpret. We employ a model explainability tool to explore the features that characterize hedges in peer-tutoring conversations, and we identify some novel features, and the benefits of such a hybrid model approach.

1 Introduction

Rapport, most simply defined as the "... relative harmony and smoothness of relations between people ..." (Spencer-Oatey, 2005), has been shown to play a role in the success of activities as varied as psychotherapy (Leach, 2005) and survey interviewing (Lune and Berg, 2017). In peer-tutoring, rapport, as measured by the annotation of thin slices of video, has been shown to be beneficial for learning outcomes (Zhao et al., 2014; Sinha and Cassell, 2015). The level of rapport rises and falls with conversational strategies deployed by tutors and tutees at appropriate times, and as a function of the content of prior turns. These strategies include self-disclosure, referring to shared experience, and, on the part of tutors, giving instructions in an indirect manner. Some work has attempted to automatically detect these strategies in the service of intelligent tutors (Zhao et al., 2016a), but only a few strategies have been attempted. Other work has concentrated on a "social reasoning module" (Romero et al., 2017) to decide which strategies should be generated in a given context, but indirectness was not among the strategies targeted. In this paper, we focus on the automatic classification of one specific strategy that is particularly important for the tutoring domain, and therefore important for intelligent tutors: hedging, a sub-part of indirectness that "softens" what we say. This work is part of a larger research program with the long-term goal of automatically generating indirectness behaviors for a tutoring agent.



I think you should add 10.

Oh **sorry**, I mean add twelve.

Hum, you have to multiply **and stuff**.

So **just** add nine.

Figure 1: A mock conversation displaying each type of hedged formulation.

According to Brown and Levinson (1987), hedges are part of the linguistic tools that interlocutors use to produce politeness, by limiting the face threat to the interlocutor (basically by limiting the extent to which the interlocutor might experience embarrassment because of some kind of poor performance). An example is "that's *kind of* a wrong answer". Hedges are also found when speakers wish to avoid losing face themselves, for example when saying ("*I think* I *might* have to add 6."). Madaio et al. (2017) found that in a peer-tutoring task, when rapport between interlocutors is low, tutees attempted more problems and correctly solved more problems when their tutors hedged instruc-

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 2160 - 2174
May 22-27, 2022

tions, which likewise points towards a "mitigation of face threat" function. Hedges can also be associated with a nonverbal component, for example averted eye gaze during criticism (Burgoon and Koper, 1984). Hedges are not, however, always appropriate, as in "I *kind of think* it's raining today." when the interlocutors can both see rain (although it might be taken as humorous). These facts about hedges motivate a way to automatically detect them and, ultimately (although not in the current work) also generate them. In both cases we first have to be able to characterize them using interpretable linguistic features, which is what we address in the current paper. Thus, in the work described here, based on linguistic descriptions of hedges (Brown and Levinson, 1987; Fraser, 2010), we built a rule-based classifier. We show that this classifier in combination with additional multimodal interpretable context-dependent features significantly improves the performance of a machine learning model for hedges, compared to a less interpretable deep learning baseline from Goel et al. (2019) using word embeddings. We also relied on a machine learning model explanation tool (Lundberg and Lee, 2017) to investigate the linguistic features related to hedges in the context of peer-tutoring, primarily to see if we could discover surprising features that the classification model would associate to hedges in this context, and we describe those below. The code of the models described in the paper is also provided. [1]

2 Related work

Hedges: According to Fraser (2010), hedging is a rhetorical strategy that attenuates the strength of a statement. One way to produce a hedge is by altering the full semantic value of a particular expression through **Propositional hedges** (also called **Approximators** in Prince et al. (1982)), as in "You are *kind of* wrong," that reduce prototypicality (i.e accuracy of the correspondence between the proposition and the reality that the speaker seeks to describe). Propositional hedges are related to fuzzy language (Lakoff, 1975), and therefore to the production of vagueness (Williamson, 2002) and uncertainty (Vincze, 2014).

A second kind are **Relational Hedges** (also called **Shields** in Prince et al. (1982)), such as "*I think that* you are wrong." or "*The doctor wants you* to stop smoking.", conveying that the proposition is considered by the speaker as subjective. In a further sub-division, **Attribution Shields**, as in "The doctor *wants you* ...", the involvement of the speaker in the truth value of the proposition is not made explicit, which allows speakers not to take a stance. As described above, Madaio et al. (2017) found that tutors who showed lower rapport with their tutees used more hedged instructions (they also employed more positive feedback), however this was only the case for tutors with a greater belief in their ability to tutor. Tutees in this context solved more problems correctly when their tutors hedged instructions. No effect of hedging was found for dyads (pairs of interlocutors) with greater social closeness. However, the authors did not look at the specific linguistic forms these teenagers used.

Rowland (2007) also describes the role that hedging plays in this age group, showing that students use both relational ("*I think that* John is smart.") and propositional ("John is *kind of* smart.") hedges for much the same shielding function of demonstrating uncertainty, to save them from the risk of embarrassment if they are wrong. The author observed that teens used few **Adaptors** (*kind of*, *somewhat*) and preferred to use **Rounders** (*around*, *close to*). However, this study was performed with an adult and two children, possibly biasing the results due to the participation of the adult investigator. Hedges have been included in virtual tutoring agents before now. (Howard et al., 2015) integrated hedges in a tutor agent for undergraduates in CS, as a way to encourage the student to take the initiative. Hedges have also been used as a way of integrating Brown and Levinson's politeness framework (Wang et al., 2008; Schneider et al., 2015) in virtual tutoring agents. Results were not broken out by strategy, but politeness in general was shown to positively influence motivation and learning, in certain conditions.

Computational methods for hedge detection: A number of studies have targeted the detection of hedges and uncertainty in text (Medlock and Briscoe, 2007; Ganter and Strube, 2009; Tang et al., 2010; Velldal, 2011; Szarvas et al., 2012), particularly following the CoNLL 2010 dataset release (Farkas et al., 2010). However, this work is not as related to hedges in conversation, as it focuses on a formal and academic language register (Hyland, 1998; Varttala, 1999). As noted by Prokofieva and Hirschberg (2014), the functions of hedges are domain- and genre-dependent, therefore this bias

---

[1] https://github.com/AnonymousHedges/HedgeDetection

towards formality implies that the existing work may not adapt well to the detection of hedges in conversation between teenagers. A consequence is that the existing work does not consider terms like "I think," since opinions rarely appear in an academic writing dataset. Instructions are also almost absent ("I think you have to add ten to both sides."), a strong limitation for the study of conversational hedges since it is in requests (including tutoring instructions) that indirect formulations mostly occur according to Blum-Kulka (1987). Prokofieva and Hirschberg (2014) also note that it is difficult to detect hedges because the word patterns associated with them have other semantic and pragmatic functions: considering "I think that you have to add x to both sides." vs "I think that you are an idiot.", it is not clear that the second use of "I think that" is an hedge marker. They advocate using machine learning approaches to deal with the ambiguity of these markers. Working on a conversational dataset, Ulinski et al. (2018) built a computational system to assess speaker commitment (i.e. at which point the speaker seems convinced by the truth value of a statement), in particular by relying on a rule-based detection system for hedges. Compared to that work, our rule-based classification model is directly detecting hedge classes, and we employ the predictions of the rule-based model as a feature for stronger machine learning models, designed to lessen the impact of the imbalance between classes. We also consider **apologies** when they serve a mitigation function (we then call them **Apologizers**), as was done by the authors of our corpus, and we also use the term **subjectivizers** as defined below, to be able to compare directly with the previous work carried out on this corpus. As far as we know, only Goel et al. (2019) have worked with a peer-tutoring dataset (the same one that we also use), and they achieved their best classification result by employing an Attention-CNN model, inspired by Adel and Schütze (2017).

3 Problem statement

We consider a set D of conversations $D = (c_1, c_2, ..., c_{|D|})$, where each conversation is composed of a sequence of independent syntactic clauses $c_i = (u_1, u_2, ..., u_M)$, where M is the number of clauses in the conversation. Note that two consecutive clauses can be produced by the same speaker. Each clause is associated with a unique label corresponding to the different hedge classes described in Table 1: $y_i \in C$ = {**Propositional Hedges**, **Apologizers**, **Subjectivizers**, **Not hedged**}. Finally, an utterance u_i can be represented as a vector of features $X = (x_1, x_2, ..., x_N)$, where N represents the number of features we used to describe a clause. Our first goal is to design a model that correctly predicts the label y_i associated to u_i. It can be understood as the following research question:

RQ1: "Which models and features can be used to automatically characterize hedges in a peer-tutoring interaction?"

Our second goal is to identify, for each hedge class, the set of features $F_{class} = \{f_k\}, k \in [1, N]$ sorted by feature importance in the classification of $class$. It corresponds to the following research question:

RQ2: "What are the most important linguistic features that characterize our hedge classes in a peer-tutoring setting?"

4 Methodology

4.1 Corpus

Data collection: The dialogue corpus used here was collected as part of a larger study on the effects of rapport-building on reciprocal peer tutoring. 24 American teenagers (mean age = 13.5, min = 12, max = 15), half male and half female, came to a lab where half of the participants were paired with a same-age, same-gender friend, and the other half paired with a stranger. The participants were assigned to a total of 12 dyads in which the participants alternated tutoring one another in linear algebra equation solving for 5 weekly hour-long sessions, for a total corpus of nearly 60 hours of face-to-face interactions. Each session was structured such that the students engaged in brief social chitchat in the beginning, then one of the students was randomly assigned to tutor the other for 20 minutes. They then engaged in another social period, and concluded with a second tutoring period where the other student was assigned the role of tutor. Audio and video data were recorded, transcribed, and segmented for clause-level dialogue annotation, providing nearly 24 000 clauses. Non-speech segments (notably fillers and laughter) were maintained. Because of temporal misalignment for parts of the corpus, many paraverbal phenomena, such as prosody, were unfortunately not available to us. Since our access to the dataset is covered by a Non-Disclosure Agreement, it cannot be released publicly. However the original experimenters' Institutional Review Board (IRB) approval allows us to view, annotate, and use the data to train models. This also allows us to provide a link to a pixelated video example in the GitHub repository of the project[2].

Data annotation: The dataset was previously annotated by Madaio et al. (2017), following an annotation manual that used hedge classes derived from Rowland (2007) (see Table 1). Only the task periods of the interactions were annotated. Comparing the annotations with the classes mentioned in the related work section, **Subjectivizers** correspond to **Relational hedges** (Fraser, 2010), **Propositional hedges** and **Extenders** correspond to **Approximators** (Prince et al., 1982) with the addition of some discourse markers such as *just*. **Apologizers** are mentioned as linguistic tools related to negative politeness in Brown and Levinson (1987). Krippendorff's alpha obtained for this corpus annotated by four coders was over 0.7 for all classes (denoting an acceptable inter-coder reliability according to Krippendorff (2004)). The dataset is widely imbalanced, with more than 90% of the utterances belonging to the **Not hedged** class.

In reviewing the corpus and the annotation manual, however, we noticed two issues. First, the annotation of the **Extenders** class was inconsistent, leading to the **Extenders** and **Propositional hedges** classes carrying similar semantic functions. We therefore merged the two classes and grouped utterances labeled as **Extenders** and those labeled as **Propositional hedges** under the heading of **Propositional hedges**. Second, the annotation of clauses containing the tokens "just" and "would" (two terms occurring frequently in the dataset that are key components of **Propositional Hedges** and **Subjectivizers** but that are not in fact hedges in all cases) was also inconsistent, leading to virtually all clauses with those two tokens being considered hedges. We therefore re-considered all the clauses associated with any of the hedge classes, as well as all the clauses in the "Not hedged" class that contained "just" or "would". The re-annotation was carried out by two annotators who achieved a Krippendorff's alpha inter-rater reliability of .9 or better for **Apologizers**, **Subjectivizers**, and **Propositional hedges** before independently re-annotating the relevant clauses. An example of a re-annotation was removing "I *would* kill you!" from the hedge classes.

4.2 Features

Label from rule-based classifier (Label RB): We use the class label predicted by the rule-based classifier described in Section 4.3 as a feature. Our hypothesis is that the machine learning model can use this information to counterbalance the class imbalance. To take into account the fact that some rules are more efficient than others, we weighted the class label resulting from the rule-based model by the precision of the rule that generated it.

Unigram and bigram: We count the number of occurrences of unigrams and bigrams of the corpus in each clause. We used the lemma of the words for unigrams and bigrams using the nltk lemmatizer (Loper, 2002) and selected unigrams and bigrams that occurred in the training dataset at least fifty times. The goal was to investigate, with a bottom-up approach, to what extent the use of certain words characterizes hedge classes in tutoring. In Section 5 we examine the overlap between these words and those *a priori* identified by the rules.

Part-of-speech (POS): Hedge classes seem to be associated with different syntactic patterns: for example, subjectivizers most often contain a personal pronoun followed by a verb, as in "I guess", "I believe", "I think". We therefore considered the number of occurrences of POS-Tag n-grams (n=1, 2, 3) as features. We used the spaCy POS-tagger and considered POS unigrams, bigrams and trigrams that occur at least 10 times in the training dataset.

LIWC: Linguistic Inquiry and Word Count (LIWC) (Pennebaker et al., 2015) is standard software for extracting the count of words belonging to specific psycho-social categories (*e.g.*, emotions, religion). It has been successfully used in the detection of conversational strategies (Zhao et al., 2016a). We therefore count the number of occurrences of all the 73 categories from LIWC.

Tutoring moves (TM): Intelligent tutoring systems rely on specific tutoring moves to successfully convey content (as do human tutors). We therefore looked at the link between the tutoring moves, as annotated in Madaio et al. (2017), and hedges. For tutors, these moves are (1) instructional directives and suggestions, (2) feedback, and (3) affirmations, mostly explicit reflections on their partners'comprehension, while for tutees, they are (1) questions, (2) feedbacks, and (3) affirmations,

---

Class	Definition	Example
Subjectivizers	Words that reduce intensity or certainty	“So then I would divide by two.”
Apologizers	Apologies used to soften direct speech acts	“Oh sorry six b.”
Propositional hedges	Qualifying words to reduce intensity or certainty of utterances	“It’s actually eight.”
Extenders	Words used to indicate uncertainty by referring to vague categories	“It’ll be the number x or whatever variable you have.”

Table 1: Definition of the classes

Prop. hedges	Apologizers	Subjectivizers	Not hedged	Total
1210	128	626	21192	23156

Table 2: Distribution of the classes

Features name	Automatic extraction	Vector size
Rule-based label	Yes	4
Unigram	Yes	~250
Bigram	Yes	~250
POS	Yes	~1200
LIWC	Yes	73
Nonverbal	No	24
Tutoring moves	No	6
Total		~1800

Table 3: List of automatically extracted and manually annotated features with their size.

mostly tentative answers.

Nonverbal and paraverbal behaviors: As in Goel et al. (2019), we included the nonverbal and paraverbal behaviors that are related to hedges. Specifically, we consider laughter and smiles, that have been shown to be effective methods of mitigation (Warner-Garcia, 2014), cut-offs indicating self-repairs, fillers like "Um", gaze shifts (annotated as ’Gaze at Partner’, ’Gaze at the Math Worksheet’, and ’Gaze elsewhere’), and head nods. Each feature was present twice in the feature vector, one time for each interlocutor. Inter-rater reliability for nonverbal behavior was 0.89 (as measured by Krippendorff’s alpha) for eye gaze, 0.75 for smile count, 0.64 for smile duration and 0.99 for head nod. Laughter is also reported in the transcript at the word level. We separate the tutor’s behaviors from those of the tutee. The collection process for these behaviors is detailed further in Zhao et al. (2016b).

The clause-level feature vector was normalized by the length of the clause (except for the rule-based label). This length was also added as a feature. Table 3 presents an overview of the final feature vector.

4.3 Classification models

The classification models used are presented here according to their level of integration of external linguistic knowledge.

Rule-based model: On the basis of the annotation manual used to construct the dataset from Madaio et al. (2017), and with descriptions of hedges from Rowland (2007), Fraser (2010) and Brown and Levinson (1987), we constructed a rule-based classifier that matches regular expressions indicative of hedges. The rules are detailed in Table 7 in the Appendix.

LGBM: Since hedges are often characterized by explicit lexical markers, we tested the assumption that a machine learning model with a knowledge-driven representation for clauses could compete with a BERT model in performance, while being much more interpretable. We relied on LightGBM, an ensemble of decision trees trained with gradient boosting (Ke et al., 2017). This model was selected because of its performance with small training datasets and because it can ignore uninformative features, but also for its training speed compared to alternative implementations of gradient boosting methods.

Multi-layer perceptron (MLP): As a simple baseline, we built a multi-layer perceptron using three sets of features: a pre-trained contextual representation of the clause (SentBERT; Reimers and Gurevych (2019)) ; the concatenation of this contextual representation of the clause and a rule-based label (not relying on the previous clauses) ; and finally the concatenation of all the features mentioned in section 4.2, without the contextualized representation.

LSTM over a sequence of clauses: Since we are working with conversational data, we also wanted to test whether taking into account the previous clauses helps to detect the type of hedge class in the next clause. Formally, we want to infer y_i using $y_i = \max_{y \in Classes} P(y|X(u_i), X(u_{i-1}), ..., X(u_{i-K}))$, where K is the number of previous clauses that the model will take into account. The

MLP model presented above infers y_i using $y_i = \max_{y \in Classes} P(y|X(u_i))$, therefore a difference of performance between the two models would be a sign that using information from the previous clauses could help to detect the hedged formulation in the current clause. We tested a LSTM model with the same representations for clauses as for the MLP model.

CNN with attention: Goel et al. (2019) established their best performance on hedge detection using a CNN model with additive attention over word (and not clause) embeddings. Contrary to the MLP and LSTM models mentioned above, this model tries to infer y_i using $y_i = \max_{y \in Classes} P(y|g(w_0), g(w_1), ..., g(w_L))$, with L representing the maximum clause length we allow, and g representing a function that turns the word $w_j,\ j \in [0, L]$ into a vector representation (for more details, please see Adel and Schütze (2017)).

BERT: To benefit from deep semantic and contextual representations of the utterances, we also fine-tuned BERT (Devlin et al., 2019) on our classification task. BERT is a pre-trained Transformers encoder (Vaswani et al., 2017) that has significantly improved the state of the art on a number of NLP tasks, including sentiment analysis. It produces a contextual representation of each word in a sentence, making it capable of disambiguating the meaning of words like "think" or "just" that are representative of certain classes of hedges. BERT, however, is notably hard to interpret.

4.4 Analysis tools

Looking at which features improve the performance of our classification models tells us whether these features are informative or not, but does not explain how these features are used by the models to make a given prediction. We therefore produced a complementary analysis using an interpretability tool. As demonstrated by (Lundberg and Lee, 2017), LightGBM internal feature importance scores are inconsistent with both the model behavior and human intuition, so we instead used a model-agnostic tool. SHAP (Lundberg and Lee, 2017) assigns to each feature an importance value (called Shapley values) for a particular prediction depending on the extent of its contribution (a detailed introduction to Shapley values and SHAP can be found in Molnar (2020)). SHAP is a model-agnostic framework, therefore the values associated with a set of features can be compared across models. It should be noted that SHAP produces explanations on a case-by-case basis, therefore it can both provide local and global explanations. For the Gradient Boosting model, we use an adapted version of SHAP (Lundberg et al., 2018), called TreeSHAP.

5 Experiments and results

5.1 Experimental setting

To detect the best set of features, we used LightGBM and proceeded incrementally, by adding the group of features we thought to be most likely associated with hedges. We did not consider the risk of relying on a sub-optimal set of features through this procedure because of the strong ability of LightGBM to ignore uninformative features. We use this incremental approach as a way to test our intuition about the performativity of groups of features (*i.e.* does adding a feature improve the performance of the model) with regard to the task of classification. To compare our models, we trained them on the 4-class task, and looked at the average of the weighted F1-scores for the three hedge classes (*i.e.* how well the models infer minority classes) that we report here as "3-classes", and at the average of the weighted F1-scores for the 4 classes, that we report as "4-classes". Details of the hyperparameters and experimental settings are provided in Appendix A.

5.2 Model comparison and feature analysis

Overall results: Table 4 presents the results obtained by the 6 models presented in Section 4.3 for the multi-class problem. Best performance (F1-score of 79.0) is obtained with LightGBM leveraging almost all the features. In the appendix (see Table 8 and Table 9) we indicate the confidence intervals to represent the significance of the differences between the models.

First, and perhaps surprisingly, we notice that the use of "Knowledge-Driven" features based on rules built from linguistic knowledge of hedges in the LightGBM model outperforms the use of pre-trained embeddings within a fine-tuned BERT model (79.0 vs. 70.6), and in the neural baseline from (Goel et al., 2019) (79.0 vs 64.5).

The low scores obtained by the LGBM, LSTM and MLP models with pre-trained sentence embeddings versus Knowledge-Driven features might signal that the word patterns characterizing hedges are not salient in these representations (i.e. the

Models	KD Feat. (KDF)	Pre-Trained Emb. (PTE)	KDF + PTE
Rule-based (3-classes)	67.6	∅	∅
MLP (3-classes)	68.5 (1.6)	35.8 (3.1)	64.8 (1.1)
Attention-CNN (3-classes)	∅	64.5 (3.0)	∅
LSTM (3-classes)	65.1 (5.7)	39.8 (8.0)	65.2 (5.1)
BERT (3-classes)	∅	**70.6 (2.3)**	∅
LGBM (3-classes)	**79.0 (1.3)**	35.0 (2.2)	**70.1 (1.4)**
Rule-based (4-classes)	94.7	∅	∅
MLP (4-classes)	94.8 (0.3)	89.7 (0.4)	93.9 (0.4)
Attention-CNN (4-classes)	∅	94.4 (0.2)	∅
LSTM (4-classes)	93.9 (1.4)	89.1 (1.4)	94.1 (1.2)
BERT (4-classes)	∅	**94.9 (0.4)**	∅
LGBM (4-classes)	**96.7 (0.2)**	91.0 (0.2)	**95.4 (0.2)**

Table 4: Averaged weighted F1-scores (and standard deviation) for the three minority classes and for the 4 classes, for all models. "KD" stands for "Knowledge-Driven", meaning that the features are derived from lexicon, n-gram models and annotations.

distance between "*I think* you should add 5." and "You should add 5." is short.). KD Features seem to provide a better separability of the classes. The combination of KD features and Pre-trained embeddings does not significantly improve the performance of the models compared to the KD Features only, which suggests that the information from the Pre-trained embeddings is redundant with the one from the KD Features. This result may be due to the high dimensionality of the input vector (868 with PCA on the KD Features; 2500 otherwise).

A second finding is that the use of gradient boosting models on top of rule-based classifiers better models the hedge classes. The other machine learning models did not prove to be as effective, except for BERT.

Feature analysis using LightGBM: Using the best performing model, Table 5 shows the role of each feature set in the prediction task. The significance of the differences is shown in Table 10 and Table 11. Compared to the rule-based model, the introduction of n-grams significantly improved the performance of our classifier, suggesting that some lexical and syntactic information describing the hedge classes was not present in the rule-based model. Looking at Table 5, we do not observe significant differences between the LGBM model using only the label rule based + (1-grams and 2-grams) and the models incorporating more features. To our surprise, neither the tutoring moves nor the nonverbal features significantly improved the performance of the model. The 2 features were included to index the specific peer tutoring context of these hedges, so this indicates that in future work we might wish to apply the current model to another context of use to see if this model of hedges is more generally applicable than we originally thought. By combining this result with the increased performance of the model using Knowledge-Driven (*i.e.* explicit) features compared to pre-trained embeddings, it would seem that hedges are above all a lexical phenomenon (*i.e.* produced by specific lexical elements).

5.3 In-depth analysis of the informative features

We trained the SHAP explanation models on LightGBM with all features. The most informative features (in absolute value) for each class are shown in Table 6, and the plots by class are presented in the Appendix. The most important features seem to be the rule-based labels, which appear in at least the fourth position for three classes (see Table 6), and in the first position for **Propositional Hedges** and **Not hedged** classes. Surprisingly, the Rule-Based label does not appear in the top 20 features for **Apologizers**. However, given that the class rarely appears in the data, the rules seldom activate, so the feature may simply be informative for a very small number of clauses. Unigrams (*Oh*, *Sorry*, *just*, *Would*, and *I*) are also present in the 5 top-ranked features. This confirms the findings mentioned in related work for the characterization of the different hedge classes (*just* with **Propositional Hedges**, *sorry* with **Apologizer**, *I* with **Subjectivizers**). The presence of *Oh* also has high importance for the characterization of **Apologizer** (n=2), as illustrated in examples such as "*Oh* sorry, that's nine.". We note that the occurrences of "*Oh sorry*" as a stand-alone clause were excluded by our rule-based model because they do not correspond to an apologizer (they cannot mitigate the content of a proposition if there is no proposition associated). This example illustrates the interest of a machine learning model approach to disambiguate the function of conventional non-propositional phrases like "*Oh sorry*".

In addition, SHAP highlights the importance of novel features whose function was not identified in the hedges literature: *(i)* what LIWC classifies as **informal words** but that are mostly interjections like *ah* and *oh* are strongly associated with **Apologizer**, as are disfluencies (n=12); *(ii)* the use of **POS tags** seems to be very relevant for characterizing the different classes (2-gram of POS tag features[3] occur in the top-ranked features of all the

---

[3] Note that there is strong redundancy between some features of LIWC and the spaCy POS tagger that both produce a "Pronoun" category, using a lexicon in the first case, and a neural inference in the second.

Models	Label RB	+ 1-gram and 2-gram	+ POS	+ LIWC	+ TM	+ Nonverbal
3-classes	68.8 (0.8)	78.2 (1.6)	78.1 (1.3)	79.0 (1.3)	78.5 (2.4)	78.7 (1.8)
4-classes	95.0 (0.2)	96.5 (0.3)	96.5 (0.2)	96.7 (0.2)	96.6 (0.4)	96.7 (0.3)

Table 5: Averaged weighted F1-scores for the three classes of hedges and the four classes, with an additive integration of KDF features in the LightGBM model. The standard deviation is computed across five folds.

Rank	Apologizer	Subjectivizers	Prop. Hedges	Not hedged
1	Function words (LIWC)	"I"	Class label	Class label
2	"Oh" (LIWC)	"Yeah"	"Would"	"Would"
3	"Sorry"	Noun (POS)	"Just"	"Yeah"
4	Affect (LIWC)	Class label	Function word (LIWC)	Noun (POS)
5	Clause length	Cognitive process (LIWC)	Netspeak (LIWC)	Cognitive process (LIWC)

Table 6: Most important clause-level features for LightGBM according to the SHAP analysis.

classes (see Figures in the Appendix). It means that there are some recurring syntactic patterns in each class; *(iii)* Regarding the **utterance size**, a clause shorter than the mean is weakly associated with **directness** (n=17) while a longer clause suggests that it contains a **Subjectivizer (n=6)**. **Apologizers** are characterized by a mean clause length (n=5), with few variations from it; *(iv)* Tutoring moves are not strong predictors of any classes: "Affirmation from tutor" is the only feature appearing as a predictor of Propositional hedges (n=20). This is consistent with the feature analysis in Table 5, suggesting that tutoring moves do not significantly improve the performance of the classifier; *(v)* **Nonverbal behaviors** do not appear as important features for the classification. This is coherent with results from (Goel et al., 2019). Note that prosody might play a role in detecting instructions that trail off, but, as described, paraverbal features were not available; *(vi) Would* plays an important role in the production of hedges, as it is strongly associated to **Propositional hedges** (n=2). It is interesting to note that, when designing the rule-based classifier, we saw it decrease in performance when we started to include *would* in our regular expression patterns, probably because the form is hard to disambiguate for a deterministic system.

While exploring the Shapley values associated to each clause, we observed that features like tutoring moves are extremely informative for a very small number of clauses (therefore not significantly influencing the overall performance of the prediction), and more or less not informative for the rest. Inferring the global importance of a feature as a mean across the shapley values in the dataset may not be the only way to explore the behavior of gradient boosting methods. It might be more useful to cluster clauses based on the importance that SHAP gives to that feature in its classification, as this could help discover sub-classes of hedges that are differentiated from the rest by their interaction with a specific feature (in the way that some **Apologizers** are characterized by an "oh"). We also note that the explanation model is sensitive to spurious correlations in the dataset, caused by the small representation of some class: for example, "nine" (n=7) and "four" (n=20) are positive predictors of **Apologizers**.

6 Conclusion and future work

Through our classification performance experiments, we showed that it is possible to use machine learning methods to diminish the ambiguity of hedges, and that the hybrid approach of using rule-based label features derived from social science (including linguistics) literature within a machine learning model helped significantly to increase the model's performance. Nonverbal behaviors and tutoring moves did not provide information at the sentence level; both the performance of the model and the feature contribution analysis suggested that their impact on the model output was not strong. This is consistent with results from Goel et al. (2019). However, in future work we would like to investigate the potential of multimodal patterns when we are able to better model sequentiality (*e.g.*, negative feedback followed by a smile). Regarding the SHAP analysis, most of the features that are considered as important are coherent with the definition of the classes (*I* for subjectivizers, *sorry* for apologizers, *just* for propositional hedges). However, we discovered that features like utterance size can also serve as indicators of certain classes of hedges. A limitation of SHAP is that it makes a feature independence assumption, which prompts the explanatory model to underestimate the importance of redundant features (like pronouns in our work). In the future we will explore explanatory models capable of taking into account the correlation between features in the dataset like SAGE (Covert et al., 2020), but suited for very imbalanced datasets. In the domain of peer-tutoring, we would like to be able to further test the link between hedges and rapport, and the link between hedges and learning gains in the subject being tutored. As noted above, this kind of study requires a fine-grained control of the language produced by one of the interlocutors, which is difficult to achieve in a human-human experience.

We note that the hedge classifier can be used not just to classify, but also to work towards improving the generation of hedges for tutor agents. In future work we will explore using the classifier to re-rank generation outputs, taking advantage of the recurring syntactic patterns (see *(ii)* in Section 5.3) to improve the generation process of hedges, and regenerating clauses that don't contain one of these syntactic patterns.

A Additional information on the experimental settings

We used PyTorch (Paszke et al., 2019) to implement the neural models. For each set of features, hyperparameters were selected using Optuna (Akiba, 2019), a parameter search framework. We re-implemented the Attention-CNN with Glove (Pennington et al., 2014) 300-D words embeddings as the vector representation. For each models, the results are cross-validated using 5 folds (we chose 5 instead of 10 to avoid having folds with too few samples per class). We corrected the loss function for class imbalance to force the model to adapt more to the less frequent classes. The strength of this correction depended on the model, and was selected because it provided a satisfying compromise between favoring recall and precision in the classification results of that model. For LightGBM, a "square root of the square root of the inverse class proportion" correction was selected. Neural models were trained using AdamW as an optimizer (Loshchilov and Hutter, 2018), and used a reduced feature vector, obtained with the application of PCA (d_{init} = 1800; d = 100 ; 99.8 % of the information is conserved). No significant performance differences were observed between the original vector and the reduced vector for training the models. To compute the SHAP values mentioned in the paper, we kept one split to perform the 5-split of the dataset, and leave 1 split to validate and early stop the model, in order to avoid overfitting. A complete configuration of hyperparameters used for each model is reported in the GitHub repository with the code of the paper: https://github.com/YannRaphalen/Hedges-Detection.

The BERT model was fine-tuned on a Nvidia Quadro RTX 8000 GPU.

Abstract

k-Nearest-Neighbor Machine Translation (kNN-MT) has been recently proposed as a non-parametric solution for domain adaptation in neural machine translation (NMT). It aims to alleviate the performance degradation of advanced MT systems in translating out-of-domain sentences by coordinating with an additional token-level feature-based retrieval module constructed from in-domain data. Previous studies (Khandelwal et al., 2021; Zheng et al., 2021a) have already demonstrated that non-parametric NMT is even superior to models fine-tuned on out-of-domain data. In spite of this success, kNN retrieval is at the expense of high latency, in particular for large datastores. To make it practical, in this paper, we explore a more efficient kNN-MT and propose to use clustering to improve the retrieval efficiency. Concretely, we first propose a cluster-based Compact Network for feature reduction in a contrastive learning manner to compress context features into 90+% lower dimensional vectors. We then suggest a cluster-based pruning solution to filter out 10%~40% redundant nodes in large datastores while retaining translation quality. Our proposed methods achieve better or comparable performance while reducing up to 57% inference latency against the advanced non-parametric MT model on several machine translation benchmarks. Experimental results indicate that the proposed methods maintain the most useful information of the original datastore and the Compact Network shows good generalization on unseen domains. Codes are available at `https://github.com/tjunlp-lab/PCKMT`.

1 Introduction

Recently, non-parametric approaches (Khandelwal et al., 2021; Zheng et al., 2021a,b; Jiang et al., 2021) have been successfully applied to neural machine translation (NMT) for domain adaptation with retrieval pipelines. Given an advanced MT model, they generally involve two steps:

Model	speed (token/s)	BLEU
MT	913.48	37.50
AK-MT (k=4)	642.43	46.32

Table 1: The inference speed comparison on the same IT-domain test set. AK-MT denotes the adaptive kNN-MT.

- It builds a cached memory, usually called $datastore$, in advance by extracting the context representations of the penultimate layer of the given NMT model corresponding to each target token from in-domain data.
- At inference, it retrieves the k nearest neighbors of the context representation for each generated token from the constructed datastore and then integrates external kNN translation probabilities derived from these retrievals to adjust the translation.

The accessibility of any provided datastore during translation makes them interpretable. Meanwhile, the reliability of these approaches gives the credit to the datastore quality. In spite of significant translation improvements, analyses on the datastore behavior have not been fully explored yet. We empirically observe that the construction of datastore is not optimal for retrieval from two aspects: retrieval latency and semantic distribution.

Retrieval Latency. As shown in Table 1, we compare both translation performance and speed between a pre-trained NMT model (Ng et al., 2019) with 270M parameters and the adaptive kNN-MT (Zheng et al., 2021a) system originated from the former on the same hardware (a P100-16GB GPU with 18 cores Intel Xeon Gold 6240 CPU @ 2.60GHz), where the later is the most advanced

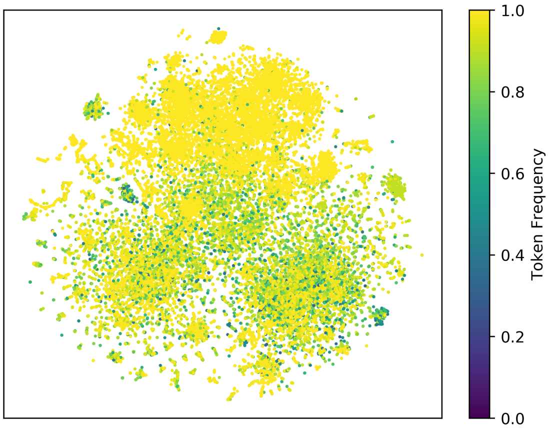

Figure 1: t-SNE visualization of IT domain features. Darker nodes denote lower frequency tokens.

retrieval-based NMT model so far.[1] It indicates that the heavy computation of retrieval within a datastore causes increased latency and makes it less practical in real-time scenarios. To address this problem, we propose an efficient pruning strategy to decrease the datastore redundancy so as to deal with the trade-off between the speed and the quality.

Semantic Distribution. For robust token-to-token retrieval, tokens with similar context are expected to be distributed close to each other to form separable and compact semantic clusters, otherwise semantic noise may hurt the retrieval effectiveness. To explore the potential of k-nearest retrieval, we visualize the feature distribution of a datastore built on the IT-domain corpus (Koehn and Knowles, 2017) in Figure 1. For the datastore constructed in the traditional way, we have 2 important findings. One is that the majority tokens are distributed in the overlapped area regardless of frequency. The other is that even the overall distribution shows a clustering effect, only a few small clusters are correctly classified with respect to frequency. Intuitively, these findings will directly and negatively affect the distance-based retrieval.

Moreover, as (Zhang et al., 2021) suggest, the dimension is highly related to retrieval speed. Preliminary studies on kNN-LM (He et al., 2021) indicate that traditional feature reduction algorithms could only maintain the original performance until the context feature dimension is reduced to a minimum required size (e.g., for feature dimension 1024, PCA requires at least 512). For NMT model, it is still challenging to reduce the feature dimension to its 10% (e.g., from 1024 to <100). To tackle this problem, we design a cluster-based training strategy where an external light-weight feature reduction network is learnt in a contrastive training manner to maximize the margin between context semantic clusters. In our experiments, we can even cut out 93.75% of the original feature size.

In summary, our main contributions are twofold:

- We propose a cluster-based Compact Network to reduce the dimension of the semantic representations and improve the translation performance by making different tokens separable to refine the retrieval results.
- We further propose a cluster-based pruning strategy by filtering redundant representations in the datastore so that our proposed methods could significantly decrease the translation latency during inference.

Experiments on multi-domain machine translation benchmarks indicate that our proposed methods are superior to existing retrieval-based machine translation systems in terms of both speed and quality.

2 Related Work and Background

In this section, we will briefly introduce the background of the adaptive kNN-MT (Zheng et al., 2021a). Adaptive kNN-MT is derived from kNN-MT (Khandelwal et al., 2021) by inserting a light-weight Meta-k Network that fuses kNN retrievals with various k to alleviate the possible noise induced by a single k. Formally, it is formulated as two steps: target-side datastore creation and Meta-k Network predictions.

Target-side Datastore Creation. The datastore constists of a set of key-value pairs. Given a bilingual sentence pair (s, t) in a corpus (S, T), a pretrained general domain NMT model autoregressively extracts the context representation h_i of the i-th target token conditioned on both source and target context $(s, t_{<i})$, denoted as $h_i = f(s, t_{<i})$. The datastore is finally constructed by taking h_i as keys and t_i as values:

$$(\mathcal{K}, \mathcal{V}) = \bigcup_{(s,t)\in(\mathcal{S},\mathcal{T})} \{(h_i, t_i), \forall\, t_i \in t\}.$$

Meta-k Network Prediction. Meta-k Network (f_β) is a two-layer feed-forward network followed by a non-linear activation function. Based on the

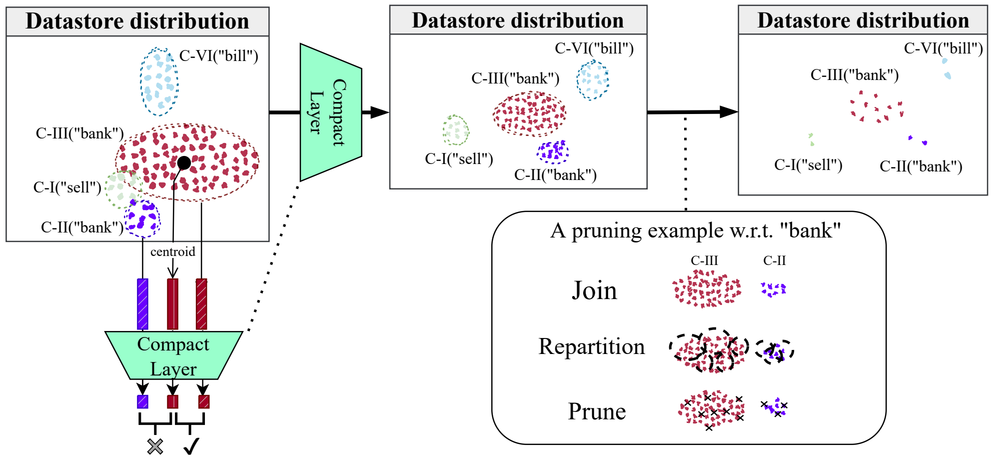

Figure 2: The diagram of the proposed approach. C-*("#") denotes the *th cluster of token "#". First, the cluster-based Compact Network is used to reduce the key's dimensionality of the original datastore and a new datastore is reconstructed. Then the cluster-based pruning is applied to reduce the datastore size.

constructed datastore, it considers a set of different ks that are smaller than an upper bound K. The standard setting for k is $\mathcal{Q} = \{0\} \cup \{k_r \in N \mid \log_2 k_r \in N, k_r \leq K\}$. K nearest neighbors of the current context query $\hat{h}_i$ from the datastore are first retrieved at the i-th decoding step. Then the square of l_2 distance from $\hat{h}_i$ to each neighbor (h_j, v_j) is denoted as $d_j = \|h_j, \hat{h}_i\|^2$. And the number of distinct values in top j neighbors are denoted as c_j. The normalized weights of each available k are computed as:

$$p_\beta(k) = \text{softmax}(f_\beta([d_1, ..., d_K; c_1, ..., c_K]))$$

where f_β denotes the Meta-k Network. For $k_r \in \mathcal{Q}$, the word prediction probability over the vocabulary w.r.t each neighbor is computed via the Gaussian kernal function:

$$p_{k_r\text{NN}}(y_i|x, \hat{y}_{<i}) \propto \sum_{\{(h_j,v_j) \mid j \leq k_r, j \in N\}} \mathbb{1}_{y_i=v_j} \exp\left(\frac{-\|h_j, \hat{h}_i\|^2}{T}\right)$$

where T denotes the temperature hyper-parameter. The ultimate prediction probability is a weighted ensemble:

$$p(t_i|s, \hat{t}_{<i}) = \sum_{k_r \in \mathcal{Q}} p_\beta(k_r) \cdot p_{k_r\text{NN}}(t_i|s, \hat{t}_{<i})$$

Note that a validation set is usually required to study the Meta-k Network before predicting on test sets. During training, only the parameters of the Meta-k Network need to update.

3 Our Approach

As shown in Figure 2, our proposed approach focuses on datastore reconstruction from the perspectives of feature compression and size pruning by utilizing cluster-based signals.

3.1 Cluster-Based Feature Compression

From Figure 1, we observe that spatially close context representations may have noisy and different semantics. During inference, it may lead to unreliable neighbors for retrieval-based NMT (see examples in Appendix D "Case Analysis") due to the entanglements from these noisy context space. We hypothesize that the reasons may be three-fold. First, the pre-trained NMT model on general domain lacks target domain-specific knowledge. Second, the high dimensional semantic space is too sparse and may contain some noisy underlying components. Third, the likelihood-maximization objective from the logits by dot-production enforces the alignment of vector directions, which is inconsistent with the spatially close expectation for the sake of both direction and length.

To address these issues, we propose a one-plus-one (f_α+f_θ) Compact Network on top of the pre-trained NMT model. The first "one" module is to transform the coarse-grained semantics of the pre-trained NMT into the fine-grained semantic clusters. The second "one" module is used to calculate our designed loss function.

To obtain coarse-grained semantic clusters, we first follow the method described in "Target-side Datastore Creation" of Section 2 to create the

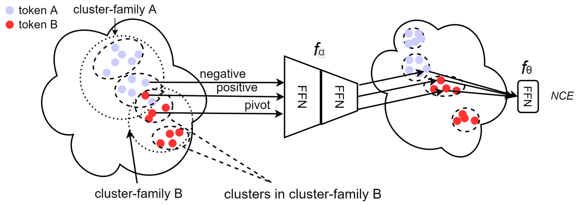

Figure 3: The Compact Network illustration. f_α is for dimension reduction and f_θ is for NCE training.

in-domain datastore. For context representations (keys) with the same target token (value), we conduct target-side clustering for the representations, shown as the left clusters in Figure 3. We denote the resulted clusters from the same value as the **cluster family** for the corresponding target token. Due to the distance-based clustering, it is guaranteed that clusters within each cluster family are not overlapped at all. However, different cluster families will have large overlapped space according to Figure 1. Therefore, our main purpose is to construct a transform that can make the cluster families separable as well.

The proposed light-weight Compact Network in Figure 3 is desired to fulfill above purpose and compress the feature dimension. The first two-layer perceptron is applied for representation compression: $f_\alpha(\cdot) = \mathrm{FFN}_2(\sigma\ (\mathrm{FFN}_1(\cdot)))$, where $\sigma(\cdot)$ denotes the Sigmoid function. The last layer f_θ is attached for transferring the compressed representations into classification logits where the output dimension depends on the number of designed categories. Note that the f_θ layer is discarded at inference.

In order to obtain the separable cluster families after f_α, we are motivated to consider several candidate contrastive regularizations to train the Compact Network.

Triplet Noise-Contrastive Estimation (NCE). For each cluster in one particular cluster family, two semantic representations are randomly sampled, one as the pivot example v_* and the other as the positive example v_+. From the cluster in a different cluster family, another semantic representation is randomly selected as the negative example v_-. Then we conduct NCE (Gutmann and Hyvärinen, 2010) with binary classification on {pivot, positive} and {pivot, negative} to predict which pair belongs to the same cluster.

$$\min_{f_\theta, f_\alpha} -\log(\sigma(f_\theta([f_\alpha(v_+); f_\alpha(v_*)])))$$
$$-\log(1-\sigma(f_\theta([f_\alpha(v_-); f_\alpha(v_*)])))$$

where the output dimension of f_θ is 1.

Triplet Distance Ranking. This is similar to the Triplet NCE. The differences are that (1) we remove the f_θ layer and (2) the objective is modified as a ranking loss by minimizing the l_2 distance between the pivot and positive examples as well as maximizing the distance between the pivot and negative ones:

$$\min_{f_\theta, f_\alpha} \|f_\alpha(v_+) - f_\alpha(v_*)\|_2$$
$$+ 1/\|f_\alpha(v_-) - f_\alpha(v_*)\|_2$$

Word Prediction Loss. To compensate the loss of linguistic information that NCE may ignore, the traditional word prediction NMT loss is also used to train the Compact Network. In this scenario, the output dimension of f_θ is the vocabulary size of the corresponding target language.

In addition, we find that dynamic pivot selection leads to unstable training as the compressed representations are forced to update toward various directions. For each cluster, we modify the dynamic pivot as a static pivot, by fixing it as the centroid. After the training converges, we can construct a new feature-compressed datastore with the output of f_α, which is used for query retrieval during the kNN-MT inference.

3.2 Cluster-Based Pruning

Apart from feature reduction, the number of key-value pairs in the compressed datastore is crucial for the translation latency as well, hence redundant tokens are encouraged to be pruned. In literature, phrase-level pruning strategies have proved efficient for statistical machine translation (SMT) (Ling et al., 2012; Zens et al., 2012). Each record in the phrase table reflects a similar semantic unit, hence one could prune parts of the records that share similar statistics, e.g., translation quality, translation cost, etc.

Enlightened by SMT, we propose an efficient pruning strategy based on n-gram metrics on the original semantic representation space. Intuitively, the entry of a key-value pair in the datastore is **redundant** if there are other key-value pairs (with the same value) holding for that the difference of their perplexity (PPL) values is smaller than a given threshold ϵ (an example is represented in Figure 4).

To make it concrete, we decrible the **translation cost** as follows. For a given n-gram phrase $(t_{i-n+1}, t_{i-n+2}, ..., t_i)$ in the translation with the corresponding token-level translation probability

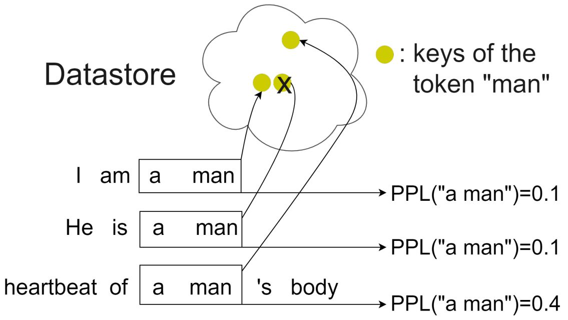

Figure 4: An example of redundant bigram "a man" with similar translation costs. "X" denotes that the node with similar PPL will be randomly deleted in pruning.

$p(t_j|s,t_{<j})\ \forall j \in \{i, i-1, ..., i-n+1\}$, we measure the translation cost of its last token (desired value in datastore) as the perplexity (PPL) of the n-gram phrase. However, when n is fixed, n-gram phrases are not always meaningful because some translations are independent of its previous target-side context (Ling et al., 2012). Hence we do not directly adopt the naive PPL as a stable translation cost but truncate it in a heuristic way. We search for the minimal PPL among all consecutive subsequences ending with that last token. Formally, given a bilingual sentence pair (s,t), we define the translation cost for each target token t_i:

$$c_{t_i} = \min_{b\in\{1,2,...,n\}} \mathrm{PPL}(p(t_{i-b+1}|s,t_{<i-b+1}),\ ...,\ p(t_{i-1}|s,t_{<i-1}),\ p(t_i|s,t_{<i}))$$

Then we can add the translation cost into the feature-compressed datastore.

$$((\mathcal{K},\mathcal{C}),\mathcal{V}) = \bigcup_{(s,t)\in(\mathcal{S},\mathcal{T})} \{((f_\alpha(h_i),c_{t_i}),t_i),\forall\, t_i \in t\}$$

For the augmented datastore described above, we only apply propagation-based clustering (Ester et al., 1996; Zhang et al., 1996) upon the translation cost c_{t_i} to get cost-similar groups, and partition the semantic representations in accordance to these groups. To get pruned datastore, we adopt uniform sampling on each group and collect them into a small key-value paired datastore. This algorithm is summarized in Algorithm 1.

```
Algorithm 1 Cluster-Based Pruning
Input:
    The expected pruning rate $r$.
    The translation cost threshold $\epsilon$.
    A preprocessed datastore $((\mathcal{K},\mathcal{C}),\mathcal{V})$.
Output:
    A new pruned datastore $(\mathcal{K}_{new},\mathcal{V}_{new})$.
1. Greedy Clustering On Translation Costs.
    $G \leftarrow \emptyset$.
    For each $v_i$ in set($\mathcal{V}$) do
        get collection $(\mathcal{K}_{v_i},\mathcal{C}_{v_i})$ paired with $v_i$
        split$_{\mathcal{C}_{v_i}}$ $\leftarrow$ cluster($\mathcal{C}_{v_i}$, $\epsilon$)
        $\mathcal{K}_{\text{split}}$ $\leftarrow$ map(split$_{\mathcal{C}_{v_i}}$, $\mathcal{K}_{v_i}$)
        $G$.extend( zip($\mathcal{K}_{\text{split}}$, $\mathcal{V}_{v_i}$) )
2. Uniform Pruning.
    $D_{\text{new}} \leftarrow \{\}$.
    For each $(k,v)$ in $G$ do
        $k_*, v_*$ = sample_by_rate($(k,v)$, $r$)
        $D_{\text{new}}$.update($k_*, v_*$)
    return $D_{\text{new}}$
```

In brief, our efficient cluster-based k-nearest neighbor machine translation can be concluded into the following steps.

- We adopt the original datastore to train Compact Network while the parameters of NMT are frozen.
- We adopt the validation set to train the Meta-k Network while the parameters of NMT and Compact Network are fixed.
- We reconstruct the feature-compressed datastore and prune it into a small datastore using our proposed n-gram pruning algorithm that will be eventually used for testing.

4 Experiments

We carried out a series of experiments to evaluate the proposed non-parametric NMT against the previous advanced counterpart on several translation benchmarks.

4.1 Datasets

We followed (Zheng et al., 2021a) to conduct all experiments on five widely used machine translation benchmarks of unique domains, including IT, Koran, Medical, Law and Subtitles. The first four domains were also used in (Zheng et al., 2021a) while the last Subtitles dataset contains a large number of target tokens, which is hence suitable to explore our pruning strategy. The statistics of these datasets are shown in Table 2. We tokenized sentences using Moses[2] and split words into subword

Dataset	Statistics of training sets					Statistics of test sets				
Domain	**Koran**	**IT**	**Medical**	**Law**	**Sub**	**Koran**	**IT**	**Medical**	**Law**	**Sub**
sentence	222K	248K	18K	467K	12.4M	2K	2K	2K	2K	2K
token	0.5M	3.6M	6.9M	19M	154M	58K	34K	57K	81K	25K

Table 2: The statistics of datasets in all experiments. “Sub" denotes Subtitles.

units (Sennrich et al., 2016) with the bpe-codes provided by (Ng et al., 2019). We applied the product quantizer with the inverted file system based on Faiss[3] to quantize the datastores and conduct retrieval. The hyper-parameters of Faiss are provided in Appendix B.

4.2 Clustering Algorithm Selection

The determination of clustering algorithms depends on computation complexity and clustering effectiveness.

- As semantic clusters in a large datastore are vague and it is hard to determine the prior quantity of clusters existing in a large datastore, clustering algorithms that hold a static cluster quantity in advance (e.g., k-Means (Hartigan and Wong, 1979)) are not fit for dataset partitioning.
- Besides, clustering complexity is not tolerant in practice when it increases up to $O(N^2)$ (e.g., Affinity Propagation (Frey and Dueck, 2007)) since N is usually extremely large for a high-quality datastore.

We eventually chose two classical clustering algorithms from candidates for exploration in our experiments: DBSCAN (Ester et al., 1996) and Birch (Zhang et al., 1996). DBSCAN was applied for clustering datastore with 100M- nodes while BIRCH was applied for clustering datastore with 100M+ nodes for the sake of computation-and-quality trade-off. In our experiments, We adopted the scikit-learn clustering implements.[4]

4.3 Baselines

We adopted the following models as our baselines.

- **Base NMT.** This is the winner model (Vaswani et al., 2017) of WMT'19 German-English News translation task[5] provided by (Ng et al., 2019), which is also used in (Zheng et al., 2021a). It is a Transformer model (Vaswani et al., 2017) with hidden size 1024.
- **Adaptive kNN-MT** (Zheng et al., 2021a). This is the benchmark model of our work.

Model	BLEU
NMT	38.35
adaptive kNN-MT	47.20
+feature-wise PCA	46.84
+weight-wise SVD	45.96
[DY] CKMT+DR	37.10
[DY] CKMT+WP	46.41
[DY] CKMT+NCE	46.58
[DY] CKMT+NCE+DR	37.33
[DY] CKMT+NCE+WP	46.42
[DY] CKMT+NCE+CL	47.48
[ST] CKMT+NCE+CL	**47.94**
[ST] CKMT+NCE+CL+DR	47.64
[ST] CKMT+NCE+CL+WP	46.88

Table 3: The BLEU performance comparison of the feature reduction methods on the IT domain. All retrieval k is set to 4. DR, NCE and WP denote the distance ranking, noise-contrastive estimation and word prediction objectives, respectively. CL denotes that all the tokens are clustered and then the triplets are selected based on these clusters. [DY] denotes that the pivot is dynamically selected while [ST] denotes static pivot selection.

In our modifications, as expected to reduce the dimension to <10% of its original size, we did greedy searching in [16, 32, 64, 128] to obtain the optimal 64 as f_α's output dimension on the IT domain validation set and then used this setting in all experiments. The detailed dimension related analysis can be found in Appendix A. Similarly we used grid search and selected bigram in the clustering-based pruning algorithm.

4.4 Evaluation

All experiments were conducted on a P100-16GB GPU with 18 cores Intel(R) Xeon(R) Gold 6240 CPU @ 2.60GHz except for the experiments in

Subsection 4.5.2 where we used 2 GPU cards to load a larger datastore. All translation results were evaluated in case-sensitive detokenized BLEU with SacreBLEU (Post, 2018).

4.5 Results

For simplicity, we refer to the base NMT model equipped with the proposed Compact Network as **CKMT** and further equipped with the pruned datastore as **PCKMT** in this section.

4.5.1 Performance of the Compact Network

On the IT domain, we first evaluated the compact layer settings mentioned in Section 3, as well as two traditional feature reduction algorithms: Principal Component Analysis (PCA) used in (He et al., 2021) and Singular Value Decomposition (SVD). We applied the PCA solution to learn feature-wise linear projection while the SVD solution to learn matrix-wise projection that decomposes the weight (W) of the last layer of the base NMT model into three matrices:

$$W_{1024*vocab\_size} = S_{1024*64} U_{64*64} V_{64*vocab\_size}$$

Then f_α can be replaced by an FFN layer with the weight $S_{1024*64} U_{64*64}$ but without bias.

As shown in Table 3, the best CKMT solution is equipped with the Compact Network trained using NCE+CL+DR. It outperforms the adaptive kNN-MT by 0.74 BLEU. Being consistent with (He et al., 2021), we find that it is difficult to use the 1024-to-64 feature-wise PCA to maintain the translation performance with such a low dimension. Basically, the distance ranking loss causes serious performance degradation. We assume that the distance minimization restraint is too strict to optimize a small datastore since both the direction and the length of a semantic vector have already been optimized. Though the word prediction (WP) can recover semantic information, its f_θ has too many parameters to be optimized on the limited IT domain datastet compared with NCE alone. Besides, we attribute the improvement obtained by the clustering (CL) to the introduced semantic disambiguation. Finally, the static pivot selection (ST) achieves an improvement of 0.46 BLEU against the dynamic method.

We refer to the best setting [ST] CKMT+NCE+CL as CKMT*, and report the results against the adaptive kNN-MT on various domains in Table 4. CKMT* gains an average improvement of 0.70 BLEU over the adaptive kNN-MT which indicates that our proposed Compact Network refines the retrieval for machine translation.

The Compact Network Training with Limited Data. It is unclear how much data are adequate at training-stage I. Hence, we gradually reduce the number of key-value pairs in the datastore to train the Compact Network as shown in Table 5. As the number decreases, the performance degrades slowly. When we use only 40% of the datastore for training, CKMT still outperforms the adaptive kNN-MT. It indicates that our proposed Compact Network is efficient and requires a small amount of key-value pairs to compress the semantic representations with contrastive loss.

Cross Domain Generalization. Is there a general Compact Network that is capable to generalize to different domains? If so, we will save the cost to train an unique Compact Network for various target domains. To explore this, we trained the Compact Network in a general domain with the large-scale Wikimatrix Corpus (Schwenk et al., 2021) and evaluated its behavior on various target domains. As the last row of Table 4 shows, it is interesting that the general CKMT* drops only 0.39 BLEU compared with 4 domain-specific datastores, and it still outperforms the adaptive kNN-MT by 0.31 BLEU. Overall speaking, the Compact Network generalizes well across different domains.

Model	Domain				Avg.
	IT	Koran	Law	Medical	
CKMT*	47.94	19.92	62.98	56.92	46.94
CKMT*+SP	43.01	19.50	59.40	52.16	43.52
CKMT*+LTP	46.78	19.28	**61.96**	55.21	45.81
CKMT*+HTP	45.95	**20.10**	59.51	55.14	45.18
CKMT*+RP	46.38	19.99	**61.96**	**55.45**	45.85
CKMT*+Ours	**47.06**	20.01	61.72	55.33	**46.03**

Table 6: Translation BLEU Results on 4 different domains with 10% pruning rate. k was set to 4. Note that CKMT* in the first row used the full datastore.

4.5.2 Performance of Pruning Methods

We tested our language-wise PPL-based pruning methods with several pruning strategies as follows.

- **Spatially Pruning by Distance (SP)**. It is a naive pruning strategy using distance-wise solution by cutting off nodes with low probability according to the distance from each node to its cluster center.
- **Low Translation Probability Pruning (LTP)**. Tokens translated with low probabilities tend to have poor translation quality, and will be pruned for datastore stability.
- **High Translation Probability Pruning (HTP)**. As the kNN probabilities are beneficial for hart-to-translate words that NMT cannot handle, it would be more encouraged to restore the tokens wrongly translated by the base NMT. In this sense, tokens paired with high confidence will be pruned.
- **Random Pruning (RP)**. We also perform the random pruning strategy alone for the target-side clusters, as the step 2 introduced in Algorithm 1.

The results on 4 different domains are shown in Table 6. Since the datastore size remains the same (10% pruned) for all pruning methods in Table 6, there is no much retrieval speed difference among these methods. Our cluster based pruning strategy generally achieves the smallest degradation. Though other strategies obtain impressive[6] results on a few domains (e.g., 10% pruned CKMT*+HTP outperforms non-pruned CKMT* by 0.18 BLEU on the Koran test set) since previous studies (i.e, (He et al., 2021)) our cluster-based pruning strategy performs the most stably on average. Note that the random pruning strategy is simple yet effective, which coincides with (He et al., 2021).

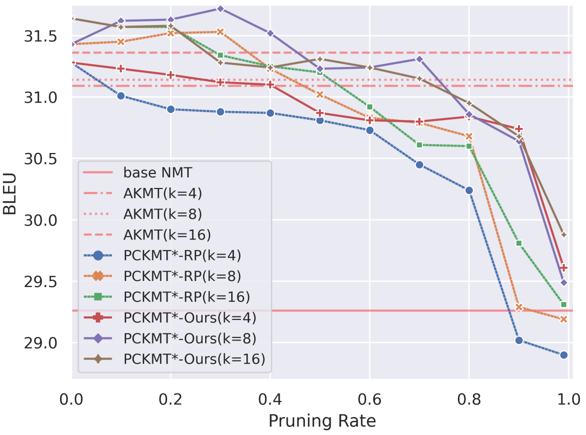

Figure 5: The BLEU comparison of pruning experiments on the Subtitles domain with increasing pruning rates. AKMT denotes the non-pruned adaptive kNN-MT.

However, we find that the in-domain data of the tested domains have limited redundancy since the average frequency of bigrams is too low (e.g., more than 0.4M unique bigrams were collected from the 3.6M IT domain datastore, on average each bigrams only has no more than 9 occurrences in the datastore). Therefore, even 10% pruning rate can lead to about 1 BLEU loss in Table 6. We leave reducing the datastore with low n-gram redundancy to our future work.

To further explore the potential of the pruning methods on large datastore, we conducted pruning experiments on Subtitles domain containing 154M keys. We tested the random pruning strategy as well because it is the second competitive pruning strategy. As Figure 5 illustrates, the proposed PCKMT*+Ours with pruning rate 30% can even outperform non-pruned CKMT*. As the pruning rate increases, PCKMT*+Ours generally outperforms PCMKT*+RP for the same k. The performance of PCKMT*+RP drops seriously (more than 1 BLEU point) when the pruning rate $\geq$ 50%, but PCKMT*+Ours sees a clear drop until the pruning rate $\geq$ 70%. When the pruning rate increases to 80+%, PCKMT*+RP even performs worse than the base NMT, but PCKMT*+Ours still outperforms it by a large margin. These results suggest that the proposed cluster-based pruning algorithm is effective for datastore reduction.

---

[6] This is in comparison to previous studies (e.g., (He et al., 2021)) that usually fail to maintain model performance when datastores are pruned to a large extent.

Model	Batch Size	k	Speed		Datastore Storage	
			sentences/s	tokens/s	original	quantization
base NMT	8	-	49	572	-	-
	64		166	1959		
adaptive kNN-MT NMT	8	16	26 (-23)	292 (-280)	295.2GB	12.2GB
	64		55 (-111)	618 (-1341)		
	8	8	26 (-23)	295 (-277)		
	64		59 (-107)	663 (-1296)		
	8	4	26 (-23)	296 (-276)		
	64		58 (-108)	660 (-1299)

	64		98 (-68)	1108 (-851)		

Table 7: The computation cost of PCKMT* with no BLEU degradation compared with the adaptive kNN-MT. PCKMT*-#% denotes PCKMT* equipped with the #% pruned datastore for retrieval during inference. The value in parentheses is the speed latency between the corresponding model and the base NMT.

Model		BLEU	Sentences/s	Tokens/s	Datastore size	Pruning rate
adaptive kNN-MT		31.36	58	660	154M	0%
k=16	CKMT*	31.64	74	849	154M	0%
	PCKMT*	31.58	85	963	123M	20%
k=8	CKMT*	31.43	78	890	154M	0%
	PCKMT*	**31.72**	**91**	**1024**	108M	30%
k=4	CKMT*	31.28	79	899	154M	0%
	PCKMT*	31.23	85	968	138M	10%

Table 8: The optimal performances of our approach on the Subtitles test set. The batch size was fixed as 64.

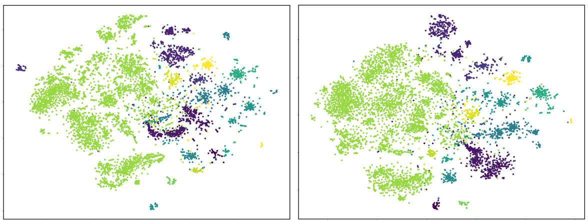

Figure 6: t-SNE visualization of the original (left) and compressed (right) semantic representations of 10 sampled tokens (one color for each token).

In Table 7, we further evaluated the computation cost of CKMT* with the same BLEU performance as the adaptive kNN-MT. With the same k and the batch size, PCKMT* achieves 27%~57% less speed latency compared with the adaptive kNN-MT. In addition, we compared our optimally performed model with baselines in Table 8. PCKMT (k=8) equipped with pruning rate 30% has the optimal performance, which obtains an improvement of 0.36 BLEU and 1.56x translation speed over the adaptive kNN-MT.

Cluster Visualization. We visualize the IT domain datastore in Figure 6 to verify our assumption that our Compact Network maps the original semantic representations to a separable distribution with less overlaps. Tokens represented by purple dots become more distinguishable with our method.

5 Conclusion

In this paper, we propose a cluster-based Compact Network for feature reduction in a contrastive learning manner to reduce 90+% context feature dimension, and suggest a cluster-based pruning strategy to prune 10%~40% redundant keys in datastore while translation quality remains unchanged. Our proposed methods achieve better or comparable performance while reducing up to 57% inference latency against the advanced non-parametric MT model on several benchmarks. For future work, it is promising to design effective feature reduction algorithms and pruning strategies based on more linguistic and cross-lingual information.

A Compact Feature Dimension

Model	Dimension	Loss	BLEU
CKMT*	128	1.82	44.42
	64	1.84	**44.49**
	32	1.88	42.41
	16	2.03	39.49
adaptive kNN-MT	-	1.82	44.20

Table 9: BLEU scores of different compact feature dimensions on the IT domain validation set.

The output dimension of the first FFN in f_α was empirically set as 4 times of the output dimension of the whole f_α. We then conducted greedy search on the IT domain validation set to obtain the optimal output dimension of f_α in our Compact Network. As shown in Table 9, 64d was the optimal setting superior to the adaptive kNN-MT.

B Hyper-parameters of Faiss

We followed the default implementation setting of (Zheng et al., 2021a). To be concrete, we adopted the FP16 precision to store keys. The number of partition-based quantization centroids was set to 1024 while the number of selected invested lists at query time in the cell-probe method[7] was set to 32. The size of per quantized vector in bytes was set to 64 except for CKMT with 16d/32d compact feature dimension in Table 9 because the output size of the quantized vectors must be smaller than the size of the input features for quantization.

C Analysis on the Number of Parameters

Model	Parameter
MT	269.7M
Adaptive kNN-MT	269.7M
CKMT*	270.0M

Table 10: The number of parameters of different models.

We compared the number of overall parameters of different systems in Table 10. It can be seen that our optimal CKMT* only requires 0.1% more parameters than the adaptive kNN-MT while it significantly decreases the latency. Hence CKMT* achieves an important speed-quality trade-off.

D Case Analysis

In this subsection, we analyze translations generated by different models on the test sets.

From the translations generated by different models in Table 11, it can be seen that CMKT* translates sentences more adequately especially for those containing ambiguous tokens because the Compact Network turns different tokens separable in the compressed semantic representation space. In this way, CKMT* tends to predict accurate words that are in line with the meaning of the source sentence rather than tokens of high frequency (e.g., “insert” objects rather “paste” objects). On the other hand, the adaptive kNN-MT translates “VolumeControl” as “api.op” by mistake while the base NMT model could correctly translate it, which suggests that the adaptive kNN-MT could surfer from noisy retrievals from the original semantic space. It can also be seen that PCKMT* makes predictions without performance degradation compared to CKMT*, although PCKMT* is equipped with a smaller datastore.

Headed-Span-Based Projective Dependency Parsing

Songlin Yang, Kewei Tu*
School of Information Science and Technology, ShanghaiTech University
Shanghai Engineering Research Center of Intelligent Vision and Imaging
`{yangsl,tukw}@shanghaitech.edu.cn`

Abstract

We propose a new method for projective dependency parsing based on headed spans. In a projective dependency tree, the largest subtree rooted at each word covers a contiguous sequence (i.e., a span) in the surface order. We call such a span marked by a root word *headed span*. A projective dependency tree can be represented as a collection of headed spans. We decompose the score of a dependency tree into the scores of the headed spans and design a novel $O(n^3)$ dynamic programming algorithm to enable global training and exact inference. Our model achieves state-of-the-art or competitive results on PTB, CTB, and UD [1].

1 Introduction

Dependency parsing is an important task in natural language processing, which has numerous applications in downstream tasks, such as opinion mining (Zhang et al., 2020a), relation extraction (Jin et al., 2020), named entity recognition (Jie and Lu, 2019), machine translation (Bugliarello and Okazaki, 2020), among others.

There are two main paradigms in dependency parsing: graph-based and transition-based methods. Graph-based methods decompose the score of a tree into the scores of parts. In the simplest first-order graph-based methods (McDonald et al., 2005, *inter alia)*, the parts are single dependency arcs. In higher-order graph-based methods (McDonald and Pereira, 2006; Carreras, 2007; Koo and Collins, 2010; Ma and Zhao, 2012), the parts are combinations of multiple arcs. Transition-based methods (Nivre and Scholz, 2004; Chen and Manning, 2014, *inter alia)* read the sentence sequentially and conduct a series of local decisions to build the final parse. Recently, transition-based methods with Pointer Networks (Vinyals et al., 2015) have obtained competitive performance to graph-based methods (Ma et al., 2018; Liu et al., 2019; Fernández-González and Gómez-Rodríguez, 2019; Fernández-González and Gómez-Rodríguez, 2021).

A main limitation of first-order graph-based methods is that they independently score each arc based solely on the two words connected by the arc. Ideally, the appropriateness of an arc should depend on the whole parse tree, particularly the subtrees rooted at the two words connected by the arc. Although subtree information could be implicitly encoded (Falenska and Kuhn, 2019) in powerful neural encoders such as LSTMs (Hochreiter and Schmidhuber, 1997) and Transformers (Vaswani et al., 2017), there is evidence that their encoding of such information is inadequate. For example, higher-order graph-based methods, which capture more subtree information by simultaneously considering multiple arcs, have been found to outperform first-order methods despite using powerful encoders (Fonseca and Martins, 2020; Zhang et al., 2020b; Wang and Tu, 2020). In contrast to the line of work on higher-order parsing, we propose a different way to incorporate more subtree information as discussed later.

Transition-based methods, on the other hand, can easily utilize information from partially built subtrees, but they have their own shortcomings. For instance, most of them cannot perform global optimization during decoding [2] and rely on greedy or beam search to find a locally optimal parse, and their sequential decoding may cause error propagation as past decision mistakes will negatively affect the decisions in the future.

To overcome the aforementioned limitations of

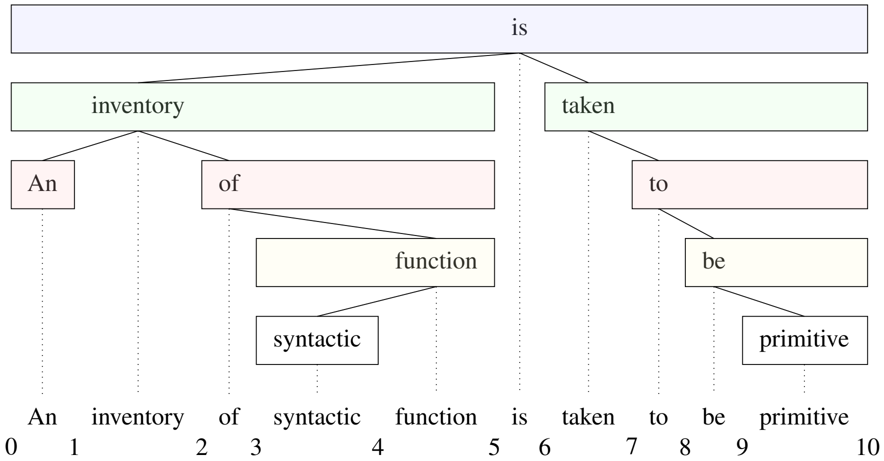

Figure 1: Illustration of a projective dependency parse tree. Each rectangle represents a headed span.

first-order graph-based and transition-based methods, we propose a new method for projective dependency parsing based on so-called headed spans. A projective dependency tree has a nice structural property that the **largest** subtree rooted at each word covers a contiguous sequence (i.e., a span) in the surface order. We call such a span marked with its root word a *headed span*. A projective dependency tree can be treated as a collection of headed spans such that each word corresponds to exactly one headed span, as illustrated in Figure 1. For example, $(0, 5, \text{inventory})$ is a headed span, in which span $(0, 5)$ has a head word *inventory*. In this view, projective dependency parsing is similar to constituency parsing as a constituency tree can be treated as a collection of constituent spans. The main difference is that in a binary constituency tree, a constituent span (i, k) is made up by two adjacent spans (i, j) and (j, k), while in a projective dependency tree, a headed span (i, k, x_h) is made up by one or more smaller headed spans and a single word span $(h - 1, h)$. For instance, $(0, 5, \text{inventory})$ is made up by $(0, 1, \text{An})$, $(1, 2)$ and $(2, 5, \text{of})$. There are a few constraints between headed spans to force projectivity (section 3). These structural constraints are the key to designing an efficient dynamic programming algorithm for exact inference.

Because of the similarity between constituency parsing and our head-span-based view of projective dependency parsing, we can draw inspirations from the constituency parsing literature to design our dependency parsing method. Specifically, span-based constituency parsers (Stern et al., 2017; Kitaev and Klein, 2018; Zhang et al., 2020c; Xin et al., 2021) decompose the score of a constituency tree into the scores of its constituent spans and use the CYK algorithm (Cocke, 1969; Younger, 1967; Kasami, 1965) for global training and inference. Built upon powerful neural encoders, they have obtained state-of-the-art performance in constituency parsing. Inspired by them, we propose to decompose the score of a projective dependency tree into the scores of headed spans and design a novel $O(n^3)$ dynamic programming algorithm for global training and exact inference, which is on par with the Eisner algorithm (Eisner, 1996) in time complexity for projective dependency parsing. We make a departure from existing graph-based methods since we do not model dependency arcs directly. Instead, the dependency arcs are *induced* from the collection of headed spans (section 3). Compared with first-order graph-based methods, our method can utilize more subtree information since a headed span contains all children (if any) of the corresponding headword (and all words within the subtree). Compared with most of transition-based methods, our method allows global training and exact inference and does not suffer from error propagation or exposure bias.

Our contributions can be summarized as follows:

- We treat a projective dependency tree as a collection of headed spans, providing a new perspective of projective dependency parsing.
- We design a novel $O(n^3)$ dynamic programming algorithm to enable global training and exact inference for our proposed model.
- We have obtained the state-of-the-art or competitive results on PTB, CTB, and UD v2.2, showing the effectiveness of our proposed method.

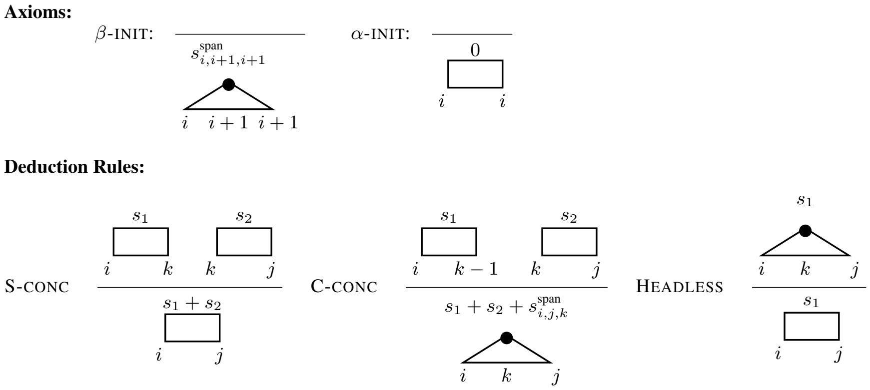

Figure 2: Deduction rules for our proposed parsing algorithm. All deduction items are annotated with their scores.

2 Parsing

We adopt the two-stage parsing strategy, i.e., we first predict an unlabeled tree and then predict the dependency labels. Given a sentence $x_1, ..., x_n$, its unlabeled projective dependency parse tree y can be regarded as a collection of headed spans (l_i, r_i, x_i) where $1 \leq i \leq n$. For each word x_i, we can find exactly one headed span (l_i, r_i, i) (where l_i and r_i are the left and right span boundaries) given parse tree y, so there are totally n headed spans in y as we can see in Figure 1. We can use a simple post-order traversal algorithm to obtain all headed spans in $O(n)$ time. We then define the score of y as:

$$s(y) = \sum_{i=1,...,n} s^{\text{span}}_{l_i,r_i,i}$$

and we show how to compute them using neural networks in the next section.

Our parsing algorithm is based on the following key observations:

- For a given parent word x_k, if it has any children to the left (right), then all headed spans of its children in this direction should be consecutive and form a larger span, which we refer to as the left (right) child span. The left (right) boundary of the headed span of x_k is the left (right) boundary of the leftmost (rightmost) child span, or $k-1$ (k) if x_k has no child to the left (right).
- If a parent word x_k has children in both directions, then its left span and right span are separated by the single word span $(k-1, k)$.

Based on these observations, we design the following parsing items: (1) $\alpha_{i,j}$: the accumulated score of span (i, j) serving as a left or right child span. (2) $\beta_{i,j,k}$: the accumulated score of the headed span (i, j, k). We use the parsing-as-deduction framework (Pereira and Warren, 1983) to describe our algorithm in Fig. 2. We draw $\alpha_{i,j}$ as rectangles and $\beta_{i,j,k}$ as triangles. The rule S-CONC is used to concatenate two consecutive child spans into a single child span; C-CONC is used to concatenate left and right child span $(i, k-1)$ and (k, j) along with the root word-span $(k-1, k)$ to form a headed span (i, j, k); HEADLESS is used to obtain a headless child span from a headed span. Fig. 2 corresponds to the following recursive formulas:

$$\beta_{i,i+1,i+1} = s^{\text{span}}_{i,i+1,i+1} \tag{1}$$

$$\alpha_{i,i} = 0 \tag{2}$$

$$\beta_{i,j,k} = \alpha_{i,k-1} + \alpha_{k,j} + s^{\text{span}}_{i,j,k} \tag{3}$$

$$\alpha_{i,j} = \max(\max_{i<k<j}(\alpha_{i,k} + \alpha_{k,j}), \max_{i<h\leq j}(\beta_{i,j,h})) \tag{4}$$

We set $\alpha_{i,i} = 0$ for the convenience of calculating $\beta_{i,j,k}$ when x_k does not have children on either side. In Eq. 4, we can see that the child span comes from either multiple smaller consecutive child spans (i.e., $\max_{i<k<j}(\alpha(i,k) + \alpha(k,j)))$ or a single headed span (i.e., $\max_{i<h\leq j}(\beta(i,j,h))))$. We also maintain backpointers based on these equations (i.e., maintain all arg max) for parsing.

A key point of our parsing algorithm is that, during backtracking, we add arcs emanated from the headword of a large headed span to **every** headword of (zero or more) smaller headed spans within the left/right child span, so that we can induce a dependency tree. Finding all smaller headed spans within left and right child spans requires finding the best segmentation, which is similar to the inference procedure of the semi-Markov CRF model

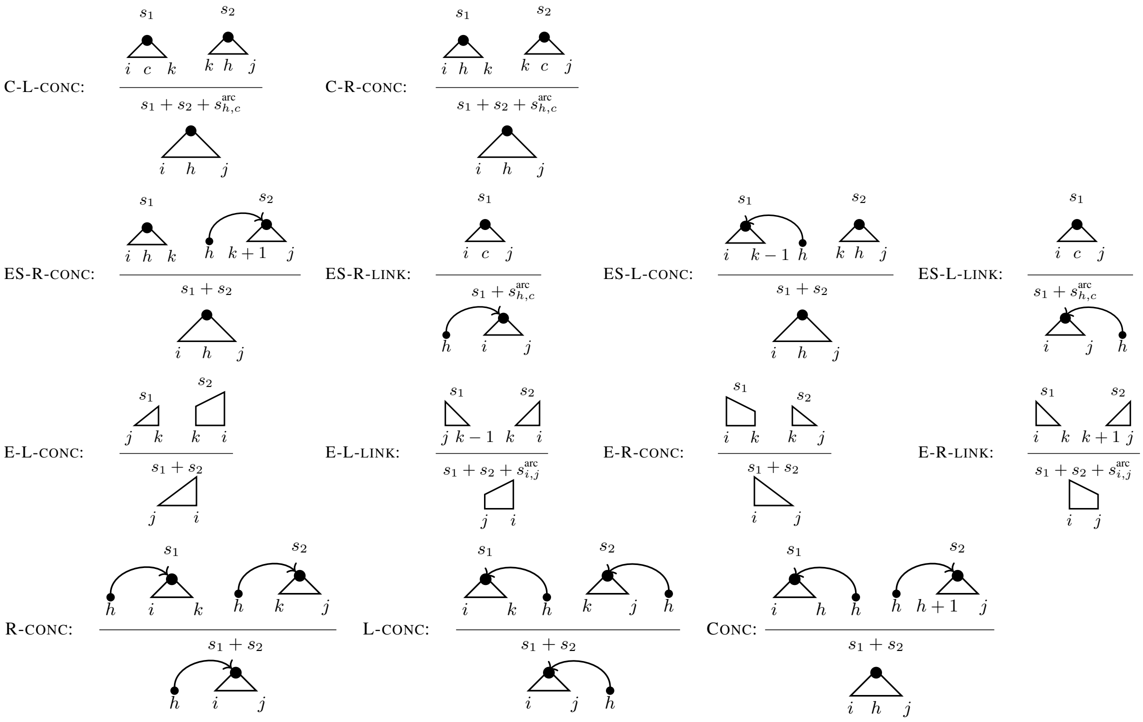

Figure 3: Deductive rules of the parsing algorithms of Collins (1996) (the first line), Eisner and Satta (1999) (the second line), Eisner (1997) (the third line). The last line is the resulting deduction rules after applying head-splitting on ES-L-CONC and ES-R-CONC. All deduction items are annotated with their scores. We only consider the pure dependency versions of these algorithms. We omit axiom items for simplicity.

(Sarawagi and Cohen, 2004). We provide the pseudocode of our parsing algorithm in Appd. A.

Parsing complexity. From Eq. 1 to 4, we can see that at most three variables (i.e., i, j, k) are required to iterate over and therefore the total parsing time complexity is $O(n^3)$.

Spurious ambiguity. Note that different order of concatenation of child spans can result in the same parse, although this does not affect finding the optimal parse.

Comparison with previous parsing algorithms. We compare our algorithm with three classical parsing algorithms (Collins, 1996; Eisner and Satta, 1999; Eisner, 1997) in order to help readers better understand our algorithm. We only consider their pure dependency versions[3] for the convenience of discussion. Fig. 2 shows the deductive rules of the three algorithms.

Collins (1996) adapt the CYK algorithm by maintaining head positions for both sides, thereby increasing the parsing complexity from $O(n^3)$ to $O(n^5)$. Their parsing items are identified by two endpoints and a head position, which is similar to our concept of headed spans superficially. However, in their algorithm, there could be multiple spans sharing the same head position within a single parse. For instance, (i, j) and (k, j) share the same head position h in C-L-CONC. In contrast, spans cannot share a head position in a single parse under our definition, because there is exactly one headed span for each word. Besides, the concatenation order of subtrees differs.

Eisner and Satta (1999) note that the linking of heads and the concatenation of subtrees can be separated (e.g., C-R-CONC can be decomposed into two rules, ES-R-CONC and ES-R-LINK) so that the parsing complexity can be reduced to $O(n^4)$. This strategy is also known as the hook trick, which reduces subtrees to headless spans (e.g., (i, c, j) to (i, j) in ES-L-LINK and ES-R-LINK).

Eisner (1997) uses the head-splitting trick to decrease parsing complexity to $O(n^3)$. The key idea is to split each subtree into a left and a right fragment, so that the head is always placed at one of the two boundaries of a fragment instead of an

---

[3] The parsing algorithms of Collins (1996) and Eisner and Satta (1999) are defined with (lexicalized) context-free grammars. Gómez-Rodríguez et al. (2008, 2011) provide their pure dependency versions, which amounts to considering arc scores only.

internal position, thereby eliminating the need of maintaining the head positions.

Our algorithm adopts a combination of the hook trick and the head-splitting trick. Starting from the rules of Eisner and Satta (1999) that apply the hook trick, we can rewrite ES-L-CONC, ES-R-CONC as L-CONC, R-CONC and CONC. It is easy to verify the equivalence of the rules before and after the rewrite[4]. The key difference is in the concatenation order of subtrees. We concatenate all subtrees to the left/right of the new head first, which can be viewed as adopting the head-splitting trick. Then, note that the position of the head is uniquely determined by the two concatenations of subtrees, and that our model does not consider s^{arc}. Consequently, we have no need to maintain head position h in L-CONC and R-CONC and can merge these two rules to S-CONC of fig. 2. Accordingly, CONC can be modified to C-CONC of fig. 2. Eliminating bookkeeping of h is how we can obtain better parsing complexity than Eisner and Satta (1999). Finally, we can incorporate span score $s^{\text{span}}_{i,j,h}$ into C-CONC.

3 Model

3.1 Neural encoding and scoring

We add <bos> (beginning of sentence) at x_0 and <eos> (end of sentence) at x_{n+1}. In the embedding layer, we apply mean-pooling to the last layer of BERT (Devlin et al., 2019) (i.e., taking the mean value of all subword embeddings) to generate dense word-level representation e_i for each token x_i [5]. Then we feed $e_0, ..., e_{n+1}$ into a 3-layer bidirectional LSTM (BiLSTM) to get $c_0, ..., c_{n+1}$, where $c_i = [f_i; b_i]$ and f_i and b_i are the forward and backward hidden states of the last BiLSTM layer at position i respectively. We then use the fencepost representation, which is commonly used in constituency parsing (Cross and Huang, 2016; Stern et al., 2017), to encode span (i, j) as $e_{i,j}$:

$$
\begin{aligned}
h_k &= [f_k, b_{k+1}] \\
e_{i,j} &= h_j - h_i
\end{aligned}
$$

After obtaining the word and span representations, we use deep biaffine function (Dozat and Manning, 2017) to score headed spans:

$$
\begin{aligned}
c'_k &= \text{MLP}_{\text{word}}(c_k) \\
e'_{i,j} &= \text{MLP}_{\text{span}}(e_{i,j}) \\
s^{\text{span}}_{i,j,k} &= \left[c'_k; 1\right]^\top W^{\text{span}} \left[e'_{i,j}; 1\right]
\end{aligned}
$$

where MLP_{word} and MLP_{span} are multi-layer perceptrons (MLPs) that project word and span representations into d-dimensional spaces respectively; $W^{\text{span}} \in \mathcal{R}^{(d+1)\times(d+1)}$.

Similarly, we use deep biaffine functions to score the labels of dependency arcs for a given gold or predicted tree [6]:

$$
\begin{aligned}
c'_i &= \text{MLP}_{\text{parent}}(c_i) \\
c'_j &= \text{MLP}_{\text{child}}(c_j) \\
s^{\text{label}}_{i,j,r} &= \left[c'_i; 1\right]^\top W^{\text{label}}_r \left[c'_j; 1\right]
\end{aligned}
$$

where $\text{MLP}_{\text{parent}}$ and $\text{MLP}_{\text{child}}$ are MLPs that map word representations into d'-dimensional spaces; $W^{\text{label}}_r \in \mathcal{R}^{(d'+1)\times(d'+1)}$ for each relation type $r \in R$ in which R is the set of all relation types.

3.2 Training loss

Following previous work, we decompose the training loss into the unlabeled parse loss and arc label loss:

$$L = L_{\text{parse}} + L_{\text{label}}$$

For L_{parse}, we can either design a local span-selection loss:

$$L^{\text{local}}_{\text{parse}} = \sum_{(i,j,k)\in y} -\log \frac{\exp(s^{\text{span}}_{i,j,k})}{\sum\limits_{0\le p\le k<q\le n} \exp(s^{\text{span}}_{p,q,k})}$$

which is akin to the head-selection loss (Dozat and Manning, 2017), or use global structural loss. Experimentally, we find that the max-margin loss (Taskar et al., 2004) (also known as structured SVM) performs best. The max-margin loss aims to maximize the margin between the score of the gold tree y and the incorrect tree y' of the highest score:

$$L_{\text{parse}} = \max(0, \max_{y'\neq y}(s(y') + \Delta(y', y) - s(y)) \tag{5}$$

---

[4] Note that this only holds for the pure dependency version, since otherwise we cannot track some intermediate constituent spans after changing the concatenation order of subtrees.

[5] For some datasets (e.g., Chinese Treebank), we concatenate the POS tag embedding with the BERT embedding as e_i.

[6] In our preliminary experiments, we find that directly calculating the scores based on parent-child word representations leads to a slightly better result (< 0.1 LAS) than those based on span representations. A possible reason is that, since LAS is arc-factorized, even if we predict a correct parent-child pair, we can predict the wrong headed spans for the parent or child or both, thereby negatively affecting the labeling scores and resulting in worse LAS. Therefore, in our work we use arc-based label scores to suit the LAS metric.

where Δ measures the difference between the incorrect tree and gold tree. Here we let Δ to be the Hamming distance (i.e., the total number of mismatches of headed spans). We can perform cost-augmented inference (Taskar et al., 2005) to compute Eq. 5.

Finally, we use cross entropy for L_{label}:

$$L_{\text{label}} = \sum_{(x_i \rightarrow x_j, r) \in y} - \log \frac{\exp(s^{\text{label}}_{i,j,r})}{\sum_{r' \in R} \exp(s^{\text{label}}_{i,j,r'})}$$

where $(x_i \rightarrow x_j, r) \in y$ denotes every dependency arc from x_i to x_j with label r in y.

4 Experiments

4.1 Data and setting

Following Wang and Tu (2020), we evaluate our proposed method on Penn Treebank (PTB) 3.0 (Marcus et al., 1993), Chinese Treebank (CTB) 5.1 (Xue et al., 2005) and 12 languages on Universal Dependencies (UD) 2.2: BG-btb, CA-ancora, CS-pdt, DE-gsd, EN-ewt, ES-ancora, FR-gsd, IT-isdt, NL-alpino, NO-rrt, RO-rrt, RU-syntagrus [7]. For PTB, we use the Stanford Dependencies conversion software of version 3.3 to obtain dependency trees. For CTB, we use head-rules from Zhang and Clark (2008) and Penn2Malt[8] to obtain dependency trees. Following Wang and Tu (2020), we use gold POS tags for CTB and UD. We do not use POS tags in PTB. For PTB/CTB, we drop all nonprojective trees during training. For UD, we use MaltParser v1.9.2 [9] to adopt the pseudo-projective transformation (Nivre and Nilsson, 2005) to convert nonprojective trees into projective trees when training, and convert back when evaluating, for both our model and reimplemented baseline model. See Appd. B for implementation details.

4.2 Evaluation methods

We report the unlabeled attachment score (UAS) and labeled attachment score (LAS) averaged from three runs with different random seeds. In each run, we select the model based on the performance on the development set. Following Wang and Tu (2020), we ignore all punctuation marks during evaluation.

Table 2: Labeled Attachment Score (LAS) on twelve languages in UD 2.2. We use ISO 639-1 codes to represent languages. † means our implementation.

	PTB		**CTB**	
	UAS	LAS	UAS	LAS
max-margin loss	97.24	95.73	93.33	92.30
span-selection loss	97.07	95.50	93.28	92.20

Table 3: The influence of training loss function on PTB and CTB.

surpassed many strong baselines, and this may be due to the proper choices of hyperparameters and the use of the max-margin loss (we observe that using the max-margin loss leads to a better performance compared with the original head-selection loss), so Biaffine+MM is a very strong baseline. It also has the same number of parameters as our methods. Our method surpasses Biaffine+MM on both datasets, showing the competitiveness of our headed-span-based method in a fair comparison with first-order graph-based parsing. Our method also obtains the state-of-the-art result among methods that only use dependency training data (HPSG+LAL uses additional constituency trees as training data, so it is not directly comparable with the other systems.).

Table 2 shows the results on UD. We can see that our reimplemented Biaffine+MM has already surpassed MFVI2O, which utilizes higher-order information. Our method outperforms Biaffine+MM by 0.14 LAS on average, validating the effectiveness of our proposed method in the multilingual scenarios.

5 Analysis

5.1 Influence of training loss function

Table 3 shows the influence of the training loss function. We find that the max-margin loss performs better on both datasets: 0.17 UAS improvement on PTB and 0.05 UAS improvement on CTB comparing to the local span-selection loss, which shows the effectiveness of using global loss.

5.2 Error analysis

As previously argued, first-order graph-based methods are insufficient to model complex subtrees, so they may have difficulties in parsing long sentences and handling long-range dependencies. To verify this, we follow (McDonald and Nivre, 2011) to plot UAS as a function of the sentence length and plot F1 scores as functions of the distance to root and dependency length on the CTB test set. We additionally plot the F1 score of the predicted headed spans against the gold headed spans with different span lengths.

From Figure 4a, we can see that Biaffine+MM has a better UAS score on short sentences (of length <=20), while for long sentences (of length >=30), our headed span-based method has a higher performance, which validates our conjecture.

Figure 4b shows the F1 score for arcs of varying distances to root. Our model is better at predicting arcs of almost all distances to root in the dependency tree, which reveals our model's superior ability to predict complex subtrees.

Figure 4c shows the F1 score for arcs of varying lengths. Both Biaffine+MM and our model have a very similar performance in predicting arcs of distance < 7, while our model is better at predicting arcs of distance >= 7, which validates the ability of our model at capturing long-range dependencies.

Figure 4d shows the F1 score for headed spans of varying lengths. We can see that when the span length is small (<=10), Biaffine+MM and our model have a very similar performance. However, our model is much better in predicting longer spans (especially for spans of length >30).

5.3 Parsing speed

Inspired by Zhang et al. (2020b) and Rush (2020) who independently propose to batchify the Eisner algorithm using `Pytorch`, we batchify our proposed method so that $O(n^2)$ out of $O(n^3)$ can be computed in parallel, which greatly accelerates parsing. We achieve a similar parsing speed of our method to the fast implementation of the Eisner algorithm by Zhang et al. (2020b): it parses 273 sentences per second, using BERT as the encoder under a single TITAN RTX GPU.

6 Related work

Dependency parsing with more complex subtree information. There has always been an interest to incorporate more complex subtree information into graph-based and transition-based methods since their invention. Before the deep learning era, it was difficult to incorporate sufficient contextual information in first-order graph-based parsers. To mitigate this, researchers develop higher-order dependency parsers to capture more contextual information (McDonald and Pereira, 2006; Carreras, 2007; Koo and Collins, 2010; Ma and Zhao, 2012). However, incorporating more complex factors worsens inference time complexity. For example, exact inference for third-order projective dependency parsing has a $O(n^4)$ time complexity and exact inference for higher-order non-projective dependency parsing is NP-hard (McDonald and Pereira, 2006). To decrease inference complexity, researchers use approximate parsing methods. Smith and Eisner (2008) use belief propagation (BP) framework for approximate inference to trade accuracy for efficiency. They show that third-order parsing can be done in $O(n^3)$ time using BP. Gormley et al. (2015) unroll the BP process and use gradient descent to train their parser in an end-to-end manner. Wang and Tu (2020) extend their work by using neural scoring functions to score factors. For higher-order non-projective parsing, researchers resort to dual decomposition algorithm (e.g., AD^3) for decoding (Martins et al., 2011, 2013). They observe that the approximate decoding algorithm often obtains exact solutions. Fonseca and Martins (2020) combine neural scoring functions and their decoding algorithms for non-projective higher-order parsing. Zheng (2017) proposes a incremental graph-based method to utilize higher-order information without hurting the advantage of global inference. Ji et al. (2019) use a graph attention network to incorporate higher-order information into the Biaffine Parser. Zhang et al. (2020b) enhance the Biaffine Parser by using a deep triaffine function to score sibling factors. Mohammadshahi and Henderson (2021) propose an iterative refinement network that injects the predicted soft trees from the previous iteration to the self-attention layers to predict the soft trees of the next iteration, so that information of the whole tree is considered in parsing. As for transition-based methods, Ma et al. (2018); Liu et al. (2019); Fernández-González and Gómez-Rodríguez (2021) incorporate sibling and grandparent information into transition-based parsing with Pointer Networks.

The hook trick and the head-splitting trick. These two tricks have been used in the parsing literature to accelerate parsing. Eisner and Satta (1999, 2000) use the hook trick to decrease the parsing complexity of lexicalized PCFGs and Tree Adjoining Grammars. Huang et al. (2005, 2009) adapt the hook trick to accelerate machine translation decoding. The parsing algorithms of Corro (2020) and Xin et al. (2021) can be viewed as adapting the hook trick to accelerate discontinuous and continuous constituency parsing, respectively. Eisner (1997); Satta and Kuhlmann (2013) use the head-splitting trick to accelerate projective and nonprojective dependency parsing.

Span-based constituency parsing. Span-based parsing is originally proposed in continuous constituency parsing (Stern et al., 2017; Kitaev and Klein, 2018; Zhang et al., 2020c; Xin et al., 2021). Span-based constituency parsers decompose the score of a constituency tree into the scores of its constituents. Recovering the highest-scoring tree can be done via the exact CYK algorithm or greedy top-down approximate inference algorithm (Stern et al., 2017). Kitaev and Klein (2018) propose a self-attentive network to improve the parsing accuracy. They separate content and positional attentions and show the improvement. Zhang et al. (2020c) use a two-stage bracketing-then-labeling framework and replace the max-margin loss with the TreeCRF loss (Finkel et al., 2008). Xin et al. (2021) recently propose a recursive semi-Markov model, incorporating sibling factor scores into the score of a tree to explicitly model n-ary branching structures. Corro (2020) adapts span-based parsing to discontinuous constituency parsing and obtains the state-of-the-art result.

7 Conclusion

In this work, we have presented a headed-span-based method for projective dependency parsing. Our proposed method can utilize more subtree information and meanwhile enjoy global training and exact inference. Experiments show the competitive performance of our method in multiple datasets. In addition to its empirical competitiveness, we believe our work provides a novel perspective of projective dependency parsing and could lay the foundation for further algorithmic advancements in the future.

A Parsing algorithm

The parsing algorithm first computes all the chart items defined above and then recovers the parse tree from top down. For a given headed span, it finds the best segmentation of left child spans and right child spans, and then adds dependency arcs from the headword of the given headed span and the headword of each child span. Finding the best segmentation is similar to the inference procedure of the semi-Markov CRF model (Sarawagi and Cohen, 2004). Then we apply the same procedure to each child headed span (within the best segmentation) recursively. We also maintain the following backtrack points in order to recover the predicted projective tree:

$$B_{i,j} = \begin{cases} 1, & \alpha_{i,j} = \max_{i<h\leq j}(\beta_{i,j,h}) \\ 0, & \alpha_{i,j} = \max_{i<k<j}(\alpha_{i,k} + \alpha_{k,j}) \end{cases}$$

$$C_{i,j} = \arg\max_{i<k<j}(\alpha_{i,k} + \alpha_{k,j})$$

$$H_{i,j} = \arg\max_{i<h\leq j}(\beta_{i,j,h})$$

The parsing algorithm is formalized in Alg.1.

B Implementation details

We use "bert-large-cased" for PTB, "bert-base-chinese" for CTB, and "bert-multilingual-cased" for UD, so the dimension of the input BERT embedding is 1024, 768, and 768 respectively. The dimension of POS tag embedding is set to 100 for CTB and UD. The hidden size of BiLSTM is set to 1000. The hidden size of biaffine functions is set

Algorithm 1 Inference algorithm for headed span-based projective dependency parsing

```
Require: Input sentence of length $n$
  Calculate all $\alpha, \beta, B, C, H$.
  arcs ← {(ROOT → $H_{0,n}$)}
  function FINDARC($i, j$)
      if $i + 1 = j$ then
          return {j}
      else if $B_{i,j} = 1$ then
          $h \leftarrow H_{i,j}$
          if i+1 < h < j then
              $L \leftarrow$ FINDARC($i, h - 1$)
              $R \leftarrow$ FINDARC($h, j$)
              Children ← $L \cup R$
          else if h = j then
              Children ← FINDARC($i, j - 1$)
          else
              Children ← FINDARC($i + 1, j$)
          end if
          for c in Children do
              arcs ← arcs ∪ ($h \rightarrow c$)
          end for
          return {h}
      else
          $c \leftarrow C_{i,j}$
          $L \leftarrow$ FINDARC($i, c$)
          $R \leftarrow$ FINDARC($c, j$)
          return $L \cup R$
      end if
  end function
  FINDARC($0, n$)
  return arcs
```

to 600 for scoring spans and arcs (used in our reimplemented Biaffine Parser), 300 for scoring labels. We add a dropout layer after the embedding layer, LSTM layers, and MLP layers. The dropout rate is set to 0.33. We use Adam (Kingma and Ba, 2015) as the optimizer with $\beta_1 = 0.9, \beta_2 = 0.9$ to train our model for 10 epochs. The maximal learning rate is $lr = 5e - 5$ for BERT and $lr = 25e - 5$ for other components. We linearly warmup the learning rate to the maximal value for the first epoch and gradually decay it to zero for the rest of the epochs. The value of gradient clipping is set to 5. We batch sentences of similar lengths to better utilize GPUs. The token number is 4000 for each batch, i.e., the sum of lengths of sentences is 4000.

Decoding Part-of-Speech from Human EEG Signals

Abstract

This work explores techniques to predict Part-of-Speech (PoS) tags from neural signals measured at millisecond resolution with electroencephalography (EEG) during text reading. We show that information about word length, frequency and word class is encoded by the brain at different post-stimulus latencies. We then demonstrate that pre-training on averaged EEG data and data augmentation techniques boost PoS single-trial EEG decoding accuracy for Transformers (but not linear SVMs). Applying optimised temporally-resolved decoding techniques we show that Transformers outperform linear SVMs on PoS tagging of unigram and bigram data more strongly when information requires integration across longer time windows.

1 Introduction

Electro-/Magnetoencephalography (EEG/MEG), which measures neural activity at millisecond resolution, is a key neuroscientific method to assess how neural representations unfold dynamically in language processing. Early event related potential (ERP) studies that rely on averaging EEG activity across multiple trials have shown that EEG signal magnitude and topography depend on word length, frequency and open vs. closed class. Word length effects arose in EEG at about 150 ms, frequency effects at 200 ms and word class effects from 400-700 ms (Osterhout et al., 1997; Brown et al., 1999; Neville et al., 1992; Münte et al., 1998; Segalowitz and Lane, 2000; Münte et al., 2001; Dufau et al., 2015). Recent studies were able to predict these and other (e.g. semantic) aspects based on single trial multi-channel EEG/MEG activity (Ling et al., 2019; Chan et al., 2011; King et al., 2020). Importantly, the aim of cognitive neuroscience studies is to dissociate when (i.e. latency) and where (i.e. brain region) specific linguistic information is explicitly encoded in neural activity. Neuroscience studies therefore typically use linear decoders and try to disentangle neural activity for linguistic and non-linguistic dimensions that covary in natural language statistics (e.g. word class vs. length).

By contrast, engineering applications mainly aim to maximise performance accuracy, utilising all available information and more powerful non-linear classifiers. Intriguingly, recent studies have shown that adding human eye tracking data (Barrett et al., 2016) or morphosyntactic information extracted from human functional magnetic resonance imaging (fMRI) signals during sentence reading, can substantially improve PoS induction (Bingel et al., 2016). Yet, morphosynactic information obtained from fMRI is limited, because fMRI measures only the slow changes in blood oxygenation, peaking 5-6 s after stimulus onset, rather than the rapid neural activity during language processing.

Contributions. This interdisciplinary paper decodes PoS tags from EEG signals with linear SVMs and Transformers, pursuing several aims relevant for neuroscience and/or engineering.

Neuroscience-focused Section 3 uses linear SVMs to define the distinct neural representations of word length, frequency and class based on a new EEG data set, in which a single subject reads an extensive syntactically annotated corpus. To dissociate these linguistic and non-linguistic aspects, typically correlated in natural language statistics, Section 3 matched the stimulus distributions for each classification task with respect to the confounding dimensions of no interest. Consistent with previous reports, we show that word length, frequency and class can be decoded at different post-stimulus latencies based on single trial and trial-averaged data. This replication part serves to validate the new EEG data set.

Methods-focused Section 4 moves beyond open

vs. closed word class decoding that were the focus of previous MEG/EEG studies and decodes 6 PoS tags from EEG activity with linear SVMs and Transformers. We show that pretraining on trial-averaged data with subsequent fine-tuning on single-trial data, alongside data augmentation, boosts PoS decoding accuracy from single-trial EEG data selectively for Transformers (but not for linear SVMs).

Engineering-focused Section 5 finally uses linear SVMs and Transformers together with pretraining and augmentation techniques from Section 4 to assess how PoS information about unigrams and bigrams becomes progressively available in EEG activity across post-stimulus time. Comparing EEG decoding from sliding and incremental time windows suggests that Transformers outperform linear SVMs particularly when information needs being integrated across longer time windows. Our results raise the possibility of combining PoS-tagging based on EEG decoding with corpora and dependency tree annotation to obtain more reliable morphosyntactic information for low-resource languages.

2 General Methods

Our experiments used a new corpus annotated with EEG data, previously acquired at the University of Birmingham following ethical approval and participant's informed consent. The EEG annotated corpus is available[1] under a public license (CC BY-SA 4.0).

Data set. The stimulus set includes 4,479 sentences (74,953 tokens) selected from the English Web Treebank (Bies et al., 2012), covering the genres *weblogs, newsgroups, reviews and Yahoo Answers*. The mean sentence length is 16.7 words (standard deviation: 12.23). 75 sessions of EEG data are included over 20 days, each lasting 20-25 minutes, from a single subject who read approximately five and a half iterations of the stimulus set (i.e. 24,323 sentences and 404,205 tokens in total, thereby substantially exceeding current freely accessible data sets, e.g. (Bhattasali et al., 2020). Three sessions were excluded because of data corruption.

The EEG data for separate text passages were divided into training, dev and test sets to avoid any temporal overlap. Further, dev and test sets were matched for length of text passages, recording dates and sentence position (initial, mid & end). The training set contains 83% of the data (19,156 sentences; 317,753 tokens), dev set 8.5% (2,704 sentences; 45,822 tokens) and test set 8.5% (2,463 sentences; 40,630 tokens).

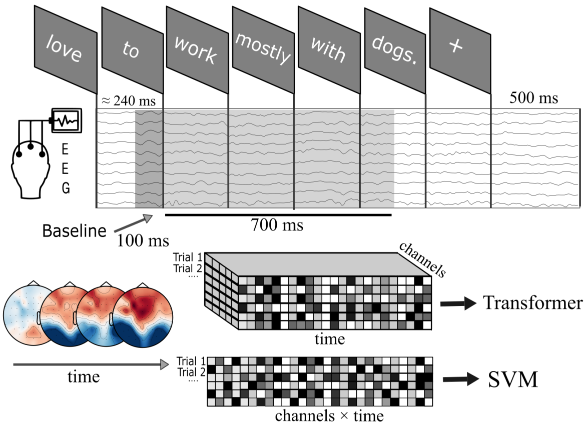

Figure 1: Example trial and EEG recording. Sentence words were presented on average approximately every 240 ms. EEG signals were extracted from -100 to 700 ms relative to word onset.

2.1 Experimental paradigm

In a Rapid Serial Visual Presentation (RSVP) paradigm, sentences were presented one word at a time, on average every ≈ 240 ms, in a white monospace font on a grey background approximately in the centre of the screen, at the optimal viewing position (Rayner et al., 2016). Each word subtended a horizontal angle 0.76° to the left and 11.81° to the right from the centre. Sentences were separated by 500 ms of a white central fixation cross (see Figure 1). On approximately 20% of the sentences in each session, the participant was prompted to verbalise the previous sentence back to the experimenter. An accuracy score of 93% across all sessions confirmed that the participant successfully attended the sentences. Stimuli were presented using PsychoPy (Peirce et al., 2019) on an LCD monitor with a resolution of 1920x1080 pixels and 60 Hz refresh rate. The subject's head was stabilised with a chin-rest.

2.2 EEG Data Acquisition and Preprocessing

Continuous EEG signals were recorded in 'reference-free' mode at a sampling rate of 1 kHz via BrainVision's PyCorder software using 64 Ag/AgCl active actiCAP slim electrodes arranged in a 10–20 layout (ActiCAP, Brain Products GmbH,

Gilching, Germany). Channel impedances were kept below 15 kΩ.

Data were preprocessed using MNE-Python (Gramfort et al., 2013). Individual EEG sessions were band-pass filtered between 1-40 Hz, down-sampled to 250 Hz and re-referenced to average reference. Noisy channels were determined based on visual inspection and interpolated. Non-neuronal components (e.g. ocular, muscular, electrical) were removed via Independent Component Analysis (ICA) individually for each recording session (an average of 4 components were removed per EEG session).

EEG signals were extracted from -100 to 700 ms relative to word onset. For baseline correction, we subtracted the channel-wise mean from -100 ms to 0 ms from the evoked post-stimulus EEG response ([0 700] ms separately for each word; see Figure 1). EEG data were spatially multivariate noise normalised using the noise covariance matrix estimated separately for each target class (Guggenmos et al., 2018). Each EEG trial was annotated with the gold part of speech tags of the current and subsequent words, their word lengths, and Zipf-logarithmic frequency scores from the Python package *WordFreq* (Speer et al., 2018).

2.3 Models and EEG decoding

The decoding analyses used linear support vector machines (SVM) (Chang and Lin, 2011) and Transformers, which can capture complex interactions of EEG data across time points. All classifiers were trained on the EEG training data, assessed on the dev set and scored on the independent test set.

Table 2: Hyperparameters of the Transformer model

Hyperparameters and early stopping were selected based on the dev set. We assessed linear SVMs and Transformers on the dev set using 10 different random seed points. We show mean classification accuracy with 68% confidence intervals (CI) over those 10 replications on the dev (Table 4, Figure 3) resp. test set (Figure 2, 4, 5). We compute statistics on test set classification responses from the model that scored the highest on the dev set (e.g. binomial or Wilcoxon signed rank tests).

For linear SVM, we used an online learning implementation of SCIKIT-LEARN (Pedregosa et al., 2011; Zhang, 2004), based on LIBSVM (Chang and Lin, 2011), with hinge loss and Stochastic Gradient Descent (SGD) optimiser. Hyperparameters were set to default except for the SGD regularisation parameter that was increased to $\alpha = 0.75$, which provided better classification accuracy on the dev set. The parameter α is inversely proportional to the C parameter in the standard SVM implementation. The online implementation also allowed us to select the best model using early stopping. The SVM was provided with EEG activity vectors as inputs, i.e. 1 x (EEG channels $\times$ time points).

For the Transformer (Vaswani et al., 2017), we conducted a model architecture and hyperparameter search (layers, learning rate, MLP dimensions, dropout rate, Encoder vs. Encoder-Decoder) on the dev set. The selected model was composed of four encoder-blocks and a final dense layer that projects the output of the last encoder-block onto the PoS tags via a softmax function. We used the Adam optimiser and early stopping. The implementation is based on the WMT example[2] of Google's novel ML frameworks *Flax/Jax*. Table 2 lists the selected hyperparameters. The Transformer received EEG channels x time points as inputs and provided a classification response for the entire time window.

We performed decoding based on (i) EEG for single-trials (i.e. no averaging), (ii) EEG averaged across three and (iii) ten trials. Averaging EEG

---

[2] https://github.com/google/flax/tree/master/examples/wmt

signals across trials increases the signal to noise ratio of the 'samples' (Grootswagers et al., 2017; Guggenmos et al., 2018; Roy et al., 2019; Tuckute et al., 2019), but ignores true variability across EEG data from different words of the same category (Münte et al., 2001). For training (resp. dev) set we generated the same number of samples for 3 and 10 trial averages as for the single trial test (resp. dev) sets via boostrapping. For the test set, we averaged data without replacement, so that examples can be entered as independent data points in statistical tests. Hence, the number of samples in the test set (but not in the training or dev sets) is smaller for 3 and 10 trial averages than single trials (Table 3).

3 Decoding word class, length, frequency

For comparison with previous research (Osterhout et al., 1997; Münte et al., 2001), we decoded word length, frequency and class with linear SVMs in a temporally-resolved fashion from 0 to 700 ms post-stimulus EEG, recorded during sentence reading.

Data set. We decoded word class from EEG via binary classification between open class words (i.e. `NOUN`, `VERB`, `ADJ`, and `PROPN`) vs. closed class words (i.e. `DET`, `ADP`, `AUX`, `PRON`, `SCONJ` and `CCONJ`). Likewise, for decoding word frequency and length, words were assigned to two classes based on the median values in the data set (i.e. Zipf-frequency > 5.91 = `HIGH` else `LOW`; word length > 4 characters = `LONG`, else `SHORT`). EEG decoding analyses were performed for single-trials, averages across 3 and 10 trials. To dissociate the distinct contributions word length, frequency and class that are highly correlated in natural language statistics, we decoded one variable by controlling for the other two variables. For instance, when decoding open vs. closed class words, we selected a subset of trials such that the joint distributions over the three confounding variables of word frequency (discretised to the nearest 0.25), length (number of characters) and sentence position (i.e. sentence initial, mid, end) were equated for the categories of open and closed class words.

To minimise confounds arising from the preceding word in the sentence, we balanced the test set with respect to the open/closed class status of the previous word. Similarly, we controlled the decoding of word frequency for word length, and the analysis of word length for word frequency, and both analyses for open/closed class and sentence position. Table 3 gives the number of examples for each analysis across training, dev and test sets.

	length	**frequency**	**class**
train	82,424	51,364	45,502
dev	12,402	7,590	5,670
test (single)	10,810	6,590	5,670
test (avg. 3)	3,603	2,196	1,890
test (avg. 10)	1,081	659	567

Table 3: Number of samples across train, dev and test set in the confound-controlled data set.

Methods. To temporally resolve how the brain encodes word length, frequency and class, we trained and tested linear SVMs on EEG signals separately for sliding windows of 64 ms (i.e. 16 time points) that shift in increments of 4 ms (i.e. one time sample). Figure 2 shows the mean accuracy values (averaged across 10 seed points) from the test set (centred on the last bin of each time window (Grootswagers et al., 2017)) with ± 68% CI. The classification responses for the test set from the model that performed best on the dev set were entered into a two-sided binomial test, separately for each time window. Solid lines in Figure 2 above the decoding accuracy time courses indicate time points that were significant at ($p < 0.05$) False Discovery Rate (FDR) corrected for multiple comparisons (Rouam, 2013) across time (i.e. 160 tests).

Results. Figure 2 (top rows of A, B, C) shows butterfly plots for the effects of word length, frequency and class across 64 electrodes. Our linear SVM decoding analysis replicates the temporal cascade of word length, frequency and class effects previously reported for EEG responses averaged across a large number of trials. The word length effect arises early at about 100 ms, previously associated with visual word processing in occipitotemporal cortices (Hauk and Pulvermüller, 2004; Pulvermüller et al., 2009; Schuster et al., 2016). Word frequency influenced neural processing later from 200 ms onwards with a slight left-hemispheric predominance (Griffiths et al., 2012). The word class effect emerged in early and late time windows with the effect at about 550 ms in line with the well-known P600 as an ERP indicator for syntactic processing (Osterhout and Holcomb, 1992; Hagoort et al., 1993; ter Keurs et al., 1999). Word length and frequency effects were stronger than the word class effect; see King et al. (2020). As expected, decoding accuracy increased when EEG signals were averaged across trials. Thus, carefully controlling each comparison of interest (e.g. word class) for the effects of no interest (e.g. word length and

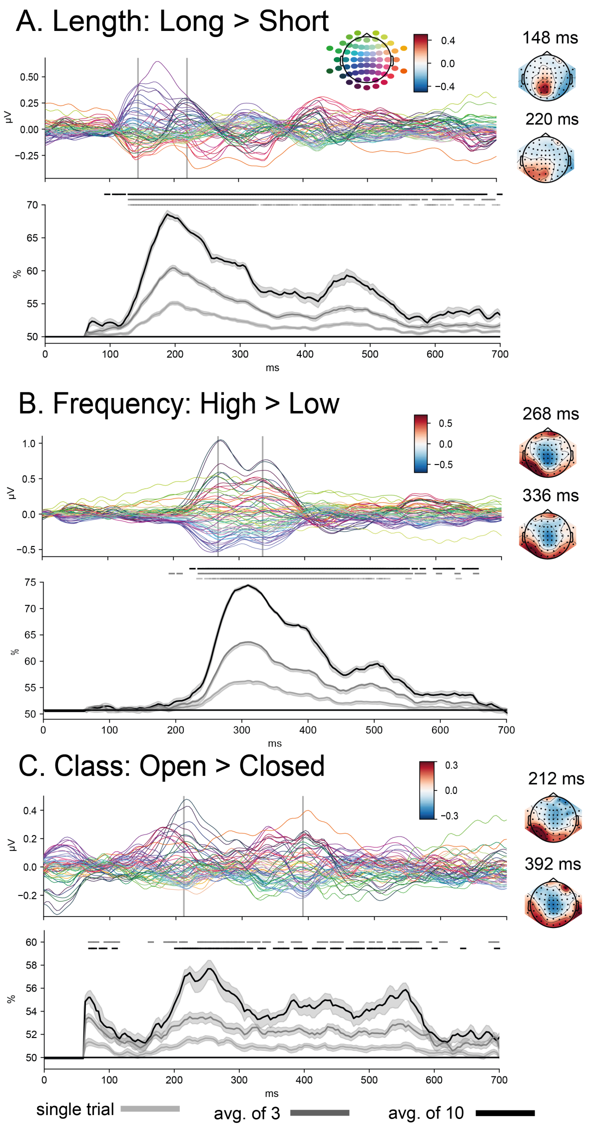

Figure 2: Butterfly plots for difference waves across all 64 channels (top rows, left), topographies (top rows, right) and time courses of decoding accuracy (bottom rows). (A) Length: `LONG` > `SHORT`, (B) Frequency: `HIGH` > `LOW`. (C) Class: `OPEN` > `CLOSED`. Each line in the butterfly plots represents an EEG channel, colour coded by its position. The EEG topographies are shown for the time points as indicated by the vertical lines. The mean decoding accuracy time courses ± 68% CI on the test set are shown for single-trials, averages of 3 and 10 trials. The horizontal lines (above the time courses) indicate the time points with decoding accuracy significantly different from chance at $p < 0.05$ FDR-corrected for multiple comparisons across time. Chance accuracy is denoted with a black line at 50%.

frequency) enabled us to dissociate word length, frequency and class effects, despite their high correlation in natural language, thereby validating our new annotated EEG data set and analysis procedure.

4 Improving training methods for PoS decoding

Moving beyond open/closed word class decoding, we assessed whether multi-class PoS decoding with SVMs and/or Transformers can be improved by (i) data augmentation, i.e. increasing the number of samples in the training set via bootstrapping and re-averaging (only applicable to 3 and 10 trial averages) and (ii) pretraining on trial-averages followed by fine-tuning of the model parameters on single-trial EEG data.

Data set. We focused on decoding of 3 open class (`NOUN`, `VERB`, `PROPN`) and 3 closed class (`ADP`, `DET`, `PRON`) PoS tags. From the word class dataset that was controlled for length and frequency effects (section 3), we selected an equal number of examples per PoS class (i.e. train: 3,470, dev: 335, test: 335, i.e. in total ≈ 20k data points; word frequency of each word > median frequency Zipf value (5.91). The samples for dev and test sets were matched for distribution of word lengths.

4.1 Data Augmentation

Methods. Using this 6-class unigram dataset, we assessed whether data augmentation via bootstrapping and re-averaging increases decoding performance for the 3 and 10 trial averages. We sampled 3 (resp. 10) individual trials with replacement from a particular PoS class and averaged them in 3 (resp. 10) trial averages. We thus trained SVMs and Transformers (over 20 random seeds) on 4 training set sizes: $N_{size} = \{20k, 100k, 250k, 500k\} \times 2$ levels of trial averaging (3 vs. 10) resulting in 8 training sets. The baseline training (resp. dev) set included as many 3 (resp. 10) trial averages as the initial single-trial training (resp. dev) set.

Results. Data augmentation systematically boosted the decoding accuracy of the Transformer but not of the SVM - most likely because of the former's greater model complexity. For both 3 and 10 trial averages the Transformer's decoding accuracy on the dev set increased from a training set size of 20k to 100k, peaking at 250k. It then declined for an even larger training size of 500k - potentially because continued bootstrapping pro-

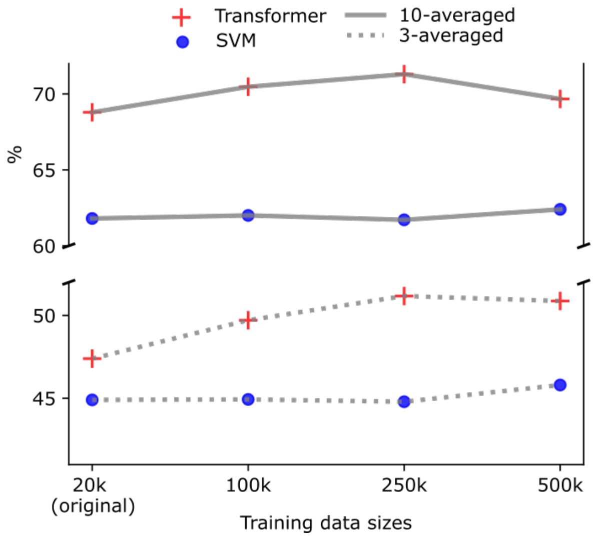

Figure 3: Dev set decoding accuracy (mean across seeds) for SVM (blue) and Transformer (red) separately for 3 and 10 trial averages and four levels of data augmentation: 20k (original), 100k, 250k and 500k. Chance decoding accuracy is 16.66%.

gressively generates dependencies amongst training samples thereby limiting their additional benefit beyond 250k. We formally assessed whether the Transformer that scored best on the dev set obtained better decoding accuracy for 250K than for the original 20k training set (n.b. we performed this statistical test on the test set, because the 3 and 10 trial averages within the dev set were not independent from one another as a result of boostrapping). Indeed, for both 3 and 10 trial averages the Transformer's (but not the SVM's) decoding accuracy was significantly better for 250k than the original 20k training set ($p < 0.01$; Wilcoxon signed-rank test).

4.2 Pretraining

Methods. The ultimate goal is to decode PoS from single-trial EEG data (rather than trial averages). We therefore assessed whether pretraining the SVM and/or Transformer on trial averages with subsequent fine-tuning on single-trial data increases decoding accuracy. Pretraining may be beneficial because trial averages have a greater signal to noise ratio. Specifically, we assessed the impact of pretraining in a 2×2 factorial design manipulating i) pretraining scheme: training in three steps (10-3-1) from 10 trial averages to 3 trial averages to single-trials vs. training in two steps (3-1) from 3 trial averages to single-trials and ii) data augmentation: training only on the original 20k vs. the 250k data set, which obtained highest dev set performance in section 4.1. We trained both SVMs and Transformers on the 2× 2 training conditions using 20 random seeds and report mean accuracy (± 68% CI, across those 20 seeds) in Table 4.

	SVM	Transformer
single-trials	31.93 (±0.62)	37.15 (±0.32)
10-3-1	31.74 (±0.51)	38.5 (±0.28)
10-3-1 (250k)	31.89 (±0.67)	39.17 (±0.33)
3-1	32.03 (±0.52)	37.83 (±0.24)
3-1 (250k)	31.79 (±0.58)	39.41 (±0.41)

Table 4: Single-trial decoding accuracies (%, mean across seeds ± 68% CI) on dev set for the SVM and Transformer: without pretraining, with 10-3-1 pretraining, with 10-3-1 and 250k data augmentation, with 3-1 pretraining, with 3-1 and 250k data augmentation

Results. For the SVM, the 3-1 pretraining without data augmentation resulted in the highest dev set accuracy (32.03%), though accuracy was only slightly better than for direct single-trial training (31.93%). For the Transformer, the 3-1 pretraining scheme with 250k data augmentation obtained the highest single-trial decoding accuracy (39.41%) on the dev set. Indeed, Wilcoxon signed-rank test (Pereira et al., 2009) confirmed that the best dev set Transformer performed significantly better on the test set after 3-1 pretraining than after direct single-trial training ($p < 0.01$).

5 Temporally-resolved PoS decoding

Sections 3 and 4 were driven by the neuroscience goal of dissociating neural representations associated with PoS from confounding factors such as word length or frequency, which are typically correlated with PoS in natural language statistics. To control for these confounds sections 3 and 4 generated data sets, in which e.g. PoS classes were equated with respect to word length. By contrast, Section 5 pursues the engineering goal of maximising PoS decoding accuracy. Here, correlations between word frequency, length and PoS class are no longer considered a confound but a useful source of information. Capitalising on the optimised 3-1 training scheme with 250k data augmentation from Section 4, section 5 will assess whether PoS information about unigrams and bigrams can be decoded from EEG signals (without any confound controls). For both unigrams and bigrams, we will first investigate how PoS information becomes available dynamically across post-stimulus time by training SVMs and Transformers on EEG signals from 64 ms sliding time windows. Second, we will assess how SVMs and Transformers integrate PoS information across post-stimulus time by training them on EEG signals from incremental time windows.

5.1 Unigrams

Data Set. We selected an equal number of examples for the 6 most frequent PoS tags (i.e. `NOUN`, `VERB`, `ADP`, `DET`, `PRON` & `PROPN`) from the data set matched for length of text passage, recording dates and sentence position, but not for word length or frequency. Each PoS class included the following number of samples - train: 28,265 , dev: 2,948, test: 3,183 examples.

Methods.We implemented the 3-1 pretraining with 250k data augmentation (section 4). For the sliding window analysis, we trained and tested SVMs and Transformers on EEG signals from 64 ms windows (i.e. 16 time points) that shifted in increments of 16 ms from 0 ms to 700 ms (i.e. resulting in a sequence of 41 decoding accuracies). For the incremental window analysis, we successively increased the initial [0 16] ms time window (i.e. 4 samples) by 4 additional sampling points resulting in a temporal sequence of 44 decoding accuracies. We computed decoding accuracies (mean across seeds, ± 68% CI) from the test set. Across time windows we compared the decoding accuracies on the test set of the best dev set SVM and Transformer using the Wilcoxon signed rank-test (reported at $p < 0.05$, FDR-corrected for multiple comparisons across time i.e. 41 resp. 44 tests).

Results. In the sliding window analysis, the decoding accuracies of SVMs and Transformers show two prominent peaks at 200 ms and 400 ms suggesting that PoS decoding relies on several aspects of information encoded in the EEG. Based on our confound-controlled analysis (section 3) the first peak reflects word length and frequency information, while the second peak is more closely related to semantic and syntactic aspects of the word. The incremental window analysis showed an accuracy benefit of 4.5% for the Transformer starting in the very first [0 16] ms time window. This difference in performance between the two models further widened, reaching a maximum advantage of 11.6% around 360 ms. Transformers thus benefit from integrating information about word frequency, length and class that arise at different post-stimulus latencies. Moreover, because PoS classes of subsequent words are correlated in natural language, the Transformer may also benefit via self-attention from information about the next word that is presented and progressively encoded in EEG activity about 240 ms after the current (i.e. to be decoded) word. Statistical testing confirmed that the Transformer significantly outperformed the SVM for all sliding and incremental windows (Wilcoxon-signed rank test, FDR-corrected at $p < 0.05$).

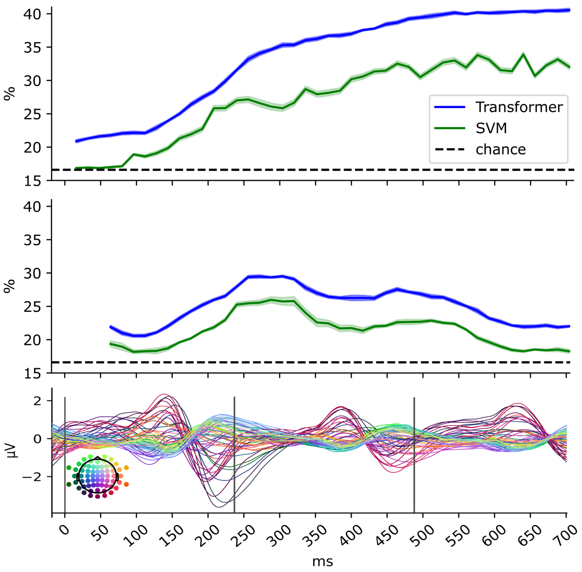

Figure 4: Unigram results: Test set decoding accuracies (mean across seeds ± 68% CI), aligned with last bin of each time window. Top: Incremental window analysis. Middle: Sliding window analysis. Bottom: ERP for `NOUN`, i.e. EEG averaged across all examples from the training set. Vertical lines indicate word onset times. All time windows are significant at $p < 0.05$ FDR-corrected.

5.2 Bigrams

To define the contributions of successive words to EEG PoS decoding in naturalistic text reading, we designed a bigram data set that artificially removes the correlations between PoS classes of subsequent words, though we note that this does not fully remove correlations between specific word tokens.

Data set. We selected 6 bigrams, in which each first word's PoS is combined equally often with two different PoS classes from the second word: `NOUN-PRON`, `NOUN-VERB`, `PRON-NOUN`, `PRON-VERB`, `VERB-NOUN` and `VERB-PRON`. As a result, the PoS class of word 1 is uninformative about the PoS class of word 2 and vice versa. Hence, prior to the presentation of word 2, the maximal possible decoding accuracy for a particular bigram is 50%. Each bigram class included the

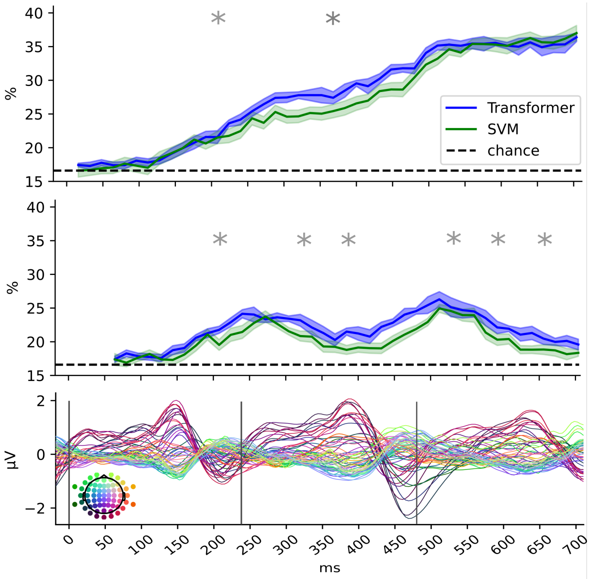

Figure 5: Bigram results: Test set decoding accuracies (mean across seeds ± 68% CI), aligned with last bin of each time window. Top: Incremental window analysis. Middle: Sliding window analysis. Bottom: ERP for VERB-PRON, i.e. EEG averaged across all examples from the training set. Vertical lines indicate word onset times. Asterisks (aligned with end of time window) indicate significance at $p < 0.05$ FDR-corrected.

following number of samples - train: 3,470, dev: 322, test: 349 examples.

Methods for details see unigram analysis.

Results Similar to the unigram results, the sliding window analysis revealed two prominent accuracy peaks at 200 ms and 500 ms. Yet, the 2nd peak was slightly later than in the unigram analysis and it was higher than the first peak only in the bigram, but not the unigram analysis. These differences between unigram and bigram decoding profiles arise, because EEG at 500 ms encodes semantic and syntactic aspects of word 1 and crucial information about word 2 of the bigram. As shown in Figure 5, the Transformer significantly outperformed the SVM in the sliding and incremental window analyses. Yet, in contrast to the unigram results, the Transformer outperformed the SVM in the incremental analysis only for windows 0-208 ms and 0-336 ms. The Transformer's smaller benefit arises mainly because our balanced design radically reduced the number of examples and thereby the Transformer's generalisation ability. It also removed the natural correlations between subsequent words on which the Transformer may have additionally capitalised in the unigram data.

6 Related Work

The confound-controlled analysis dissociated word length, frequency and class effects in EEG. This replication of earlier ERP (Osterhout et al., 1997; Münte et al., 1998) and MEG decoding work (King et al., 2020) validates a new EEG data set for an extensive morphosyntactically gold annotated corpus; c.f. Bhattasali et al. (2020). Transformers successfully decoded 6 PoS tags from single trial EEG with data augmentation and 3-1 pretraining (≈ 40% accuracy), raising the possibility to boost PoS induction with EEG-decoded PoS tags. While we acknowledge that our results are limited to EEG data from a single subject, given the spatial smoothness of EEG scalp topographies, we envision pretraining on EEG obtained from different participants. Further, because human brains generate similar neural signatures for word classes across different languages (c.f. Yudes (2016); Münte et al. (2001); Hagoort et al. (2003)), pretraining PoS-EEG decoders on large morphosyntactically annotated EEG datasets for English followed by fine-tuning on a smaller annotated EEG data set for a low-resource language may enable successful generalisation to EEG obtained from reading non-annotated texts in this low-resource language. PoS-induction jointly based on annotated texts and EEG signals could thus be transformative for corpus generation of low-resource languages.

7 Conclusion

Combining neural signals measured at millisecond resolution with EEG and a linguistically annotated corpus, this work shows - to the best of our knowledge - the first time that unigram and bigram PoS tags can be decoded successfully from single-trial EEG data. Temporally-resolved EEG decoding unraveled how information about linguistic and non-linguistic aspects evolved dynamically across time. Unsurprisingly, Transformers with self-attention mechanisms outperformed SVMs across all experiments. In particular, they benefited from integrating information across time, data augmentation and pretraining methods. Our work paves the way for future applications that incorporate human brain signals in traditional NLP methods.

Abstract

Recent works on *Lottery Ticket Hypothesis* have shown that pre-trained language models (PLMs) contain smaller matching subnetworks (winning tickets) which are capable of reaching accuracy comparable to the original models. However, these tickets are proved to be not robust to adversarial examples, and even worse than their PLM counterparts. To address this problem, we propose a novel method based on learning binary weight masks to identify robust tickets hidden in the original PLMs. Since the loss is not differentiable for the binary mask, we assign the hard concrete distribution to the masks and encourage their sparsity using a smoothing approximation of L_0 regularization. Furthermore, we design an adversarial loss objective to guide the search for robust tickets and ensure that the tickets perform well both in accuracy and robustness. Experimental results show the significant improvement of the proposed method over previous work on adversarial robustness evaluation.

1 Introduction

Large-scale pre-trained language models (PLMs), such as BERT (Devlin et al., 2019), Roberta (Liu et al., 2019) and T5 (Raffel et al., 2019) have achieved great success in the field of natural language processing. As more transformer layers are stacked with larger self-attention blocks, the complexity of PLMs increases rapidly. Due to the over-parametrization of PLMs, some Transformer heads and even layers can be pruned without significant losses in performance (Michel et al., 2019; Kovaleva et al., 2019; Rogers et al., 2020).

The Lottery Ticket Hypothesis suggests an over-parameterized network contains certain subnetworks (i.e., winning tickets) that can match the performance of the original model when trained in isolation (Frankle and Carbin, 2019). Chen et al. (2020); Prasanna et al. (2020) also find these winning tickets exist in PLMs. Chen et al. (2020) prune BERT in an unstructured fashion and obtain winning tickets at sparsity from 40% to 90%. Prasanna et al. (2020) aim at finding structurally sparse tickets for BERT by pruning entire attention heads and MLP. Previous works mainly focused on using winning tickets to reduce model size and speed up training time (Chen et al., 2021), while little work has been done to explore more benefits, such as better adversarial robustness than the original model.

As we all know, PLMs are vulnerable to adversarial examples that are legitimately crafted by imposing imperceptible perturbations on normal examples (Jin et al., 2020; Garg and Ramakrishnan, 2020; Wang et al., 2021). Recent studies have shown that pruned subnetworks of PLMs are even less robust than their PLM counterparts (Xu et al., 2021; Du et al., 2021). Xu et al. (2021) observe that when fine-tuning the pruned model again, the model yields a lower robustness. Du et al. (2021) clarify the above phenomenon further: the compressed models overfit on shortcut samples and thus perform consistently less robust than the uncompressed large model on adversarial test sets.

In this work, our goal is to find robust PLM tickets that, when fine-tuned on downstream tasks, achieve matching test performance but are more robust than the original PLMs. In order to make the topology structure of tickets learnable, we assign binary masks to pre-trained weights to determine which connections need to be removed. To solve discrete optimization problem of binary masks, we assume the masks follow a hard concrete distribution (a soft version of the Bernoulli distribution), which can be solved using Gumbel-Softmax trick (Louizos et al., 2018). We then use an adversarial loss objective to guide the search for robust tickets and an approximate L_O regularization is used to encourage the sparsity

of robust tickets. Robust tickets can be used as a robust substitute of original PLMs to fine-tune downstream tasks. Experimental results show that robust tickets achieve a significant improvement in adversarial robustness on various tasks and maintain a matching accuracy. Our codes are publicly available at *Github*[1].

The main contributions of our work are summarized as follows:

- We demonstrate that PLMs contain robust tickets with matching accuracy but better robustness than the original network.
- We propose a novel and effective technique to find the robust tickets based on learnable binary masks rather than the traditional iterative magnitude-based pruning.
- We provide a new perspective to explain the vulnerability of PLMs on adversarial examples: some weights of PLMs do not contribute to the accuracy but may harm the robustness.

2 Related Work

2.1 Textual Adversarial Attack and Defense

Textual attacks typically generate explicit adversarial examples by replacing the components of sentences with their counterparts and maintaining a high similarity in semantics (Ren et al., 2019) or embedding space (Li et al., 2020). These adversarial attackers can be divided into character-level (Gao et al., 2018), word-level (Ren et al., 2019; Zang et al., 2020; Jin et al., 2020; Li et al., 2020) and multi-level (Li et al., 2018). In response to adversarial attackers, various adversarial defense methods are proposed to improve model robustness. Adversarial training solves a min-max robust optimization and is generally considered as one of the strongest defense methods (Madry et al., 2018; Zhu et al., 2020; Li and Qiu, 2020). Adversarial data augmentation (ADA) has been widely adopted to improve robustness by adding textual adversarial examples during training (Jin et al., 2020; Si et al., 2021). However, ADA is not sufficient to cover the entire perturbed search space, which grows exponentially with the length of the input text. Some regularization methods, such as smoothness-inducing regularization (Jiang et al., 2020) and information bottleneck regularization (Wang et al., 2020), are also beneficial for robustness. Different from the above methods, we dig robust tickets from original BERT, and the subnetworks we find have better robustness after fine-tuning.

2.2 Lottery Ticket Hypothesis

Lottery Ticket Hypothesis (LTH) suggests the existence of certain sparse subnetworks (i.e., winning tickets) at initialization that can achieve almost the same test performance compared to the original model (Frankle and Carbin, 2019). In the field of NLP, previous works find that the winning tickets also exist in Transformers and LSTM (Yu et al., 2020; Renda et al., 2020). Evci et al. (2020) propose a method to optimize the topology of the sparse network during training without sacrificing accuracy relative to existing dense-to-sparse training methods. Chen et al. (2020) find that PLMs such as BERT contain winning tickets with a sparsity of 40% to 90%, and the winning tickets found in the mask language modeling task can universally be transfered to other downstream tasks. Prasanna et al. (2020) find structurally sparse winning tickets for BERT, and they notice that all subnetworks (winning tickets and randomly pruned subnetworks) have comparable performance when fine-tuned on downstream tasks. Chen et al. (2021) propose an efficient BERT training method using Early-bird lottery tickets to reduce the training time and inference time. Some recent studies have tried to dig out more features of winning tickets. Zhang et al. (2021) demonstrate that even in biased models (which focus on spurious correlations) there still exist unbiased winning tickets. Liang et al. (2021) observe that at a certain sparsity, the generalization performance of the winning tickets can not only match but also exceed that of the full model. (Du et al., 2021; Xu et al., 2021) show that the winning tickets that only consider accuracy are over-fitting on easy samples and generalize poorly on adversarial examples. Our work makes the first attempt to find the robust winning tickets for PLMs.

2.3 Robustness in Model Pruning

Learning to identify a subnetwork with high adversarial robustness is widely discussed in the field of computer vision. Post-train pruning approaches require a pre-trained model with adversarial robustness before pruning (Sehwag et al., 2019; Gui et al., 2019). In-train pruning methods integrate the pruning process into the robust learning process, which jointly optimize the model

---

[1] https://github.com/ruizheng20/robust_ticket

parameters and pruning connections (Vemparala et al., 2021; Ye et al., 2019). Sehwag et al. (2020) integrate the robust training objective into the pruning process and remove the connections based on importance scores. In our work, we focus on finding robust tickets hidden in original PLMs rather than pruning subnetworks from a robust model.

3 The Robust Ticket Framework

In this section, we propose a novel pruning method to extract robust tickets of PLMs by learning binary weights masks with an adversarial loss objective. Furthermore, we articulate the Robust Lottery Ticket Hypothesis: the full PLM contains subnetworks (robust tickets) that can achieve better adversarial robustness and comparable accuracy.

3.1 Revisiting Lottery Ticket Hypothesis

Denote $f(\theta)$ as a PLM with parameters θ that has been fine-tuned on a downstream task. A subnetwork of $f(\theta)$ can be denoted as $f(m \odot \theta)$, where m are binary masks with the same dimension as θ and $\odot$ is the Hadamard product operator. LTH suggests that, for a network initialized with θ_0, the Iterative Magnitude Pruning (IMP) can identify a mask m, such that the subnetwork $f(x; m \odot \theta_0)$ can be trained to almost the same performance to the full model $f(\theta_0)$ in a comparable number of iterations. Such a subnetwork $f(x; m \odot \theta_0)$ is called as *winning tickets*, including both the structure mask m and initialization θ_0. IMP iteratively removes the weights with the smallest magnitudes from $m \odot \theta$ until a certain sparsity is reached. However, the magnitude-based pruning is not suitable for robustness-aware techniques (Vemparala et al., 2021; Sehwag et al., 2020).

3.2 Discovering Robust Tickets

Our goal is to learn the sparse subnetwork, however, the training loss is not differentiable for the binary masks. A simple choice is to adopt a straight-through estimator to approximate the derivative (Bengio et al., 2013). Unfortunately, this approach ignores the Heaviside function in the likelihood and results in biased gradients. Thus, we resort to a practical method to learn sparse neural networks (Louizos et al., 2018).

In our method, we assume each mask m_i to be a independent random variable that follows a hard concrete distribution $\mathrm{HardConcrete}(\log \alpha_i, \beta_i)$ with temperature β_i and location α_i (Louizos et al., 2018):

$$\mu_i \sim \mathcal{U}(0,1), \tag{1}$$

$$s_i = \sigma\left(\frac{1}{\beta_i}\left(\log\frac{\mu_i}{1-\mu_i} + \log\alpha_i\right)\right), \tag{2}$$

$$m_i = \min\left(1, \max\left(0, s_i\left(\zeta - \gamma\right) + \gamma\right)\right), \tag{3}$$

where σ denotes the sigmoid function, $\gamma = -0.1$, $\zeta = 1.1$ are constants, and u_i is the sample drawn from uniform distribution $\mathcal{U}(0,1)$. The random variable s_i follows a binary concrete (or Gumbel-Softmax) distribution, which is a smoothing approximation of the discrete Bernoulli distribution (Maddison et al., 2017; Jang et al., 2017). Samples from the binary concrete distribution are identical to samples from a Bernoulli distribution with probability α_i as $\beta_i \to 0$. The location α_i in (2) allows for gradient-based optimization through reparametrization tricks. Using (3), the s_i larger than $\frac{1-\gamma}{\zeta-\gamma}$ is rounded to 1, whereas the value smaller than $\frac{-\gamma}{\zeta-\gamma}$ is rounded to 0. To encourage the sparsity, we penalize the L_0 complexity of masks based on the probability which are non-zero:

$$\mathcal{R}(m) = \frac{1}{|m|}\sum_{i=1}^{|m|}\sigma\left(\log\alpha_i - \beta_i \log\frac{-\gamma}{\zeta}\right). \tag{4}$$

During the inference stage, the mask $\hat{m}_i$ can be estimated through a hard concrete gate:

$$\min\left(1, \max\left(0, \sigma\left(\log\alpha_i\right)\left(\zeta-\gamma\right)+\gamma\right)\right). \tag{5}$$

3.2.1 Adversarial Loss Objective

To find the connections responsible for adversarial robustness, we incorporate the adversarial loss into the mask learning objective:

$$\min_m \underbrace{\mathbb{E}_{(x,y)\sim\mathcal{D}} \max_{\|\delta\|\le\epsilon} \mathcal{L}\left(f(x+\delta; m\odot\theta), y\right)}_{\mathcal{L}_{adv}(m)}, \tag{6}$$

where (x, y) is a data point from dataset $\mathcal{D}$, δ is the perturbation that constrained within the ϵ ball. The inner maximization problem in (6) is to find the worst-case adversarial examples to maximize the classification loss, while the outer minimization problem in (6) aims at optimizing the masks to minimize the loss of adversarial examples, i.e., $\mathcal{L}_{adv}(m)$.

Adversarial attack method, typically with PGD, can be used to solve the inner maximization problem. PGD applies the K-step stochastic gradient descent to search for the perturbation δ (Madry et al., 2018):

$$\delta_{k+1} = \prod_{\|\delta\| \leq \epsilon} \left(\delta_k + \eta \frac{g(\delta_k)}{\|g(\delta_k)\|} \right), \tag{7}$$

where $g(\delta_k) = \nabla_x \mathcal{L}(f(x + \delta_k; m \odot \theta), y)$, δ_k is the perturbation in k-th step and $\prod_{\|\delta\| \leq \epsilon}(\cdot)$ projects the perturbation back onto the Frobenius normalization ball. Then robust training optimizes the network on adversarially perturbed input $x + \delta_K$. Through the above process, we can conveniently obtain a large number of adversarial examples for training.

By integrating the L_0 complexity regularizer into the training process of masks, our adversarial loss objective becomes:

$$\min_m \mathcal{L}_{adv}(m) + \mathcal{R}(m), \tag{8}$$

where λ denotes regularization strength.

3.2.2 Effect of Regularization Strength

The selection of the regularization strength λ decides the quality of robust tickets. Results carried on SST-2 in Fig.1 show that eventually more than 90% of the masks will be very close to 0 or 1, and the L_0 complexity regularizer $\mathcal{R}(m)$ will converge to a fixed value. As λ increases, $\mathcal{R}(m)$ decreases (the sparsity of the subnetwork increases). The training of the adversarial loss objective in (8) is insensitive to the λ, and in all experiments, λ is chosen in the range $[0.1, 1]$. In the Appendix A, we show more details about mask learning process.

3.3 Drawing and Retraining Winning Tickets

After training the masks m, we use the location parameters $\log \alpha$ of masks to extract robust tickets. For the Gumbel-Softmax distribution in (2), α_i is the expectation (confidence) of random variable s_i, i.e, $\mathbb{E}\{s_i\} = \alpha_i$. Thus, we prune the weights whose masks have the smallest expectation. We prune all attention heads and intermediate neurons in an unstructured manner, which empirically has better performance than structured pruning. Unlike the Lottery Ticket Hypothesis that requires iterative magnitude pruning, the proposed method is a one-shot pruning method that can obtain subnetworks of any sparsity. Then we retrain (i.e., fine-tune) the robust tickets $f(m \odot \theta_0)$ on downstream tasks.

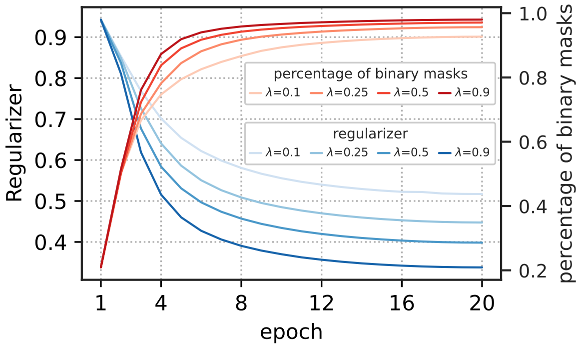

Figure 1: Effect of regularization strength λ on regularizer $\mathcal{R}(m)$, and the percentage of masks that exact 0 and 1.

3.4 Robust Lottery Tickets Hypothesis

In the context of adversarial robustness, we seek winning tickets that balance accuracy and robustness, and then we state and demonstrate Robust Lottery Tickets Hypothesis.

Robust Lottery Tickets Hypothesis: A pre-trained language model, such as BERT, contains some subnetworks (robust tickets) initialized by pre-trained weights, and when these subnetworks are trained in isolation, they can achieve better adversarial robustness and comparable accuracy. In addition, robust tickets retain an important characteristic of traditional lottery tickets —the ability to speed up the training process.

The practical merits of Robust Lottery Ticket Hypothesis: 1) It provides an effective pruning method that can reduce memory constraints during inference time by identifying well-performing smaller networks which can fit in memory. 2) Our proposed robust ticket is more robust than the existing defense methods, so it can be used as a defense method.

4 Experiments

We conduct several experiments to demonstrate the effectiveness of our method. We first compare the proposed method with baseline methods in terms of clean accuracy and robust evaluation. Then, we perform an ablation study to illustrate the role of sparse mask learning and adversarial loss objective in our method. In addition, we try to further flesh out our method with several additional analysis experiments. Following the official BERT implementation (Devlin et al., 2019; Wolf et al., 2020), we use BERT$_{\text{BASE}}$ as our backbone model for all experiments.

4.1 Datasets

We evaluate our method mainly on three text classification datasets: Internet Movie Database (IMDB, Maas et al., 2011) , AG News corpus (AGNEWS, Zhang et al., 2015) and Stanford Sentiment Treebank of binary classification (SST-2, Socher et al., 2013). We also test our method on other types of tasks in GLUE, such as MNLI, QNLI, QQP. The labels of GLUE test sets are not available, so GLUE test sets cannot be used for adversarial attacks. The results of GLUE tasks are tested on the official development set, and we divide 10% training data as the development set.

4.2 Baselines

We compare our **RobustT** (**Robust T**ickets) with recently proposed adversarial defense methods and the standard lottery ticket.

Fine-tune (Devlin et al., 2019): The official BERT implementation on downstream tasks. **FreeLB** (Zhu et al., 2020): An enhanced gradient-based adversarial training method which is not targeted at specific attack methods. **InfoBERT** (Wang et al., 2020): A learning framework for robust model fine-tuning from an information-theoretic perspective. This method claims that it has obtained a better representation of data features. **LTH** (Chen et al., 2020): For a range of downstream tasks, BERT contains winning lottery tickets at 40% to 90% sparsity. **Random**: Subnetworks with the same layer-wise sparsity of the above RobustT, but their structures are randomly pruned from the original BERT.

4.3 Robust Evaluation

Three widely accepted attack methods are used to verify the ability of our proposed method against baselines (Li et al., 2021). **BERT-Attack** (Li et al., 2020) is a method using BERT to generate adversarial text, and thus the generated adversarial examples are fluent and semantically preserved. **TextFooler** (Jin et al., 2020) first identify the important words in the sentences, and then replace them with synonyms that are semantically similar and grammatically correct until the prediction changes. **TextBugger** (Li et al., 2018) is an adversarial attack method that generates misspelled words by using character-level and word-level perturbations.

The evaluation metrics adopted in our experimental analyses are listed as follows: **Clean accuracy (Clean%)** denotes the accuracy on the clean test dataset. **Accuracy under attack (Aua%)** refers to the model's prediction accuracy facing specific adversarial attacks. **Attack success rate (Suc%)** is the ratio of the number of texts successfully perturbed by an attack method to the total number of texts to be attempted. **Number of Queries (#Query)** is the average number of times the attacker queries the model, which means the more the average query number is, the harder the defense model is to be compromised. For a robust method, higher clean accuracy, accuracy under attack, and query times are expected, as well as lower attack success rate.

4.4 Implementation Details

We fine-tune the original BERT using the default settings on downstream tasks. We train 20 epochs to discover the robust tickets from the fine-tuned BERT, and then we retrain the robust tickets using default settings of BERT-base. The K-step PGD requires K forward-backward passes through the network, which is time consuming. Thus, we turn to FreeLB, which accumulates gradients in multiple forward passes and then passing gradients backward once. For our approach, we prune robust tickets in the range of 10% and 90% sparsity and report the best one in terms of robustness in our main experiments. For a fair comparison, the sparsity of LTH is the same as that of robust tickets. All experimental results are the average of 5 trials with different seeds. More implementation details and hyperparameters are provided in the Appendix B. We implement all models in MindSpore.

4.5 Main Results on Robustness Evaluation

Table 1 shows the results of robust tickets and other baselines under adversarial attack. We can observe that: 1) Original BERT and BERT-tickets fail to perform well on adversarial robustness evaluation, and the BERT-tickets even show lower robustness than BERT, indicating that it is difficult for the pruned subnetworks to fight against adversarial attacks when only test accuracy is considered. This result is consistent with the results in (Du et al., 2021; Xu et al., 2021). 2) The proposed robust ticket achieves a significant improvement of robustness over the original BERT and other adversarial defense methods. Robust tickets use a better robust structure to resist adversarial attacks, which is different from the previous methods aimed at solving robust optimization problems. 3) In

Table 2: Adversarial robustness evaluation of RobustT on QNLI, MNLI and QQP datasets. Compare with the original BERT, fine-tuning on robust tickets improves the adversarial robustness.

Dataset	Method	Clean%	Aua%
IMDB	**RobustT**$_{20\%}$	93.8	**55.6**
	w/o Mask Leaning	**94.0**	15.1
	w/o Adv	93.4	5.4
AGNEWS	**RobustT**$_{40\%}$	**94.9**	**28.5**
	w/o Mask Learning	94.2	16.1
	w/o Adv	94.5	8.8
SST-2	**RobustT**$_{30\%}$	90.9	**26.7**
	w/o Mask Learning	**92.2**	6.2
	w/o Adv	91.2	3.5

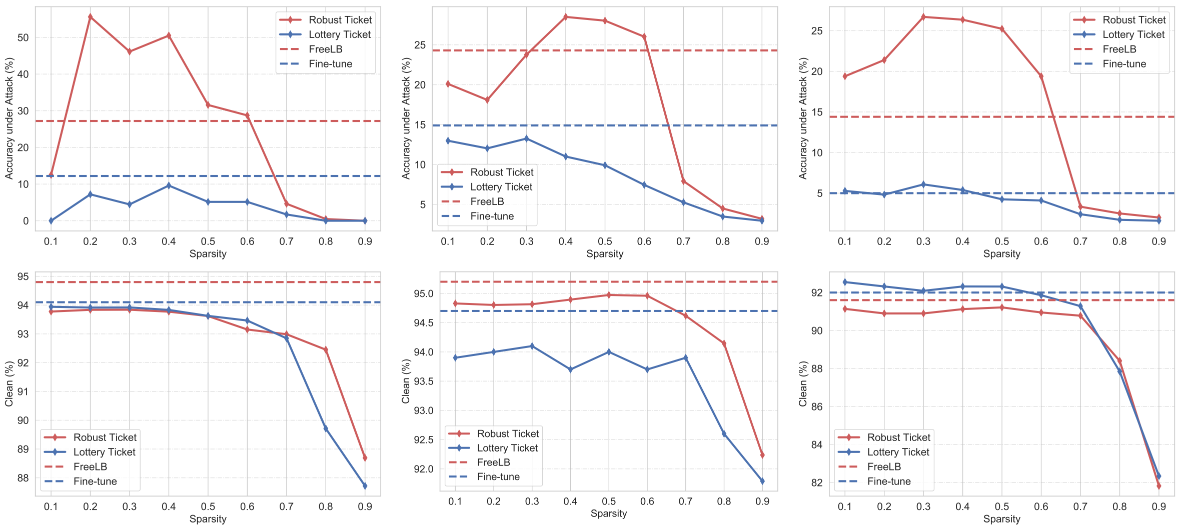
Table 3: Ablation study on text classification datasets. **Aua**% is obtained after using TextFooler attack.

both AGNEWS and IMDB, the randomly pruned subnetwork loses only about 1 performance point in test accuracy, but performs poorly in adversarial robustness. This suggests that robust tickets are more difficult to discovered than traditional lottery tickets. 4) Robust tickets sacrifice accuracy performance in SST-2 and IMDB. We speculate that this may be due to the trade-off between accuracy and robustness (Tsipras et al., 2019).

We also evaluate the performance of our proposed method on more tasks. From Table 2, we can see that our proposed method yields significant improvements of robustness over the original BERT on QNLI, MNLI and QQP datasets. There is a significant improvement even compared with InfoBERT and FreeLB.

4.6 Ablation Study

To better illustrate the contribution of each component of our method, we perform the ablation study by removing the following components: sparse mask learning (but with IMP instead) and adversarial loss objective (Adv). The test results are shown in Table 3. We can observe that: 1)



(a) IMDB (b) AGNEWS (c) SST-2

Figure 2: Fine-tuning evaluation results of the robust ticket, the traditional lottery ticket, FreeLB and the original BERT fine-tuning under various sparsity levels. The adversarial robustness improves as the compression ratio grows until a certain threshold, then the robustness deteriorates. **Aua**% is obtained after using TextFooler attack.

Mask learning is important for performance and IMP does not identify robust subnetworks well (Vemparala et al., 2021). 2) Without adversarial loss objective, the proposed method identifies subnetworks that perform well in terms of clean accuracy, but does not provide any improvement in terms of robustness.

5 Discussion

In this section, we study how the implementation of robust tickets affects the model's robustness.

5.1 Impact of Sparsity on Robust Tickets

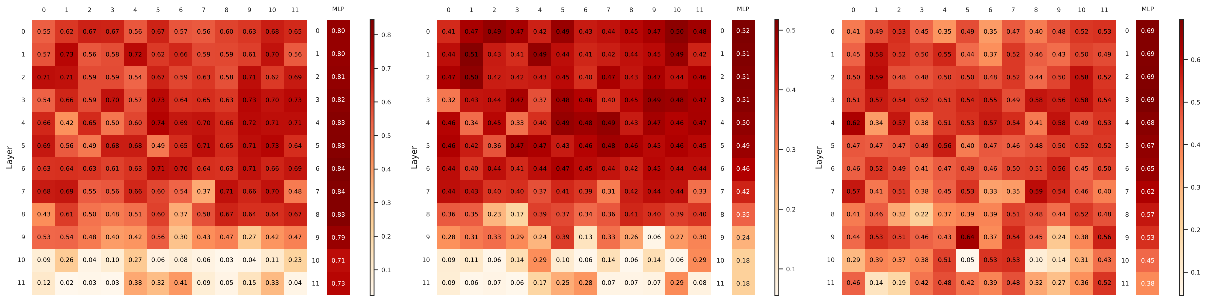
The proposed method can prune out a subnetwork with arbitrary sparsity based on the confidence of masks. In Fig.2, we compare the robust tickets and traditional lottery tickets across all sparsities. When the sparsity increases to a certain level, the robustness decreases faster than the accuracy, which indicates that the robustness is more likely to be affected by the model structure than the accuracy. Therefore, it is more difficult to find a robust ticket from BERT. The accuracy of the subnetwork is slowly decreasing with increasing sparsity, but the robustness shows a different trend. The change in robustness can be roughly divided into three phases: The robustness improves as the sparsity grows until a certain threshold; beyond this threshold, the robustness deteriorates but is still better than that of the lottery tickets. In the end, when being highly compressed, the robust network collapses into a lottery network. A similar phenomenon is also be observed (Liang et al., 2021). The robustness performance curve is not as smooth as the accuracy, this may be due to the gap between the adversarial loss objective and the real textual attacks.

5.2 Sparsity Pattern

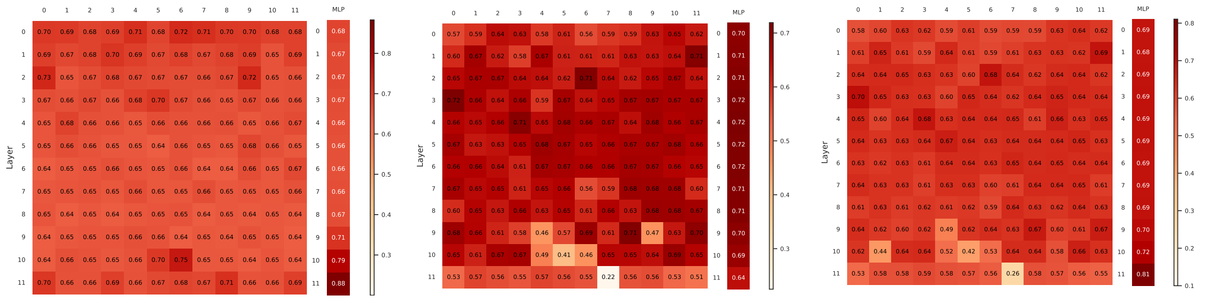
Fig.3 shows the sparsity patterns of robust tickets on all six datasets. We can clearly find that the pruning rate increases from bottom to top on the text classification tasks (IMDB, SST2, AGNEWS), while it is more uniform in the natural language inference tasks (MNLI and QNLI) and Quora question pairs (QQP). Recent works show that BERT encodes a rich hierarchy of linguistic information. Taking the advantage of the probing task, Jawahar et al. (2019) indicate that the surface information features are encoded at the bottom, syntactic information features are in the middle network, and semantic information features in the top. Therefore, we speculate that the sparsity pattern of robust tickets is task-dependent.

5.3 Speedup Training Process

An important property of winning tickets is to accelerate the convergence of the training process (Chen et al., 2021; You et al., 2020). The training curve in Fig.4 shows that the convergence speed of robust tickets is much faster compared with the default fine-tuning and FreeLB. Moreover, the convergence rate of both accuracy and robustness



(a) IMDB (b) SST-2 (c) AGNEWS



(d) MNLI (e) QNLI (f) QQP

Figure 3: Heatmaps of sparsity patterns found on different tasks, each cell gives the percentage of surviving weights in self-attention heads and MLPs. The sparsity patterns on IMDB and SST-2 are similar, which may be due to the fact that they are both text classification datasets based on movie reviews.

is accelerating. The traditional lottery tickets converge faster than our method, which may be due to the fact that robust tickets require maintaining a trade-off between robustness and accuracy.

5.4 The Importance of Robust Tickets Initialization and Structure

To better understand which factor, initialization or structure, has a greater impact on the robust ticket, we conduct corresponding analysis studies. We avoid the effect of initializations by re-initializing the weights of robust tickets. To avoid the effect of structures and preserve the effect of initializations, we use the full BERT and re-initialize the weights that are not contained in the robust tickets. **Aua**% is obtained after using TextFooler attack. The results are shown in Table 4.

5.4.1 Importance of initialization

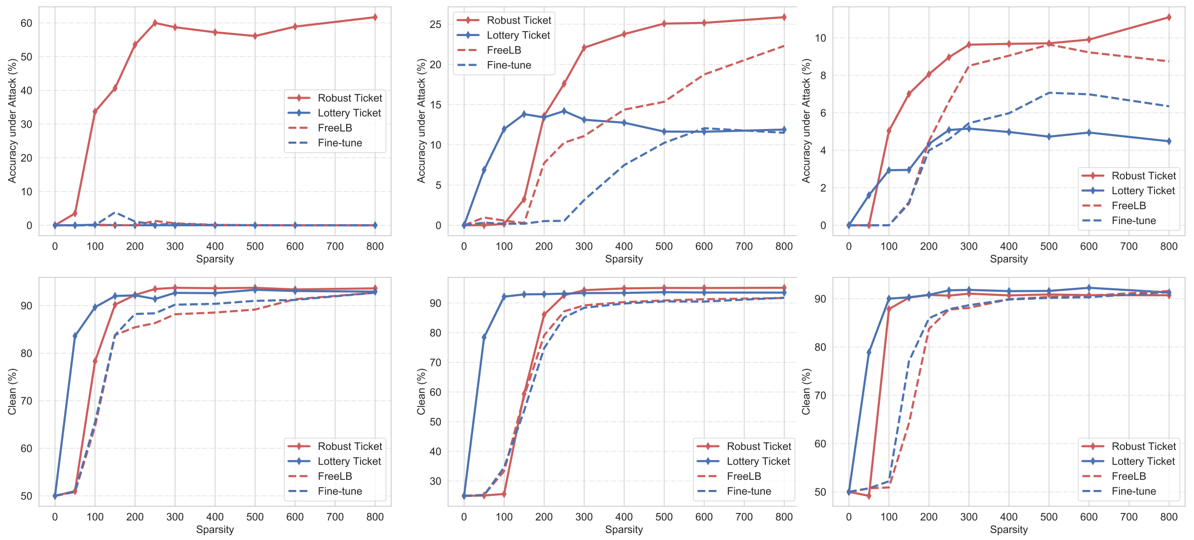
LTH suggests that the winning tickets can not be learned effectively without its original initialization. For our robust BERT tickets, their initializations are pre-trained weights. Table 4 shows the failure of robust tickets when the random re-initialization is performed.

Dataset	Method	Clean%	Aua%
IMDB	**RobustT**$_{20\%}$	**93.7**	**55.6**
	w/o Initialization	87.9	0.2
	w/o Structure	93.7	13.4
	w/o Structure+Longer	93.6	18.6
AGNEWS	**RobustT**$_{40\%}$	**94.9**	**28.5**
	w/o Initialization	92.4	0.4
	w/o Structure	94.9	21.8
	w/o Structure+Longer	94.8	24.6
SST-2	**RobustT**$_{30\%}$	90.9	26.7
	w/o Initialization	83.1	2.1
	w/o Structure	**92.0**	15.7
	w/o Structure+Longer	91.9	**27.5**

Table 4: Importance of robust ticket initialization and structure. Our results show that the initialization of robust tickets seems to be more important than the structure, although both of them play a role.

5.4.2 Importance of structure

Frankle and Carbin (2019) hypothesize that the structure of winning tickets encodes an inductive bias customized for the learning task at hand. Although removing this inductive bias reduces performance compared to the robust tickets, it still outperforms the original BERT, and its



(a) IMDB (b) AGNEWS (c) SST-2

Figure 4: Clean accuracy and accuracy under attack as training proceeds. Robust tickets accelerate both accuracy and robustness. **Aua**% is obtained after using TextFooler attack.

performance improves further with longer training time (3 epochs → 10 epochs). It can be seen that the initializations of some pre-training weights may lead to a decrease in the robustness of the model.

6 Conclusion

In this paper, we articulate and demonstrate the Robust Lottery Ticket Hypothesis for PLMs: the full PLM contains subnetworks (robust tickets) that can achieve a better robustness performance. We propose an effective method to solve the ticket selection problem by encouraging weights that are not responsible for robustness to become exactly zero. Experiments on various tasks corroborate the effectiveness of our method. We also find that pre-trained weights may be a key factor affecting the robustness on downstream tasks.

A The Effect of Regularization Strength during Mask Learning

In section 3.2.2, we show the mask learning curves for various regularization strengths λ in SST-2 dataset. The results on more datasets are shown in the Fig.5, where we can observe that the mask learning process is insensitive to the regularization strength, and the convergence of masks is eventually achieved.

B Implementation Details

B.1 Details for Fine-tuning Models

We report the hyperparameters used for fine-tuning the BERT-base and retraining the winning tickets in table 5.

Hypeparameters	**Values**
Optimizer	Adamw(Loshchilov and Hutter, 2019)
Learning rate	2×10^{-5}
Dropout	0.1
Weight decay	1×10^{-2}
Batch size	16 or 32
Gradient clip	$(-1, 1)$
Epochs	3
Bias-correction	True

Table 5: Hyperparameters used for fine-tuning the BERT-base and retraining the winning tickets.

B.2 Details for Adversarial Attack

We use textattack (Morris et al., 2020) to implement the adversarial attack methods. For all attack methods, we use the default parameters of third-party libraries. Adversarial robustness evaluation metrics (e.g., **Aua**% and **#Query**) are evaluated on the all 872 test samples for SST-2, 500 randomly selected test samples for IMDB, and 1000 randomly selected test samples for other datasets.

B.3 Hyperparameters

Adversarial loss objective introduces four widely used hyperparameters: the perturbation step size η, the initial magnitude of perturbations ϵ_0, the number of adversarial steps s, and we do not constrain the bound of perturbations. In addition, we also report two important hyperparameters during mask learning. They are mask learning rate γ and regularization penalty coefficient λ. The weight decay wd in the optimizer are also changed compared with default settings to make the mask sparsity rate converge better. We list the hyperparameters used for each tasks in Table 6.

Datasets	η	γ	λ	ϵ_0	s	wd
SST2	0.03	0.1	0.5	0.05	5	$1e-6$
AGNEWS	0.03	0.05	0.5	0.05	5	$1e-6$
IMDB	0.03	0.1	0.5	0.05	5	$1e-6$
QQP	0.04	0.05	0.1	0.05	3	$1e-6$

Abstract

Tuning pre-trained language models (PLMs) with task-specific prompts has been a promising approach for text classification. Particularly, previous studies suggest that prompt-tuning has remarkable superiority in the low-data scenario over the generic fine-tuning methods with extra classifiers. The core idea of prompt-tuning is to insert text pieces, i.e., template, to the input and transform a classification problem into a masked language modeling problem, where a crucial step is to construct a projection, i.e., verbalizer, between a label space and a label word space. A verbalizer is usually handcrafted or searched by gradient descent, which may lack coverage and bring considerable bias and high variances to the results. In this work, we focus on incorporating external knowledge into the verbalizer, forming a *knowledgeable prompt-tuning* (KPT), to improve and stabilize prompt-tuning. Specifically, we expand the label word space of the verbalizer using external knowledge bases (KBs) and refine the expanded label word space with the PLM itself before predicting with the expanded label word space. Extensive experiments on zero and few-shot text classification tasks demonstrate the effectiveness of knowledgeable prompt-tuning. Our source code is publicly available at `https://github.com/thunlp/KnowledgeablePromptTuning`.

1 Introduction

Recent years have witnessed the prominence of Pretrained Language Models (PLMs) (Peters et al., 2018; Radford et al., 2018; Devlin et al., 2019; Raffel et al., 2020; Xu et al., 2021) due to their superior performance on a wide range of language-related downstream tasks such as text classification (Kowsari et al., 2019), question answering (Rajpurkar et al., 2016), and machine reading comprehension (Nguyen et al., 2016). To fathom the principles of such effectiveness of PLMs, researchers have conducted extensive studies and suggested that PLMs have obtained rich knowledge during pre-training (Petroni et al., 2019; Davison et al., 2019). Hence, how to stimulate and exploit such knowledge is receiving increasing attention.

One conventional approach to achieve that is fine-tuning (Devlin et al., 2019), where we add extra classifiers on the top of PLMs and further train the models under classification objectives. Fine-tuning has achieved satisfying results on supervised tasks. However, since the extra classifier requires adequate training instances to tune, it is still challenging to apply fine-tuning in few-shot learning (Brown et al., 2020) and zero-shot learning (Yin et al., 2019) scenarios. Originated from GPT-3 (Brown et al., 2020) and LAMA (Petroni et al., 2019, 2020), a series of studies using prompts (Schick and Schütze, 2021a; Liu et al., 2021) for model tuning bridge the gap between pre-training objective and down-stream tasks, and demonstrate that such discrete or continuous prompts induce better performances for PLMs on few-shot and zero-shot tasks.

A typical way to use prompts is to wrap the input sentence into a natural language template and let the PLM conduct masked language modeling. For instance, to classify the topic of a sentence $\mathbf{x}$: "What's the relation between speed and acceleration?" into the "SCIENCE" category, we wrap it into a template: "A `[MASK]` question: $\mathbf{x}$". The prediction is made based on the probability that the word "science" is filled in the "`[MASK]`" token. The mapping from *label words* (e.g., "science") to the specific class (e.g., class SCIENCE) is called the *verbalizer* (Schick and Schütze, 2021a), which bridges a projection between the vocabulary and the label space and has a great influence on the performance of classification (Gao et al., 2021).

Most existing works use manual verbalizers (Schick and Schütze, 2021a,b), in which the

Volume 1: Long Papers, pages 2225 - 2240
May 22-27, 2022

designers manually think up a single word to indicate each class. To ease the human effort of designing the class name, some works propose to learn the label words using discrete search (Schick et al., 2020) or gradient descent (Liu et al., 2021; Hambardzumyan et al., 2021). However, the learned-from-scratch verbalizer, lack of human prior knowledge, is still *considerably inferior* to the manual verbalizers (see Appendix A for pilot experiments), especially in few-shot setting, and even not applicable in zero-shot setting, which leaves the manual verbalizer a decent choice in many cases.

However, manual verbalizers usually determine the predictions based on limited information. For instance, in the above example, the mapping {science}→ SCIENCE means that only predicting the word "science" for the `[MASK]` token is regarded as correct during inference, regardless of the predictions on other relevant words such as "physics" and "maths", which are also informative. Such handcrafted one-one mapping limits the coverage of label words, thus lacking enough information for prediction and introducing bias into the verbalizer. Therefore, manual verbalizers are hard to be optimal in text classification, where the semantics of label words are crucial for predictions.

The optimization-based expansion, though can be combined with manual verbalizers to yield better performance, only induces a few words or embeddings that are close to the class name in terms of word sense or embedding distance. Thus they are difficult to infer words across granularities (e.g. from "science" to "physics"). If we can expand the verbalizer of the above example into {science, physics} → SCIENCE, the probability of making correct predictions will be considerably enhanced. Therefore, to improve the coverage and reduce the bias of the manual verbalizer, we present to incorporate external knowledge into the verbalizers to facilitate prompt-tuning, namely, *knowledgeable prompt-tuning* (KPT). Since our expansion is not based on optimization, it will also be more favorable for zero-shot learning.

Specifically, KPT contains three steps: construction, refinement, and utilization. (1) Firstly, in the construction stage, we use external KBs to generate a set of label words for each label (in § 3.2). Note that the expanded label words are not simply synonyms of each other, but cover different granularities and perspectives, thus are more comprehensive and unbiased than the class name. (2) Secondly, to cope with the noise in the unsupervised expansion of label words, we propose four refinement methods, namely, frequency refinement, relevance refinement, contextualized calibration, and learnable refinement (in § 3.3), whose effectiveness is studied thoroughly in § 4. (3) Finally, we apply either a vanilla average loss function or a weighted average loss function for the utilization of expanded verbalizers, which map the scores on a set of label words to the scores of the labels.

We conduct extensive experiments on zero-shot and few-shot text classification tasks. The empirical results show that KPT can reduce the error rate of classification by 16%, 18%, 10%, 7% on average in 0, 1, 5, 10 shot experiments, respectively, which shows the effectiveness of KPT. In addition to the performance boost, KPT also reduces the prediction variances consistently in few-shot experiments and yields more stable performances.

2 Related Work

Two groups of research are related to KPT: prompt-tuning, and the verbalizer construction.

Prompt-tuning. Since the emergence of GPT-3 (Brown et al., 2020), prompt-tuning has received considerable attention. GPT-3 (Brown et al., 2020) demonstrates that with prompt-tuning and in-context learning, the large-scale language models can achieve superior performance in the low-data regime. The following works (Schick and Schütze, 2021a,b) argue that small-scale language models (Radford et al., 2018; Devlin et al., 2019; Liu et al., 2019; Lan et al., 2020) can also achieve decent performance using prompt-tuning. Prompt-tuning has been applied to a large variety of tasks such as Text Classification (Schick and Schütze, 2021a), Natural Language Understanding (Schick and Schütze, 2021b; Liu et al., 2021) , Relation Extraction (Han et al., 2021; Chen et al., 2021), and Knowledge Probing (Petroni et al., 2019; Liu et al., 2021), etc.

Verbalizer Construction. As introduced in § 1, the verbalizer is an important component in prompt-tuning and has a strong influence on the performance of prompt-tuning (Holtzman et al., 2021; Gao et al., 2021). Most works use human-written verbalizers (Schick and Schütze, 2021a), which are highly biased towards personal vocabulary and do not have enough coverage. Some other studies (Gao et al., 2021; Shin et al., 2020; Liu et al., 2021; Schick et al., 2020) design automatic verbalizer searching methods for better ver-

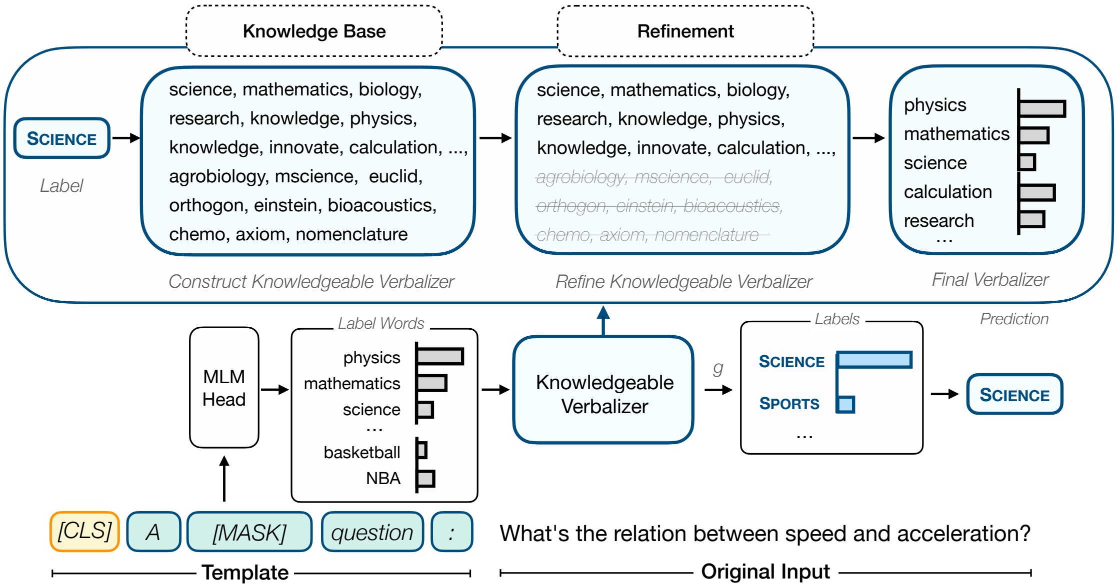

Figure 1: The illustration of KPT , the knowledgeable verbalizer maps the predictions over label words into labels. And the above part is the construction, refinement and utilization processes of KPT .

balizer choices, however, their methods require adequate training set and validation set for optimization. Moreover, the automatically determined verbalizers are usually synonym of the class name, which differs from our intuition of expanding the verbalizer with a set of diverse and comprehensive label words using external KB. Schick et al. (2020) and Shin et al. (2020) also try multiple label words for each class. The optimal size of their label words set for each class is generally less than 10, which lacks coverage when used in text classification tasks.

3 Knowledgeable Prompt-tuning

In this section, we present our methods to incorporate external knowledge into a prompt verbalizer. We first introduce the overall paradigm of prompt-tuning and then elucidate how to construct, refine and utilize the knowledgeable prompt.

3.1 Overview

Let $\mathcal{M}$ be a language model pre-trained on large scale corpora. In text classification task, an input sequence $\mathbf{x} = (x_0, x_1, ..., x_n)$ is classified into a class label $y \in \mathcal{Y}$. Prompt-tuning formalizes the classification task into a masked language modeling problem. Specifically, prompt-tuning wraps the input sequence with a *template*, which is a piece of natural language text. For example, assuming we need to classify the sentence $\mathbf{x}$ =“What's the relation between speed and acceleration?” into label SCIENCE (labeled as 1) or SPORTS (labeled as 2), we wrap it into

$$\mathbf{x}_{\mathrm{p}} = \texttt{[CLS]}\ \text{A}\ \texttt{[MASK]}\ \text{question} : \mathbf{x}$$

Then $\mathcal{M}$ gives the probability of each word v in the vocabulary being filled in `[MASK]` token $P_{\mathcal{M}}(\texttt{[MASK]} = v|\mathbf{x}_{\mathrm{p}})$. To map the probabilities of words into the probabilities of labels, we define a *verbalizer* as a mapping f from a few words in the vocabulary, which form the *label word* set $\mathcal{V}$, to the label space $\mathcal{Y}$, i.e., $f\colon \mathcal{V} \mapsto \mathcal{Y}$. We use $\mathcal{V}_y$ to denote the subset of $\mathcal{V}$ that is mapped into a specific label y, $\cup_{y\in\mathcal{Y}}\mathcal{V}_y = \mathcal{V}$. Then the probability of label y, i.e., $P(y|\mathbf{x}_{\mathrm{p}})$, is calculated as

$$P(y|\mathbf{x}_{\mathrm{p}}) = g\left(P_{\mathcal{M}}(\texttt{[MASK]}=v|\mathbf{x}_{\mathrm{p}})|v \in \mathcal{V}_y\right), \quad (1)$$

where g is a function transforming the probability of label words into the probability of the label. In the above example, regular prompt-tuning may define $\mathcal{V}_1 = \{\text{“science”}\}$, $\mathcal{V}_2 = \{\text{“sports”}\}$ and g as an identity function, then if the probability of “science” is larger than “sports”, we classify the instance into SCIENCE.

We propose KPT, which mainly focuses on using external knowledge to improve verbalizers in prompt-tuning. In KPT , we use KBs to generate multiple label words related to each class y, e.g., $\mathcal{V}_1 = \{\text{“science”}, \text{“physics”}, ...\}$. And we propose four refinement methods to eliminate the noise in the expanded $\mathcal{V}$. Finally, we explore the vanilla average and weighted average approaches for the utilization of the expanded $\mathcal{V}$. The details are in the following sections.

3.2 Verbalizer Construction

The process of predicting masked words based on the context is not a single-choice procedure, that is, there is no standard correct answer, but abundant words may fit this context. Therefore, the label words mapped by a verbalizer should be equipped by two attributes: *wide coverage* and *little subjective bias*. Such a comprehensive projection is crucial to the imitation of pre-training, which is the essence of prompt-tuning. Fortunately, external structured knowledge could simultaneously meet both requirements. In this section, we introduce how we use external knowledge for two text classification tasks: topic classification and sentiment classification.

For topic classification, the core issue is to extract label words related to the topic from all aspects and granularities. From this perspective, we choose Related Words [1], a knowledge graph $\mathcal{G}$ aggregated from multiple resources, including word embeddings, ConceptNet (Speer et al., 2017), WordNet (Pedersen et al., 2004), etc., as our external KB. The edges denote "relevance" relations and are annotated with relevance scores. We presume the the name of each class v_0 is correct and use them as the anchor node to get the neighborhood nodes $N_{\mathcal{G}}(v_0)$ whose scores are larger than a threshold η as the related words [2]. Thus, each class is mapped into a set of label words $\mathcal{V}_y = N_{\mathcal{G}}(v_0) \cup \{v_0\}$. For binary sentiment classification, the primary goal is to extend the binary sentiment to sentiment of more granualities and aspects. We use the sentiment dictionary summarized by previous researchers [3,4]. Several examples of the label words in the KPT are in Table 1.

3.3 Verbalizer Refinement

Although we have constructed a knowledgeable verbalizer that contains comprehensive label words, the collected label words can be very noisy since the vocabulary of the KB is not tailored for the PLM. Thus it is necessary to refine such verbalizer by retaining high-quality words. In this section, we propose four refinement methods addressing different problems of the noisy label words.

Frequency Refinement. The first problem is to handle the rare words. We assume that several words in the KB are rare to the PLM, thus the prediction probabilities on these words tend to be inaccurate. Instead of using a word-frequency dictionary, we propose to use *contextualized prior* of the label words to remove these words. Specifically, given a text classification task, we denote the distribution of the sentences $\mathbf{x}$ in the corpus as $\mathcal{D}$. For each sentence in the distribution, we wrap it into the template and calculate the predicted probability for each label word v in the masked position $P_{\mathcal{M}}(\texttt{[MASK]}{=}v|\mathbf{x}_{\mathrm{p}})$. By taking the expectation of the probability over the entire distribution of sentences, we can get the prior distribution of the label words in the masked position. We formalize it as

$$P_{\mathcal{D}}(v) = \mathbb{E}_{\mathbf{x}\sim\mathcal{D}} P_{\mathcal{M}}(\texttt{[MASK]}{=}v|\mathbf{x}_{\mathrm{p}}). \quad (2)$$

Empirically, we found that using a small-size *unlabeled support set* $\tilde{\mathcal{C}}$ sampled from the training set and with labels removed, will yield a satisfying estimate of the above expectation. Thus, assuming that the input samples $\{\mathbf{x} \in \tilde{\mathcal{C}}\}$ have a uniform prior distribution, the contextualized prior is approximated by

$$P_{\mathcal{D}}(v) \approx \frac{1}{|\tilde{\mathcal{C}}|} \sum_{\mathbf{x}\in\tilde{\mathcal{C}}} P_{\mathcal{M}}(\texttt{[MASK]}{=}v|\mathbf{x}_{\mathrm{p}}). \quad (3)$$

Then we remove the label words whose prior probabilities are less than a threshold. Details can be found in Appendix C.

Relevance Refinement. As our construction of knowledgeable label words is fully unsupervised, some label words may be more relevant to their belonging class than the others. To measure the relevance of a label word to each class, we obtain the prediction probability of the label word on the support set $\tilde{\mathcal{C}}$ as the vector representation $\mathbf{q}^v$ of the label words, i.e., $\mathbf{q}^v$'s i-th element is

$$\mathbf{q}^v_i = P_{\mathcal{M}}(\texttt{[MASK]} = v|\mathbf{x}_{i\mathrm{p}}), \mathbf{x}_i \in \tilde{\mathcal{C}}, \quad (4)$$

where $\mathbf{x}_{i\mathrm{p}}$ represents the sentence x_i combined with the template p.

To estimate the class's representation, we presume that the name of each class v_0, such as "science" for SCIENCE, though lack of coverage, is very relevant to the class. Then we use the vector representation $\mathbf{q}^{v_0}$ of the these names as the

---

Dataset	Label	Label Words
AG's News	POLITICS	politics, government, diplomatic, law, aristotle, diplomatical, governance ...
	SPORTS	sports, athletics, gymnastics, sportsman, competition, cycling, soccer ...
IMDB	NEGATIVE	abysmal, adverse, alarming, angry, annoy, anxious, apathy, appalling ...
	POSITIVE	absolutely, accepted, acclaimed, accomplish, accomplishment ...

Table 1: Examples of the expanded label words.

class's representation $\mathbf{q}^y$. Therefore the relevance score between a label word v and a class y is calculated as the cosine similarity between the two representation:

$$r(v, y) = \cos(\mathbf{q}^v, \mathbf{q}^y) = \cos(\mathbf{q}^v, \mathbf{q}^{v_0}). \quad (5)$$

Moreover, some label words may contribute positively to multiple classes, resulting in confusion between classes. For example, the potential label word "physiology" of class SCIENCE may also be assigned with a high probability in a sentence of class SPORTS. To mitigate such confusion and filter the less relevant label words, we design a metric that favors the label word with high relevance *merely* to its belonging class and low relevance to other classes:

$$R(v) = r(v, f(v)) \frac{|\mathcal{Y}| - 1}{\sum_{y \in \mathcal{Y}, y \neq f(v)} (r(v, y))}, \quad (6)$$

where $f(v)$ is the corresponding class of v.

Ideally, a good label word should at least has a higher relevance score for its belonging class than the average relevance score for the other classes. Therefore, we remove the label words with $R(v) < 1$. In practice, we have a slight modification to Equation (6), please refer to appendix C for details.

Essentially, this Relevance Refinement adopts the idea of the classical TF-IDF (Jones, 1972) algorithm which estimates the relevance of a word to a document. It prefers to use a word that is relevant to a specific document while irrelevant to other documents as the keyword of the document. In KPT, a class is analogous to a document, while a label word is comparable to the word in the document. From this perspective, equation (6) is a variant of TF-IDF metric.

Contextualized Calibration. The third problem is the drastic difference in the prior probabilities of label words. As previous works (Zhao et al., 2021; Holtzman et al., 2021) have shown, some label words are less likely to be predicted than the others, regardless of the label of input sentences, resulting in a biased prediction. In our setting, the label words in the KB tend to have more diverse prior probabilities, resulting in a severer problem (see Table 2). Therefore, we use the contextualized prior of label words to calibrate the predicted distribution, namely, *contextualized calibration* (CC):

$$\tilde{P}_{\mathcal{M}}(\texttt{[MASK]}{=}v|\mathbf{x}_{\mathrm{p}}) \propto \frac{P_{\mathcal{M}}(\texttt{[MASK]}{=}v|\mathbf{x}_{\mathrm{p}})}{P_{\mathcal{D}}(v)} \quad (7)$$

where $P_{\mathcal{D}}(v)$ is the prior probability of the label word. The final probability is normalized to 1.

Learnable Refinement. In few-shot learning, the refinement can be strengthen by a learning process. Specifically we assign a learnable weight w_v to each label word v (may be already refined by the previous methods). The weights form a vector $\mathbf{w} \in \mathbb{R}^{|\mathcal{V}|}$, which is initialized to be a zero vector. The weights are normalized within each $\mathcal{V}_y$:

$$\alpha_v = \frac{\exp(w_v)}{\sum_{u \in \mathcal{V}_y} \exp(w_u)}. \quad (8)$$

Intuitively, in the training process, a small weight is expected to be learned for a noisy label word to minimize its influence on the prediction. Note that in few-shot setting, calibration may not be necessary because the probability of a label word can be trained to the desired magnitude, i.e., $\tilde{P}_{\mathcal{M}}(\texttt{[MASK]}{=}v|\mathbf{x}_{\mathrm{p}}) = P_{\mathcal{M}}(\texttt{[MASK]}{=}v|\mathbf{x}_{\mathrm{p}})$.

In addition to these refinement methods, since many label words are out-of-vocabulary for the PLM and are split into multiple tokens by the tokenizer. For these words, we simply use the average prediction score of each token as the prediction score for the word. The influence of this simple approach is studied in Appendix D.3.

3.4 Verbalizer Utilization

The final problem is how to map the predicted probability on each refined label word to the decision of the class label y.

Average. After refinement, we can assume that each label word of a class contributes equally to predicting the label. Therefore, we use the average of the predicted scores on $\mathcal{V}_y$ as the predicted score for label y. The predicted label $\hat{y}$ is

$$\hat{y} = \underset{y \in \mathcal{Y}}{\operatorname{argmax}} \frac{\sum_{v \in \mathcal{V}_y} \tilde{P}_{\mathcal{M}}(\texttt{[MASK]} = v|\mathbf{x}_\text{p})}{|\mathcal{V}_y|}. \quad (9)$$

We use this method in zero-shot learning since there is no parameter to be trained.

Weighted Average. In few-shot setting, supported by the Learnable Refinement, we adopt a weighted average of label words' scores as the prediction score. The refinement weights α_v are used as the weights for averaging. Thus, the predicted $\hat{y}$ is

$$\hat{y} = \operatorname{argmax}_{y \in \mathcal{Y}} \frac{\exp\left(s(y|\mathbf{x}_\text{p})\right)}{\sum_{y'} \exp\left(s(y'|\mathbf{x}_\text{p})\right)}, \quad (10)$$

where $s(y|\mathbf{x}_\text{p})$ is

$$s(y|\mathbf{x}_\text{p}) = \sum_{v \in \mathcal{V}_y} \alpha_v \log P_{\mathcal{M}}(\texttt{[MASK]}{=}v|\mathbf{x}_\text{p}). \quad (11)$$

This objective function is suitable for continuous optimization by applying a cross-entropy loss on the predicted probability.

3.5 Theoretical Illustration of KPT

We provide a theoretical illustration of the KPT framwork in Appendix B.

4 Experiments

We evaluate KPT on five text classification datasets to demonstrate the effectiveness of incorporating external knowledge into prompt-tuning.

4.1 Datasets and Templates

We carry out experiments on three topic classification datasets: AG's News (Zhang et al., 2015), DBPedia (Lehmann et al., 2015), and Yahoo (Zhang et al., 2015), and two sentiment classification datasets: IMDB (Maas et al., 2011) and Amazon (McAuley and Leskovec, 2013). The statistics of the datasets are shown in Table 7. The detailed information and the statistics of each dataset is in Appendix E.

We test all prompt-based methods using four manual templates and report both the average results (with standard error) of the four templates and the results of the best template (shown in (brackets)). The reasons for using manual templates and the specific templates for each dataset are in Appendix E.

4.2 Experiment Settings

Our experiments are based on OpenPrompt (Ding et al., 2021), which is an open-source toolkit to conduct prompt learning. For the PLM, we use RoBERTa$_\text{large}$ (Liu et al., 2019) for all experiments. For test metrics, we use Micro-F1 in all experiments. For all zero-shot experiments, we repeat the experiments 3 times using different random seeds if randomness is introduced in the experiments, and for all few-shot experiments, we repeat 5 times. Note that considering the four templates and five/three random seeds, each reported score of prompt-based methods is *the average of 20/12 experiments*, which greatly reduces the randomness of the evaluation results. For the refinement based on the support set $\tilde{\mathcal{C}}$, the size of the unlabeled support set $|\tilde{\mathcal{C}}|$ is 200. For few-shot learning, we conduct 1, 5, 10, and 20-shot experiments. For a k-shot experiment, we sample k instances of each class from the original training set to form the few-shot training set and sample another k instances per class to form the validation set. We tune the entire model for 5 epochs and choose the checkpoint with the best validation performance to test. Other hyper-parameters can be found in Appendix F.

4.3 Baselines

In this subsection, we introduce the baselines we compare with. To better understand our proposed methods, we also compare within the performance of KPT using different configuration.

Fine-tuning (FT). Traditional fine-tuning method inputs the hidden embedding of `[CLS]` token of the PLM into the classification layer to make predictions. Note that fine-tuning can not be applied to the zero-shot setting, since the classification layer is randomly initialized.

Prompt-tuning (PT). The regular prompt-tuning method uses the class name as the only label word for each class, which is used in PET (Schick and Schütze, 2021a) and most existing works. For a fair comparison, we do not use the tricks in PET, such as self-training and prompt ensemble, which are orthogonal to our contributions.

Automatic Verbalizer (AUTO). The automatic verbalizer is proposed by PETAL (Schick et al., 2020), which uses *labeled* data to select the most informative label words *inside* a PLM's vocabulary. It is targeted at the situation when no manually defined class names are available. It's not obvious how to combine it with the manually de-

fined class name to boost the performance, and how it can be applied in a zero-shot setting. Therefore we only compare it in the few-shot setting with no class name information given.

Soft Verbalizer (SOFT). The soft verbalizer is proposed by WARP (Hambardzumyan et al., 2021). They use a continuous vector for each class and use the dot product between the masked language model output and the class vector to produce the probability for each class. In our experiments, its class vectors are initialized with the class names' word embedding, since it is more effective with manual class names as the initial values (see Appendix A). As an optimization-based method, Soft Verbalizer is not applicable in the zero-shot setting.

PT+CC. For zero-shot setting, we further introduce PT combined with our proposed contextualized calibration[5] as a baseline to see how much improvement is made by contextualized calibration instead of knowledgeable verbalizers.

For **KPT** , we experiment with different variants to better understand the proposed methods such as refinement. **-FR**, **-RR**, **-CC** and **-LR** is the variant that does not conduct Frequency Refinement, Relevance Refinement, Contextualized Calibration, and Learnable Refinement, respectively. In few-shot experiments, we presume that the supervised training data can train the output probability of each label word to the desired magnitude, thus we don't use CC and FR in the KPT . This decision is justified in Appendix D.2.

4.4 Main Results

In this subsection, we introduce the specific results and provide possible insights of KPT .

Zero-shot. From Table 2, we see that all the variants of KPT , except for KPT-CC, consistently outperforms PT and PT+CC baselines, which indicates the effectiveness of our methods. Comparison between PT and PT+CC proves that Contextualized Calibration is very effective in the zero-shot setting. The results of KPT-FR-RR-CC, which is the variant without any refinement, reveal the label noise is severe in the automatically constructed knowledgeable label words. The gap between KPT-FR-RR and KPT-FR-RR-CC is larger than the gap between PT+CC and PT, demonstrating the drastic difference in the prior probabilities of the knowledgeable label words as we hypothesized in § 3.3. Comparison between KPT, KPT-FR, KPT-FR-RR proves the effectiveness of the refinement methods.

For the analysis regarding each type of classification task, we observe that the performance boost compared to the baselines in topic classification is higher than sentiment classification, which we conjecture that topic classification requires more external knowledge than sentiment classification. While CC offers huge improvement (on average +13%) over PT baseline, the incorporation of external knowledge further improves over PT+CC up to 11% on DBPedia, and 6% on AG's News and Yahoo. We also observe that the improvement brought by the refinement methods is more noticeable for topic classification tasks. By looking at the fraction of label words maintained after the refinement process (See appendix D.4), we conjecture that the sentiment dictionary that we used in sentiment classification tasks contains little noise. Moreover, the improvement brought by the refinement process justifies the resilience of our methods to recover from noisy label words.

Few-shot. From Table 3, we first find out that prompt-based methods win over fine-tuning by a dramatic margin under nearly all situations. The gap enlarges as the shot becomes fewer. Comparing the baseline methods, the Soft Verbalizer (SOFT) generally wins over the Manual Verbalizer(PT) by a slight margin. However, automatic verbalizer (AUTO), although free of manual effort, lags behind the other verbalizers especially in a low-shot setting. The reason is obvious since the selection of label words among the vocabulary becomes inaccurate when labeled data is limited.

When comparing KPT with the baseline methods, we find KPT or its variants consistently outperform all baseline methods. On average, 17.8% , 10.3%, and 7.4% error rate reduction from the best baseline methods are achieved on 1, 5, and 10 shot experiments, respectively. Comparing within the variants of KPT , we find that RR and LR are generally effective across shots on topic classification dataset, while in sentiment classification dataset, KPT works well without the refinements, which is consistent with our previous assumptions that the sentiment dictionary has little noise. Note that the KPT-RR variant does not utilize any unlabeled support set $\tilde{\mathcal{C}}$ since we do not conduct CC and FR by default in few-shot learning. This variant is still superior to the baseline methods in most cases. In terms of variance, we can see that KPT enjoys smaller variances than baseline methods in most cases, demonstrating that the better coverage of label words stabilizes the training.

For 20-shot experiments, we can see that the gap between different methods narrows as the training data becomes sufficient. However, KPT and its variants still win by a consistent margin over the baseline methods. Surprisingly, with more training data, LR does not become more powerful as we may hypothesize. We conjecture that it is because all label words, even with some noise, *can* serve as training objectives for prompt tuning. This perspective is similar to Gao et al. (2021) that using "bad"

---

[5] The same support sets are used as KPT .

as a label word for the class "positive" can still preform classification although the performance degrades.

5 Analysis

Ablation studies about our refinement methods have been shown in the previous section. In this section and Appendix D, we conduct more in-depth analyses on the proposed methods.

5.1 Diversity of Top Predicted Words

One advantage of KPT is that it can generate diverse label words across different granularities. To specifically quantify such diversity, we conduct a case study. For the correctly predicted sentences of a class y, we count the frequency of label words $v \in \mathcal{V}_y$ appearing in the top-5 predictions for the `[MASK]` position. Then we report the top-15 frequent label words in Figure 2. Due to space limit, only the results of SPORTS and BUSINESS category of AG's News are shown. As shown in Figure 2, a diversity of label words, instead of mainly the original class names, are predicted. And the predicted label words cover various aspects of the corresponding topic. For example, for the topic SPORTS, the predicted "leagues", "football", and "coach" are related to it from different angles.

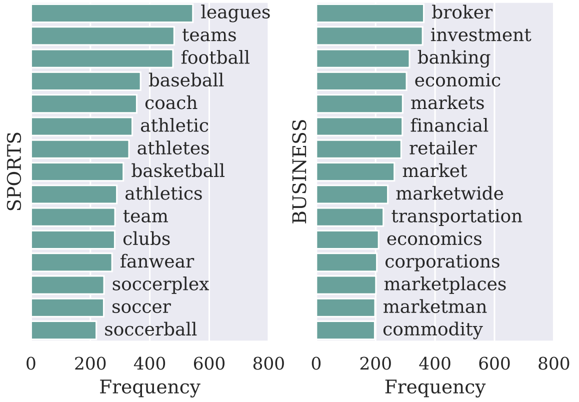

Figure 2: Frequent words appearing in the top-5 predictions. The results for two classes: SPORTS (left) and BUSINESS (right) are drawn.

5.2 Other Analyses

In addition to the visualization, we study the influence of the support set's size on zero-shot text classification in Appendix D.1. Then we justify that few-shot learning via labeled data eases the need for calibration and frequency-based refinement in Appendix D.2. We also demonstrate that our approach to handling the out-of-vocabulary (OOV) words is reasonable in Appendix D.3. Moreover, we take a closer look at the refinement process by analyzing the fraction of label words maintained during refinement in Appendix D.4. Finally, we discuss the potential use of the proposed methods when knowledge bases resources are not readily available in Appendix D.5.

6 Conclusion

In this paper, we propose KPT , which expands the verbalizer in prompt-tuning using the external KB. To better utilize the KB, we propose refinement methods for the knowledgeable verbalizer. The experiments show the potential of KPT in both zero-shot settings and few-shot settings. For future work, there are open questions related to our research for investigation: (1) Better approaches for combining KB and prompt-tuning in terms of template construction and verbalizer design. (2) Incorporating external knowledge into prompt-tuning for other tasks such as text generation.

Contributions

Zhiyuan Liu, Huadong Wang and Shengding Hu proposed the idea and led the research. Shengding Hu designed the methods and conducted the experiments. Ning Ding and Shengding Hu wrote the abstract, introduction (Section 1) and method (Section 3) part of the paper. Shengding Hu finished the other parts. Ning Ding, Huadong Wang and Zhiyuan Liu thoroughly revised the whole paper. Jingang Wang, Juanzi Li, Wei Wu and Maosong Sun proofread the paper and provided valuable comments.

Acknowledgements

Ethical Considerations

This work proposes knowledgeable prompt tuning which uses external knowledge bases to construct the verbalizer. Users should be aware of the potential error in the external KBs, or even the injection of malicious words.

A Pilot Experiments

As pointed out by (Gao et al., 2021), manually defined verbalizer is competitive or even better than automatically searched/optimized verbalizers, which strengthens our motivation to improve over manual verbalizers by injecting more external human knowledge. To further illustrate the advantage of manual verbalizer, we conduct pilot experiments in soft verbalizer. Soft Verbalizer (Hambardzumyan et al., 2021) can be initialized with the predefined class name as the label words, which is adopted by us as a baseline in Table 3. It can also be randomly initialized without the manually defined class names. We test the performance of Soft Verbalizer with and without the manually defined class name in 5 and 10 shot experiments. From Table 4, we can see that the gaps between the variants are generally large. Therefore further improving the verbalizer with manually defined class name is a promising direction than the learned-from-scratch verbalizer without any human prior.

B A Theoretical Illustration of KPT

In this section we provide a theoretical analysis of the whole framework used by KPT . In prompt tuning, given a text $\mathbf{x}$, we wrap it into a template to form a wrapped sentence $\mathbf{x}_\mathrm{p}$. We then predict the probability of the label word v using a PLM:

$$p(\texttt{[M]}{=}v|\mathbf{x}) = P_{\mathcal{M}}(\texttt{[M]}{=}v|\mathbf{x}_\mathrm{p}), \tag{12}$$

where `[M]` is short for `[MASK]`, denoting the label word's prediction at the masked position of the template.

Then, if multiple label words are used to contribute to a single label, the predicted probability of the label is defined by marginalizing the probability of predicting all the label words, i.e.,

$$p(\mathrm{Y}{=}y|\mathbf{x}){=}\sum_{v\in V_y} p(\mathrm{Y}{=}y,\, \texttt{[M]}{=}v|\mathbf{x}). \tag{13}$$

Since the prediction of Y is independent of $\mathbf{x}$ given v, we can write Equation (13) into

$$\begin{aligned}&\sum_{v\in V_y} p(\mathrm{Y} = y|\,\texttt{[M]}{=}v)p(\texttt{[M]}{=}v|\mathbf{x})\\ =&\sum_{v\in V_y} p(\mathrm{Y} = y|\,\texttt{[M]}{=}v)P_{\mathcal{M}}(\texttt{[M]}{=}v|\mathbf{x}_\mathrm{p}).\end{aligned} \tag{14}$$

Using the Bayes Theorem and assuming a balanced classification problem, Equation (14) can be transformed into

Shot	Method	AG's News	DBPedia	Yahoo	Amazon	IMDB
5	SOFT	82.8 ± 2.7 (84.3)	97.0 ± 0.6 (97.2)	61.8 ± 1.8 (63.1)	93.2 ± 1.6 (94.2)	91.6 ± 3.4 (93.9)
	SOFT w.o. M	63.4 ± 11.3 (64.7)	82.1 ± 5.9 (86.1)	24.5 ± 6.2 (27.2)	79.2 ± 10.5 (85.5)	83.6 ± 11.5 (93.4)
10	SOFT	85.0 ± 2.8 (86.7)	97.6 ± 0.4 (97.8)	64.5 ± 2.2 (65.0)	93.9 ± 1.7 (93.9)	91.8 ± 2.6 (93.0)
	SOFT w.o. M	77.4 ± 4.8 (79.1)	94.9 ± 2.5 (95.9)	42.6 ± 8.3 (48.1)	92.9 ± 2.0 (94.0)	88.7 ± 9.7 (93.8)

Table 4: Pilot experiment on soft verbalizer justifies the need of human (expert) knowledge into the verbalizer. SOFT is the soft verbalizer with class name and SOFT w.o. M is the variant without the manual verbalizer.

$$\sum_{v\in V_{\mathcal{Y}}} \frac{p(\texttt{[M]}{=}v|\mathrm{Y}=y)p(\mathrm{Y}=y)}{p(\texttt{[M]}{=}v)} P_{\mathcal{M}}(\texttt{[M]}{=}v|\mathbf{x}_{\mathrm{p}})$$

$$\propto \sum_{v\in V_{\mathcal{Y}}} \frac{p(\texttt{[M]}{=}v|\mathrm{Y}=y)}{p(\texttt{[M]}{=}v)} P_{\mathcal{M}}(\texttt{[M]}{=}v|\mathbf{x}_{\mathrm{p}}). \quad (15)$$

Now, the prediction probability of the label is composed of three parts.

(1) The first part $p(v|\mathrm{Y}=y)$ is the probability of predicting the specific label word v given the class label y. Intuitively, if a label word is relevant to label y, this term will be assigned a high probability. In KPT , the **Relevance Refinement** estimate this probability using a quantized objective, i.e., if a relevance score exceeds the threshold 1, it will be maintained, otherwise, it will be filtered. On the other hand, **Learnable Refinement** estimates this probability using continuous weights.

(2) The second part is $p(\texttt{[M]}{=}v)$ in the denominator. This term is actually the prior probability of label words v, which is estimated by our **Contextualized Calibration**. Previous works also try to approach this term using a context-free manner (Holtzman et al., 2021; Zhao et al., 2021).

(3) The last term $P_{\mathcal{M}}(\texttt{[MASK]}= v|\mathbf{x}_{\mathrm{p}})$ is the probability of the label words v predicted by the PLM, which is the only component in most works such as Manual Verbalizers (Schick and Schütze, 2021a), yielding a sub-optimial solution compared to KPT .

Verbalizers with multiple label words for a class label can all be formalized into this framework once they use Equation (13) as their backbone hypothesis. However, to the best of our knowledge, KPT is the first to combine all of the three components to form a powerful verbalizer.

C Practical Issues of Refinement

In this section, we detail the refinement process by making some practical modifications to the methods in § 3.3.

Frequency Refinement. For Frequency Refinement, since the absolute value distribution of the contextualized prior probability may be different for each task, determining a specific threshold of the contextualized prior probability may be tricky and elusive. We use a ranking-based threshold, i.e., we filter the label words that appear in the lower half of the contextualized prior probability.

Relevance Refinement. For Relevance Refinement, we observe that in the classification task with only a few classes, it's better to provide a stricter criterion to ensure that the relevance scores of a label word to *any other* class is lower than the score to the belonging class, i.e., *maximum* in the term of IDF-score is preferred. To keep a unified criterion, we use a norm-based IDF-score.

$$R^d(v) = r(v, f(v))\Big(\frac{|\mathcal{Y}|-1}{\sum_{y\in\mathcal{Y}, y\neq f(v)} r(v,y)^d}\Big)^{1/d} \quad (16)$$

where

$$d = \frac{C}{|\mathcal{Y}|-2+\epsilon} + 1, C > 0. \quad (17)$$

This criterion will approximate the maximum value in $\{r(v,y)|y \in |\mathcal{Y}|, y \neq f(v)\}$ in classification with only a few labels, and revert to the mean score in Equation (6) when conducting classification with many labels. We take $C = 10$ (without trial and error) in the experiments. And $0 < \epsilon \ll 1$ is a small number to prevent numerical error.

D Further Analyses and Ablation Studies

D.1 Calibration and Contextualized Calibration.

In fine-tuning, calibration has been studied under the topic of prediction confidence and out-of-distribution detection (Kong et al., 2020). Recently, it got renascent attention in prompt learning (Zhao et al., 2021; Holtzman et al., 2021). In prompt learning, the PLM has a natural tendency to predict one word over another word regardless of the

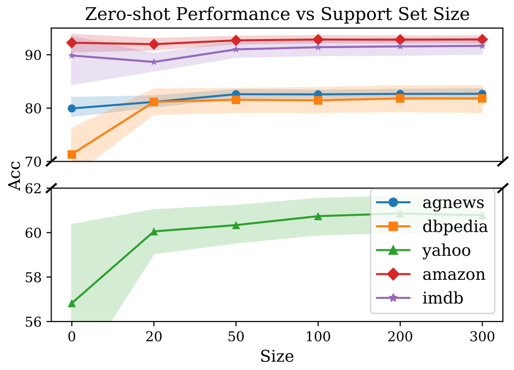

Figure 3: Support set size w.r.t. zero-shot performance. The points at size=0 are the performances of PMI_{DC}.

real sentence input. For example, GPT-3 prefers to predict "positive" over "negative" given "N/A" as the input sentence (Zhao et al., 2021). Therefore the calibration is crucial (see Table 2) when no posterior optimization is conducted, i.e., in zero-shot learning. Existing methods such as PMI_{DC} propose only using the empty template without filling the template with the instances in the corpus, for example, "A `[Mask]` question :", to produce the calibration logits. Our proposed Contextualized Calibration utilizes a limited amount of unlabeled support data to yield significantly better results. However, since we target the data-scarce scenario, we study in detail the amount of unlabeled data necessary to produce a satisfying calibration result. In Figure 3, we draw the performance of KPT - RR with different support set sizes $|\tilde{\mathcal{C}}|$. We also draw the performance of PMI_{DC} on the $|\tilde{\mathcal{C}}| = 0$ for comparison.

From Figure 3, we find that $|\tilde{\mathcal{C}}| \sim 50$ is enough to yield a satisfying calibration. Contextualized calibrate is more effective in classification with many classes, while calibrate without the context is effective in classification with few classes.

In addition, we *must point out* that if we have a set of sentences to classify in real-world scenarios, we can use these sentences themselves as the support set to conduct more accurate Contextualized Calibration.

D.2 Supervised Data Ease the Need for Calibration.

Although calibration is crucial for the zero-shot setting, we do not perform calibration for the few-shot setting because we assume that the posterior probability of the label words can be trained to the desired magnitude with only a few training instances. We also do not perform Frequency Refinement for few-shot learning due to the same assumption. To verify the assumption empirically, we add both Contextualized Calibration and Frequency Refinement to KPT and test the performance under different settings. The results are shown in Table 5. The performance comparison to KPT without CC and FR in Table 3 are shown using up arrows and down arrows. We can see that except in Yahoo, the improvement is not consistent for even negative, which supports our assumption that the need for calibration is greatly eased with the supervised input data.

D.3 How to Handle the OOV Label Words?

Since the knowledgeable verbalizer is expanded using external resources which may not be tailored for the vocabulary of PLM. Thus, many label words are out-of-vocabulary (OOV) and are split into multiple tokens by the tokenizer. For these words, as mentioned in § 3.3, we average the prediction probability of each token in the *single* `[MASK]` position, which may not be very reasonable at the first glance. Therefore, we conduct an ablation study that whether forcing the label words to be a single token in the vocabulary of the PLM leads to better performance. The results under different shots are shown in Table 6. Surprisingly, making the single-token restriction does not yield stable improvement, instead, in many cases, the performance degrades by minor margins. Therefore we conclude that our method to handle OOV label words that are split by the tokenizer into multiple tokens is simple yet reasonable. More importantly, the label words expanded by the knowledge bases but not in the PLM's vocabulary *can* serves as good label words in prompt tuning as well.

D.4 Visualization of the Refinement Process.

In this section, we report the number of label words that remained after Frequency Refinement and Relevance Refinement process. As we can see, these refinement methods remove a large fraction of label words while retaining the ones that are most informative. However, even the fewest number of remaining label words exceeds 100, which is far more than the number of label words in the previous works (Schick et al., 2020). The broad coverage of label words contributes to the success of KPT .

Shot	Method	AG's News	DBPedia	Yahoo	Amazon	IMDB

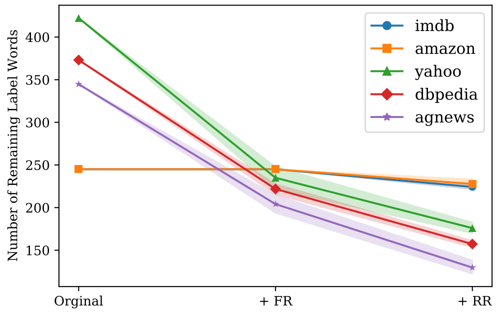

Figure 4: The number of remaining label words after Frequency Refinement and Relevance Refinement.

D.5 Potential Usage without External KB.

Although KBs are ubiquitous in natural language processing, there are cases that no readily available KBs can be found for specific tasks. For these tasks, if we have enough unlabeled corpus, we can use the methods proposed by LOTClass (Meng et al., 2020) to mine potential label words from the corpus. More specifically, LOTClass (Meng et al., 2020) uses a self-supervised objective to train the PLM to extract the topic-related words from the whole unlabeled training corpus. Experiments that combine KPT with LOTClass are beyond the scope of our work, but we believe the combination of the two can be very effective.

E Datasets and Templates

We carry out experiments on three topic classification datasets: AG's News (Zhang et al., 2015), DBPedia (Lehmann et al., 2015), and Yahoo (Zhang et al., 2015), and two sentiment classification datasets: IMDB (Maas et al., 2011) and Amazon (McAuley and Leskovec, 2013). The statistics of the datasets are shown in Table 7.

Name	Type	# Class	Test Size
AG's News	Topic	4	7600
DBPedia	Topic	14	70000
Yahoo	Topic	10	60000
Amazon	Sentiment	2	10000
IMDB	Sentiment	2	25000

Table 7: The statistics of each dataset.

Due to the rich expert knowledge contained, the manual templates are proven to be competitive with or better than auto-generated templates (Gao et al., 2021) even though they are simpler to be constructed. Therefore we use manual templates in our experiments. Manual templates are also more applicable than auto-generated templates in the zero-shot setting. To mitigate the influence of different templates, we test KPT under four manual templates that are either introduced by (Schick and Schütze, 2021a) or tailored to fit the dataset for each experimental configuration. The templates for each dataset is listed below.

AG's News. AG's News is a news' topic classification dataset. In this dataset, we follow PET (Schick and Schütze, 2021a) to design the templates. However, their best performance pattern $T_1(\mathbf{x})$ = "`[MASK]` news : $\mathbf{x}$" requires the `[MASK]` token to be capitalized, which is not suitable for the label words in KB. And some of their templates are not informative and yield low performances. Therefore, we define four slightly changed templates:

$T_1(\mathbf{x}) =$ A `[MASK]` news : $\mathbf{x}$
$T_2(\mathbf{x}) = \mathbf{x}$ This topic is about `[MASK]`.
$T_3(\mathbf{x}) =$ [Category : `[MASK]`] $\mathbf{x}$
$T_4(\mathbf{x}) =$ [Topic : `[MASK]`] $\mathbf{x}$

DBPedia. In a DBPedia sample, we are given a paragraph $\mathbf{b}$ paired with a title $\mathbf{a}$, in which the title is the subject of paragraph. The task is to determine the topic (or the type) of the subject. Different from other topic classifications, the paragraph can emphasize topics that are different from the title. For example, in a paragraph about an audio company, the main paragraph talks about music, albums, etc., but the correct label is "company" rather than "music". Therefore, we define the following templates:

$T_1(\mathbf{a}, \mathbf{b}) = \mathbf{a}\ \mathbf{b}\ \tilde{\mathbf{a}}$ is a `[MASK]` .
$T_2(\mathbf{a}, \mathbf{b}) = \mathbf{a}\ \mathbf{b}$ In this sentence, $\tilde{\mathbf{a}}$ is a `[MASK]` .
$T_3(\mathbf{a}, \mathbf{b}) = \mathbf{a}\ \mathbf{b}$ The type of $\tilde{\mathbf{a}}$ is `[MASK]`.
$T_4(\mathbf{a}, \mathbf{b}) = \mathbf{a}\ \mathbf{b}$ The category of $\tilde{\mathbf{a}}$ is `[MASK]`.

where $\tilde{\mathbf{a}}$ means removing the last punctuate in the title.

Yahoo. Yahoo is a topic classification dataset about the questions raised in yahoo website (Zhang et al., 2015). We use the same templates as AG's News, except that we change the word "news" into "question" in the $T_1(\mathbf{x})$:

$T_1(\mathbf{x}) =$ A `[MASK]` question : $\mathbf{x}$
$T_2(\mathbf{x}) = \mathbf{x}$ This topic is about `[MASK]`.
$T_3(\mathbf{x}) =$ [Category : `[MASK]`] $\mathbf{x}$
$T_4(\mathbf{x}) =$ [Topic : `[MASK]`] $\mathbf{x}$

IMDB. IMDB is a sentiment classification dataset about movie reviews. Similar to the template defined in (Schick and Schütze, 2021a) for sentiment classification, we define the following template:

$T_1(\mathbf{x}) =$ It was `[MASK]` . $\mathbf{x}$
$T_2(\mathbf{x}) =$ Just `[MASK]` ! $\mathbf{x}$
$T_3(\mathbf{x}) = \mathbf{x}$ All in all, it was `[MASK]`.
$T_4(\mathbf{x}) = \mathbf{x}$ In summary, the film was `[MASK]`.

Amazon. Amazon is another sentiment classification dataset , we define the following template:

$T_1(\mathbf{x}) =$ It was `[MASK]` . $\mathbf{x}$
$T_2(\mathbf{x}) =$ Just `[MASK]` ! $\mathbf{x}$
$T_3(\mathbf{x}) = \mathbf{x}$ All in all, it was `[MASK]`.
$T_4(\mathbf{x}) = \mathbf{x}$ In summary, it was `[MASK]`".

Since the test set of amazon is unnecessarily large for efficient testing, we randomly sample 10,000 samples from the 400,000 test samples to test, which is proven to have tiny influence on the performance in our pilot experiments.

F Experimental Settings

We list the hyper-parameters in Table 8. Most of the hyper-parameters are the default parameters from Huggingface Transformers[6].

Hyper-parameter	Dataset	Value
truncate length	AG's News, DBPedia, Yahoo	128
truncate length	Amazon, Imdb	512
warmup steps	All	0
learning rate	All	3e-5
maximum epochs	All	5
adam epsilon	All	1e-8

Table 8: Hyper-parameter settings.

For soft verbalizer, we use a learning rate of $3e-4$ to its soft label words' embeddings to encourage a faster convergence.

Abstract

Fine-grained entity typing (FGET) aims to classify named entity mentions into fine-grained entity types, which is meaningful for entity-related NLP tasks. For FGET, a key challenge is the low-resource problem — the complex entity type hierarchy makes it difficult to manually label data. Especially for those languages other than English, human-labeled data is extremely scarce. In this paper, we propose a cross-lingual contrastive learning framework to learn FGET models for low-resource languages. Specifically, we use multi-lingual pre-trained language models (PLMs) as the backbone to transfer the typing knowledge from high-resource languages (such as English) to low-resource languages (such as Chinese). Furthermore, we introduce entity-pair-oriented heuristic rules as well as machine translation to obtain cross-lingual distantly-supervised data, and apply cross-lingual contrastive learning on the distantly-supervised data to enhance the backbone PLMs. Experimental results show that by applying our framework, we can easily learn effective FGET models for low-resource languages, even without any language-specific human-labeled data. Our code is also available at https://github.com/thunlp/CrossET.

1 Introduction

Recently, various efforts have been devoted to exploring fine-grained entity typing (FGET) (Ling and Weld, 2012; Li et al., 2020), aiming to identify concrete fine-grained entity types for named entity mentions in sentences (Figure 1). Since the type information of named entity mentions is useful for understanding textual semantics, FGET is widely applied to enhance entity-related tasks, such as coreference resolution (Khosla and Rose, 2020), entity linking (Onoe and Durrett, 2020; Chen et al., 2020a), relation extraction (Ren et al., 2017; Zhou and Chen, 2021) and event extraction (Nguyen et al., 2016; Yang and Mitchell, 2016).

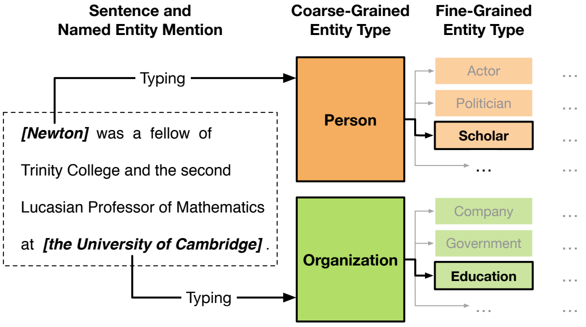

Figure 1: The illustration of classifying named entity mentions in sentences into fine-grained entity types.

Despite the success of FGET, the low-resource problem is always a challenge of FGET, since the complex type hierarchy makes it difficult to manually label data. To alleviate the low-resource problem, besides utilizing auto-labeled data (Ling and Weld, 2012; Gillick et al., 2014; Xin et al., 2018; Dai et al., 2021), manually building FGET datasets is the most effective approach (Sang and De Meulder, 2003; Hovy et al., 2006; Ling and Weld, 2012; Choi et al., 2018; Ding et al., 2021). However, existing FGET datasets are mainly in English. For datasets in specific languages other than English, such as Chinese (Lee et al., 2020), Japanese (Suzuki et al., 2016), Dutch and Spanish (van Erp and Vossen, 2017), their scale and quality are not comparable to those English datasets. In this paper, we introduce a cross-lingual framework to learn FGET models for low-resource languages, via utilizing the data in high-resource languages

(e.g. utilizing English datasets).

Transferring the typing knowledge from high-resource languages to low-resource languages is not easy. As different languages have quite different patterns, it is challenging to understand the semantics of both high-resource and low-resource languages at the same time. With only a few examples of low-resource languages and no parallel data, it is also hard to bridge different languages for knowledge transfer. To handle these issues: (1) we use multi-lingual pre-trained language models (PLMs) as backbone. Multi-lingual PLMs such as M-BERT (Devlin et al., 2019) are pre-trained on large-scale multi-lingual corpora, taking it as the backbone can well encode data in different languages into the same semantic space (Han et al., 2021). (2) we apply heuristic rules and cross-lingual contrastive learning to bridge multiple languages. We design several entity-pair-oriented heuristic rules to obtain distant supervision, which can automatically annotate entity types by utilizing latent relations between entity pairs. Machine translation is used on the auto-labeled data to establish a connection between high-resource and low-resource languages. Finally, we apply contrastive learning to learn similarities between cross-lingual auto-labeled types, instead of using pseudo-labels to learn a classifier, which can enhance the type recognition ability and reduce the side effect of auto-labeled data.

For convenience, we name our cross-lingual contrastive learning framework "CROSS-C" in the following sections. We conduct experiments on two popular FGET datasets: Open-Entity (Choi et al., 2018) and Few-NERD (Ding et al., 2021), and translate their test sets into non-English versions to evaluate the effectiveness of CROSS-C for low-resource languages. Quantitative experimental results show that applying CROSS-C can easily train effective FGET models for low-resource languages, even without any language-specific human-labeled data. Besides quantitative experiments, we also provide some visualization of feature spaces and conduct case studies for qualitative analysis to show how CROSS-C works.

2 Method

In this section, we will introduce our cross-lingual framework to learn FGET models for low-resource languages. We will first give some essential notations and definitions, and then elaborate on the details of our framework.

2.1 Notations and Definitions

As shown in Figure 1, given a sentence x and one named entity mention m in the sentence, our goal is to determine types from a fine-grained type set $\mathcal{T}$ according to the sentence context for the mention m. Note that FGET is a multi-label classification problem, since multiple types can be assigned to a single named entity mention.

For a high-resource language h, sufficient human-labeled data $\{\mathcal{X}_h, \mathcal{Y}_h\}$ exists, where $\mathcal{X}_h = \{x_{h,1}, x_{h,2}, \ldots\}$ is the sentence set and $\mathcal{Y}_h = \{y_{h,1}, y_{h,2}, \ldots\}$ is the label set. Each sentence $x_{h,i} \in \mathcal{X}_h$ contains a named entity mention $m_{h,i}$, and $y_{h,i} \subseteq \mathcal{T}$ is the fine-grained type set of the named entity mention $m_{h,i}$.

Similarly, we define the dataset $\{\mathcal{X}_l, \mathcal{Y}_l\}$ for a low-resource language l, where $|\mathcal{X}_l| \ll |\mathcal{X}_h|$ [1]. In this paper, we use $\{\mathcal{X}_h, \mathcal{Y}_h\}$, $\{\mathcal{X}_l, \mathcal{Y}_l\}$ and large-scale unlabeled multi-lingual data to train a FGET model for the low-resource language l.

2.2 Multi-Lingual Pre-Trained Encoder

We use multi-lingual BERT (M-BERT) (Devlin et al., 2019) as the framework backbone to encode the input. M-BERT has the same architecture as BERT, but is pre-trained on the multi-lingual corpora in 104 languages. Therefore, M-BERT has a good ability to transfer knowledge across languages (Pires et al., 2019; Selvaraj et al., 2021), making it suits our setting well. Note that, our framework does not depend on a specific PLM, any other multi-lingual PLMs can also be used as the backbone to encode the input.

Given a sentence $x = [w_1, \ldots, m, \ldots, w_n]$, where m is the named entity mention, we additionally insert an entity marker `[ENT]` on each side of the mention m. By feeding the sentence with entity markers into M-BERT, we can get representations $[\mathbf{h}_{w_1}, \ldots, \mathbf{h}_{\texttt{[ENT]}}, \mathbf{h}_m, \mathbf{h}_{\texttt{[ENT]}}, \ldots, \mathbf{h}_{w_n}]$ for all input tokens. The left entity marker representation $\mathbf{h}_{\texttt{[ENT]}}$ is used to represent the named entity mention. For simplicity, we denote this process as $\mathbf{m} = \texttt{M-PLM}(x)$, where $\mathbf{m}$ is the entity mention representation and x is the input sentence. Given each entity type $t \in \mathcal{T}$, the probability that the mention m in the sentence x can be classified as

---

[1] In our experiments, we focus on handling a difficult and extreme case $|\mathcal{X}_l| = 0$, i.e, there is no any human-labeled data for the low-resource language l.

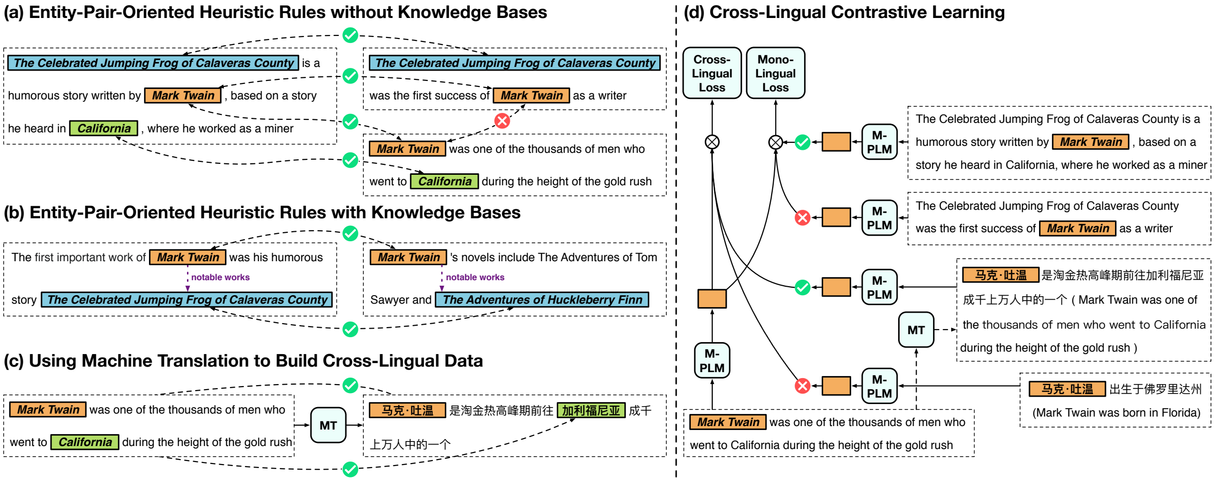

Figure 2: The illustration of entity-pair-oriented heuristic rules and cross-lingual contrastive learning. In this example, we want to transfer the typing knowledge from English to Chinese.

the type t is given as

$$P_\theta(t|x) = \sigma(\mathbf{t}^\intercal \texttt{M-PLM}(x)), \tag{1}$$

where σ is the sigmoid function, $\mathbf{t}$ is the representation of the entity type t, and θ indicates all learnable model parameters.

With the data $\{\mathcal{X}_h, \mathcal{Y}_h\}$ in the high-resource language h and the data $\{\mathcal{X}_l, \mathcal{Y}_l\}$ in the low-resource language l, the overall optimization objective is as

$$\arg\max_\theta \left[\mathcal{L}_{\text{high}}(\theta) + \mathcal{L}_{\text{low}}(\theta)\right], \tag{2}$$

where $\mathcal{L}_{\text{high}}(\theta)$ and $\mathcal{L}_{\text{low}}(\theta)$ respectively indicate the loss functions for the high-resource language h and the low-resource language l. These loss functions are defined as

$$\begin{aligned}\mathcal{L}_{\text{high}}(\theta) &= \frac{1}{|\mathcal{X}_h|}\sum_{i=1}^{|\mathcal{X}_h|}\sum_{t\in\mathcal{T}}\big[\delta_{t\in y_{h,i}}\log P_\theta(t|x_{h,i}) \\ &\quad + (1-\delta_{t\in y_{h,i}})\log(1-P_\theta(t|x_{h,i}))\big], \\ \mathcal{L}_{\text{low}}(\theta) &= \frac{1}{|\mathcal{X}_l|}\sum_{i=1}^{|\mathcal{X}_l|}\sum_{t\in\mathcal{T}}\big[\delta_{t\in y_{l,i}}\log P_\theta(t|x_{l,i}) \\ &\quad + (1-\delta_{t\in y_{l,i}})\log(1-P_\theta(t|x_{l,i}))\big].\end{aligned} \tag{3}$$

For the function δ_c, if the condition c is satisfied, then $\delta_c = 1$, otherwise $\delta_c = 0$.

2.3 Heuristic Rules for Data Augmentation

As we mentioned before, there are only a few human-labeled examples in low-resource languages. Although multi-lingual PLMs can provide an effective backbone to understand multilingual semantics, more examples are still required to bridge different languages.

The existing distantly-supervised methods annotate the mentions of the same entity in multiple sentences with the same pseudo label (Ling and Weld, 2012; Gillick et al., 2014; Xin et al., 2018). However, in Figure 2, the mention "Mark Twain" requires to be annotated with "writer" or "miner" according to specific semantics. Hence, these single-entity-oriented heuristic rules inevitably bring much noise.

To this end, we introduce heuristic rules orienting entity pairs to automatically annotate data with less noise. Instead of annotating specific entity types, we annotate whether two named entity mentions are of similar types. On the one hand, this strategy can consider the correlation and similarity between different types. On the other hand, this strategy is suitable for contrastive learning, which can reduce the side effect of data noise. In fact, in relation extraction, recent works have adopted similar strategies (Soares et al., 2019; Peng et al., 2020) and achieved promising results. More specifically, as shown in Figure 2, we take three rules to obtain distantly-supervised data:

(1) **Rules without knowledge bases**. As shown in Figure 2(a), without using knowledge bases, if one entity pair is mentioned by two sentences, the mentions of the same entity in these two sentences are considered to have similar types.

(2) **Rules with knowledge bases**. As shown in Figure 2(b), by using knowledge bases, if entity pairs in two sentences have same relations in knowledge bases, and these pairs have shared entities, the mentions of corresponding entities are considered to have similar types.

(3) **Building cross-lingual data with machine translation**. As shown in Figure 2(c), we use machine translation to translate the data from the high-resource language to the low-resource language. Owing to the translation, the above-mentioned auto-labeled examples and their translated versions constitute a cross-lingual distantly-supervised dataset.

By making full advantage of distant supervision and machine translation, we can greatly expand our dataset to bridge high-resource and low-resource languages, and further transfer the typing knowledge between these languages. To make FGET models pay more attention to textual contexts rather than merely focusing on entity names, we use the `[MASK]` token to mask named entity mentions with a probability of 0.5.

2.4 Cross-Lingual Contrastive Learning

With all above-mentioned heuristic rules in Section 2.3, we can get the distantly-supervised data $\tilde{\mathcal{X}}_h = \{\tilde{x}_{h,1}, \tilde{x}_{h,2}, \ldots\}$ in the high-resource language h, the distantly-supervised data $\tilde{\mathcal{X}}_l = \{\tilde{x}_{l,1}, \tilde{x}_{l,2}, \ldots\}$ in the low-resource language l, and the translated data $\tilde{\mathcal{X}}_t = \{\tilde{x}_{t,1}, \tilde{x}_{t,2}, \ldots\}$. Given any two sentences x_1, x_2 in these distantly-supervised datasets, we use the function $s(x_1, x_2)$ to measure the similarity between the entity mentions of the two sentences. In practice, we take the cosine similarity with temperature τ as the function $s(x_1, x_2)$:

$$s(x_1, x_2) = \frac{\texttt{M-PLM}(x_1)^{\intercal}\texttt{M-PLM}(x_2)}{\|\texttt{M-PLM}(x_1)\| \cdot \|\texttt{M-PLM}(x_2)\| \cdot \tau}, \quad (4)$$

where $\texttt{M-PLM}(\cdot)$ is the entity mention representation computed by multi-lingual PLMs.

The cross-lingual contrastive learning consists of two important objectives. One is the mono-lingual objective for each language, and the other is the cross-lingual objective. For both the high-resource language h and the low-resource language l, their mono-lingual objectives are defined as follows,

$$\begin{aligned}
\mathcal{L}_{\text{mono-h}}(\theta) &= \frac{1}{|\tilde{\mathcal{X}}_h|}\sum_{i=1}^{|\tilde{\mathcal{X}}_h|}\big[\log\sum_{\tilde{p}\in\mathcal{P}(\tilde{x}_{h,i})} e^{s(\tilde{x}_{h,i},\tilde{p})} \\
&- \log(\sum_{\tilde{p}\in\mathcal{P}(\tilde{x}_{h,i})} e^{s(\tilde{x}_{h,i},\tilde{p})} + \sum_{\tilde{n}\in\mathcal{N}(\tilde{x}_{h,i})} e^{s(\tilde{x}_{h,i},\tilde{n})})\big], \\
\mathcal{L}_{\text{mono-l}}(\theta) &= \frac{1}{|\tilde{\mathcal{X}}_l|}\sum_{i=1}^{|\tilde{\mathcal{X}}_l|}\big[\log\sum_{\tilde{p}\in\mathcal{P}(\tilde{x}_{l,i})} e^{s(\tilde{x}_{l,i},\tilde{p})} \\
&- \log(\sum_{\tilde{p}\in\mathcal{P}(\tilde{x}_{l,i})} e^{s(\tilde{x}_{l,i},\tilde{p})} + \sum_{\tilde{n}\in\mathcal{N}(\tilde{x}_{l,i})} e^{s(\tilde{x}_{l,i},\tilde{n})})\big],
\end{aligned} \quad (5)$$

where $\mathcal{P}(\tilde{x}_{h,i}) \subseteq \tilde{\mathcal{X}}_h$ and $\mathcal{N}(\tilde{x}_{h,i}) \subseteq \tilde{\mathcal{X}}_h$ are respectively the positive set and the negative set of the example $\tilde{x}_{h,i}$. $\mathcal{P}(\tilde{x}_{l,i})$ and $\mathcal{N}(\tilde{x}_{l,i})$ are defined in a similar way for the example $\tilde{x}_{l,i}$.

To ensure that the model does not push the representations of different languages far away, so that the low-resource language l can benefit from the high-resource language h, we further use $\tilde{\mathcal{X}}_h$ and its translated set $\tilde{\mathcal{X}}_t$ to define the cross-lingual objective as follows,

$$\begin{aligned}
\mathcal{L}_{\text{cross}}(\theta) &= \frac{1}{|\tilde{\mathcal{X}}_t|}\sum_{i=1}^{|\tilde{\mathcal{X}}_t|}\big[\log\sum_{\tilde{p}\in\mathcal{P}(\tilde{x}_{t,i})} e^{s(\tilde{x}_{t,i},\tilde{p})} \\
&- \log(\sum_{j=1}^{|\tilde{\mathcal{X}}_t|}\delta_{i\neq j} e^{s(\tilde{x}_{t,i},\tilde{x}_{t,j})} + \sum_{j=1}^{|\tilde{\mathcal{X}}_h|} e^{s(\tilde{x}_{t,i},\tilde{x}_{h,j})})\big],
\end{aligned} \quad (6)$$

where $\mathcal{P}(\tilde{x}_{t,i}) \subseteq \tilde{\mathcal{X}}_h \cup \tilde{\mathcal{X}}_t$ is the positive set of the example $\tilde{x}_{t,i}$. The final objective of the cross-lingual contrastive learning is to optimize

$$\arg\max_{\theta}\,[\mathcal{L}_{\text{cross}}(\theta) + \mathcal{L}_{\text{mono-r}}(\theta) + \mathcal{L}_{\text{mono-l}}(\theta)]. \quad (7)$$

2.5 Pre-Training and Fine-Tuning

We divide the whole learning process into two stages: pre-training and fine-tuning. The pre-training stage is to use Eq. (7) to optimize parameters on the distantly-supervised data. Considering computational efficiency, every time we sample a batch of examples for contrastive learning, and then sample multiple positive examples for each example in the batch. After the pre-training stage, we use Eq. (2) to fine-tune parameters on human-labeled data to learn classifiers for FGET.

3 Experiment

In this section, we evaluate the effectiveness of our framework CROSS-C on two typical entity-related datasets: Open-Entity and Few-NERD. For each dataset, we conduct experiments in both low-resource (few-shot or zero-shot) and full-set settings. In addition to quantitative experiments, to further show how our method works, we also provide some visualization of feature spaces for qualitative analysis.

3.1 Dataset Settings

Open-Entity (Choi et al., 2018) and **Few-NERD** (Ding et al., 2021) are both popular FGET datasets. Open-Entity includes 9 general types and 121 fine-grained types. Each example in Open-Entity may correspond to multiple entity types.

Few-NERD includes 8 general types and 66 fine-grained types. Both of these two datasets have a clear type hierarchy, which is suitable for evaluating the model performance on the entity typing task. In our experiments, we require models to predict both general types and fine-grained types for each entity mention in sentences.

3.2 Experimental Settings

In this paper, we select English as a high-resource language and Chinese as a low-resource language. We attempt to use human-labeled English data and large-scale unlabeled multi-lingual data for learning, to obtain an effective Chinese FGET model. This is very difficult, since no any Chinese human-labeled data is used in this process.

To obtain distantly-supervised data, we apply our heuristic rules to automatically annotate the English and Chinese Wikipedia pages [2]. We then use machine translation (Klein et al., 2017; Tan et al., 2020) to translate the English distant-supervised examples into corresponding Chinese versions for cross-lingual contrastive learning.

All test sets of Open-Entity and Few-NERD are translated into Chinese for evaluation. Although the test set built by machine translation may exist some errors, the overall semantics of the translated examples can still support determining the types of entity mentions. Taking human-labeled examples for evaluation is better, yet large-scale human-annotated entity typing datasets are still lacking. The experiments are performed under three settings:

Few-shot setting. This setting requires models to infer entity types with a few supervised examples. We randomly sample 2, 4, 8, 16 examples for each entity type for training.

Zero-shot setting. This setting requires models to infer entity types without any supervised training, i.e., no human-labeled example is used for training.

Full-set setting. In this setting, all supervised examples in datasets are used for training.

We follow the widely-used setting of Ling and Weld (2012), use the loose micro F_1 scores to evaluate the performance of models.

3.3 Baseline Settings

We use M-BERT (Devlin et al., 2019) as the backbone [3] to implement all baseline models and our model **"CROSS-C"**. We use **"F-T"** to denote directly using English human-labeled data to fine-tune M-BERT, which is demonstrated the effectiveness in Selvaraj et al. (2021). We use **"MONO-C"** to denote only using mono-lingual contrastive learning objectives for pre-training, and then use English human-labeled data to fine-tune pre-trained parameters. All above-mentioned models are optimized by AdamW with the learning rate $\{$5e-6,1e-5,3e-5,5e-5$\}$. The batch size used for pre-training and fine-tuning is from $\{$8,16,32,64,128,256$\}$. For cross-lingual contrastive learning, we only traverse large-scale distantly-supervised data once. For fine-tuning models on human-labeled data, the epochs are from $\{$1,3,5,7,10$\}$. The temperature τ used for the cosine similarity is 0.5.

3.4 The Overall Performance in Low-Resource Settings

The results of few-shot entity typing for Chinese are reported in Table 1. The table shows that:

(1) Using a multi-lingual PLM as the backbone can lead to an effective FGET model for those low-resource languages. All methods, including both the baseline models and our CROSS-C, can achieve non-trivial entity typing results on the Chinese test sets, without using any Chinese human-labeled examples for training models.

(2) Using distantly-supervised data for contrastive learning can significantly improve the typing capabilities of the backbone PLMs. Compared with directly fine-tuning a multi-lingual PLM with human-labeled data in high-resource languages, conducting contrastive learning on multi-lingual distantly-supervised data can better bridge high-resource languages and low-resource languages, which is beneficial to obtain effective models in low-resource languages.

(3) Compared with mono-lingual contrastive learning, our cross-lingual contrastive learning can better improve the transfer of typing knowledge from high-resource languages to low-resource languages. Our CROSS-C achieves the best results in all shot settings. And the improvements of CROSS-C will gradually increase as the number of shots decreases. These results show that our method can effectively improve model performance for low-resource languages even without any high-quality supervised language-specific data.

We also report the entity typing performance on the original English test sets in Table 2. From the

Table 3: The zero-shot performance (%) on the Chinese test sets. All these models do not use any supervised examples to tune models for entity typing. ↑ represents the improvements over M-BERT.

table we can see:

(1) In our low-resource settings, although there are no human-labeled Chinese data at all, there are still some high-quality English examples for each entity type. Therefore, the improvements of contrastive learning on the English test sets are not as obvious as on the Chinese test sets. However, compared with directly fine-tuning PLMs, contrastive learning methods still bring significant improvements, demonstrating the power of using distant supervision for data augmentation.

(2) Owing to multi-lingual data, which makes models in multiple languages learn from each other, our cross-lingual contrastive learning further brings additional improvements over the mono-lingual contrastive learning. This proves the effectiveness of our cross-lingual contrastive framework.

Table 3 shows the results of zero-shot entity typing on the Chinese test sets. In this table, we can see that: without a trained type classifier, our cross-lingual contrastive learning still brings the backbone PLM a strong type recognition ability in the pre-training stage.

3.5 The Overall Performance in Full-Set Settings

We show the model performance curve as the number of supervised examples increases in Figure 3. Note that only the supervised examples of the high-resource language English are used for training models. There is still no human-labeled data for the low-resource language Chinese. The results in the figure show that:

(1) For high-resource languages, by using more supervised examples, the improvements brought by contrastive learning are gradually decreasing, which is in line with our intuition. But we should also notice that even in the full-set setting, contrastive learning methods achieve comparable or even slightly better results than fine-tuning PLMs. This means that taking contrastive learning can well reduce the impact of data noise while enhanc-

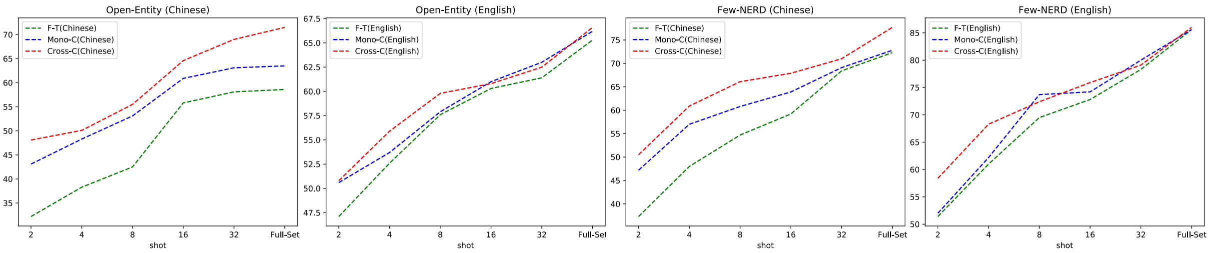

Figure 3: The model performance (%) curve as the number of supervised examples increases. We report the F_1 scores (%) on both the Chinese and English test sets.

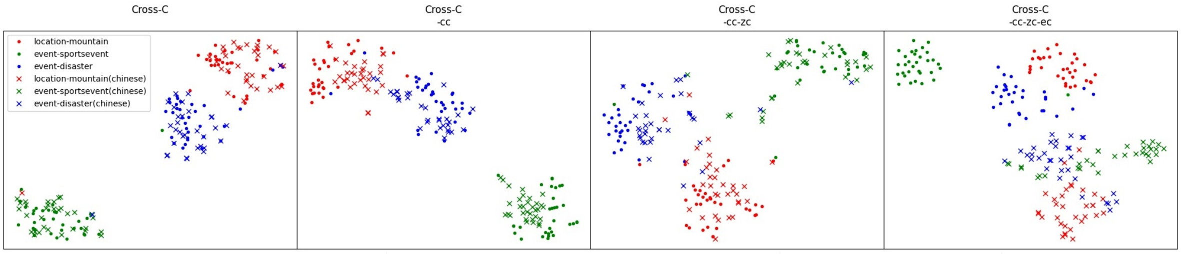

Figure 4: The model visualization during the ablation experiments for CROSS-C. We select some typical entity types in the dataset Few-NERD and their corresponding examples for visualization.

ing performance by making full use of distantly-supervised data.

(2) In both low-resource and full-set settings, the results of our contrastive learning on the Chinese test sets are always significantly higher than other baseline models. This shows that our framework can utilize the supervised data of high-resource languages and large-scale unlabeled multi-lingual data to handle FGET for low-resource languages.

3.6 Ablation Experiments and Model Visualization

In order to show how our CROSS-C works more intuitively, we conduct comprehensive ablation experiments. The results of the ablation experiments are shown in Table , where "−cc" means that we drop the cross-lingual contrastive objective for pre-training the backbone PLM, "−zc" means that we drop the mono-lingual contrastive objective on the Chinese distantly-supervised data, and "−ec" means that we drop the mono-lingual contrastive objective on the English distantly-supervised data. From Table , we can find that: both the mono-lingual contrastive objectives and the cross-lingual objective play an important role in enhancing the backbone PLM, and the combination of them can lead to greater improvements. This is also the reason that our cross-lingual contrastive learning includes both mono-lingual and cross-lingual contrastive objectives for pre-training the backbone.

We also give the visualization of the model during the ablation experiments of CROSS-C in Figure 4. From the visualization results, we can find that it is difficult to bridge high-resource languages and low-resource languages without using any contrastive learning. As we gradually increase the number of contrastive learning objectives, the distinction between entity types becomes more obvious, and the fusion of multi-lingual semantics also becomes better.

4 Related Work

As one of the most important tasks in the field of information extraction, FGET has been studied for a long time. Ling and Weld (2012); Yosef et al. (2012) first propose to classify named entity mentions into various fine-grained entity types, instead of just a few coarse-grained types (Sang and De Meulder, 2003; Hovy et al., 2006). Since fine-grained types bring informative semantics for language understanding, these types are widely used to enhance entity-related NLP tasks, such as coreference resolution (Khosla and Rose, 2020), entity linking (Onoe and Durrett, 2020; Chen et al., 2020a), relation extraction (Ren et al., 2017; Zhou and Chen, 2021) and event extraction (Nguyen et al., 2016; Yang and Mitchell, 2016). Some recent efforts further incorporate entity types to learn

entity-enhanced PLMs (Zhang et al., 2019; Sun et al., 2019; Liu et al., 2020).

Distantly-supervised FGET methods. Since entity types have complex hierarchies, manually annotating FGET data is not easy, and thus the low-resource problem is one of the key challenges of FGET. To alleviate this issue, distantly-supervised methods have been widely explored for FGET. One typical distantly-supervised approach is using knowledge bases to automatically annotate entities mentioned in the text. Ling and Weld (2012); Gillick et al. (2014) collect anchors in the Wikipedia pages that correspond to entities in knowledge bases, and then label these anchors with entity types in knowledge bases. This approach is then followed by a series of works (Ren et al., 2017; Xin et al., 2018; Choi et al., 2018; Dai et al., 2019; Jin et al., 2019; Lee et al., 2020) to obtain pseudo labels. Other approaches use various noun phrases in sentences as type pseudo labels (Dai et al., 2020, 2021), which can make full use of the recently proposed PLMs for data augmentation.

Human-labeled FGET datasets. In addition to the distantly-supervised methods, the construction of FGET datasets is also advancing. CoNLL (Sang and De Meulder, 2003) and Ontonotes (Hovy et al., 2006) are the earliest datasets, although they just cover several coarse-grained types. Then, Ling and Weld (2012); Gillick et al. (2014); Ding et al. (2021) introduce about a hundred fine-grained types and annotate a large number of examples for each type. Choi et al. (2018) further extend FGET by introducing an ultra-fine set containing thousands of types. Since annotating FGET examples is time-consuming and labor-intensive, many of the ultra-fine types proposed by Choi et al. (2018) only have distantly-supervised examples. However, all these efforts only focus on English. There are also some efforts to build datasets in other languages, such as Chinese (Lee et al., 2020), Japanese (Suzuki et al., 2016), Dutch and Spanish (van Erp and Vossen, 2017), but the scale and quality of these non-English datasets are still not comparable with English datasets, i.e., non-English human-labeled data are still scarce.

Cross-lingual and contrastive learning for FGET. Although cross-lingual learning has been widely explored in entity linking (Sil et al., 2018; Upadhyay et al., 2018; Rijhwani et al., 2019) and named entity recognition (Pan et al., 2017; Xie et al., 2018; Rahimi et al., 2019; Zhou et al., 2019), cross-lingual entity typing has not yet been explored much (Selvaraj et al., 2021). For contrastive learning (Chen et al., 2020b; Oord et al., 2018), some preliminary works have explored it for extracting relations between entities (Soares et al., 2019) and achieved promising results. Peng et al. (2020) further use contrastive learning to analyze the impact of entity information on relation extraction. Similar to cross-lingual learning, the exploration of contrastive learning for FGET is still in the preliminary stage.

5 Conclusion and Future Work

In this paper, to learn effective FGET models for those low-resource languages, we propose an effective cross-lingual contrastive learning framework CROSS-C to transfer the typing knowledge from high-resource languages to low-resource languages. Specifically, the framework CROSS-C uses a multi-lingual PLM — M-BERT as the framework backbone, which can simultaneously capture multi-lingual semantics in a unified feature space. Furthermore, to bridge the gap between high-resource languages and low-resource languages, we introduce entity-pair-oriented heuristic rules as well as machine translation to automatically obtain high-quality cross-lingual data, and then apply cross-lingual contrastive learning on this distantly-supervised data to enhance the backbone PLM. The experimental results show that by applying CROSS-C, the typing knowledge can be transferred from high-resource languages to low-resource languages, and we can learn effective FGET models without any language-specific human-labeled data for those low-resource languages. In the future:

(1) We will explore how to better utilize unsupervised data to deal with the low-resource problem of FGET, such as using better PLMs and more effective tuning methods.

(2) We will also promote the construction of cross-lingual FGET datasets, which will advance the development of FGET in specific languages, especially for those low-resource languages other than English.

Abstract

Data augmentation is an effective solution to data scarcity in low-resource scenarios. However, when applied to token-level tasks such as NER, data augmentation methods often suffer from token-label misalignment, which leads to unsatsifactory performance. In this work, we propose Masked Entity Language Modeling (MELM) as a novel data augmentation framework for low-resource NER. To alleviate the token-label misalignment issue, we explicitly inject NER labels into sentence context, and thus the fine-tuned MELM is able to predict masked entity tokens by explicitly conditioning on their labels. Thereby, MELM generates high-quality augmented data with novel entities, which provides rich entity regularity knowledge and boosts NER performance. When training data from multiple languages are available, we also integrate MELM with code-mixing for further improvement. We demonstrate the effectiveness of MELM on monolingual, cross-lingual and multilingual NER across various low-resource levels. Experimental results show that our MELM presents substantial improvement over the baseline methods.[1]

1 Introduction

Named entity recognition (NER) is a fundamental NLP task which aims to locate named entity mentions and classify them into predefined categories. As a subtask of information extraction, it serves as a key building block for information retrieval (Banerjee et al., 2019), question answering (Fabbri et al., 2020) and text summarization systems (Nallapati et al., 2016) etc. However, except a few high-resource languages / domains, the majority of languages / domains have limited amount of labeled data.

Since manually annotating sufficient labeled data for each language / domain is expensive, low-resource NER (Cotterell and Duh, 2017; Feng et al., 2018; Zhou et al., 2019; Rijhwani et al., 2020) has received increasing attention in the research community over the past years. As an effective solution to data scarcity in low-resource scenarios, data augmentation enlarges the training set by applying label-preserving transformations. Typical data augmentation methods for NLP include (1) word-level modification (Wei and Zou, 2019; Kobayashi, 2018; Wu et al., 2019; Kumar et al., 2020) and (2) back-translation (Sennrich et al., 2016; Fadaee et al., 2017; Dong et al., 2017; Yu et al., 2018).

Despite the effectiveness on sentence-level tasks, they suffer from the token-label misalignment issue when applied to token-level tasks like NER. More specifically, word-level modification might replace an entity with alternatives that mismatch the original label. Back-translation creates augmented texts that largely preserve the original content. However, it hinges on external word alignment tools for propagating the labels from the original input to the augmented text, which has proved to be error-prone.

To apply data augmentation on token-level tasks, Dai and Adel (2020) proposed to randomly substitute entity mentions with existing entities of the same class. They avoided the token-label misalignment issue but the entity diversity does not increase. Besides, the substituted entity might not fit into the original context. Li et al. (2020a) avoided the token-label misalignment issue by only diversifying the context, where they replaced context (having 'O' label) tokens using MASS (Song et al., 2019) and left the entities (i.e. aspect terms in their task) completely unchanged. However, according to the NER evaluations in Lin et al. (2020), augmentation on context gave marginal improvement on pretrained-LM-based NER models.

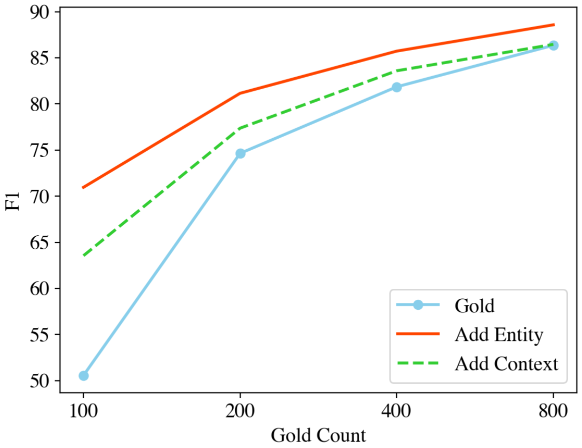

Figure 1: Effectiveness comparison between diversifying entities and diversifying context. Given N gold samples, **Add Entity** substitutes their entities with new entities from extra gold samples. In contrary, **Add Context** reuses existing entities and inserts them into context of extra gold samples. Both methods yield N augmented samples.

Our preliminary results on low-resource NER (see Figure 1) also demonstrate that diversifying entities in the training data is more effective than introducing more context patterns. Inspired by the aforementioned observations, we propose Masked Entity Language Modeling (MELM) as a data augmentation framework for low-resource NER, which generates augmented data with diverse entities while alleviating the challenge of token-label misalignment. MELM is built upon pretrained Masked Language Models (MLM), and it is further finetuned on corrupted training sentences with only entity tokens being randomly masked to facilitate entity-oriented token replacement. Simply masking and replacing entity tokens using the finetuned MLM is still insufficient because the predicted entity might not align with the original label. Taking the sentence shown in Figure 2b as an example, after masking the named entity "European Union" (Organization), the finetuned MLM could predict it as "Washington has". Such prediction fits the context but it is not aligned with the original labels. To alleviate the misalignment, our MELM additionally introduces a labeled sequence linearization strategy, which respectively inserts one label token before and after each entity token and regards the inserted label tokens as the normal context tokens during masked language modeling. Therefore, the prediction of the masked token is conditioned on not only the context but the entity's label as well.

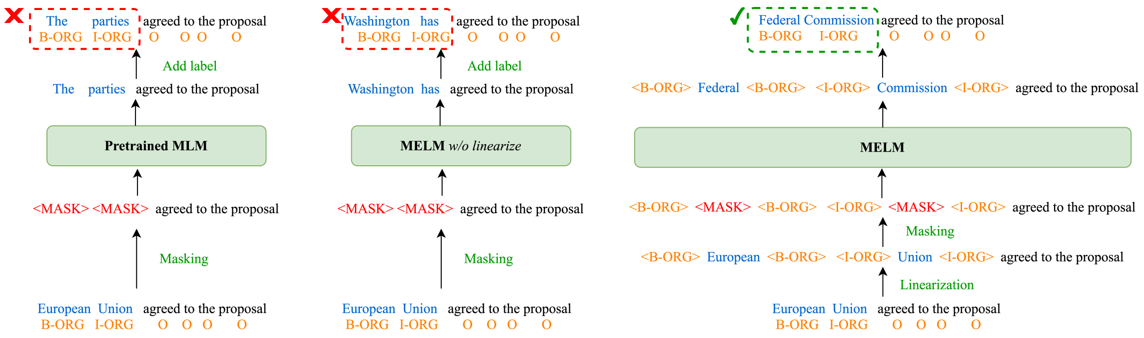
After injecting label information and finetuning on the label-enhanced NER data, our MELM can exploit rich knowledge from pre-training to increase entity diversity while greatly reducing token-label misalignment. Code-mixing (Singh et al., 2019; Qin et al., 2020; Zhang et al., 2021) achieved promising results by creating additional code-mixed samples using the available multilingual training sets, which is particularly beneficial when the training data of each language is scarce. Fortunately, in the scenarios of multilingual low-resource NER, our MELM can also be applied on the code-mixed examples for further performance gains. We first apply code-mixing by replacing entities in a source language sentence with the same type entities of a foreign language. However, even though token-label alignment is guaranteed by replacing with entities of the same type, the candidate entity might not best fit into the original context (for example, replacing a government department with a football club). To solve this problem, we propose an entity similarity search algorithm based on bilingual embedding to retrieve the most semantically similar entity from the training entities in other languages. Finally, after adding language markers to the code-mixed data, we use them to fine-tune MELM for generating more code-mixed augmented data.

To summarize, the main contributions of this paper are as follows: (1) we present a novel framework which jointly exploits sentence context and entity labels for entity-based data augmentation. It consistently achieves substantial improvement when evaluated on monolingual, cross-lingual, and multilingual low-resource NER; (2) the proposed labeled sequence linearization strategy effectively alleviates the problem of token-label misalignment during augmentation; (3) an entity similarity search algorithm is developed to better bridge entity-based data augmentation and code-mixing in multilingual scenarios.

2 Method

Fig. 2c presents the work flow of our proposed data augmentation framework. We first perform labeled sequence linearization to insert the entity label tokens into the NER training sentences (Section 2.1). Then, we fine-tune the proposed MELM on linearized sequences (Section 2.2) and create augmented data by generating diverse entities via

Note: Colors indicate different token types. Examples: (1) Entity Token: European Union; (2) Label Token: <B-ORG> <I-ORG>; (3) Masked Entity: <MASK>



(a) (b) (c)

Figure 2: Comparison of different data augmentation methods, color printing is preferred. (a) augmentation with pretrained MLM (b) augmentation with MELM without linearization (c) augmentation with MELM

masked entity prediction (Section 2.3).

The augmented data undergoes post-processing (Section 2.4) and is combined with the original training set for training the NER model. Algorithm 1 gives the pseudo-code for the overall framework. Under multilingual scenarios, we propose an entity similarity search algorithm as a refined code-mixing strategy (Section 2.5) and apply our MELM on the union set of gold training data and code-mixed data for further performance improvement.

2.1 Labeled Sequence Linearization

To minimize the amount of generated tokens incompatible with the original labels, we design a labeled sequence linearization strategy to explicitly take label information into consideration during masked language modeling. Specifically, as shown in Figure 2c, we add the label token before and after each entity token and treat them as normal context tokens. The yielded linearized sequence is utilized to further finetune our MELM so that its prediction is additionally conditioned on the inserted label tokens. Note that, we initialize the embeddings of label tokens with those of tokens semantically related to the label names (e.g., “organization” for ⟨ B-ORG ⟩). By doing so, the linearized sequence is semantically closer to a natural sentence and the difficulty of finetuning on linearized sequence could be reduced (Kumar et al., 2020).

2.2 Fine-tuning MELM

Unlike MLM, only entity tokens are masked during MELM fine-tuning. At the beginning of each fine-tuning epoch, we randomly mask entity tokens in the linearized sentence X with masking ratio η.

Then, given the corrupted sentence $\tilde{X}$ as input, our MELM is trained to maximize the probabilities of the masked entity tokens and reconstruct the linearized sequence X:

$$\max_{\theta} \quad \log p_{\theta}(X|\tilde{X}) \approx \sum_{i=1}^{n} m_i \log p_{\theta}(x_i|\tilde{X}) \quad (1)$$

where θ represents the parameters of MELM, n is the number of tokens in $\tilde{X}$, x_i is the original token in X, $m_i = 1$ if x_i is masked and otherwise $m_i = 0$. Through the above fine-tuning process, the proposed MELM learns to make use of both contexts and label information to predict the masked entity tokens. As we will demonstrate in Section 4.1, the predictions generated by the fine-tuned MELM are significantly more coherent with the original entity label, compared to those from other methods.

2.3 Data Generation

To generate augmented training data for NER, we apply the fine-tuned MELM to replace entities in the original training samples. Specifically, given a corrupted sequence, MELM outputs the probability of each token in the vocabulary being the masked entity token. However, as the MELM is fine-tuned on the same training set, directly picking the most probable token as the replacement is likely to return the masked entity token in the original training sample, and might fail to produce a novel augmented sentence. Therefore, we propose to *randomly sample* the replacement from the top *k* most probable components of the probability distribution. Formally, given the probability distribution

Algorithm 1 Masked Entity Language Modeling (MELM)

```
Given $\mathbb{D}_{\text{train}}, \mathcal{M}$        ▷ Given gold traning set $\mathbb{D}_{\text{train}}$ and pretrained MLM $\mathcal{M}$
$\mathbb{D}_{\text{masked}} \leftarrow \emptyset, \mathbb{D}_{\text{aug}} \leftarrow \emptyset$
for $\{X, Y\} \in \mathbb{D}_{\text{train}}$ do
    $\tilde{X} \leftarrow$ LINEARIZE$(X, Y)$        ▷ Labeled sequence linearization
    $\tilde{X} \leftarrow$ FINETUNEMASK$(\tilde{X}, \eta)$        ▷ Randomly mask entities for fine-tuning
    $\mathbb{D}_{\text{masked}} \leftarrow \mathbb{D}_{\text{masked}} \cup \{\tilde{X}\}$
end for
$\mathcal{M}_{\text{finetune}} \leftarrow$ FINETUNE$(\mathcal{M}, \mathbb{D}_{\text{masked}})$        ▷ Fine-tune MELM on masked linearized sequences
for $\{X, Y\} \in \mathbb{D}_{\text{masked}}$ do
    repeat $R$ times:
        $\tilde{X} \leftarrow$ LINEARIZE$(X, Y)$        ▷ Labeled sequence linearization
        $\tilde{X} \leftarrow$ GENMASK$(\tilde{X}, \mu)$        ▷ Randomly mask entities for generation
        $X_{\text{aug}} \leftarrow$ RANDCHOICE$(\mathcal{M}_{\text{finetune}}(\tilde{X}), \text{Top } k = 5)$        ▷ Generate augmented data with fine-tuned MELM
        $\mathbb{D}_{\text{aug}} \leftarrow \mathbb{D}_{\text{aug}} \cup \{X_{\text{aug}}\}$
end for
$\mathbb{D}_{\text{aug}} \leftarrow$ POSTPROCESS$(\mathbb{D}_{\text{aug}})$        ▷ Post-processing
return $\mathbb{D}_{\text{train}} \cup \mathbb{D}_{\text{aug}}$
```

$P(x_i|\tilde{X})$ for a masked token, we first select a set $V_i^k \subseteq V$ of the k most likely candidates. Then, we fetch the replacement $\hat{x}_i$ via random sampling from V_i^k. After obtaining the generated sequence, we remove the label tokens and use the remaining parts as the augmented training data. For each sentence in the original training set, we repeat the above generation procedure R rounds to produce R augmented examples.

To increase the diversity of augmented data, we adopt a different masking strategy from train time. For each entity mention comprising of n tokens, we randomly sample a dynamic masking rate ϵ from Gaussian distribution $\mathcal{N}(\mu, \sigma^2)$, where the Gaussian variance σ^2 is set as $1/n^2$. Thus, the same sentence will have different masking results in each of the R augmentation rounds, resulting in more varied augmented data.

2.4 Post-Processing

To remove noisy and less informative samples from the augmented data, the generated augmented data undergoes post-processing. Specifically, we train a NER model with the available gold training samples and use it to automatically assign NER tags to each augmented sentence. Only augmented sentences whose predicted labels are consistent with the their original labels are kept. The post-processed augmented training set $\mathbb{D}_{\text{aug}}$ is combined with the gold training set $\mathbb{D}_{\text{train}}$ to train the final NER tagger.

2.5 Extending to Multilingual Scenarios

When extending low-resource NER to multilingual scenarios, it is straightforward to separately apply the proposed MELM on language-specific data for performance improvement. Nevertheless, it offers higher potential to enable MELM on top of code-mixing techniques, which proved to be effective in enhancing multilingual learning (Singh et al., 2019; Qin et al., 2020; Zhang et al., 2021). In this paper, with the aim of bridging MELM augmentation and code-mixing, we propose an entity similarity search algorithm to perform MELM-friendly code-mixing.

Specifically, given the gold training sets $\{\mathbb{D}_{\text{train}}^{\ell} \mid \ell \in \mathbb{L}\}$ over a set $\mathbb{L}$ of languages, we first collect label-wise entity sets $\mathbb{E}^{\ell,y}$, which consists of the entities appearing in $\mathbb{D}_{\text{train}}^{\ell}$ and belonging to class y. To apply code-mixing on a source language sentence $X^{\ell_{\text{src}}}$, we aim to substitute a mentioned entity $\mathbf{e}$ of label y with a target language entity $\mathbf{e}_{sub} \in \mathbb{E}^{\ell_{\text{tgt}},y}$, where the target language is sampled as $\ell_{\text{tgt}} \sim \mathcal{U}(\mathbb{L} \setminus \{\ell_{\text{src}}\})$. Instead of randomly selecting $\mathbf{e}_{sub}$ from $\mathbb{E}^{\ell_{\text{tgt}},y}$, we choose to retrieve the entity with the highest semantic similarity to $\mathbf{e}$ as $\mathbf{e}_{sub}$. Practically, we introduce MUSE bilingual embeddings (Conneau et al., 2017) and calculate the entity's embedding $\texttt{Emb}(\mathbf{e})$ by averaging the embeddings of the entity tokens:

$$\texttt{Emb}(\mathbf{e}) = \frac{1}{|\mathbf{e}|} \sum_{i=1}^{|\mathbf{e}|} \text{MUSE}_{\ell_{\text{src}},\ell_{\text{tgt}}}(\mathbf{e}_i) \tag{2}$$

where $\text{MUSE}_{\ell_{\text{src}},\ell_{\text{tgt}}}$ denotes the $\ell_{\text{src}} - \ell_{\text{tgt}}$ aligned embeddings and $\mathbf{e}_i$ is the i-th token of $\mathbf{e}$. Next, we obtain the target-language entity $\mathbf{e}_{sub}$ semantically closest to $\mathbf{e}$ as follows:

$$\mathbf{e}_{sub} = \underset{\tilde{\mathbf{e}} \in \mathbb{E}^{\ell_{\text{tgt}},y}}{\text{argmax}} \; f(\texttt{Emb}(\mathbf{e}), \texttt{Emb}(\tilde{\mathbf{e}})) \tag{3}$$

$f(\cdot, \cdot)$ here is the cosine similarity function. The output entity $\mathbf{e}_{sub}$ is then used to replace $\mathbf{e}$ to create a code-mixed sentence more suitable for MELM augmentation. To generate more augmented data with diverse entities, we further apply MELM on the gold and code-mixed data. Since the training data now contains entities from multiple languages, we also prepend a language marker to the entity token to help MELM differentiate different languages, as shown in Figure 3.

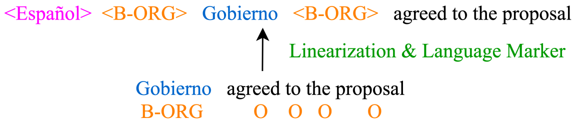


Figure 3: Applying MELM on gold and code-mixed data. Language markers (e.g., <Español>) are inserted during linearization.

3 Experiments

To comprehensively evaluate the effectiveness of the proposed MELM on low-resource NER, we consider three evaluation scenarios: **monolingual**, **zero-shot cross-lingual** and **multilingual** low-resource NER.

3.1 Dataset

We conduct experiments on CoNLL NER dataset (Tjong Kim Sang, 2002; Tjong Kim Sang and De Meulder, 2003) of four languages where $\mathbb{L}$ = {English (En), German (De), Spanish (Es), Dutch (Nl)}. For each language $\ell \in \mathbb{L}$, we first sample N sentences from the full training set as $\mathbb{D}^{\ell,N}_{\text{train}}$, where $N \in \{100, 200, 400, 800\}$ to simulate different low-resource levels. For a realistic data split ratio, we also downscale the full development set to N samples as $\mathbb{D}^{\ell,N}_{\text{dev}}$. The full test set for each language is adopted as $\mathbb{D}^{\ell}_{\text{test}}$ for evaluation.

For **monolingual** experiments on language ℓ with low-resource level $N \in \{100, 200, 400, 800\}$, we use $\mathbb{D}^{\ell,N}_{\text{train}}$ as the gold training data, $\mathbb{D}^{\ell,N}_{\text{dev}}$ as the development set and $\mathbb{D}^{\ell}_{\text{test}}$ as the test set. For **zero-shot cross-lingual** experiments with low-resource level $N \in \{100, 200, 400, 800\}$, we use $\mathbb{D}^{\text{En},N}_{\text{train}}$ as the source language gold training data, $\mathbb{D}^{\text{En},N}_{\text{dev}}$ as the development set and $\mathbb{D}^{\text{De}}_{\text{test}}$, $\mathbb{D}^{\text{Es}}_{\text{test}}$ and $\mathbb{D}^{\text{Nl}}_{\text{test}}$ as target language test sets. Under **multilingual** settings where N training data from each language is available ($N \in \{100, 200, 400\}$), we use $\bigcup_{\ell \in \mathbb{L}} \mathbb{D}^{\ell,N}_{\text{train}}$ as the gold training data, $\bigcup_{\ell \in \mathbb{L}} \mathbb{D}^{\ell,N}_{\text{dev}}$ as the development set and evaluate on $\mathbb{D}^{\text{En}}_{\text{test}}$, $\mathbb{D}^{\text{De}}_{\text{test}}$, $\mathbb{D}^{\text{Es}}_{\text{test}}$ and $\mathbb{D}^{\text{Nl}}_{\text{test}}$, respectively.

3.2 Experimental Setting

MELM Fine-tuning We use XLM-RoBERTa-base (Conneau et al., 2020) with a language-modeling head to initialize MELM parameters. MELM is fine-tuned for 20 epochs using Adam optimizer (Kingma and Ba, 2015) with batch size set to 30 and learning rate set to $1e-5$.

NER Model We use XLM-RoBERTa-Large (Conneau et al., 2020) with CRF head (Lample et al., 2016) as the NER model for our experiments[2]. We adopt Adamw optimizer (Loshchilov and Hutter, 2019) with learning rate set to $2e-5$ and set batch size to 16. The NER model is trained for 10 epochs and the best model is selected according to dev set performance. The trained model is evaluated on test sets and we report the averaged Micro-F1 scores over 3 runs.

Hyperparameter Tuning The masking rate η in MELM fine-tuning, the Gaussian mean μ for MELM generation and the number of MELM augmentation rounds R are set as 0.7, 0.5 and 3, respectively. All of these hyperparameters are tuned on the dev set with grid search. Details of the hyperparameter tuning can be found in Appendix A.1

3.3 Baseline Methods

To elaborate the effectiveness of the proposed MELM, we compare it with the following methods:

Gold-Only The NER model is trained on only the original gold training set.

Label-wise Substitution Dai and Adel (2020) randomly substituted named entities with existing entities of the same entity type from the original training set.

MLM-Entity We randomly mask entity tokens and directly utilize a pretrained MLM for data augmentation without fine-tuning and labeled sequence linearization as used in MELM. The prediction of a masked entity token does not consider label information but solely relies on the context words.

DAGA Ding et al. (2020) firstly linearized NER labels into the input sentences and then use them to train an autoregressive language model. The language model was used to synthesize augmented

---

[2] `https://github.com/allanj/pytorch_neural_crf`

data from scratch, where both context and entities are generated simultaneously.

MulDA Liu et al. (2021) fine-tuned mBART(Liu et al., 2020) on linearized multilingual NER data to generate augmented data with new context and entities.

3.4 Experimental Results

3.4.1 Monolingual and Cross-lingual NER

As illustrated on the left side of Table 1, the proposed MELM consistently achieves the best averaged results across different low-resource levels, demonstrating its effectiveness on monolingual NER. Compared to the best-performing baselines, our MELM obtains 6.3, 1.6, 1.3, 0.38 absolute gains on 100, 200, 400 and 800 levels, respectively. Cross-lingual NER results are shown on the right side of Table 2. Again, on each of the designed low-resource levels, our MELM is superior to baseline methods in terms of the averaged F1 scores. We also notice that, given 100 Nl training samples, the Gold-Only method without data augmentation almost fails to converge while the monolingual F1 of our MELM reaches 66.6, suggesting that data augmentation is crucial for NER when the annotated training data is extremely scarce.

To assess the efficacy of the proposed labeled sequence linearization (Section 2.1), we directly fine-tune MELM on masked sentences without linearization (as shown in Figure 2b), denoted as MELM *w/o linearize* in Table 1. We observe a considerable performance drop compared with MELM, which proves the label information injected via linearization indeed helps MELM differentiate different entity types, and generate entities compatible with the original label.

Taking a closer look at the baseline methods, we notice that the monolingual performance of Label-wise is still unsatisfactory in most cases. One probable reason is that only existing entities within the training data are used for replacement and the entity diversity after augmentation is not increased. Moreover, randomly sampling an entity of the same type for replacement is likely to cause incompatibility between the context and the entity, yielding a noisy augmented sample for NER training. Although MLM-Entity tries to mitigate these two issues by employing a pretrained MLM to generate novel tokens that fit into the context, the generated tokens might not be consistent with the original labels. Our MELM also promotes the entity diversity of augmented data by exploiting pretrained model for data augmentation.

In the meantime, equipped with the labeled sequence linearization strategy, MELM augmentation is explicitly guided by the label information and the token-label misalignment is largely alleviated, leading to superior results in comparison to Lable-wise and MLM-Entity.

We also compare with DAGA (Ding et al., 2020), which generates augmented data from scratch using an autoregressive language model trained on gold NER data. Although DAGA is competitive on low-resource levels of 400 and 800, it still underperforms the proposed MELM by a large margin when the training size reduces to 100 or 200. We attribute this to the disfluent and ungrammatical sentences generated from the undertrained language model. Instead of generating augmented data from scratch, MELM focuses on modifying entity tokens and leave the context unchanged, which guarantees the quality of augmented sentences even under extremely low-resource settings.

3.4.2 Multilingual NER

For multilingual low-resource NER, we firstly directly apply MELM on the concatenation of training sets from multiple languages. As shown in Table 2, MELM-*gold* achieves substantial improvement over the Gold-only baseline, which is consistent with monolingual and cross-lingual results. We compare with MulDA (Liu et al., 2021) as a baseline data augmentation method. MulDA generates augmented data autoregressively with an mBART model, which is fine-tuned on NER data with inserted label tokens. At the low-resource levels in our experimental settings, MulDA is less effective and even leads to deteriorated performance. The unsatisfactory performance mainly results from the discrepancy between pretraining and fine-tuning due to the inserted label tokens. Given very few training samples, it is difficult to adapt mBART to capture the distribution of the inserted label tokens, and thus MulDA struggles to generate fluent and grammatical sentences from scratch. In comparison, our proposed method preserves the original context and introduce less syntactic noise in the augmented data. To further leverage the benefits of code-mixing in multilingual NER, we experiment with two code-mixing methods: (1) Code-Mix-*random*, which randomly substitutes entities with existing entities of the same type from other languages, and (2) Code-Mix-*ess*, which adopts

Table 2: Results of multilingual low-resource NER. Gold training set contains the same number of training samples from each language. **Avg** is the averaged result over all languages.

the proposed entity similarity search algorithm in Section 2.5 as the code-mixing strategy.

Experimental results in Table 2 show that both methods are able to achieve improved performance over Gold-Only. This observation suggests that code-mixing techniques, either random code-mixing or code-mixing via our entity similarity search, are indeed helpful for multilingual NER. Comparing these two methods, the performance gains brought by Code-Mix-*ess* are more significant and consistent across different low-resource levels, which demonstrates the effectiveness of our proposed entity similarity search algorithm. Applying MELM on both gold data and code-mixed data from Code-Mix-*ess*, the multilingual NER results are further improved. In summary, our proposed MELM is well-suited for multilingual NER, which can be integrated with our code-mixing technique to achieve further improvement.

4 Further Analysis

4.1 Case Study

Apart from the quantitative results, we further analyze the augmented data to demonstrate the effectiveness of our MELM in maintaining the consistency between the original label and the augmented token. Table 3 presents examples of the top-5 predictions from pretrained MLM, MELM *w/o linearize* and MELM. As we can see, the pretrained MLM, which does not introduce any design or contraint on data augmentation, tends to generate high-frequency words such as “the”, “he” and “she”, and the majority of generated words do not belong to the original entity class. Being finetuned on NER data with entity-oriented masking, MELM

Text	EU	rejects	German	call to boycott	British	Lamb
Label	B-ORG	O	B-MISC	O O O	B-MISC	O
MLM	Britain, EU,UK, Trump, US		US, a, UN, the, UK		the, a, black, white, young	
MELM *w/o linearize*	EU, Australia, US, UN, Israel		German, Indian, the, Washington, Union		Chinese, British, raw, California, Australian	
MELM	EU, Greenpeace, Amnesty, UN, Reuters		German, British, Dutch, French, EU		African, British, Guinean, white, French

MELM *w/o linearize*	French, German, British, Swiss, Russian			Reuters, Pompeo, Blair Hill, AFP		
MELM	French, White, Walker, Ferguson, David			NBC, AFP, Greenpeace, BBC, Anonymous		

Table 3: Examples of the top-5 predictions by MLM, MELM *w/o linearize* and MELM. Predictions that do not belong to the original class are highlighed in red.

w/o linearize is able to generate more entity-related tokens.

However, without the explicit guidance from entity labels, it is still too difficult for MELM *w/o linearize* to make valid predictions solely based on the ambiguous context (e.g., both "Pompeo" (PER) and "Reuters" (ORG) are compatible with the context of Example #2), which leads to token-label misalignment. Compared to the above methods, our MELM take both label information and context into consideration, and thus generates more entities that fit into the context and align with the original label as well. Moreover, it is noteworthy that MELM can leverage the knowledge from pretrained model to generate real-world entities that do not exist in the original NER dataset (e.g., "Greenpeace" and "Amnesty"), which essentially increases the entity diversity in training data.

4.2 Number of Unique Entities

As demonstrated in Lin et al. (2020) and our preliminary experiments in Figure 1, introducing unseen entities can effectively provide more entity regularity knowledge, and helps to improve NER performance. Therefore, we examine the amount of unique entities introduced by different methods. As there might be token-label misalignment in the augmented data, we firstly train an 'oracle' NER model on the full CoNLL dataset and then use it to tag training data of MELM and different baseline methods. For each method, we count the total number of unique entities whose labels match the labels assigned by the 'oracle' model. As shown in Figure 4, while many augmented entities from MLM-Entity, DAGA and MELM *w/o linearize* are filtered out due to token-label misalignment, we note that MELM introduces a significantly larger number of unseen entities in the augmented data. Therefore MELM is able to provide richer entity regularity knowledge, which explains its superiority over the baseline methods.

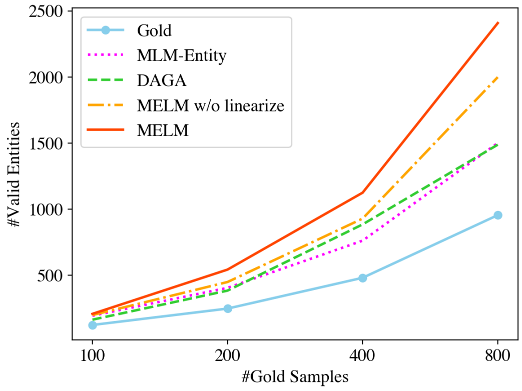

Figure 4: Comparison between the number of unique valid entities introduced by different methods

5 Related Work

On sentence level tasks, one line of data augmentation methods are built upon word-level modifications, which can be based on synonym replacement (Wei and Zou, 2019), LSTM language model (Kobayashi, 2018), MLM (Wu et al., 2019; Kumar et al., 2020), auto-regressive pretrained LM (Kumar et al., 2020), or constituent-based tagging schemes (Zhong et al., 2020). However, these methods suffer from token-label misalignment when applied to token-level tasks such as NER, which requires sophisticated post-processing to remove noisy samples in augmented data (Bari et al., 2021; Zhong and Cambria, 2021).

Existing works avoid token-label misalignment by replacing entities with existing entities of the same class (Dai and Adel, 2020), or only modifying context works and leaving entities / aspect terms unchanged (Li et al., 2020a). Others attempt to produce augmented data by training / fine-tuning a generative language model on linearized labeled sequences (Ding et al., 2020; Liu et al., 2020).

Backtranslation (Sennrich et al., 2016; Fadaee et al., 2017; Dong et al., 2017; Yu et al., 2018) translates source language sentences into a target language, and subsequently back to the source language, which preserve the overall semantics of the original sentences. On token-level tasks, however, they hinge on external word alignment tools for label propagation, which are often error-prone (Tsai et al., 2016; Li et al., 2020b).

6 Conclusion

We have proposed MELM as a data augmentation framework for low-resource NER. Through labeled sequence linearization, we enable MELM to explicitly condition on label information when predicting masked entity tokens. Thus, our MELM effectively alleviates the token-label misalignment issue and generates augmented data with novel entities by exploiting pretrained knowledge. Under multilingual settings, we integrate MELM with code-mixing for further performance gains. Extensive experiments show that the proposed framework demonstrates encouraging performance gains on monolingual, cross-lingual and multilingual NER across various low-resource levels.

A Appendix

A.1 Hyperparameter Tuning

Masking hyperparameters. To determine the optimal setting for fine-tune mask rate η and generation masking parameter μ, we conduct a grid search on both hyperparameters in range $[0.3, 0.5, 0.7]$. We finetune MELM and generate English augmented data on CoNLL following our method in Section 2. The augmented data is used to train a NER tagger and its performance on English dev set is recorded. As shown in Table 4, we achieve the best dev set F1 when $\eta = 0.7$ and $\mu = 0.5$, which is adopted for the rest of this work.

		η		
		0.3	0.5	0.7
	0.3	76.90	75.64	78.08
μ	0.5	76.16	78.06	**78.56**
	0.7	75.94	78.09	78.37

Table 4: Dev set F1 for masking hyperparameter tuning.

Number of augmentation rounds. Merging augmented data from multiple rounds increase entity diversity until it saturates at certain point. Continuing adding in more augmented data begins to amplify the noise in augmented data and leads to decreasing performance. To determine the optimum number of augmentation rounds R, we merge different amount of augmented data with English gold data to train a NER tagger, with R ranging from 1 to 6. As shown in Table 5, dev set F1 increases with increasing amount of augmented data until R=3, and starts to drop further beyond. Therefore, we choose $R = 3$ for all of our experiments.

R	1	2	3	4	5	6
Dev F1	92.35	92.36	**92.84**	92.72	92.59	92.39

Table 5: Dev set F1 for number of augmentation rounds.

A.2 Statistics for Reproducibility

In this section, we present the validation F1 averaged among 3 runs of MELM under different languages and low-resource levels. We also summarize the estimated time for fine-tuning MELM and the number of parameters used. We separately show the statistics of monolingual (Table 6), cross-lingual (Table 7) and multilingual (Table 8) NER.

Abstract

Learning representations of words in a continuous space is perhaps the most fundamental task in NLP, however words interact in ways much richer than vector dot product similarity can provide. Many relationships between words can be expressed set-theoretically, for example adjective-noun compounds (eg. "red cars"⊆"cars") and homographs (eg. "tongue"∩"body" should be similar to "mouth", while "tongue"∩"language" should be similar to "dialect") have natural set-theoretic interpretations. Box embeddings are a novel region-based representation which provide the capability to perform these set-theoretic operations. In this work, we provide a fuzzy-set interpretation of box embeddings, and learn box representations of words using a set-theoretic training objective. We demonstrate improved performance on various word similarity tasks, particularly on less common words, and perform a quantitative and qualitative analysis exploring the additional unique expressivity provided by Word2Box.

1 Introduction

The concept of learning a distributed representation for a word has fundamentally changed the field of natural language processing. The introduction of efficient methods for training vector representations of words in Word2Vec (Mikolov et al., 2013), and later GloVe (Pennington et al.) as well as FastText (Bojanowski et al., 2017) revolutionized the field, paving the way for the recent wave of deep architectures for language modeling, all of which implicitly rely on this fundamental notion that a word can be effectively represented by a vector.

While now ubiquitous, the concept of representing a word as a single point in space is not particularly natural. All senses and contexts, levels of abstraction, variants and modifications which the word may represent are forced to be captured by the specification of a single location in Euclidean space. It is thus unsurprising that a number of alternatives have been proposed.

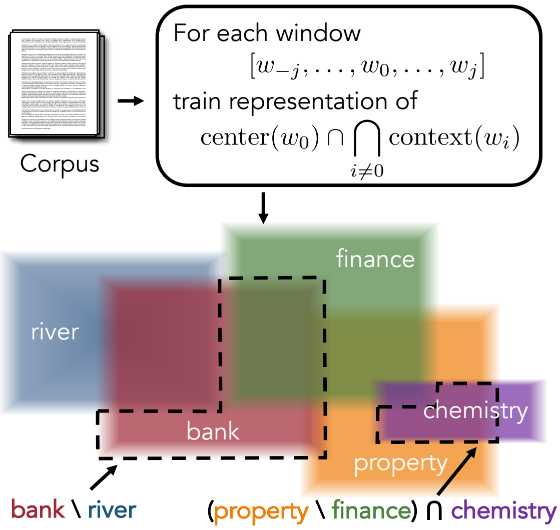

Figure 1: Given a corpus, Gumbel Boxes are trained as a fuzzy sets representing sets of windows with given center or context words. The representations can then be queried using multiple set-theoretic operations. In the graphic, `bank\river` overlaps highly with `finance`, and we would also expect high overlap with other boxes (not depicted) such as `firm` or `brokerage` (see Table 6). Similarly, we would expect boxes for chemical properties such as `hardness` or `solubility` to overlap with the dotted region indicating `property\finance∩chemistry`, and indeed we do observe such overlaps in the Word2Box model (see Table 7).

Gaussian embeddings (Vilnis and McCallum, 2015) propose modeling words using densities in latent space as a way to explicitly capture uncertainty. Poincaré embeddings (Tifrea et al., 2019) attempt to capture a latent hierarchical graph between words by embedding words as vectors in hyperbolic space. Trained over large corpora via similar unsupervised objectives as vector baselines, these models demonstrate an improvement on word

similarity tasks, giving evidence to the notion that vectors are not capturing all relevant structure from their unsupervised training objective.

A more recent line of work explores region-based embeddings, which use geometric objects such as disks (Suzuki et al., 2019), cones (Vendrov et al., 2016; Lai and Hockenmaier, 2017; Ganea et al., 2018), and boxes (Vilnis et al., 2018) to represent entities. These models are often motivated by the need to express asymmetry, benefit from particular inductive biases, or benefit from calibrated probabilistic semantics. In the context of word representation, their ability to represent words using geometric objects with well-defined intersection, union, and difference operations is of interest, as we may expect these operations to translate to the words being represented in a meaningful way.

In this work, we introduce WORD2BOX, a region-based embedding for words where each word is represented by an n-dimensional hyperrectangle or "box". Of the region-based embeddings, boxes were chosen as the operations of intersection, union, and difference are easily calculable. Specifically, we use a variant of box embeddings known as Gumbel boxes, introduced in (Dasgupta et al., 2020). Our objective (both for training and inference) is inherently set-theoretic, not probabilistic, and as such we first provide a fuzzy-set interpretation of Gumbel boxes yielding rigorously defined mathematical operations for intersection, union, and difference of Gumbel boxes.

We train boxes on a large corpus in an unsupervised manner with a continuous bag of words (CBOW) training objective, using the intersection of boxes representing the context words as the representation for the context. The resulting model demonstrates improved performance compared to vector baselines on a large number of word similarity benchmarks. We also compare the models' abilities to handle set-theoretic queries, and find that the box model outperforms the vector model 90% of the time. Inspecting the model outputs qualitatively also demonstrates that WORD2BOX can provide sensible answers to a wide range of set-theoretic queries.

2 Background

Notation Let $V = \{v_i\}_{i=1}^N$ denote the vocabulary, indexed in a fixed but arbitrary order. A sentence $\mathbf{s} = (s_1, \ldots, s_j)$ is simply a (variable-length) sequence of elements in our vocab $s_i \in V$. We view our corpus $C = \{\mathbf{s}_i\}$ as a multiset [1] of all sentences in our corpus. Given some fixed "window size" ℓ, for each word s_i in a sentence $\mathbf{s}$ we can consider the window centered at i,

$$\mathbf{w}_i = [s_{i-\ell}, \ldots, s_i, \ldots, s_{i+\ell}],$$

where we omit any indices exceeding the bounds of the sentence. Given a window $\mathbf{w}_i$ we denote the center word using $\mathrm{cen}(\mathbf{w}_i) = s_i$, and denote all remaining words as the context $\mathrm{con}(\mathbf{w}_i)$. We let C_W be the multiset of all windows in the corpus.

2.1 Fuzzy sets

Given any ambient space U a set $S \subseteq U$ can be represented by its characteristic function $\mathbb{1}_S : U \to \{0, 1\}$ such that $\mathbb{1}_S(u) = 1 \iff u \in S$. This definition can be generalized to consider functions $m : U \to [0, 1]$, in which case we call the pair $A = (U, m)$ a *fuzzy set* and $m = m_A$ is known as the *membership function* (Zadeh, 1965; Klir and Yuan, 1996). There is historical precedent for the use of fuzzy sets in computational linguistics (Zheleznіak et al., 2019a; Lee and Zadeh, 1969). More generally, fuzzy sets are naturally required any time we would like to learn a set representation in a gradient-based model, as hard membership assignments would not allow for gradient flow.

In order to extend the notion of set intersection to fuzzy sets, it is necessary to define a *t-norm*, which is a binary operation $\top : [0, 1] \times [0, 1] \to [0, 1]$ which is commutative, monotonic, associative, and equal to the identity when either input is 1. The $\min$ and product operations are common examples of t-norms. Given any t-norm, the intersection of fuzzy sets A and B has membership function $m_{A\cap B}(x) = \top(m_A(x), m_B(x))$. Any t-norm has a corresponding t-conorm which is given by $\bot(a, b) = 1 - \top(1 - a, 1 - b)$; for $\min$ the t-conorm is $\max$, and for product the t-conorm is the probabilistic sum, $\bot_{\text{sum}}(a, b) = a + b - ab$. This defines the union between fuzzy sets, where $m_{A\cup B}(x) = \bot(m_A(x), m_B(x))$. Finally, the complement of a fuzzy set simply has member function $m_{A^c}(x) = 1 - m_A(x)$.

2.2 Box embeddings

Box embeddings, introduced in (Vilnis et al., 2018), represent elements $\mathbf{x}$ of some set X as a Cartesian

---

[1] A *multiset* is a set which allows for repetition, or equivalently a sequence where order is ignored.

product of intervals,

$$\begin{aligned}\operatorname{Box}(\mathbf{x}) &:= \prod_{i=1}^{d}[x_i^-, x_i^+] \\ &= [x_1^-, x_1^+] \times \cdots \times [x_d^-, x_d^+] \subseteq \mathbb{R}^d.\end{aligned} \tag{1}$$

The volume of a box is simply the multiplication of the side-lengths,

$$|\operatorname{Box}(\mathbf{x})| = \prod_{i=1}^{d} \max(0, x_i^+ - x_i^-),$$

and when two boxes intersect, their intersection is

$$\begin{aligned}&\operatorname{Box}(\mathbf{x}) \cap \operatorname{Box}(\mathbf{y}) \\ &\quad = \prod_{i=1}^{d}[\max(x_i^-, y_i^-), \min(x_i^+, y_i^+)].\end{aligned}$$

Boxes are trained via gradient descent, and these hard $\min$ and $\max$ operations result in large areas of the parameter space with no gradient signal. Dasgupta et al. (2020) address this problem by modeling the corners of the boxes $\{x_i^\pm\}$ with Gumbel random variables, $\{X_i^\pm\}$, where the probability of any point $\mathbf{z} \in \mathbb{R}^d$ being inside the box $\operatorname{Box}_G(\mathbf{x})$ is given by

$$P(\mathbf{z} \in \operatorname{Box}_G(\mathbf{x})) = \prod_{i=1}^{d} P(z_i > X_i^-)P(z_i < X_i^+).$$

For clarity, we will denote the original ("hard") boxes as Box, and the Gumbel boxes as Box_G. The Gumbel distribution was chosen as it was min/max stable, thus the intersection $\operatorname{Box}_G(\mathbf{x}) \cap \operatorname{Box}_G(\mathbf{y})$ which was defined as a new box with corners modeled by the random variables $\{Z_i^\pm\}$ where

$$Z_i^- := \max(X_i^-, Y_i^-) \text{ and } Z_i^+ := \min(X_i^+, Y_i^+)$$

is actually a Gumbel box as well. Boratko et al. (2021) observed that

$$\begin{aligned}&P(\mathbf{z} \in \operatorname{Box}_G(\mathbf{x}) \cap \operatorname{Box}_G(\mathbf{y})) = \\ &\qquad P(\mathbf{z} \in \operatorname{Box}_G(\mathbf{x}))P(\mathbf{z} \in \operatorname{Box}_G(\mathbf{y})),\end{aligned} \tag{2}$$

and also provided a rigorous probabilistic interpretation for Gumbel boxes when embedded in a space of finite measure, leading to natural notions of "union" and "intersection" based on these operations of the random variables (Boratko et al., 2021).

In this work, we do not embed the boxes in a space of finite measure, but instead interpret them as *fuzzy sets*, where the above probability (of a point $\mathbf{z}$ being inside the Gumbel box) acts as a soft membership function.

3 Fuzzy Sets of Windows

In this section, we describe the motivation for using fuzzy sets to represent words, starting with an approach using traditional sets.

First, given a word $v \in V$, we can consider the windows centered at v,

$$\operatorname{cen}_W(v) := \{w \in C_W : \operatorname{cen}(w) = v\},$$

and the set of windows whose context contains v,

$$\operatorname{con}_W(v) := \{w \in C_W : \operatorname{con}(w) \ni v\}.$$

Note that cen_W is a function which takes in a word and returns a set of windows, whereas cen is a function which takes in a window and returns the center word, and a similar distinction holds for con_W and con.

A given window is thus contained inside the intersection of the sets described above, namely

$$\begin{aligned}&[w_{-j}, \dots, w_0, \dots, w_j] \\ &\qquad\qquad \in \operatorname{cen}_W(w_0) \cap \bigcap_{i \neq 0} \operatorname{con}_W(w_i).\end{aligned}$$

As an example, the window

$$\mathbf{w} = \text{"quick brown fox jumps over"},$$

is contained inside the cen_W("fox") set, as well as con_W("quick"), con_W("brown"), con_W("jumps"), con_W("over"). With this formulation, the intersection of the con_W sets provide a natural choice of representation for the context. We might hope that $\operatorname{cen}_W(v)$ provides a reasonable representation for the word v itself, however by our set theoretic definition for any $u \neq v$ we have $\operatorname{cen}_W(u) \cap \operatorname{cen}_W(v) = \emptyset$.

We would like the representation of u to overlap with v if u has "similar meaning" to v, i.e. we would like to consider

$$\widetilde{\operatorname{cen}_W}(v) := \{w \in W : \operatorname{cen}(w) \text{ similar to } v\}.$$

A crisp definition of *meaning* or *similarity* is not possible (Hill et al., 2015; Finkelstein et al., 2001) due to individual subjectivity. Inter-annotator agreement for Hill et al. (2015) is only 0.67, for example, which makes it clear that $\widetilde{\operatorname{cen}_W}(v)$ could not possibly be represented as a traditional set. Instead, it seems natural to consider $\widetilde{\operatorname{cen}_W}(v)$ as represented by a fuzzy set (W, m), where $m(w) \in$

$[0,1]$ can be thought of as capturing graded similarity between v and $\mathrm{cen}(w)$.[2] In the same way, we can define

$$\widetilde{\mathrm{con}_W}(v) := \{w \in W : \mathrm{con}(v) \ni w \text{ similar to } v\},$$

which would also be represented as a fuzzy set.[3]

As we wish to capture these similarities with a machine learning model, we now must find trainable representations of fuzzy sets.

Remark 1. Our objective of learning trainable representations for these sets provides an additional practical motivation for using fuzzy sets - namely, the hard assignment of elements to a set is not differentiable. Any gradient-descent based learning algorithm which seeks to represent sets will have to consider a smoothed variant of the characteristic function, which thus leads to fuzzy sets.

4 Gumbel Boxes as Fuzzy Sets

In this section we will describe how we model fuzzy sets using Gumbel boxes (Dasgupta et al., 2020). As noted in Section 2.2, the Gumbel Box model represents entities $\mathbf{x} \in X$ by $\mathrm{Box}_G(\mathbf{x})$ with corners modeled by Gumbel random variables $\{X_i^{\pm}\}$. The probability of a point $\mathbf{z} \in \mathbb{R}^d$ being inside this box is

$$P(\mathbf{z} \in \mathrm{Box}_G(\mathbf{x})) = \prod_{i=1}^{d} P(z_i > X_i^-) P(z_i < X_i^+).$$

Since this is contained in $[0,1]$, we have that $(\mathbb{R}^d, P(\mathbf{z} \in \mathrm{Box}_G(\mathbf{x}))$ is a fuzzy set. For clarity, we will refer to this fuzzy set as $\mathrm{Box}_F(\mathbf{x})$.

The set complement operation has a very natural interpretation in this setting, as $\mathrm{Box}_F(\mathbf{x})^c$ has membership function $1 - P(\mathbf{z} \in \mathrm{Box}_G(\mathbf{x}))$, that is, the probability of $\mathbf{z}$ not being inside the Gumbel box. The product t-norm is a very natural choice as well, as the intersection $\mathrm{Box}_F(\mathbf{x}) \cap \mathrm{Box}_F(\mathbf{y})$ will have membership function $P(\mathbf{z} \in \mathrm{Box}_G(\mathbf{x})) P(\mathbf{z} \in \mathrm{Box}_G(\mathbf{y}))$, which is precisely the membership function associated with $\mathrm{Box}_G(\mathbf{x}) \cap \mathrm{Box}_G(\mathbf{y})$, where here the intersection is between Gumbel boxes as defined in Dasgupta et al. (2020). Finally, we find that the membership function for the union $\mathrm{Box}_F(\mathbf{x}) \cup \mathrm{Box}_F(\mathbf{y})$ is given (via the t-conorm) by

$$\begin{aligned} &P(\mathbf{z} \in \mathrm{Box}_G(\mathbf{x})) + P(\mathbf{z} \in \mathrm{Box}_G(\mathbf{y})) - \\ &\qquad P(\mathbf{z} \in \mathrm{Box}_G(\mathbf{x}) P(\mathbf{z} \in \mathrm{Box}_G(\mathbf{y})). \end{aligned} \tag{3}$$

Remark 2. Prior work on Gumbel boxes had not defined a union operation on Gumbel boxes, however (3) has several pleasing properties apart from being a natural consequence of using the product t-norm. First, it can be directly interpreted as the probability of $\mathbf{z}$ being inside $\mathrm{Box}_G(\mathbf{x})$ or $\mathrm{Box}_G(\mathbf{y})$. Second, if the Gumbel boxes were embedded in a space of finite measure, as in Boratko et al. (2021), integrating (3) would yield the probability corresponding to $P(\mathrm{Box}(\mathbf{x}) \cup \mathrm{Box}(\mathbf{y}))$.

To calculate the size of the fuzzy set $\mathrm{Box}_F(\mathbf{x})$ we integrate the membership function over $\mathbb{R}^d$,

$$|\,\mathrm{Box}_F(\mathbf{x})| = \int_{\mathbb{R}^d} P(\mathbf{z} \in \mathrm{Box}_G(\mathbf{x}))\, d\mathbf{z}.$$

The connection between this integral and that which was approximated in Dasgupta et al. (2020) is provided by Lemma 3 of Boratko et al. (2021), and thus we have

$$|\,\mathrm{Box}_F(\mathbf{x})| \approx \prod_{i=1}^{d} \beta \log\left(1 + \exp\left(\frac{\mu_i^+ - \mu_i^-}{\beta} - 2\gamma\right)\right)$$

where μ_i^-, μ_i^+ are the location parameters for the Gumbel random variables X_i^-, X_i^+, respectively. As mentioned in Section 2.2, Gumbel boxes are closed under intersection, i.e. $\mathrm{Box}_G(\mathbf{x}) \cap \mathrm{Box}_G(\mathbf{y})$ is also a Gumbel box, which implies that the size of the fuzzy intersection

$$\begin{aligned} &|\,\mathrm{Box}_F(\mathbf{x}) \cap \mathrm{Box}_F(\mathbf{y})| \\ &\quad = \int_{\mathbb{R}^d} P(\mathbf{z} \in \mathrm{Box}_G(\mathbf{x})) P(\mathbf{z} \in \mathrm{Box}_G(\mathbf{y}))\, d\mathbf{z} \\ &\quad = \int_{\mathbb{R}^d} P(\mathbf{z} \in \mathrm{Box}_G(\mathbf{x}) \cap \mathrm{Box}_G(\mathbf{y}))\, d\mathbf{z} \end{aligned}$$

can be approximated as well. As both of these are tractable, integrating (3) is also possible via linearity. Similarly, we can calculate the size of fuzzy set differences, such as

$$\begin{aligned} &|\,\mathrm{Box}_F(\mathbf{x}) \setminus \mathrm{Box}_F(\mathbf{y})| = \\ &\int_{\mathbb{R}^d} P(\mathbf{z} \in \mathrm{Box}_G(\mathbf{x}))[1 - P(\mathbf{z} \in \mathrm{Box}_G(\mathbf{y}))]\, d\mathbf{z}. \end{aligned}$$

By exploiting linearity and closure under intersection, it is possible to calculate the size of arbitrary fuzzy intersections, unions, and set differences, as well as any combination of such operations.

---

[2] For an even more tangible definition, we can consider $m(w)$ the percentage of people who consider u to be similar to $\mathrm{cen}(w)$ when used in context $\mathrm{con}(w)$.

[3] Note that this gives a principled reason to use different representation for $\widetilde{\mathrm{cen}_W}(v)$ and $\widetilde{\mathrm{con}_W}(v)$, as they fundamentally represent different sets.

Remark 3. If our boxes were embedded in a space of finite measure, as in Boratko et al. (2021), the sizes of these fuzzy sets would correspond to the intersection, union, and negation of the binary random variables they represent.

5 Training

In this section we describe our method of training fuzzy box representations of words, which we refer to as WORD2BOX.

In Section 3 we defined the fuzzy sets $\widetilde{\text{cen}_W}(v)$ and $\widetilde{\text{cen}_W}(v)$, and in Section 4 we established that Gumbel boxes can be interpreted as fuzzy sets, thus for WORD2BOX we propose to learn center and context box representations

$$\text{cen}_B(v) := \text{Box}_F(\widetilde{\text{cen}_W}(v))$$
$$\text{con}_B(v) := \text{Box}_F(\widetilde{\text{con}_W}(v)).$$

Given a window, $\mathbf{w} = [w_{-j}, \ldots, w_0, \ldots, w_j]$, we noted that $\mathbf{w}$ must exist in the intersection,

$$\widetilde{\text{cen}_W}(w_0) \cap \bigcap_{i \neq 0} \widetilde{\text{con}_W}(w_i) \tag{4}$$

and thus we consider a max-margin training objective where the score for a given window is given as

$$f(\mathbf{w}) := \left| \text{cen}_B(w_0) \cap \bigcap_{i \neq 0} \text{con}_B(w_i) \right|. \tag{5}$$

To create a negative example $\mathbf{w}'$ we follow the same procedure as CBOW from Mikolov et al. (2013), replacing center words with a word sampled from the unigram distribution raised to the $3/4$. We also subsample the context words as in Mikolov et al. (2013). As a vector baseline, we compare with a WORD2VEC model trained in CBOW-style. We attach the source code with supplementary material.

6 Experiments and Results

We evaluate both WORD2VEC and WORD2BOX on several quantitative and qualitative tasks that cover the aspects of semantic similarity, relatedness, lexical ambiguity, and uncertainty. Following the previous relevant works (Athiwaratkun and Wilson, 2018; Meyer and Lewis, 2020; Baroni et al., 2012), we train on the lemmatized WaCkypedia corpora (Baroni et al., 2009), specifically ukWaC which is an English language corpus created by web crawling. After additional pre-processing (details in appendix A) the corpus contains around 0.9 billion tokens, with just more than 112k unique tokens in the vocabulary. Noting that an n-dimensional box actually has $2n$ parameters (for min and max coordinates), we compare 128-dimensional WORD2VEC embeddings and 64-dimensional WORD2BOX embeddings for all our experiments. We train over 60 different models for both the methods for 10 epochs using random sampling on a wide range of hyperparameters (please refer to appendix C for details including learning rate, batch size, negative sampling, sub-sampling threshold, etc.). In order to ensure that the only difference between the models was the representation itself, we implemented a version of WORD2VEC in PyTorch, including the negative sampling and subsampling procedures recommended in (Mikolov et al., 2013), using the original implementation as a reference. As we intended to train on GPU, however, our implementation differs from the original in that we use Stochastic Gradient Descent with varying batch sizes. We provide our source code at `https://github.com/iesl/word2box`.

6.1 Word Similarity Benchmarks

We primarily evaluate our method on several word similarity benchmarks: SimLex-999 (Hill et al., 2015), WS-353 (Finkelstein et al., 2001), YP-130 (Yang and Powers, 2006), MEN (Bruni et al., 2014), MC-30 (Miller and Charles, 1991), RG-65 (Rubenstein and Goodenough, 1965), VERB-143 (Baker et al., 2014), Stanford RW (Luong et al., 2013), Mturk-287 (Radinsky et al., 2011) and Mturk-771 (Halawi et al., 2012). These datasets consist of pairs of words (both noun and verb pairs) that are annotated by human evaluators for semantic similarity and relatedness.

In table 1 we compare the WORD2BOX and WORD2VEC models which perform best on the similarity benchmarks. We observe that WORD2BOX outperforms WORD2VEC (as well as the results reported by other baselines) in the majority of the word similarity tasks. We outperform WORD2VEC by a large margin in Stanford RW and YP-130, which are the rare-word datasets for noun and verb respectively. Noticing this effect, we enumerated the frequency distribution of each dataset. The datasets fall in different sections of the frequency spectrum, e.g., Stanford RW (Luong et al., 2013) only contains rare words which make its median frequency to be 5,683, whereas

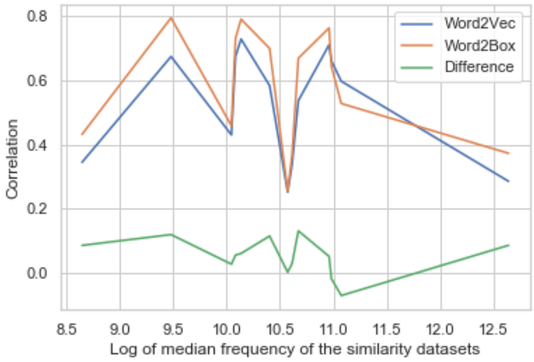

Figure 2: This plot depicts the gain in correlation score for WORD2BOX against WORD2VEC is much higher for the low and mid frequency range.

WS-353 (Rel) (Finkelstein et al., 2001) contains many more common words, with a median frequency of 64,490. We also observe a larger relative performance improvement over WORD2VEC on other datasets which have low to median frequency words, e.g. MC-30, MEN-Tr-3K, and RG-65, all with median frequency less than 25k. The order they appear in the table and the subsequent plots is lowest to highest frequency, left to right. Please refer to Appendix B for details.

In figure 2, we see that WORD2BOX outperforms WORD2VEC more significantly with less common words. In order to investigate further, we selected four datasets (RW-Stanford (rare words), Simelex-999, SimVerb-3500,WS-353 (Rel)), truncated them at a frequency threshold, and calculated the correlation for different levels of this threshold. In figure 3, we demonstrate how the performance gap between WORD2BOX and WORD2VEC changes as increasing amount frequent words are added to these similarity datasets. We posit that the geometry of box embeddings is more flexible in the way it handles sets of mutually disjoint words (such as rare words) which all co-occur with a more common word. Boxes have exponentially many corners, relative to their dimension, allowing extreme flexibility in the possible arrangements of intersection to represent complicated co-occurrances.

6.2 Set Theoretic Operations

All the senses, contexts and abstractions of a word can not be captured accurately using a point vector, and must be captured with sets. In this section, we evaluate our models capability of representing sets by performing set operations with the trained models.

6.2.1 Dataset

Homographs, words with identical spelling but distinct meanings, and polysemous words are ideal choice of probe for this purpose, as demonstrated by the "bank", "river" and "finance" example of Figure 1. We constructed set-theoretic logical operations on words based on common polysemous words and homographs (Nelson et al., 1980). For example, the word "property" will have association with words related both "asset" and "attribute", and thus the union of the later two should be close to the original word "property". Likewise, the intersection set of "property" and "math" should contain many words related to mathematical properties or concepts.

To this end, we created a dataset consisting of triples (A, B, C) where $A \circ B$ should yield a set similar to C, for various set-theoretic operations $\circ$. In this task, given two words A and B and a set theoretic operation $\circ$, we try to find the rank of word C in the sorted list based on the set similarity (vector similarity scores for the vectors) score between $A \circ B$ and all words in the vocab. The dataset consists of 52 examples for both Union and Negation, and 20 examples for Intersection. The details of the dataset can be found in Appendix D.

6.2.2 Quantitative Results

In Table 2, we report the percentage of times WORD2BOX outperforms WORD2VEC, i.e. the model yields better rank for the word C. Note that it is not clear how to design the union, difference or the intersection operations with vectors. We consider several relevant choices, including component-wise operations (addition, subtraction, min and max) which yield a representation for $A \circ B$, as well as operations which operate on the scores - eg. score max pooling ranks each word X using $\max(A \cdot X, B \cdot X)$, and similarly for score min pooling. The purpose of these operations is to mimic the essence of union and intersection in the vector space, however, it is evident that the trained vector geometry is not harmonious to this construction as well.

We observe that almost of all the values are more than 0.9, meaning that WORD2BOX yields a higher rank for the target C than WORD2VEC over 90% of the time. This empirically validates that our model is indeed capturing the underlying set theoretic aspects of the words in the corpus.

Table 1: Similarity: We evaluate our box embedding model Word2Box against a standard vector baseline Word2Vec. For comparison, we also include the reported results for Gaussian and Poincaré embeddings, however we note that these may not be directly comparable as many other aspects (eg. corpus, vocab size, sampling method, training process, etc.) may be different between these models.

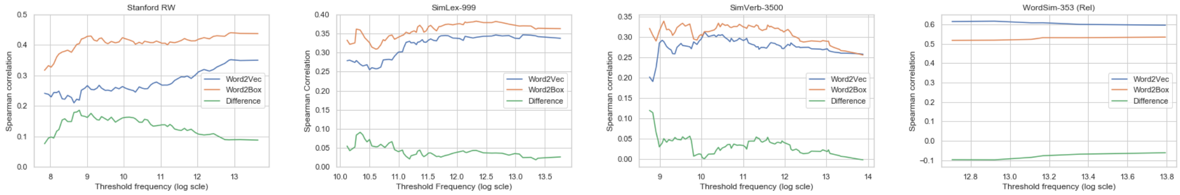

Figure 3: We plot the Spearman's correlation score vs Threshold frequency in log scale for Stanford RW, Simelex-999 SimVerb-3500, WS-353 (Rel). The correlation value is calculated on the word pairs where both of them have frequency less than the threshold frequency.

Word2Box Word2Vec	$A \cap B$	$A \setminus B$	$A \cup B$

$\max(A \cdot X, B \cdot X)$	0.95	0.84	0.94
$\min(A \cdot X, B \cdot X)$	1.0	0.80	0.84

Table 2: Percentage of queries for which Word2Box set operations return the target word with higher rank than the given vector operation for Word2Vec. Scores higher than 0.5 means that Word2Box outperformed Word2Vec. For subsequent qualitative comparisons we take the vector operation which performs most favorably for Word2Vec.

6.2.3 Qualitative Analysis

In this section, we present some interesting examples of set theoretic queries on words, with different degrees of complexities. For all the tables in this section, we perform the set-operations on the query words and present the ranked list of most similar words to the output query. Many of these queries are based on the aforementioned homographs, for which there are natural expectations of what various set-theoretic operations should capture. Our results are presented in Table 3-7.

The results in Table 4 look reasonable for both models, as is to be expected since this is simply the similarity function for each model. Even increasing to a single intersection, as in Table 5, starts to demonstrate that Word2Vec may often return very low-frequency words. In Table 6, we observe that set difference of "property" and "land" yields a set of words that are related to attributes of science subjects, eg. algebra or chemistry. We wanted to examine how the model would handle more complicated queries, for example if we first perform "property"\"finance" and then further intersect with "algebra" or "chemistry", does the introduction of the relatively high-frequency "finance" term cause the model to struggle to recapture these items? In Table 7 we observe that the outputs for Word2Box do indeed correspond to properties of those sub-fields of science, whereas the results in Word2Vec focus strongly on "finance". In general, we observe better consistency of Word2Box with all the example logical queries.

7 Related Work

Learning distributional vector representations from a raw corpus was introduced in Mikolov et al. (2013), quickly followed by various improvements (Pennington et al.; Bojanowski et al., 2017). More recently, vector representations which incorporate contextual information have shown significant improvements (Peters et al., 2018; Devlin et al., 2019; Radford et al., 2019; Brown et al., 2020). As these models require context, however, Word2Vec-style approaches are still relevant in settings where such context is unavailable.

Hyperbolic representations (Nickel and Kiela, 2017; Ganea et al., 2018; Chamberlain et al., 2017) have become popular in recent years. Most related to our setting, Tifrea et al. (2019) propose a hyperbolic analog to GloVe, with the motivation that the hyperbolic embeddings will discover a la-

Table 7: Comparison of set difference followed by intersection operation

tent hierarchical structure between words.[4] Vilnis and McCallum (2015) use Gaussian distributions to represent each word, and KL Divergence as a score function. [5] Athiwaratkun and Wilson (2018) extended such representations by adding certain thresholds for each distribution. For a different purpose, Ren and Leskovec (2020) use Beta Distributions to model logical operations between words. Our work can be seen as a region-based analog to these models.

Of the region-based embeddings, Suzuki et al. (2019) uses hyperbolic disks, and Ganea et al. (2018) uses hyperbolic cones, however these are not closed under intersection nor are their intersections easily computable. Vendrov et al. (2016) and Lai and Hockenmaier (2017) use an axis-aligned cone to represent a specific relation between words/sentences, for example an entailment relation. Vilnis et al. (2018) extends Lai and Hockenmaier (2017) by adding an upper-bound, provably increasing the representational capacity of the model. Li et al. (2019) and Dasgupta et al. (2020) are improved training methods to handle the difficulties inherent in gradient-descent based region learning. Ren et al. (2020) and Abboud et al. (2020) use a box-based adjustment of their loss functions, which suggest learning per-entity thresholds are beneficial. Chen et al. (2021) use box embeddings to model uncertain knowledge graphs, Onoe et al. (2021) use boxes for fined grained entity typing, and Patel et al. (2022) use boxes for multi-label classification.

Fuzzy sets, a generalization of sets, have been widely studied in the context of clustering (Bezdek and Harris, 1978), decision theory (Zimmermann, 1987) and linguistics (De Cock et al., 2000). However, the use of fuzzy sets in NLP has been fairly limited. Bhat et al. (2020) normalized each dimension of a word vector against all the word vectors in the vocabulary and interpret them as probability features that enabled them to perform fuzzy set theoretic operations with the words. Zhao and Mao (2018) and Zhelezniak et al. (2019b) build fuzzy set representations of sentences using pre-trained vector embeddings for words and show the usefulness such representations on semantic textual similarity (STS) tasks. Jimenez et al. (2013, 2014) use the soft-cardinality features for a fuzzy set representation of a sentence to perform the task of entailment and textual relatedness. All these works, use pre-trained vector embeddings for the words to form fuzzy sets representing sentences. However, in this work we learn fuzzy set representations for words from corpus.

8 Conclusion

In this work we have demonstrated that box embeddings can not only effectively train to represent pairwise similarity but also can capture the rich set-theoretic structure of words via unsupervised training. This is a consequence of the fact that Gumbel boxes are an efficient parameterization of fuzzy sets, with sufficient representational capacity to model complicated co-occurrance interactions while, at the same time, allowing for tractable computation and gradient-based training of set-theoretic queries. The set-theoretic representation capabilities of box models allow them to generalize in a calibrated manner, leading to a more coherent and self-consistent model of sets.

A Preprocessing

The WaCKypedia corpus has been tokenized and lemmatized. We used the lemmatized version of the corpus, however it was observed that various tokens were not split as they should have been (eg. “1.5billion” -> “1.5 billion”). We split tokens using regex criteria to identify words and numbers. All punctuation was removed from the corpus, all numbers were replaced with a “<num>” token, and all words were made lowercase. We also removed any words which included non-ascii symbols. After this step, the entire corpus was tokenized once more, and any token occurring less than 100 times was dropped.

C Hyperparameters

As discussed in Section 6, we train on 128 dimensional WORD2VEC and 64 dimensional WORD2BOX models for 10 epochs. We ran at least 60 runs for each of the models with random seed and randomly chose hyperparamter from the following range - batch_size:[2048, 4096, 8192, 16384, 32768], learning rate log_uniform[exp(-1), exp(-10)], Window_size: [5, 6, 7, 8, 9, 10], negative_samples: [2, 5, 10, 20], sub_sampling threshold: [0.001, 0.0001]. The best working hyperparameter sets and the corresponding checkpoints can be found here:

D Dataset for Set Theoretic Queries

In this section, we describe the dataset for set theoretic evaluation. We evaluate on *set-intersection*, *set-difference*, *set-union* queries. For each of these tasks, we create queries of the form $< A, B, A \circ B >$, where, $\circ$ is any of the mentioned set operation. In case of *set-union*, we find homographs to be an excellent choice as they are words describing multiple different choices of words. We choose commonly used homographs from list of homographs available in wikipedia (Wikipedia contributors, 2022) to construct this dataset. We manually eliminated many of the words which are rare or when the homographs are referring to concepts which are semantically similar. We provide some examples of the dataset for union queries in table 10. Also, note that we can perform the task for *set-difference* by just swapping the B and $A \cup B$, since $B = (A \cup B) \setminus A$, i.e., if we subtract one concept from the homographs then we must get back a set containing the other concept. So the same table is being used for *set-difference* task. We manually create a small evaluation set for the *set-intersection* task, listed in Table 9.

Abstract

Traditionally, a debate usually requires a manual preparation process, including reading plenty of articles, selecting the claims, identifying the stances of the claims, seeking the evidence for the claims, etc. As the AI debate attracts more attention these years, it is worth exploring the methods to automate the tedious process involved in the debating system. In this work, we introduce a comprehensive and large dataset named IAM, which can be applied to a series of argument mining tasks, including claim extraction, stance classification, evidence extraction, etc. Our dataset is collected from over 1k articles related to 123 topics. Near 70k sentences in the dataset are fully annotated based on their argument properties (e.g., claims, stances, evidence, etc.). We further propose two new integrated argument mining tasks associated with the debate preparation process: (1) claim extraction with stance classification (CESC) and (2) claim-evidence pair extraction (CEPE). We adopt a pipeline approach and an end-to-end method for each integrated task separately. Promising experimental results are reported to show the values and challenges of our proposed tasks, and motivate future research on argument mining. [1]

1 Introduction

Debating has a long history and wide application scenarios in education field (Stab and Gurevych, 2014; Persing and Ng, 2016; Stab and Gurevych, 2017), political domain (Lippi and Torroni, 2016; Duthie et al., 2016; Menini et al., 2018), legal actions (Mochales and Moens, 2011; Grabmair et al., 2015; Teruel et al., 2018), etc. It usually involves tons of manual preparation steps, including reading the articles, selecting the claims, identifying the claim stances to the topics, looking for the evidence of the claims, etc. Since the machine has shown promising potential in processing large quantities of information in many other natural language processing tasks, it is also worthwhile to explore the methods for automating the manual process involved in debating.

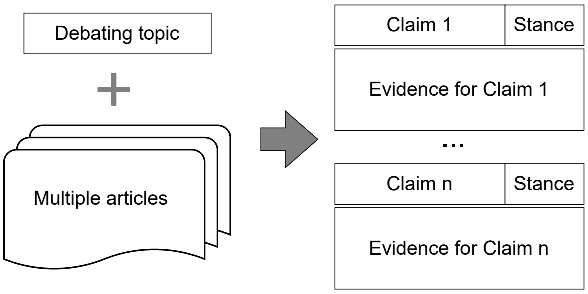

Figure 1: A flow chart showing the debating preparation process.

Argument mining (AM), as the core of a debating system (Bar-Haim et al., 2021), has received more attention in the past few years. Several AM tasks and datasets have been proposed to work towards automatic AI debate, such as: context dependent claim detection (CDCD) (Levy et al., 2014), claim stance classification (CSC) (Bar-Haim et al., 2017; Chen et al., 2019) , context dependent evidence detection (CDED) (Rinott et al., 2015), etc. All the above tasks are essential elements for AM and they are mutually reinforcing in the debating preparation process. In this work, we aim at automating the debating preparation process as shown in Figure 1. Specifically, providing with the debating topic and several related articles, we intend to extract the claims with their stances, and also the evidence supporting the claims.

However, none of the existing works can facilitate the study of all these tasks at the same time. Motivated by this, we introduce a comprehensive dataset named IAM to support the research of these tasks. We create our dataset by first collecting over

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 2277 - 2287
May 22-27, 2022

100 topics from online forums and then exploring over 1k articles related to these topics. All the sentences in those articles are fully-annotated following a set of carefully defined annotation guidelines. Given a specific topic, the annotators have to distinguish whether the given sentence is a claim to this topic and identify the relation between the selected claim and the topic (i.e., support or contest). Then given the claims, the annotators have to browse the contexts to find evidence supporting the claims. With all the labeled information, researchers can work towards these primary argument mining tasks simultaneously.

To better coordinate these individual tasks together, we propose two new integrated tasks: claim extraction with stance classification (CESC) and claim-evidence pair extraction (CEPE). Instead of treating the existing tasks (i.e., CDCD, CSC, CDED) as individual ones, the two proposed tasks can integrate the relevant primary tasks together, which are more practical and more effective in the debating preparation process. The CESC task can be divided into two subtasks: the claim detection task and the stance classification task. Intuitively, we conduct experiments on the CESC task with a pipeline approach to combine the two subtasks. As the two subtasks are mutually reinforcing each other, we also adopt an end-to-end classification model with multiple labels (i.e., support, contest, and no relation). The CEPE task is composed of the claim detection task and the evidence detection task. Similar to the annotation procedure, we apply a pipeline method to tackle this problem by first detecting the claims given the topics and then identifying the corresponding evidence of each claim. We also use a multi-task model to extract both claims and evidence as well as their pairing relation simultaneously. We conduct extensive experiments on our dataset to verify the effectiveness of our models and shed light on the challenges of our proposed tasks.

To summarize, our contributions are as follows. (1) We introduce a fully-annotated argument mining dataset and provide thorough data analysis. This is the first dataset that supports comprehensive argument mining tasks. (2) We are the first to propose the CESC and CEPE tasks, which are practical task settings in the argument mining field and able to enlighten future research on this. (3) We conduct preliminary experiments for all proposed tasks with the new dataset.

2 Related Work

In recent years, there is a tremendous amount of research effort in the computational argumentation research field (Eger et al., 2017; Bar-Haim et al., 2021), such as argument components identification (Levy et al., 2014; Rinott et al., 2015; Lippi and Torroni, 2016; Daxenberger et al., 2017), argument classification and clustering (Reimers et al., 2019), argument relation prediction (Boltužić and Šnajder, 2016; Chakrabarty et al., 2019), argument pair extraction (Cabrio and Villata, 2012; Cheng et al., 2020, 2021), argument quality assessment (Habernal and Gurevych, 2016; Wachsmuth et al., 2017; Gretz et al., 2020; Toledo et al., 2019), listening comprehension (Mirkin et al., 2018), etc.

Meanwhile, researchers have been exploring new datasets and methods to automate the debating preparation process, such as project debater (Slonim et al., 2021), etc. Bilu et al. (2019) work on the argument invention task in the debating field to automatically identify which of these arguments are relevant to the topic. Li et al. (2020) explore the role of argument structure in online debate persuasion. Levy et al. (2014) introduce a dataset with labeled claims and work on the task of context-dependent claim detection (CDCD). Bar-Haim et al. (2017) modify Aharoni et al. (2014)'s dataset by further labeling the claim stances, and tackle the problem of stance classification of context-dependent claims. Rinott et al. (2015) propose a task of detecting context-dependent evidence that supports a given claim (CDED) and also introduce a new dataset for this task.

Unlike previous works with a specific focus on only one argument mining task, we introduce a comprehensive dataset that is able to support different tasks related to the debating system. Such a dataset not only enlightens future research on the argument mining field but also shows strong potential for various practical applications. Another difference is that existing tasks (e.g., CDCD, CDED, CSC, etc.) could be considered as subtasks in the emerging wider field of argumentation mining (Levy et al., 2014). While in this paper, we propose two integrated tasks (i.e., CESC and CEPE) incorporating the existing subtasks in the debating system, which takes a step forward to automatic AI debate. A more detailed comparison to the most representative and relevant previous datasets will be shown in Section 3.3.

	Topic: Will artificial intelligence replace humans	Claim	Stance	Evidence
1	Job opportunities will grow with the advent of AI; however, some jobs might be lost because AI would replace them.	C_1	+1	
2	Any job that involves repetitive tasks is at risk of being replaced.	C_2	+1	
3	In 2017, Gartner predicted 500,000 jobs would be created because of AI, but also predicted that up to 900,000 jobs could be lost because of it.			E_1 | E_2
4	The number of industrial robots has increased significantly since the 2000s.			E_3
5	The low operating costs of robots make them competitive with human workers.			E_3
6	In the finance sector, computer algorithms can execute stock trades much faster than a human, needing only a fraction of a second.			E_3
7	As these technologies become cheaper and more accessible, they will be implemented more widely, and humans might be increasingly replaced by AI.	C_3	+1	
8	According to Harvard Business Review, most operations groups adopting RPA have promised their employees that automation would not result in layoffs.	C_4	-1	E_4
9	AI is incredibly smart, but it will never match human creativity.	C_5	-1	

Table 1: Sample topic and labeled claims with their stances and evidence. Note that different blocks refer to the sentences from different articles, and we only extract claim-evidence pairs from the same article. For clarity, we label the indices in ascending order, which may not reflect the real indices in the dataset.

3 IAM Dataset

We introduce a large and comprehensive dataset to facilitate the study of several essential AM tasks in the debating system. We describe the collection process, annotation details and data analysis here.

3.1 Data Collection

First, we collect 123 debating topics with a wide variety from online forums. For each topic, we explore around 10 articles from English Wikipedia with promising content. The most number of articles explored for one topic is 16, while the least number is 2. This is because it is difficult to find enough resources for unpopular topics such as “Should nuclear waste be buried in the ground”. However, most topics (i.e., 91 topics) are relatively popular with more than 8 related articles collected for each of them. In total, there are 1,010 articles collected for all the topics. After we obtain all the relevant articles, we use the NLTK package (Bird et al., 2009) to split the corpus into 69,666 sentences from these articles for further annotation.

3.2 Data Annotation

The annotation process is mainly separated into two stages: (1) detecting the claims given the topics, (2) detecting the evidence given the claims. A context-dependent claim (CDC), claim in short, is a general and concise statement that directly supports or contests the given topic (Levy et al., 2014). The annotators are asked to extract the claims by following this definition. Meanwhile, the annotators have to identify the stance of the extracted claim towards the given topic. In the second stage, the annotators have to read through the context surrounding the claims, and extract the evidence following that a piece of context-dependent evidence (CDE) is a text segment that directly supports a claim in the context of the topic. Since only the surrounding sentences are content-relevant in most cases, we only search 10 to 15 sentences before and after the claim sentence to label the evidence. Note that the claim itself could be the evidence as well.

Professional data annotators are hired from a data annotation company and are fully paid for their work. Each sentence is labeled by 2 professional annotators working independently in the first round. 69,666 sentences are labeled in total and the Cohen’s kappa is 0.44 between the two annotators, which is a reasonable and relatively high agreement considering the annotation complexity (Aharoni et al., 2014; Levy et al., 2014). Whenever there is any inconsistency, the third professional annotator will judge the annotation result in the confirmation phase to resolve the disagreement.

Table 1 shows a sample topic “Will artificial intelligence replace humans” and its labeled claims with their stances and evidence. The claims are labeled as “C_index” and the evidence is labeled as “E_index”. For stances, “+1” represents the current claim supporting the topic, while “-1” represents the claim contesting the topic. A claim and a piece of evidence form a claim-evidence pair (CEP) if the indices match with each other under a specific

	Topics	Articles	Articles with claims	Claims	Support	Contest	Claims with evidence	Evidence	CEPs
Levy et al. (2014)	32	326	-	976	-	-	-	-	-
Rinott et al. (2015)	39	274	274	1,734	-	-	1,040	3,057	5,029*
Aharoni et al. (2014)	33 (12)	586	321 (104)	1,392	-	-	(350)	(1,291)	1,476*
Bar-Haim et al. (2017)	55	-	-	2,394	1,324	1,070	-	-	-
IAM (Ours)	123	1,010	814	4,890	2,613	2,277	3,302	9,384	10,635

Table 2: Overall statistics comparison of the existing datasets and our dataset. Note that: (1) in Aharoni et al. (2014)'s dataset, the numbers in the parenthesis refer to the evidence labeling data; (2) the numbers with * are calculated by us since they are not shown in the original papers.

	Ours
Avg. length of all sentences	21.05
Avg. length of claims	23.44
Avg. length of evidence	25.09
Avg. % vocab shared in each CEP	20.14%
Avg. % vocab shared in each sent pair	8.73%

Table 3: Dataset statistics on argument lengths and vocabulary sharing.

topic. A piece of evidence can support multiple claims, such as Sent 3, as a piece of evidence, it supports two claims, i.e. Sent 1 and 2. Similarly, a claim can have different evidence, such as Sent 7, as a claim, it has three paired evidence sentences (i.e., Sent 4 - 6). As mentioned, one sentence can be considered as both the claim and the evidence. For instance, in Sent 8, there is a clear and concise statement "automation would not result in layoffs" contesting the given topic directly, which is considered as a claim. There is also a text segment at the beginning of the sentence showing the testimony from an organization (i.e., "Harvard Business Review") directly supporting this claim stated in the latter part of the sentence. Therefore, this sentence is labeled as evidence as well. Last but not least, there are some claims without evidence found in the context in our dataset, such as Sent 9.

3.3 Dataset Analysis

We present the dataset statistics comparison with existing datasets in Table 2, and list the key differences below. First, as mentioned earlier, the existing datasets have their own focus on particular tasks, and none of them can support all the essential argument mining tasks related to the debate preparation process. Levy et al. (2014) only label data for claims, Rinott et al. (2015) only focus on detecting the evidence given the claims, Aharoni et al. (2014) only label a partial dataset for evidence, and Bar-Haim et al. (2017) only tackle the claim stance classification problem. In contrast, our dataset is fully annotated for all the key elements related to argument mining tasks, including claims, stances, evidence, and relations among them. Although combining Aharoni et al. (2014) and Bar-Haim et al. (2017)'s datasets can obtain a comprehensive dataset with 12 topics supporting all the subtasks, in terms of the dataset size, our dataset is significantly larger than it and the existing datasets. We explore 123 topics in total, which is more than twice of Bar-Haim et al. (2017)'s dataset. Accordingly, we obtain much more claims and evidence by human annotation on all sentences in the corpus, as compared to the previous datasets, which could add potential value to the argument mining community.

Table 3 shows more statistics of our dataset. In terms of the sentence lengths in our dataset, the average number of words in a sentence is around 21. The average length of sentences containing claims is generally longer, and evidence is even slightly longer. However, since the length differences are subtle, it shows the challenges to distinguish the claims and evidence using the length differences among the sentences. We also calculate the average percentage of vocabulary shared between each claim-evidence sentence pair, which is 20.14%; while the same percentage between any two sentences from our corpus is only 8.73%. This shows that extracting CEP is a reasonable task as it has a higher percentage of vocabulary sharing than other sentence pairs, but it is also challenging as the absolute percentage is still low.

4 Tasks

In the debating system, our ultimate goal is to automate the whole debate preparation process as shown in Figure 1. With the introduced annotated dataset, we can tackle all core subtasks involved in the process at the same time. In this section, we first review the existing subtasks, and then propose two integrated argument mining tasks.

4.1 Existing Tasks

Task 1: Claim Extraction Similar to the CDCD task proposed by Levy et al. (2014), this task is defined as: given a specific debating topic and related articles, automatically extract the claims from the articles. Claim extraction is a primary argument mining task as the claim is a key argument component.

Task 2: Stance Classification As introduced by Bar-Haim et al. (2017), this task is defined as: given a topic and a set of claims extracted for it, determine for each claim whether it supports or contests the topic. As shown in Table 2, the number of claims from two stances is approximately balanced (i.e., 53.4% are support and 46.6% are contest).

Task 3: Evidence Extraction In Rinott et al. (2015)'s work, this task is defined as: given a concrete topic, a relevant claim, and potentially relevant documents, the model is required to automatically pinpoint the evidence within these documents. In this paper, we only explore the evidence candidate sentences from the surrounding sentences of the claims, as long-distance sentences may not be content-relevant in most cases.

4.2 Integrated Tasks

In order to further automate the debating preparation process, exploring integrated tasks rather than individual subtasks is non-trivial. In this work, we introduce two integrated argument mining tasks as below to better study the subtasks together.

Task 4: Claim Extraction with Stance Classification (CESC) Since claims stand at a clear position towards a given topic, the sentences with clear stances should have a higher possibility to be the claims. Hence, identifying the stances of the claims is supposed to benefit the claim extraction task. By combining Task 1 and Task 2, we define the first integrated task as: given a specific topic and relevant articles, extract the claims from the articles and also identify the stance of the claims towards the topic.

Task 5: Claim-Evidence Pair Extraction (CEPE) Since evidence is clearly supporting the corresponding claims in an article, claims and evidence are mutually reinforcing each other in the context. Therefore, we hypothesize the claim extraction task and the evidence extraction task may benefit each other. By combining Task 1 and Task 3, we define the second integrated task as: given a specific topic and relevant articles, extract the claim-evidence pairs (CEPs) from the articles.

5 Approaches

To tackle the two integrated tasks, we first adopt a pipeline approach to pipe the corresponding subtasks together by using sentence-pair classification on each subtask. We also propose two end-to-end models for the two integrated tasks.

5.1 Sentence-pair Classification

We formulate Task 1, Task 2, and Task 3 as sentence-pair classification tasks. We train a sentence-pair classifier based on pre-trained models such as BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019). The sentence pairs are concatenated and fed into the pre-trained model to get the hidden state of the "[CLS]" token. Then, a linear classifier will predict the relation between the two sentences. Specifically, for Task 1, the topic and the article sentence are concatenated and fed into the model. If they belong to the same pair, the article sentence is considered as a claim, and vice versa. For Task 2, the model predicts the stance between a topic and a claim. Task 3 is similar to Task 1, where the model predicts if the given claim and the article sentence form a pair, i.e., if the sentence is a piece of evidence of the claim. All these three tasks can be considered as binary classification tasks, and cross-entropy loss is used as the loss function.

Negative Sampling For Task 1 and Task 3, the binary labels are unbalanced as the number of claims and pieces of evidence is far smaller than the total number of sentences. To overcome this difficulty, we adopt negative sampling techniques (Mikolov et al., 2013). During the training of these two tasks, for each claim/evidence sentence, we randomly select a certain amount of non-claim/non-evidence sentences as negative samples. These negative samples together with all claims/evidence form a new training dataset for each task.

5.2 Multi-Label Model for CESC

Apart from the pipeline approach, we propose a multi-label model for CESC. Instead of handling the two subtasks separately, we concatenate the topic and article sentences to feed into a pre-trained model and define 3 output labels specifically for this task: support, contest, and no-relation. Support and contest refer to those claims with their corresponding stances to the topic, while no-relation stands for non-claims. Since the sentence pairs with no-relation labels are much more than those with support/contest, we also apply negative sampling here for a more balanced training process.

5.3 Multi-Task Model for CEPE

Inspired from Cheng et al. (2021)'s work, we adopt a multi-task model (i.e., an attention-guided multi-cross encoding-based model) for the CEPE task. Provided with a sequence of article sentences and the topic, we first concatenate the topic and individual sentences as the claim candidates, and use the sequence of article sentences as the evidence candidates. We reformulate the claim extraction and evidence extraction subtasks as sequence labeling problems. Then, the sequence of claim candidates and the sequence of evidence candidates go through the pre-trained models to obtain their sentence embeddings respectively. To predict whether two sentences form a claim-evidence pair, we adopt a table-filling approach by pairing each sentence in the claim candidates with each sentence in the evidence candidates to form a table. All three features (i.e., claim candidates, evidence candidates, table) update each other through the attention-guided multi-cross encoding layer as described in Cheng et al. (2021)'s work. Lastly, the two sequence features are used to predict their sequence labels, the table features are used for pair prediction between each claim and evidence. Compared to the pipeline approach, this multi-task model has stronger subtask coordination capability, as the shared information between the two subtasks is learned explicitly through the multi-cross encoder.

6 Experiments

6.1 Experimental Settings

We split our dataset randomly by a ratio of 8:1:1 for training, development, and testing. The dataset statistics are shown in Table 4. In the training set, since the number of claims (3,871) and the number of non-claims (51,673) are not balanced with a ratio of 1:13.3, we conduct experiments by selecting different numbers of negative samples and evaluate the effectiveness of the negative sampling strategy. It turns out that using 5 random negative samples for each claim performs the best. For each claim with evidence, 10 to 15 sentences before and after the claims are chosen to be the evidence candidates. The negative sampling strategy is also applied for the evidence candidates in the training set, where the ratio of positive samples (i.e., 7,278 pieces of evidence) to negative samples (i.e., 50,120 pieces of non-evidence) is 1:6.9. It turns out that using 1 random negative sample for each piece of evidence is the best.

	train	dev	test
# sents as claim candidates	55,544	7,057	7,065
# claims	3,871	492	527
# support claims	2,098	259	256
# contest claims	1,773	233	271
# claims with evidence	2,616	347	375
% claims with evidence	67.6%	70.3%	71.2%
# sents as evidence candidates	57,398	7,487	8,172
# pieces of evidence	7,278	909	1,108
Avg. # pieces of evidence per claim	2.78	2.62	2.95

Table 4: Dataset statistics split on train/dev/test sets.

We implement the sentence-pair classification model and the multi-label model for CESC with the aid of SimpleTransformers (Rajapakse, 2019). The multi-task model for CEPE is based on the implementation of the multi-task framework by Cheng et al. (2021). All models are run with V100 GPU. We train our models for 10 epochs. We experiment with two pre-trained models: BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019). Batch size is set as 128 for claim extraction and stance classification, and 16 for evidence extraction. We use 1 encoding layer for the multi-task model, and other parameters are the same as the previous work. [2]

For the claim and evidence extraction subtasks, besides Macro F_1 and Micro F_1, we also report the claim-class F_1 and the evidence-class F_1, respectively. For CESC, we additionally report the claim-class F_1 of different stances (i.e., support and contest). For the claim stance classification subtask, we report overall accuracy and F_1 for each class, as this task can be simply considered as a binary classification problem with balanced labels. For CEPE, we report precision, recall, and F_1.

6.2 Main Results on Existing Tasks

Claim Extraction Performance Table 5 shows the performance on Task 1. The classification model with pre-trained RoBERTa-base performs

---

[2] More details about hyper-parameter settings (i.e., batch sizes in the sentence-pair classification model, number of layers in the multi-task model), runtime and performance on the development set could be found in Appendix A.

Models	Macro F_1	Micro F_1	Claim F_1

RoBERTa-base	**81.21**	**81.21**	**81.21**

Table 6: Stance classification performance.

Models	Macro F_1	Micro F_1	Evi. F_1
BERT-base-cased (T+C)	58.17	72.75	38.15
RoBERTa-base (T+C)	62.43	78.13	**40.89**
BERT-base-cased (C)	58.01	72.65	37.92
RoBERTa-base (C)	**63.37**	**80.29**	40.16

Table 7: Evidence extraction performance.

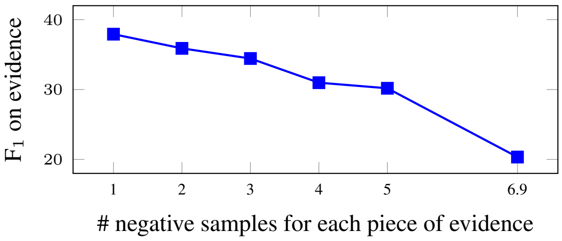

Figure 3: Effect of negative sampling for evidence extraction with BERT-base-cased (C).

slightly better than with BERT-base-cased. Recall that we adopt the negative sampling strategy for these two models by randomly selecting 5 negative samples during the training phase. We also compare the performance of using different numbers of negative samples for each claim as shown in Figure 2. Generally speaking, the model performs better as the number of negative samples increases from 1 to 5, and starts to drop afterward. As the ratio is more balanced, i.e., from no sampling (1:13.3) to 5 negative samples, the F_1 score increases as expected. As the number of negative samples decreases further to 1, the ratio is even more balanced. However, it sacrifices the number of training data, which leads to worse performance.

Stance Classification Performance Table 6 shows the performance on Task 2. In both models, the F_1 scores on each stance are very close to each other, which is as expected because the two stances are balanced as shown in Table 4. Although the pretrained RoBERTa model outperforms the BERT model, there is still ample room for improvement as the accuracy of the RoBERTa model (81.21) is not relatively high for a binary classification task. One possible reason is that some claim sentences are too long to intuitively show the stances. For example, for the topic "Should vaccination be mandatory", a claim sentence "Young children are often at increased risk for illness and death related to infectious diseases, and vaccine delays may leave them vulnerable at ages with a high risk of contracting several vaccine-preventable diseases." is classified as "+1" according to the human evaluation, but is predicted as "-1" from the RoBERTa model.

Evidence Extraction Performance Table 7 shows the performance on Task 3. Again, the RoBERTa model performs better than the BERT model. For this task, we experiment with two settings: (1) given the topic and the claim (T+C), (2) only given the claim (C), to identify the evidence from the candidate sentences. For the (T+C) setting, we simply concatenate the topic and the claim as a sentence, and pair up with the evidence candidates to predict whether it is a piece of evidence of the given claim under the specific topic. Comparing the results of these two settings, adding the topic sentences as inputs does not significantly improve the performance further, which suggests that claims have a closer relation with evidence, while the topic is not a decisive factor to evidence extraction. Here, 1 negative sample for each evidence sentence is randomly selected. The comparison of different numbers of negative samples is shown in Figure 3. Unlike the trend shown in the claim extraction task, the model achieves the best performance when the ratio is exactly balanced at 1:1.

6.3 Main Results on Integrated Tasks

For these two integrated tasks, we first use a pipeline method to pipe the best performing model on each corresponding subtask together, and then

Models	Macro F_1	Micro F_1	Support F_1	Contest F_1
Pipeline	55.95	88.56	33.39	40.10
Multi-label	**60.25**	**91.22**	**38.34**	**47.31**

Table 8: CESC task performance.

Models	Precision	Recall	F_1
Pipeline	16.58	22.11	18.95
Traversal	24.06	**38.74**	29.69
Multi-task	**43.54**	30.57	**35.92**

Table 9: CEPE task performance.

Topic: Should we ban human cloning	**Gold**	**PL**	**MT**
Claim: Cloning humans could reduce the impact of diseases in ways that vaccinations cannot.	C	C	C
This method could help countries like Japan who are struggling with low birth rates.		E	
The Japanese culture could see a reduction of up to 40 million people by the year 2060 without the introduction of cloning measures.		E	
Human cloning could help us to begin curing genetic diseases such as cystic fibrosis or thalassemia.	E	E	E
Genetic modification could also help us deal with complicated maladies such as heart disease or schizophrenia.	E		E

Table 10: Examples of model predictions for CEPE task. PL stands for the pipeline, and MT stands for the multi-task. We select four sentences from the evidence candidates to demonstrate the prediction results here.

compare the overall performance with the proposed end-to-end models.

CESC Task Performance Table 8 shows the results of two approaches for the CESC task. For both two methods, we randomly select 5 negative samples for each positive sample (i.e., claim) during training. The pipeline model trains two subtasks independently and pipes them together to predict whether a sentence is a claim and its stance. Although it achieves the best performance on each subtask, the overall performance is poorer than the multi-label model. It shows that identifying the stances of the claims can benefit the claim extraction subtask, and such a multi-label model is beneficial to the integrated CESC task.

CEPE Task Performance Table 9 shows the overall performance comparison among different approaches. Apart from the pipeline and the multi-task models as mentioned, we add another baseline model named "traversal". In this model, all possible pairs of "topic + claim candidate" and "evidence candidate" are concatenated and fed into the sentence-pair classification model. Both the traversal model and the multi-task model outperform the pipeline model in terms of the overall F_1 score, which implies the importance of handling these two subtasks together. The better performance of the multi-task model over the traversal model demonstrates the strong subtask coordination capability of the multi-task architecture.

6.4 Case Study

We present a few examples in Table 10 to compare the prediction results from the pipeline approach and the multi-task method for the CEPE task. Given the topic "should we ban human cloning", both models successfully identify the claim sentence. The first two sentences are not labeled as evidence supporting this claim based on the human annotation. The multi-task model labels these two sentences correctly, while the pipeline model predicts them as evidence by mistake. We notice that phrases of giving examples (e.g., "countries like") and numbers (e.g., "40 million", "year 2060") are very common elements in evidence, which are the typical evidence types like demonstration with examples and numerical evidence. We further explore the label predictions of these two sentences toward other claims and observe the pipeline approach classifies them as evidence as well. Without understanding the true meaning of the sentences, the pipeline approach only learns the common words and the structure. For the third evidence candidate, both models correctly predict this sentence and the extracted claim as a claim-evidence pair. However, the pipeline model fails to identify the last evidence candidate sentence as a piece of evidence supporting the extracted claim. This is plausibly because the claim and the last evidence candidate sentence share few vocabularies. Although "genetic modification" is different from "cloning humans", they still share some similarities in terms of semantic comprehension in the context, thus the second sentence can also support the claim. Compared to the pipeline approach simply using the sentence-pair classification on the current sentences step by step, the multi-task model can learn a better sentence representation by utilizing the context information and coordinating two subtasks explicitly through the attention-guided multi-cross encoding layer, which finally leads to better performance. See Appendix B for more examples.

7 Conclusions

In this paper, we introduce a comprehensive and large dataset named IAM for argument mining to facilitate the study of multiple tasks involved in the debating system. Apart from the existing primary argument mining tasks for debating, we propose two integrated tasks to work towards the debate automation, namely CESC and CEPE. We experiment with a pipeline method and an end-to-end approach for both integrated tasks. Experimental results and analysis are presented as baselines for future research, and demonstrate the value of our proposed tasks and dataset. In the future, we will continue studying the relations among the argument mining subtasks and also explore more useful research tasks in the debating system.

A More Experimental Details

A.1 Hyper-parameters

We manually tune the hyper-parameters in our models. Table 11 shows the results on claim extraction task with different batch sizes from 8 to 128. Here, we use the pre-trained RoBERTa-base model. 5 negative samples are randomly chosen for each claim during training. When the batch size is 128, the model achieves the best performance.

Models	Batch size	Macro F_1	Micro F_1	Claim F_1
RoBERTa-base	8	68.44	91.24	41.65
RoBERTa-base	16	70.92	**92.17**	45.94
RoBERTa-base	32	71.59	90.97	48.82
RoBERTa-base	64	72.11	91.89	48.85
RoBERTa-base	128	**72.36**	91.09	**50.35**

Table 11: Claim extraction performance with different batch sizes.

Table 12 shows the results of using different batch sizes ranging from 8 to 128 for the stance classification task. Each model (i.e., BERT and RoBERTa) achieves the best performance when the batch size is 128.

Models	Batch size	Accuracy
BERT-base-cased	8	69.45
BERT-base-cased	16	68.50
BERT-base-cased	32	76.28
BERT-base-cased	64	65.09
BERT-base-cased	128	73.43
RoBERTa-base	8	70.97
RoBERTa-base	16	75.71
RoBERTa-base	32	78.37
RoBERTa-base	64	79.32
RoBERTa-base	128	**81.21**

Table 12: Results of different batch sizes for stance classification task.

Table 13 shows the effect of using different numbers of layers in the multi-task model. More model details regarding each layer could be found in (Cheng et al., 2021)'s work. The multi-task model achieves the best F_1 score when the number of layers is 1.

Layers	Precision	Recall	F_1
1	43.54	**30.57**	**35.92**
2	44.79	26.60	33.38
3	**45.65**	22.64	30.27

Table 13: Effect of different numbers of layers used in the multi-task model.

A.2 Runtime and Validation Performance

In Table 14, we present the running time and the results on the development set of the multi-task model on the CEPE task. As the number of layers increases, it requires a longer training time.

Layers	RT (min)	Dev P.	Dev R.	Dev F_1
1	15	33.31	20.66	25.50
2	22	39.81	18.68	25.43
3	29	40.59	18.36	25.28

Table 14: Runtime (RT) per epoch (minutes), the precision (P.), recall (R.) and F_1 on the development set of the multi-task model with differnt numbers of layers.

B More Case Study

Table 15 shows more example predictions generated by the pipeline approach and the multi-task model for the CEPE task. In these examples, the multi-task model identifies most of the claim-evidence pairs while the pipeline method fails to do so. For the second topic which is shown earlier in Section 3.2, the pipeline model fails to detect the claim sentence nor the evidence sentence.

Topic: Should we fight for the Olympics	**Gold**	**PL**	**MT**
Claim: These often impose costs for years to come.	C	C	C
Sydney's Olympic stadium costs the city $30 million a year to maintain.	E		E
Beijing's famous "Bird's Nest" stadium cost $460 million to build and requires $10 million a year to maintain, and sits mostly unused.	E		E
Topic: Will artificial intelligence replace humans			
Claim: Any job that involves repetitive tasks is at risk of being replaced.	C		C
In 2017, Gartner predicted 500,000 jobs would be created because of AI, but also predicted that up to 900,000 jobs could be lost because of it.	E		E
Topic: Should we implement the network real-name system			
Claim: Real-name policy blurs the boundaries between personal information and personal privacy.	C	C	C
Due to the vague boundaries between privacy and personal information, today people are willing to distinguish this boundary between online behavior and offline ID.	E		
For example, as an Internet user, my words and deeds on the Internet, personal information published, such as political positions, belong to my personal information.	E		E
But once it matches my true identity, it is personal privacy.	E		E

[2]`hpchan@um.edu.mo`, [3]`lifuh@vt.edu`

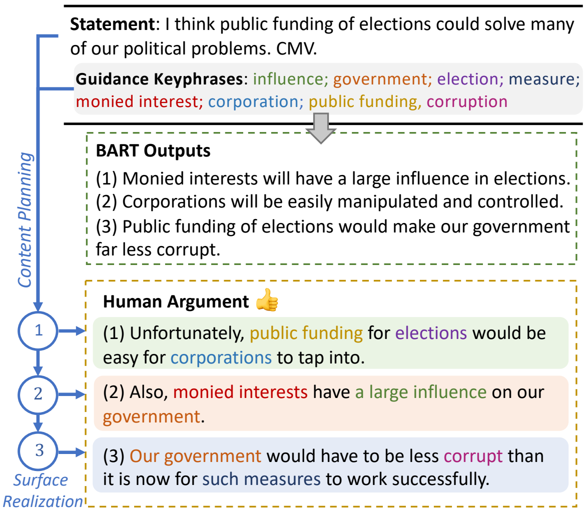
Abstract

Despite recent progress of pre-trained language models on generating fluent text, existing methods still suffer from incoherence problems in long-form text generation tasks that require proper content control and planning to form a coherent high-level logical flow. In this work, we propose PLANET, a novel generation framework leveraging autoregressive self-attention mechanism to conduct content planning and surface realization dynamically. To guide the generation of output sentences, our framework enriches the Transformer decoder with latent representations to maintain sentence-level semantic plans grounded by bag-of-words. Moreover, we introduce a new coherence-based contrastive learning objective to further improve the coherence of output. Extensive experiments are conducted on two challenging long-form text generation tasks including counter-argument generation and opinion article generation. Both automatic and human evaluations show that our method significantly outperforms strong baselines and generates more coherent texts with richer contents.

1 Introduction

Neural sequence-to-sequence (seq2seq) models are dominant methods for text generation nowadays, which are trained to maximize the log-likelihood over targets in an end-to-end fashion (Cho et al., 2014). Recently, pre-trained methods such as GPT-2 (Radford et al., 2019) and BART (Lewis et al., 2020) have achieved promising results by leveraging large-scale data. While these models can generate fluent results, they still fall short of producing coherent long-form texts with multiple sentences (Dou et al., 2021).

Long text generation, especially opinion generation, usually requires the model to (1) conduct proper content selection and ordering (i.e., "*what to say and when to say it*") to form a coherent high-level logical flow, and (2) appropriately reflect the



Statement: I think public funding of elections could solve many of our political problems. CMV.

Guidance Keyphrases: influence; government; election; measure; monied interest; corporation; public funding, corruption

BART Outputs
(1) Monied interests will have a large influence in elections.
(2) Corporations will be easily manipulated and controlled.
(3) Public funding of elections would make our government far less corrupt.

Human Argument 👍
(1) Unfortunately, public funding for elections would be easy for corporations to tap into.
(2) Also, monied interests have a large influence on our government.
(3) Our government would have to be less corrupt than it is now for such measures to work successfully.

Figure 1: Sample counter-arguments on Reddit ChangeMyView. Given a statement and a set of unordered keyphrases as guidance talking points, BART generates an incoherent output. In contrast, human writer conducts content planning and keyphrase selection for each sentence to form a coherent counter-argument.

text plans into final outputs (i.e.,"*how to say it*"). We present an example of counter-argument generation in Figure 1: given a statement on a controversial topic and a set of keyphrases as guidance talking points, the task aims to produce an argument with a different stance to refute the statement (Hua et al., 2019). Human writer assigns keyphrases for each sentence to form a coherent logical flow (e.g., "*corporations easily tap into public funding*" → "*they also have large influence on government*" → "*the current government is still corrupt*") and produces the final counter-argument that "*public funding won't solve the election problems*". In contrast, although BART learns to include keyphrases and generate an argument relevant to the statement, it suffers from incoherence issues such as incorrect usage of keyphrases (not "*corporations*" but '*election*" that "*be manipulated and controlled*") and wrong stance ("*public funding would make government less corrupt*"), and fails to maintain smooth transitions between sentences (e.g., sentence 2 and

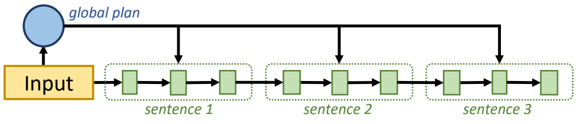
Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 2288 - 2305
May 22-27, 2022 ©2022 Association for Computational Linguistics

3 are unrelated) and form a coherent text.

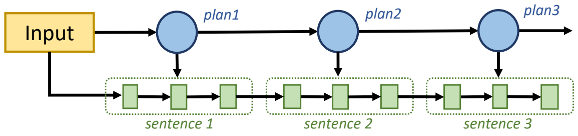
To solve the above defects, various text planning methods were proposed to improve the coherence of the generated text. The first type of methods (Kang and Hovy, 2020; Fu et al., 2020; Kong et al., 2021) leverage a latent variable as a global plan to guide the generation process, as illustrated in Figure 2 (a). However, these methods do not consider fine-grained sentence-level planning. The second line of methods (Hua and Wang, 2020; Goldfarb-Tarrant et al., 2020) first produce sentence-level content plans, and then pass content plans to a surface realization module to generate the output words, as shown in Figure 2 (b). Nevertheless, the planning and surface realization components are disjointed and may lead to cascading errors (Hua et al., 2021).

In this work, we propose **PLANET**, a novel text generation framework that dynamically performs content planning and surface realization in autoregressive Transformers. As shown in Figure 2 (c), for each target sentence, an autoregressive decoder first performs dynamic content planning by producing a latent representation (SN_j) as a semantic guidance, and then generates the sentence words. Both the content planning and surface realization are achieved dynamically by the autoregressive self-attention in a unified way: to generate a sentence (e.g., sentence 3), the latent representation (SN_3) attends the previous latent representations ($\mathrm{SN}_{1,2}$, solid blue arrows) and previous context (sentence 1 and 2, dashed blue arrows) to plan its overall semantic content; Then, each output position in the sentence attends the corresponding latent representation (SN_3, solid green arrow) and the previous words (dashed green arrows), and optionally select keyphrases (gray arrow) to decide the exact wording. To supervise the latent representations, we further introduce a sentence-level bag-of-words prediction auxiliary task to provide supervision signals of the lexical semantics of the corresponding sentence. In this way, our framework can be trained end-to-end and easily applied to pre-trained autoregressive Transformers.

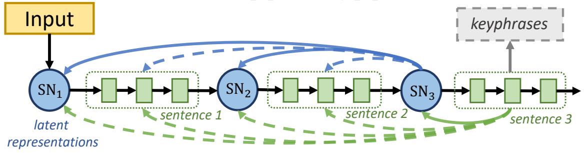
Furthermore, to empower our model to distinguish coherent and incoherent targets and generate more coherent outputs, we propose a novel coherence-based contrastive learning objective with different strategies to construct negative samples. We evaluate our model on two long-form opinion generation tasks: (1) counter-argument generation with Reddit/ChangeMyView dataset, and (2) opinion article generation from the New York Times Opinion corpus. Automatic evaluations show that our proposed method significantly outperforms strong baselines and generates more coherent texts with richer contents. Human evaluations further indicate that our model can properly leverage guidance keyphrases and generate better results on both datasets.



(a) Global planning pipeline



(b) Two-step planning pipeline



(c) Our dynamic planning with self-attention

Figure 2: Comparison of different content planning. For (c), the blue arrow denotes the attention flows for latent representations and the green one for target words. The attention of tokens within the same sentence is omitted. We highlight the attention flows related to the content planning with solid lines for sentence 3. Best viewed in color.

The overall contributions of our work are:

- A unified framework that dynamically conducts content planning and surface realization by leveraging the autoregressive self-attention, with a novel sentence-level bag-of-words auxiliary task to guide the semantic content of each sentence;
- A new coherence-based contrastive learning method with different negative sample construction strategies to improve the coherence of outputs;
- Our approach outperforms strong baselines for both automatic and human evaluations on two challenging long-form text generation tasks.

2 Related Work

Text Planning for Neural Generation. Traditional text generation pipeline leverages text planning component to decide on the high-level structures (McKeown, 1985; Reiter and Dale, 1997; Hovy, 1990; Carenini and Moore, 2006). Earlier work incorporates text planning into neural seq2seq structures by introducing hierarchical decoders (Yao et al., 2019; Moryossef et al., 2019;

Shen et al., 2019). However, these methods are hard to be applied to pre-trained models because of the modifications of model architecture. Several studies design separate modules for text planning and surface realization (Hua and Wang, 2020; Tan et al., 2021; Goldfarb-Tarrant et al., 2020), which lead to a disconnection of the two components and often produce undesired outputs (Castro Ferreira et al., 2019). Recently, Rashkin et al. (2020) present a memory-based model to keep track of the content usage and generate paragraphs recurrently. Nevertheless, they do not consider sentence-level text planning which is critical to maintain high-level logical flow for opinion text generation. Hua et al. (2021) propose a mixed language model to perform content selection and ordering. However, they encode multiple content items separately and do not fully consider the interactions among content items. In contrast to these prior studies, our model conducts sentence-level text planning and surface realization dynamically by introducing high-level latent representations for target sentences, and can be incorporated into pre-trained autoregressive Transformers.

Coherent Long-form Text Generation. Recent work tackles this problem on the tasks including story generation (Fan et al., 2019; Xu et al., 2020), paragraph completion (Kang and Hovy, 2020), text infilling (Huang et al., 2020), long-form conversation (Xu et al., 2021) and news article generation (Rashkin et al., 2020; Tan et al., 2021). To solve the incoherence issue, one type of work adopts the plan-then-generate strategy as discussed above. Some work also incorporates discourse and structured information into generation process to improve output coherence (Jiang et al., 2021; Ji and Huang, 2021; Bosselut et al., 2018). Recently, Guan et al. (2021) propose two auxiliary objectives of similarity prediction and order discrimination to improve coherence. In this work, we focus on long-form opinion text generation which requires an appropriate combination of credible talking points with rigorous reasoning (Hua et al., 2019), and apply dynamic content planning with a coherence-based contrastive objective to improve output coherence.

Controllable Text Generation. Our work is closely related to controllable generation (Prabhumoye et al., 2020). In this regard, typical studies manipulate sentiments (Hu et al., 2017), style (Gao et al., 2019; Du and Ji, 2021; Hu et al., 2021), syntax (Chen et al., 2019), and keywords (Keskar et al., 2019; He et al., 2020; Wu et al., 2020) to steer the generation process. We use topical keyphrases as guidance talking points and require the model to properly organize and reflect keyphrases for long-form opinion text generation.

3 Our PLANET Framework

3.1 Framework Overview

Task Description. We follow the previous work (Hua and Wang, 2020) and model the long-form opinion generation task by considering the input of (1) a statement $\boldsymbol{x}$ which can be a proposition for argument generation or a title for opinion-article generation, and (2) a set of unordered keyphrases $\boldsymbol{m} = \{\boldsymbol{m}_i\}$ related to the statement, serving as topical guidance signal. The output $\boldsymbol{y}$ is an opinion text consisting of multiple sentences and properly reflects the keyphrases in a coherent way.

Our framework is based on the seq2seq structure, and we adopt BART (Lewis et al., 2020) as the base model. [1] The overall framework is shown in Figure 3. The bi-directional encoder first encodes the statement and keyphrases, and the decoder then generates the output in an autoregressive manner:

$$\hat{\boldsymbol{y}} = \text{argmax} \prod_{t=1}^{n} P(y_t|\boldsymbol{y}_{1:t-1}, \boldsymbol{x}, \boldsymbol{m}), \tag{1}$$

where n is the number of target words. The statement and keyphrases are concatenated, with a segmenter inserted between adjacent keyphrases to indicate the keyphrase boundary.

We conduct content planning and surface realization dynamically by leveraging the autoregressive self-attention mechanism. For each target sentence, we introduce a latent representation SN to represent its global semantic information and guide surface realization (§ 3.2), then the sentence words attend the latent representation and dynamically select keyphrases (§ 3.3). After that, a sentence-level bag-of-words planning is introduced to enhance the latent representations (§ 3.4). Finally, we devise a contrastive learning (CL) objective to further improve the coherence of the output text (§ 3.5).

3.2 Latent Representation Learning

We introduce a latent representation for each target sentence to represent the overall semantic information and guide the generation of the sentence words.

---

[1] Our method can be also applied to other autoregressive pre-trained language models.

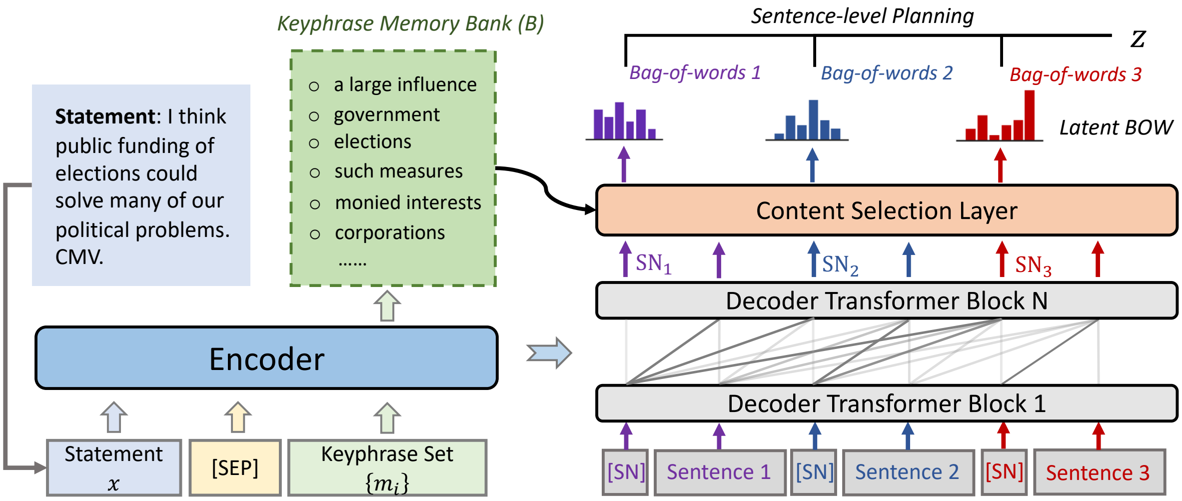


Figure 3: Overview of our framework. The encoder takes as input a statement and a set of keyphrases, and generates a keyphrase memory bank $\mathcal{B}$. The decoder conducts content planning and surface realization dynamically by the autoregressive self-attention to produce a coherent output. Meanwhile, the latent representations (SN) predict bag-of-words as global semantic plans and guide the surface realization of each target sentence. We highlight attention flows related to the content planning.

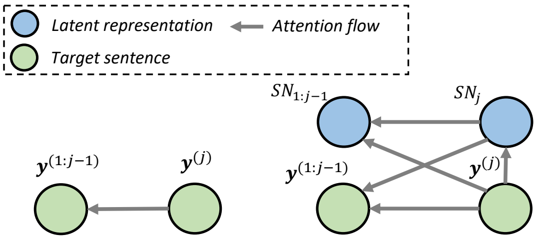

(a) Vanilla autoregressive (b) Our dynamic planning

Figure 4: Attention flow of our dynamic planning and surface realization. $\boldsymbol{y}^{(j)}$ represents the words of the j-th sentence.

In particular, we insert a special token [SN] before every target sentence, and regard the hidden states of the decoder at the positions corresponding to [SN] as the latent representations of the target sentences. This has been shown effective by previous work (Guan et al., 2021; Li et al., 2021).

The workflow of our dynamic planning and realization is shown in Figure 4. For the vanilla autoregressive decoder, the generation of each token only depends on the previously generated tokens. In our framework, when producing the j-th output sentence $\boldsymbol{y}^{(j)}$, the latent representation SN_j is first obtained by attending the previous latent representations $\mathrm{SN}_{1:j-1}$ and words in previous sentences $\boldsymbol{y}^{(1:j-1)}$. Then for sentence-level surface realization, each token in the current sentence $\boldsymbol{y}^{(j)}$ attends the previously generated words and latent representations $\mathrm{SN}_{1:j-1}$, as well as the current latent representation SN_j as the guidance. A unique advantage of such modeling is that *the content planning and surface realization can be performed simultaneously and incorporated into any pre-trained autoregressive language models, further optimized in an end-to-end fashion.*

3.3 Content Selection

Based on the guidance of latent representations, each sentence word conducts content selection by incorporating keyphrases into decoder hidden states to decide which keyphrases to be reflected during generation. We first feed the keyphrases to the encoder to obtain hidden representations. We then construct a keyphrase memory bank $\mathcal{B}$ by gathering the top layer representations of the segment tokens (each keyphrase is represented by the segment token before it). After that, a content selection layer retrieves keyphrase information from the keyphrase bank and integrates the selected information into the decoding process.

Content Selection Layer. At each decoding step t, the top layer representation of the Transformer decoder $\boldsymbol{h}_t$ attends the keyphrase memory bank via multi-head attention:

$$\boldsymbol{c}_t = \text{MH-ATTENTION}(\boldsymbol{h}_t, \mathcal{B}, \mathcal{B}), \tag{2}$$

where $\boldsymbol{c}_t$ is a context vector that embeds the selected keyphrase information, $\boldsymbol{h}_t$ is the query, and $\mathcal{B}$ acts as the key and value for multi-head attention. Then we incorporate the keyphrase context $\boldsymbol{c}_t$ into the decoder hidden state via a feed-forward layer followed by a residual connection (RC):

$$\boldsymbol{h}_t^d = \mathrm{RC}(\boldsymbol{W}_s \tanh(\boldsymbol{W}_h \boldsymbol{h}_t + \boldsymbol{W}_c \boldsymbol{c}_t + \boldsymbol{b}_s), \boldsymbol{h}_t). \tag{3}$$

Finally, the enhanced hidden state $\boldsymbol{h}_t^d$ will be passed to another feed-forward layer with softmax to estimate the probability of each output word:

$$P(y_t|\boldsymbol{y}_{1:t-1}) = \text{softmax}(\boldsymbol{W}_o\boldsymbol{h}_t^d + \boldsymbol{b}_o), \quad (4)$$

where $\boldsymbol{W}_*$ and $\boldsymbol{b}_*$ are trainable parameters.

3.4 Sentence-level Bag-of-words Planning

We propose an auxiliary task of sentence-level bag-of-words (BOW) planning to supervise the latent representations. The goal is to ground the meaning of the latent representations with the bag-of-words (Fu et al., 2020) of target sentences to reflect the global semantic plans. Formally, we define the BOW of the j-th target sentence z_j as a categorical distribution over the entire vocabulary:

$$p(z_j|\text{SN}_j) = \text{softmax}(\text{MLP}(\text{SN}_j)), \quad (5)$$

where MLP$(*)$ is parameterized as a multi-layer feed-forward network. We expect this distribution to capture the overall semantic plan of the corresponding sentence, and enhance SN to guide the surface realization of sentence words by conditioning the probability of each word on the latent representations: $p(y_t|\boldsymbol{y}_{1:t-1}, \text{SN}_{1:s_{j_t}})$, where s_{j_t} denotes the sentence index of the token y_t. This conditional probability can be naturally satisfied by the autoregressive decoding process.

The loss of the task is to maximize the likelihood of predicting the BOW of each target sentence:

$$\mathcal{L}_{\text{BOW}} = -\frac{1}{J}\sum_j\sum_l \log p(z_{jl}|\text{SN}_j), \quad (6)$$

where J is the number of target sentence, and $p(z_{jl}|\text{SN}_j)$ denotes the estimated probability of the l-th element in the bag of words for the j-th target sentence.

3.5 Coherence-based Contrastive Learning

We further design a contrastive learning (CL)-based training objective to enhance the content planning and drive our model to learn a preference of coherent outputs over incoherent ones.

Negative Sample Construction. One challenge for contrastive learning is how to construct negative samples to effectively train the model towards the desired goals. We consider the original target as a positive sample representing a logically coherent output with gold planning, and construct negative samples as incoherent ones. In particular, for a positive target, we create 4 negative samples based on the following strategies: (1) *SHUFFLE*, where we randomly shuffle the target sentences to encourage the model to learn the correct sentence order; (2) *REPLACE*, where we randomly replace 50% of the original target sentences with random sentences from the corpus to facilitate the model to learn better content organization; (3) *DIFFERENT*, where we completely replace the original target sentences with a new set that are annotated as the target of a different input from the corpus; (4) *MASK*, where we randomly mask 20% of the non-stop target words that are related to any keyphrases from the keyphrase set, and adopt BART to fill the masked tokens since BART is naturally a denoising model. We enforce the filled negative target to be different from the original one.

Coherence-based Contrastive Loss. Since we aim to encourage the model to distinguish between coherent and incoherent targets and generate outputs with coherent logical flows, we design a novel coherence-based contrastive learning objective. Given a source-target pair, the model projects the output feature from the content selection layer to a coherence score between 0 and 1. Formally, for the i-th source-target pair, we enforce the score of the original target (r_i^+) to be larger than all corresponding negatives ($\{r_{ik}^-\}$) by a fixed margin ϕ:

$$\mathcal{L}_{\text{CL}}(r_i^+, \{r_{ik}^-\}) = \sum_k \max(0, \phi + r_{ik}^- - r_i^+), \quad (7)$$

$$r_i^+ = \text{F}(\text{AvgPool}(\boldsymbol{W}_{cl}\boldsymbol{H}_i^{d+} + \boldsymbol{b}_{cl})), \quad (8)$$

$$r_{ik}^- = \text{F}(\text{AvgPool}(\boldsymbol{W}_{cl}\boldsymbol{H}_{ik}^{d-} + \boldsymbol{b}_{cl})), \quad (9)$$

where F$(*)$ is a nonlinear transformation with sigmoid, $\boldsymbol{H}_i^{d+}$ and $\boldsymbol{H}_{ik}^{d-}$ are output features from the content selection layer for the positive and the k-th negative sample, and AvgPool$(*)$ is the average pooling to compute a fixed-size vector. In this way, we expect the model to assign higher probability to the coherent target than incoherent ones.

3.6 Training Objective

We jointly optimize our model for content planning and surface realization by combining the objectives for the sentence-level BOW planning ($\mathcal{L}_{\text{BOW}}$), the word-level generation by cross-entropy loss over the target tokens ($\mathcal{L}_{\text{GEN}}$) , and the contrastive learning loss ($\mathcal{L}_{\text{CL}}$): $\mathcal{L} = \mathcal{L}_{\text{GEN}} + \alpha\mathcal{L}_{\text{BOW}} + \beta\mathcal{L}_{\text{CL}}$, where α and β are tuned as hyper-parameters.

Dataset	Train	Val.	Test	|State|	|Target|	# KP
ArgGen	42.5k	6.5k	7.5k	19.4	116.6	20.6
OpinionGen	47.6k	5.0k	5.0k	9.0	198.2	16.2

Table 1: Statistics of the datasets. |State| and |Target| represent number of words of input statement and target, and #KP denotes the average number of guidance keyphrases.

4 Experimental Setups

4.1 Tasks and Datasets

We conduct experiments on two long-form opinion generation datasets of distinct domains: (1) Argument Generation (**ArgGen**) (Hua et al., 2019), where the model is required to generate a counter-argument to refute a given proposition; (2) Opinion Article Generation (**OpinionGen**) (Hua and Wang, 2020), to produce an opinion article given a title. The data statistics are shown in Table 1.

Argument Generation. We first apply data from Reddit *r/ChangeMyView* (CMV) for argument generation. We consider the original poster (OP) title as the statement, and the high-quality argument replies (with community endorsement) as the targets. Note that we consider the full argument replies as targets. The noun phrases and verb phrases that contain at least one topic signature word (Lin and Hovy, 2000) are extracted to form the guidance keyphrases.

Opinion Article Generation. For generating opinion articles, we consider samples from the New York Times (NYT) corpus (Sandhaus, 2008), with articles whose taxonomy labels include *Top/Opinion*. The articles with less than three sentences or more than 10 sentences are discarded. We further exclude articles containing more than 250 tokens considering the limited computing resources. 57,600 articles are randomly selected as the final dataset. We apply the same method as in argument generation to extract topical guidance keyphrases. The article title is regarded as the input statement.

4.2 Baselines and Comparisons

We compare our model against the following baselines : (1) **RETRIEVAL** (Stab et al., 2018) which retrieves targets based on TF-IDF weights of words from the training set. We keep the top-ranked results as outputs; (2) **HIERPLAN** (Hua et al., 2019) which is an end-to-end trained generation model with a hierarchical decoder to perform sentence-level content planning and surface generation; (3) **FULLSEQ2SEQ** (Schiller et al., 2021) where we fine-tune BART with keyphrases concatenated to the input statements; (4) **SSPLANER** (Kang and Hovy, 2020) is a global planning method which first conducts content prediction and then guides the surface generation with the predicted contents; (5) **SEPPLAN** is a two-stage planning model similar to Hua and Wang (2020), where we first fine-tune a BART as the planner to generate the ordered keyphrase plans for each target sentence, and then fine-tune another BART as the generator to produce final outputs based on the statement and keyphrase plans. The details of SEPPLAN are in the Appendix A.2.

4.3 Training and Decoding Details

We use the BART-base version in all experiments for both our method and baselines. We truncate both input statement and output target to at most 256 tokens during training. For the BOW planning loss ($\mathcal{L}_{\text{BOW}}$), we consider the salient content words as the ground-truth bag of words for each target sentence. For the training objective, we set α as 0.2 for ArgGen and 0.3 for OpinionGen, and β as 0.2 based on the validation performance. The margin for contrastive loss is set as 0.5 for ArgGen and OpinionGen according to the validation performance. We optimize our model with AdamW (Loshchilov and Hutter, 2017). During the decoding time, we apply nucleus sampling (Holtzman et al., 2019) with a cumulative probability threshold of 0.9, and the maximum of generation steps are 150 for ArgGen and 200 OpinionGen. More training and decoding details are in the Appendix A.2.

5 Results and Analysis

5.1 Automatic Results

We first evaluate our model with BLEU (Papineni et al., 2002), ROUGE (Lin, 2004), and METEOR (Denkowski and Lavie, 2014). The results are shown in Table 2.

Our PLANET$_{\text{w/o CL}}$ model (without contrastive loss) consistently outperforms all baseline methods. In particular, compared with FULLSEQ2SEQ and SSPLANER which are also fine-tuned based on BART with the same inputs, the substantial improvements underscore the effectiveness of our dynamic content planning to generate better outputs. Meanwhile, the significant lead over HIERPLAN indicates the importance of incorporating

	ArgGen				OpinionGen

Table 2: Experimental results on argument generation (ArgGen) and opinion article generation (OpinionGen). PLANET$_{\text{w/o CL}}$ is our model variant without contrastive loss. We report BLEU-2, ROUGE-2 recall, METEOR and average output lengths (Len.). *: significantly better than all other methods without asterisks (Welch's t-test, $p < 0.05$).

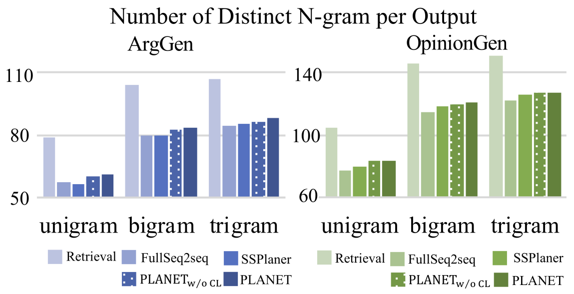

Figure 5: Average number of distinct n-grams per output.

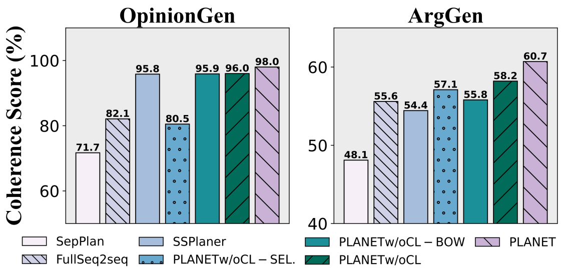

Figure 6: Automatic evaluation on output coherence.

content planning into pre-trained language models. Furthermore, PLANET$_{\text{w/o CL}}$ significantly outperforms SepPlan, which confirms that the end-to-end training in our approach can mitigate the disconnection issue of the two-stage generation pipeline and produce superior results.

Among our model variants, removing content selection (w/o SEL.) and BOW planning (w/o BOW) both lead to performance decrease. This demonstrates the importance of the components that help the model conduct effective content planning. In addition, we observe that incorporating the contrastive loss (PLANET) brings performance gains on automatic results, especially with significant improvements on BLEU scores. This suggests that *our contrastive loss can guide the model to more precisely use keyphrases and reflect the keyphrase information in the outputs*. We provide further analysis on the keyphrase usage in Section 5.2.

Content Richness. To evaluate content richness, we employ Distinct n-gram (Li et al., 2016) that calculates the number of distinct n-grams per output in Figure 5. Retrieval achieves the highest distinct results on both datasets since it returns top-ranked human-written texts with the most distinct words. Among generative methods, our dynamic planning model PLANET$_{\text{w/o CL}}$ outperforms all baselines on both datasets. In addition, after applying contrastive loss, our PLANET model generates even more unique n-grams. The results imply our dynamic content planning and contrastive loss can enable the model to generate richer contents.

Automatic Evaluation on Coherence. We fine-tune BERT (Devlin et al., 2019) on each dataset to automatically evaluate the output coherence, which predicts a score between 0 and 1 for each output. The higher score indicates a more coherent output. The coherence model details are in Appendix A.3.

The results are shown in Figure 6. Among all methods, PLANET achieves the highest coherence scores on both datasets, suggesting that our dynamic planning and contrastive loss are effective to improve the coherence of outputs. In contrast, SepPlan has the lowest scores, indicating that decoupling planning and decoding stages may lead to cascading errors. Compared to FullSeq2seq and SSPlaner, our PLANET$_{\text{w/o CL}}$ model without contrastive loss also maintains better coherence, which confirms that incorporating dynamic content planning essentially promotes coherence for long text generation. Moreover, we observe that the results on OpinionGen are consistently better than

System	OpinionGen (%)	ArgGen (%)
PLANET	98.03	60.71
w/o SHUFFLE	96.20	59.30
w/o REPLACE	96.02	58.41
w/o DIFFERENT	96.11	59.95
w/o MASK	96.16	59.58

Table 3: Coherence scores for different negative strategies.

those on the ArgGen dataset. A possible reason is that arguments in ArgGen are collected from social networks and contain more colloquial and informal expressions, making it harder to learn the implicit logical coherence. We leave this for future work.

Ablation on Contrastive Sample Construction. We study the contribution of each negative sample construction strategy for improving the coherence of the outputs. As in Table 3, removing each strategy leads to a performance degradation, indicating the effectiveness of all types of negative samples to enhance the contrastive learning. Among all negatives, removing *REPLACE* shows the most effects on both datasets. We hypothesize that replacing target sentences breaks the original logical flow and thus is more likely to encourage the model to focus on the global coherence. In contrast, *DIFFERENT* shows the least effects. One possible explanation is that this strategy focuses more on topical relatedness between the input and output, instead of the logical flow within the output as the negative sample itself is inherently coherent.

5.2 Human Evaluation

We hire three proficient English speakers as human judges to evaluate model outputs on a scale of 1 (worst) to 5 (best) for: (1) **topic relatedness** which measures whether the output is relevant and consistent to the input; (2) **coherence** which measures the high-level logical flow and transition among sentences; and (3) **content richness**, measuring the amount of informative talking points and specific details. We also ask judges to select top-ranked results based on the overall quality, and ties are allowed. 50 random samples are selected from each task. The detailed guidelines of human evaluations are provided in the Appendix B.

The results are shown in Table 4. Both our model variants achieve better results than FullSeq2seq on all aspects, underscoring the effectiveness of our dynamic planning to promote output coherence. Moreover, introducing contrastive objective further improves output quality on the above aspects, and the outputs are more likely to be top-ranked. Overall, the human results verify the capability of our dynamic planning and contrastive objective to generate high-quality long-form texts.

Task	Model	Rel.	Coh.	Rich.	Top-1
ArgGen	FullSeq2seq	2.25	2.47	2.57	20.7%
	$\text{PLANET}_{\text{w/o CL}}$	2.79	2.83	3.10	30.0%
	PLANET	**2.83**	**2.89**	**3.21**	**33.3%**
OpinionGen	FullSeq2seq	3.65	3.19	3.44	16.0%
	$\text{PLANET}_{\text{w/o CL}}$	3.81	3.27	3.64	28.7%
	PLANET	**3.89**	**3.47**	**3.81**	**37.3%**

Table 4: Human evaluation on relatedness (Rel.), coherence (Coh.), content richness (Rich.) and % of evaluations a model being ranked in top 1 based on the overall quality. All Krippendorff's $\alpha \geq 0.34$, with specific values in the Appendix B.

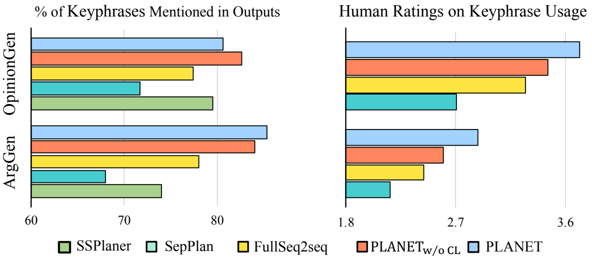

Figure 7: Left: percentage of keyphrases that are mentioned in outputs. Right: human evaluation on keyphrase usage.

Appropriateness of Keyphrase Usage. We further study how keyphrases are utilized in outputs. We first compute the percentage of keyphrases mentioned in outputs, as in the left of Figure 7. Among all models, SepPlan uses the least keyphrases in final outputs. However, its intermediate planning results cover more than 95% of keyphrases. This confirms that the two-stage method results in a disconnection problem between the planning module and the surface realization module, and the outputs are not guaranteed to reflect the plans. Compared to FullSeq2seq and SSPlaner, our methods cover more keyphrases, suggesting that our dynamic planning and keyphrase selection are useful to help the model better incorporate the guidance signal into outputs.

We further select 50 random samples for both tasks and ask the same human judges to score the outputs from 1 (worst) to 5 (best) on the correctness of keyphrase usage: whether the model uses keyphrases adequately as main talking points when generating outputs. Results in Figure 7 (right) indicate that our models tend to use more keyphrases and properly organize them in the out-

Statement: Absolute free speech doesn‘t exist - real debate is about where to draw the line

PLANET: ① Absolute free speech exists in a **conceptual**, **legal**, and **practical** way. ② The **simple fact** that it exists is obvious. ③ If you're going to say something in **a legal way**, at any time, the **consequences** should be the consequences. ④ It's not that absolute free speech doesn't exist, but the **conceptual way** you could interpret it is much **more practical**. ⑤ **The internet** has made it much more obvious that you could use it any way you wanted.

> **BOW**: ① free, speech, concept ② simple, obvious ③ consequences, legal, illegal ④ freedom, case, practical ⑤ internet, easy

FULLSEQ2SEQ: Absolute free speech exists in a conceptual (and probably legal) way. There is the simple fact that absolute free speech exists in a legal way. It's obvious what the consequences are for someone, but it can be done any time. In many cases, it's very practical to do something like this in a legal way because the internet makes it very obvious.

Statement: Millions of mothers can't choose not to work

PLANET: ① **Single mothers** have to decide how to raise their children. ② But the choice mothers have has often been made to work, **juggling financial responsibilities** that make it all the more difficult. ③ While it is true that many **families** have **no such choice**, the **reality is the same**: **single mothers** have **little options**. ④ And while it is true that **a family of two or more lowers pay** and is likely to take many times the **cost of similar work**, the reality is that it may not be that simple (...)

> **BOW**: ① child, parent, children ② work, choice, mother ③ choice, family, mother ④ work, pay, children, family

FULLSEQ2SEQ: Crittenden is right about single mothers' choice to choose not to work, in her book "the choice mothers make" But the sad reality of working families is that it is the reality that Ms. Crittenden and many others, in juggling financial responsibilities, are forced to choose not to work. If they are lucky enough to be able to keep their jobs, they can be at similar work as nannies. But the sad reality is that the choice mothers make is no longer one wage earner (...)

Figure 8: Sample outputs on ArgGen (Upper) and OpinionGen (Lower). For our model results, the phrases relevant to the guidance keyphrases are highlighted in colors, and the words related to the corresponding BOW are underlined. Best viewed in color.

puts compared to all baseline methods. Although on OpinionGen our contrastive model mentions fewer keyphrases, human judges rate it with higher scores for keyphrase usage. We speculate that this can be attribute to the *MASK* strategy for negative sample construction in contrastive learning, which helps to improve the model ability on the appropriate usage of keyphrases. The above results confirm that PLANET can properly utilize the keyphrases and reflect the contents in the outputs.

5.3 Sample Outputs and Discussions

We show two sample outputs on both tasks and highlight the phrases relevant to the guidance keyphrases in Figure 8. We can see that on both tasks, our model effectively leverages guidance keyphrases as main talking points, and properly organizes and reuses the keyphrases to form a coherent output. In contrast, FULLSEQ2SEQ suffers from incoherence issues such as repetition (e.g., the first and second argument sentences) and inconsistent stance (e.g., "*choose not to work*" in generated opinion article). This indicates that our dynamic planning is effective to guide the model to better leverage keyphrases in the outputs.

We also present the predicted BOW of our model for each generated sentence. As can be seen, our model predicts most of the salient content words of the target sentences and effectively reflects the semantic plans in the generated sentences, suggesting that our latent representations are useful to capture the global semantic information of each sentence and conduct content planning during the generation process. However, there is still a large gap compared with human written texts, inspiring the future work on long-form text generation. More sample outputs are provided in Appendix D.

6 Conclusion

We present a novel generation framework to dynamically conduct content planning and surface realization in large autoregressive Transformers by leveraging self-attention and high-level latent representations. The latent representations are grounded by bag-of-words that measures the overall semantic plan of each target sentence. We further introduce a novel coherence-based contrastive objective with different negative sample construction strategies to improve output coherence. Experiment results on two opinion text generation tasks demonstrate that our model can generate high-quality outputs with better coherence and content richness.

Acknowledgements

We thank the anonymous reviewers, area chair, and senior area chairs for their constructive suggestions on our work. We also thank Xinyu Hua for the helpful discussions. Hou Pong Chan was supported by the Science and Technology Development Fund, Macau SAR (Grant No. 0101/2019/A2), and the Multi-year Research Grant from the University of Macau (Grant No. MYRG2020-00054-FST). Lifu Huang also thanks the support from the Amazon Research Awards.

Ethics Statement

We recognize that our method may generate fabricated and potentially harmful contents due to the systematic biases of pre-training using heterogeneous web corpora and the open-ended generation characteristics of the opinion generation tasks. Therefore, we urge the users to carefully examine the ethical influence of the generated outputs and cautiously apply the system in real-world applications.

A Experiment Details

A.1 Additional Experimental Results

In table 2 we report automatic results on both tasks. Here we present additional automatic results of BLEU-3 and ROUGE-L (recall) in Table 5 and Table 6.

A.2 Training and Decoding Details

Model Training. Our model is built based on BART, and we use BART-base version for all experiments. Our model contains 185M parameters in total. The batch size is set to be 8, and the maximum training epoch is set as 15 for non-contrastive training and 18 for contrastive training. We truncate both the input statement and output target to be at most 256 tokens during training. We resize the BART embedding matrix with a new token [SN] and insert a [SN] token before each target sentence. This is also done for baselines for a fair comparison. For computing resources, we use NVIDIA Tesla V100 GPUs with 32 GB memory for all experiments, and utilize the mixed-precision (FP16) to improve the computational efficiency. For contrastive learning, for each positive target, we construct 4 negatives using the strategies described in Section 3.5 respectively. The best model checkpoint is chosen based on the validation loss. Our model takes around 4-5 hours for training, and 30 minutes for decoding on V100 GPUs.

Decoding. During decoding time, we apply the nucleus sampling (Holtzman et al., 2019), and set $k = 10$ and $p = 0.9$. Considering the computational cost, we limit the maximum of generation steps to 150 for argument generation on ArgGen and 200 for opinion article generation on OpinionGen. To reduce variance introduced by sampling-based decoding method, we decode three times and average the results for automatic evaluations. For our model, we enforce each target sentence to start with a [SN] token during inference: we pre-define a list of sentence end markers, and when the model finishes generating a sentence, we enforce the next generated token to be [SN], although we find in most cases the model can automatically generate [SN]. The generation process stops when the model generates the <EOS> token. In this way, the model can automatically decide on how many sentences to be generated, and conduct content planning and surface realization in a dynamic way.

Details for SepPlan. We design a two-stage generation method, SepPlan, as a baseline model by fine-tuning two independent BART models for content planning and surface realization respectively, similar to Hua and Wang (2020). In particular, the planner BART takes a statement and unordered keyphrase as inputs, and autoregressively generates content plans as a sequence of tokens for every target sentence, where each content plan is represented by the ordered keyphrases with the same order as they appear in the corresponding sentence. Segmenter is added between sentence plans to indicate the sentence boundary. Then the generator

---

[2] https://www.nltk.org/

[3] https://pypi.org/project/rouge-score/

BART consumes the concatenation of the statement and content plans to produce the final results. During training, the ground-truth content plans are used to train the generator, and during inference the predicted plans are used. For decoding, we apply beam search for the planner and nucleus sampling for the generator. Note that Hua and Wang (2020) applies BERT as planner in their original paper, and we replace BERT with BART as BART gives better performance in our experiments.

A.3 Training Details for Coherence Model

We propose a neural coherence model to evaluate output coherence. Concretely, we fine-tune BERT (Devlin et al., 2019) on each dataset to compute the coherence scores. Instead of computing the overall coherence scores by measuring and aggregating the coherence of its adjacent sentence pairs (Xu et al., 2019), we fine-tune BERT on the whole text to better learn the global coherence (Xing and Carenini, 2021).

For training, we follow Sharma et al. (2019) and adopt hinge loss to teach the model to assign higher scores to coherent targets than incoherent ones. The score is normalized into [0, 1] with sigmoid function, and the margin is set to be 0.8. Since each target usually contains multiple sentences, we insert a separator token [SEP] between each adjacent sentence pair. For data construction, we consider the original text as a positive sample, and randomly shuffle sentences to construct negative ones. The test accuracy is 94.3% on OpinionGen and 73.0% on ArgGen, respectively. This implies that our coherence model can be used as a reliable metric to evaluate the output coherence.

B Details for Human Evaluation

We present 55 random samples on each task for human evaluation, and the first 5 samples are used only for calibration [4]. We anonymize the models and shuffle the outputs to the annotators. We evaluate model outputs on the following aspects, and the detailed guidelines are in Table 8:

- **Relatedness**: whether the output is relevant and consistent to the input;
- **Coherence:** whether the overall logical flow is appropriate and the transitions among sentences are natural and smooth;
- **Content Richness:** whether outputs contain substantial talking points and convey specific details;
- **Overall Ranking:** this is a general assessment that whether you think the output ranks top among all candidates. Ties are allowed, which means you can choose multiple outputs as top-ranking for a sample.

Task	Rel.	Coh.	Rich.	KP-Use.
ArgGen	0.49	0.34	0.40	0.44
OpinionGen	0.41	0.46	0.37	0.36

Table 7: Krippendorff's α for human evaluation on relatedness (Rel.), coherence (Coh.), content richness (Rich.) and keyphrase usage (KP-Use.).

To measure agreement among human judges, we compute Krippendorff's α for each aspects. The values for all aspects on both datasets are presented in Table 7. As can be seen, all values are equal or larger than 0.34, indicating a general consensus among the judges.

C Discussions on Limitations and Future Directions

Here we discuss the limitations of our work and the potential directions for future studies. Long-form text generation is a challenging task which requires the model to properly select and organize contents, and faithfully reflect the plans in surface realization, in order to form a coherent output. The results suggest that our dynamic content planning can effectively leverage keyphrases and generate more coherent and richer texts than strong baseline methods. Nevertheless, there is still a gap compared with human written outputs. Also, in this paper we follow previous work to study the keyphrases guided generation (Hua and Wang, 2020; Rashkin et al., 2020), where we assume the availability of keyphrases as guidance signals. For the scenarios where guided keyphrases are not available in test time, one can use either retrieval-based methods (Hua et al., 2019; Wu et al., 2020) or a separate knowledge-enhanced generative module to obtain guided keyphrases. However, this is out of the scope of this work.

We believe there are several promising directions to explore in the future. First direction can be applying our dynamic planning method into pretrainning or post-pretrainning stage. One advantage of our model is that it does not require additional annotated data (the keyphrases and BOW labels can be automatically constructed with off-the-shelf tools as described in data processing). Leveraging

---

[4] The payment for each human judge is 20 dollars per hour.

massive pretraining data would be very helpful to further improve the model performance on long-text generation in various domains.

Second, one can study different supervision signals to train the latent representations. In this work we apply bag-of-words to ground the latent representations, which aims to capture the overall semantic information. Other supervision signals such as discourse structures and entity usage are also very important for modeling coherence. Considering these aspects into planning can further improve the output coherence. Meanwhile, coherence is a broad definition including topical relatedness, causal relationship, temporal ordering and discourse structures (Li and Jurafsky, 2017). Designing different supervision signals to tackle specific aspects for coherence would also be a promising direction.

Third, in this work we consider keyphrases as guidance signals to control the generation. Future work can incorporate different guidance signals from heterogeneous sources such as structured knowledge and commonsense information to further improve the output quality.

D Additional Sample Outputs

We present additional examples on argument generation in ArgGen and opinion article generation in OpinionGen from Figure 9 to Figure 12.

	Relatedness
1	The output is very generic and irrelevant to the statement
3	The output is tangential to the statement and mentions some relevant concepts or entities, but in general is not precisely on topic
5	The output is highly relevant to the statement and fully on topic
	Coherence
1	The sentences are completely disconnected and unrelated, without any overall logical structure
3	The output sentences are somehow connected or on the same topic, but the transition is not smooth, and the overall logical flow is not strong to convey a progression of idea
5	The output is completely coherent with natural and smooth transition among sentences, and the high-level logical flow is strong to form a good progression
	Content Richness
1	The output is very generic with no specific information or talking points
3	The output contains several talking points or key information to form an opinion text
5	The output contains sufficient key points and informative contents to from a strong counter-argument or opinion article.

Table 8: Explanations on human evaluation for aspect scales.

Statement: CMV: journalism has become so biased in this country that it has lost its relevance.

PLANET: ① True journalism is **biased by definition**. ② You have to have **sources** in order to read the news, especially when **the facts and propaganda** are coming out. ③ You need to know **a piece** or two about their policies. ④ This includes reading from **a wide range of opinions**. ⑤ You can be **swayed by the emotion** of rage. ⑥ A lot of **great journalists** and pundits are coming out with their favor. ⑦ The AP is no actor. ⑧ BBC has been relentless in **their editorial and their propaganda**. ⑨ NPR has tried to **push conservative candidates** and push their favor in a public and this is reflected in their **editorial and news**.

BOW: ① journal, biased, media ② news, fact, propaganda, media ③ news, media, ④ people, political, lot ⑤ emotion, rage, news ⑥ good, public, news, ⑦ media, main ⑧ BBC, news, ⑨ public, candidates, political, popular

FULLSEQ2SEQ: The AP is biased by definition. They are biased because they are biased by their bias. A lot of true journalism is achieved by the emotion of outrage and propaganda, and no actor can objectively prove this. They are biased by their biases, because they want to push conservative candidates' policies and favorites to an audience that is more informed than they are themselves. So if you want a piece of true journalism from a public that doesn't want to read the news, then you need sources and sources to get the facts. You need great journalists to listen to your sources. BBC, NPR, the AP, and the like.

Figure 9: Sample outputs on ArgGen. For our results, we present the bag-of-words predicted for each sentence, and the phrases relevant to the guidance keyphrases are highlighted in bold.

Statement: CMV: the European Parliament should be elected on transnational lists

PLANET: ① A big issue with the EU is that **the formation of government** would **face a similar problem** as the **federalization** of the United States. ② **The US constitution** included **major guarantees** for autonomy, a **separate national voice** for all and a broader level of **governance**. ③ A lot of **Euro-skeptic countries** have been concerned about secession at the start of the EU, but the EU has been able to **reduce these concern**. ④ Euro-skeptic countries are more likely to **balance state autonomy**, and thus need a **slow-motion version** of government. ⑤ if the EU were to step down, it would be violating by the

BOW: ① government, issue, EU, federalization ② democracy, constitution, governance, independence ③ EU, countries, states ④ government, federal, state ⑤ violated, EU, constitution, government

FULLSEQ2SEQ: The United States was a major hot point in US politics from the start, and was a slow-motion version of the US constitution that included major guarantees of independence, and a separate national voice for all. Many countries now want to balance state autonomy with autonomy. This would mean that many would face a similar problem with the federalization of the US. But it would also reduce these concern to a broader level. I don't think we should be at war with the EU for the federalization of the US, but that is a big issue. It would be very different from creeping federalization of the US as a whole. I don't think that the United States would do well without a big issue like the

Figure 10: Sample outputs on ArgGen. For our results, we present the bag-of-words predicted for each sentence, and the phrases relevant to the guidance keyphrases are highlighted in bold.

Statement: Endangered species will gain from reform

PLANET: ① To the editor: I agree with your April 19 **column attack legislation** to reform **the endangered species act**. ② But it is important to focus on how it **improves the recovery** of endangered species. ③ In an April 28 editorial, **representative Richard Pombo** of California and 125 other democrats called on the federal government to **provide habitat** for the endangered species. ④ This would have been good for the species as well as the economy. ⑤ It would have been good for the species, as it would help the economy. ⑥ The endangered species act allows homeowners to **protect habitat** without **forcing private landowners** to pay taxes to protect it. ⑦ If landowners were allowed to sell off their **critical habitat**, they would pay for the maintenance of homes and homes. ⑧ And if owners paid taxes to protect habitat, it would help **attract these species** to their area. ⑨ David h. Lindman Washington, April 30, 1997 the writer is an environmental advocate.

BOW: ① endangered, act, April, species ② species, endangered, protect, ③ protect, endangered, species, land, support ④ life, species, economy, ⑤ protect, species, park ⑥ owners, species, protection, bill ⑦ landowners, habitat, park, housing, ⑧ homes, build, land, ⑨ writer, address

FULLSEQ2SEQ: To the editor: while i applaud your call to reform the endangered species act, your April 19 column attack legislation that would allow the states to force private landowners to provide habitat for endangered species. In an April 28 editorial, representative Richard Pombo of Texas and 125 other democrats wrote that "the species cannot be exploited to attract these species to this program." However, there are other ways to exploit these species: the endangered species act is a law requiring the state to provide habitat for endangered species and requiring the states to provide a plan to protect habitat for the species. If the endangered species act is enacted, it will be in effect, and will be a significant step toward conservation. The bill is a response to the plight of the endangered species act and will help improve its financing. Daniel s. Bennett New York, April 30, 1999 the writer is chairman of the house appropriations committee.

Figure 11: Sample outputs on OpinionGen. For our results, we present the bag-of-words predicted for each sentence, and the phrases relevant to the guidance keyphrases are highlighted in bold.

Statement: Protect inmates' rights

PLANET: ① To the editor: **Elisabeth Sara** (op-ed, Jan. 1) argues that **stripping inmates** of **civil legal assistance** would not result in a lasting peace or in freeing them from incarceration. ② Yet the Bush administration has not spent the last 10 years **exorcising the demons** of discrimination against federally **financed prisoners**. ③ Prisoners' **legitimate civil rights complaints** should be heard in court. ④ it is time for the administration to begin **stripping inmates** of their rights and **redeeming the debts** owed them by the government. ⑤ The government must make sure that they receive **adequate funds** for housing, education and legal services. ⑥ It must ensure that their rights are protected and that they receive the same level of support for the **legal services** they deserve. ⑦ David Jacobs New York, Jan. 2, 2002 the writer is a fellow at the Brennan center for justice, Columbia university.

BOW: ① editor, prison, rights, civil ② prisoners, legal, treatment, fair ③ legitimate, rights, prison ④ system, stripping, access ⑤ housing, cost, services, affordable ⑥ support, money, services, deserve ⑦ writer, director, center, new, york

FULLSEQ2SEQ: To the editor: Elisabeth Sara's article "exorcising the demons of jail" (April 19) is a powerful reminder that the system of state-financed prisoners' rights is stripping inmates of their right to equal opportunity, access to legal services and a chance to make real progress in redeeming the debts they have been stripped to the bone. Without adequate financing and affordable legal counsel, thousands of prison-financed prisoners will never be able to get their civil legal assistance they deserve. Joseph Jacobs new York, April 20, 2006 the writer is a staff attorney at the Brennan center for justice.

Figure 12: Sample outputs on OpinionGen. For our results, we present the bag-of-words predicted for each sentence, and the phrases relevant to the guidance keyphrases are highlighted in bold.

CTRLEval: An Unsupervised Reference-Free Metric for Evaluating Controlled Text Generation

Abstract

Existing reference-free metrics have obvious limitations for evaluating controlled text generation models. Unsupervised metrics can only provide a task-agnostic evaluation result which correlates weakly with human judgments, whereas supervised ones may overfit task-specific data with poor generalization ability to other datasets. In this paper, we propose an unsupervised reference-free metric called *CTRLEval*, which evaluates controlled text generation from different aspects by formulating each aspect into multiple text infilling tasks. On top of these tasks, the metric assembles the generation probabilities from a pre-trained language model without any model training. Experimental results show that our metric has higher correlations with human judgments than other baselines, while obtaining better generalization of evaluating generated texts from different models and with different qualities[1].

1 Introduction

Controlled text generation aims to generate texts under some control variables, including prespecified content prefixes and attribute labels (such as sentiments and topics). Controlled text generation has been significantly advanced by large-scale pre-trained models with respect to generation quality and various control variables (Keskar et al., 2019; Dathathri et al., 2020; Yang and Klein, 2021; Liu et al., 2021a; Chan et al., 2021).

Despite the great success of these generation models, it becomes critical to evaluate the quality of generated texts accurately. Most of the existing studies adopt unsupervised and supervised metrics to measure the quality of generated texts under different combinations of control variables (Dathathri et al., 2020; Chan et al., 2021). The evaluation is commonly conducted in a reference-free setting because it is challenging to collect sufficient high-quality references for each input of control variables in this open-ended text generation task (Dathathri et al., 2020).

However, both unsupervised and supervised metrics have shown limitations in the evaluation of controlled text generation: 1) Unsupervised metrics such as perplexity (Brown et al., 1992) can only provide task-agnostic evaluation regarding the overall quality of generated texts. However, controlled text generation tasks typically involve multiple evaluation aspects (Deng et al., 2021), including the quality of generated texts themselves and the relationship between generated texts and control variables. It is thus not surprising that existing unsupervised metrics without multi-aspect interpretability have low correlations with human judgments (Hashimoto et al., 2019). 2) Supervised metrics are commonly trained on the datasets of specific tasks to measure the corresponding aspects of generated texts (e.g., evaluating whether a generated text is accordant with the sentiment label) (Dathathri et al., 2020; Chan et al., 2021). This may cause over-fitting to task-specific data and degrade the generalization ability of metrics (Garbacea et al., 2019), thereby giving unstable evaluation of generated texts from different models or with different qualities (Guan and Huang, 2020).

To deal with the above issues, we propose an unsupervised reference-free metric called *CTRLEval* for evaluating controlled text generation models. This metric performs evaluation from different aspects without any training on task-specific data. Specifically, we formulate the evaluation of each aspect into "fill-in-the-blank" tasks whose input and output patterns can be designed based on the definition of the aspect. Then, we utilize a pre-trained model whose pre-training task is text in-

May 22-27, 2022

filling (such as PEGASUS (Zhang et al., 2020a)) as our base model, and fuse the generation probabilities from these "fill-in-the-blank" tasks as the evaluation result. To alleviate the potential bias caused by the task design (Zhao et al., 2021), we devise multiple text infilling tasks for each aspect and use the weighted sum of all the results as the final score. In this paper, we consider three aspects which are commonly used to measure the performance of controlled text generation models, including coherence (Yuan et al., 2021), consistency (Rashkin et al., 2020), and attribute relevance (Dathathri et al., 2020). These evaluation aspects cover both the quality of generated texts and the relationship between generated texts and different control variables, which can provide a comprehensive evaluation result for controlled text generation. Experimental results show that our metric can maintain the generalization ability and achieve stable performance faced with model drift and quality drift.

Our main contributions are as follows:

- We propose an unsupervised reference-free metric called CTRLEval for evaluating controlled text generation. This metric formulates three evaluation aspects (i.e., coherence, consistency, and attribute relevance) into multiple text infilling tasks, and utilizes the ensemble of generation probabilities from a pre-trained language model as the evaluation results.

- We conduct experiments on two benchmark tasks including sentiment-controlled and topic-controlled text generation based on our collected evaluation set. Experimental results show that our proposed metric has higher correlations with human judgments, while obtaining better generalization of evaluating generated texts from different models and with different qualities.

2 Related Work

2.1 Controlled Text Generation

Early studies on controlled text generation adopt attribute label embeddings (Ficler and Goldberg, 2017; Zhou et al., 2018) or latent variables (Hu et al., 2017; Ke et al., 2018; Zhou and Wang, 2018) to learn the complex relationship between control variables and generated texts. With the development of large-scale generative pre-trained models, it is costly to re-train or fine-tune pre-trained models on the corpora with attribute annotations (Keskar et al., 2019). Recent works resort to decoding-time methods and directly make pre-trained models generate texts towards desired attributes during inference, including PPLM (Dathathri et al., 2020), GeDi (Krause et al., 2020), FUDGE (Yang and Klein, 2021) and DEXPERTS (Liu et al., 2021a). These works rely heavily on human evaluation because existing reference-free metrics including unsupervised and supervised ones are shown to have evident limitations for evaluating controlled text generation (Dathathri et al., 2020).

2.2 Evaluation Metric for Text Generation

Automatic evaluation metrics are important for natural language generation tasks, which can be simply divided into referenced, reference-free (also known as unreferenced) and hybrid metrics: 1) Referenced metrics usually measure the relevance between generated texts and reference texts via lexicon overlap (such as BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005) and ROUGE (Lin, 2004)) or embedding similarity (such as MoverScore (Zhao et al., 2019), BERTScore (Zhang et al., 2020b) and MARS (Liu et al., 2021b)). 2) Reference-free metrics directly evaluate the quality of generated texts without references. Since unsupervised metrics like perplexity (Brown et al., 1992) and distinct n-grams (Li et al., 2016) can only provide a task-agnostic result which correlates weakly with human judgments (Hashimoto et al., 2019; Tevet and Berant, 2021), most of the reference-free metrics resort to supervised models. Specifically, they are trained to fit human-annotated ratings / labels (such as discriminator scores (Shen et al., 2017)) or distinguish human-written texts from negative samples (such as UNION (Guan and Huang, 2020)). 3) Hybrid metrics contain both referenced and reference-free scores, such as RUBER (Tao et al., 2018; Ghazarian et al., 2019), BLEURT (Sellam et al., 2020) and BARTScore (Yuan et al., 2021).

Compared with existing reference-free metrics which are unsupervised, our metric can support the evaluation of generated texts from different aspects via the full utilization of pre-trained models and the formulation of text infilling tasks, which fits the evaluation protocol of controlled text generation well. Also, in contrast with supervised reference-free metrics, our metric can avoid over-

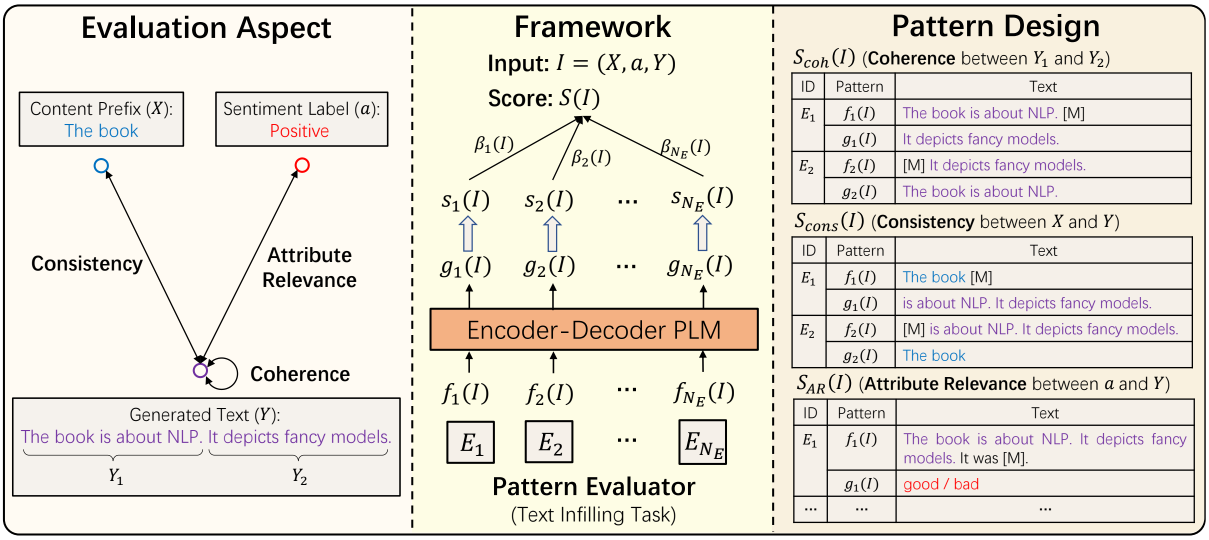

Figure 1: Overview of CTRLEval. **Left**: The three evaluation aspects measure the relationship among content prefixes, attribute labels, and generated texts. **Medium**: The evaluation result $S(I)$ is computed based on the ensemble of the scores from pattern evaluators $E_j (1 \le j \le N_E)$. The score $s_j(I)$ of each pattern evaluator E_j is obtained by the generation probability of the encoder-decoder pre-trained language model in the text infilling task, with the input of $f_j(I)$ and the output of $g_j(I)$. **Right**: The evaluation results for three aspects $S_{coh}(I)$ / $S_{cons}(I)$ / $S_{AR}(I)$ are acquired by the corresponding pattern evaluators, respectively.

fitting task-specific data and maintain better generalization ability to evaluate generated texts from different models and with different qualities.

3 Method

3.1 Task Definition and Method Overview

Given the input $I = (X, a, Y)$ which consists of a content prefix X, an attribute label a, and a generated text Y, our goal is to acquire three evaluation results for coherence, consistency and attribute relevance, respectively.

As shown in Figure 1, our main idea is to formulate each evaluation aspect into multiple text infilling tasks and utilize the ensemble of the scores from each task as the final evaluation results. We denote each text infilling task as a *pattern evaluator* , which means evaluation with different input and output patterns. Inspired by the recent works on pattern-exploiting training (Schick and Schütze, 2021a,b) and prompt tuning (Gu et al., 2021), we define each pattern evaluator as $E = (f, g)$, which consists of two pattern functions to build the input and output sequence of text infilling tasks, respectively. The score of each pattern evaluator is acquired from the generation probability of the encoder-decoder pre-trained language model whose pre-training task is to generate the masked part from the remaining texts of the input. For each aspect, we devise multiple pattern evaluators to alleviate the potential bias caused by the pattern design (Zhao et al., 2021), and weight the scores of all the evaluators to obtain the final result:

$$S(I) = \sum_{j=1}^{N_E} \beta_j(I) \cdot s_j(I) \qquad (1)$$

where N_E is the number of pattern evaluators, $S(I)$ denotes the overall score for each aspect, $\beta_j(I)$ is a factor to weight the pattern evaluators of the corresponding aspect and $s_j(I)$ indicates the score of each pattern evaluator based on the generation probability of the pre-trained model.

3.2 Evaluation Aspect

3.2.1 Coherence

Coherence aims to measure whether the sentences in the generated text are semantically relevant to compose a coherent body (Vakulenko et al., 2018; Yuan et al., 2021), which reflects the quality of the generated text itself. Assume that the generated text Y consists of M sentences, i.e., $Y = (Y_1, Y_2, \cdots, Y_M)$, we devise M pattern evaluators $E_j = (f_j, g_j)(1 \le j \le M)$ to measure the relevance between each sentence and all the remaining sentences:

$$f_j(I) = Y_{\backslash j} = Y_1 \cdots Y_{j-1} \, \texttt{[M]} \, Y_{j+1} \cdots Y_M \qquad (2)$$

$$g_j(I) = Y_j \qquad (3)$$

where $Y_{\backslash j}$ indicates the generated text Y with the j-th sentence replaced by a mask token `[M]`. The score of each pattern evaluator E_j can be computed via the log probability of the pre-trained model P_θ:

$$s_j(I) = \log P_\theta(g_j(I)|f_j(I)) = \log P_\theta(Y_j|Y_{\backslash j}) \tag{4}$$

Since specific and informative sentences are more likely to impact the quality of the whole text, we adopt normalized inverse sentence frequency (NISF) (Zhang et al., 2018) of the output sentence which can reflect its specificity to weight each pattern evaluator:

$$\beta_j(I) = \mathrm{NISF}(Y_j) = \frac{\mathrm{ISF}(Y_j)}{\sum_{k=1}^{M} \mathrm{ISF}(Y_k)} \tag{5}$$

$$\mathrm{ISF}(Y_j) = \max_{w \in Y_j} \mathrm{IWF}(w) \tag{6}$$

where the inverse sentence frequency (ISF) of Y_j is computed by the maximum inverse word frequency (IWF) of the words in Y_j. We estimate IWF on a general corpus BookCorpus (Zhu et al., 2015), which is commonly adopted as the pre-training dataset in the existing works (Devlin et al., 2019):

$$\mathrm{IWF}(w) = \frac{\log(1 + |C|)}{f_w} \tag{7}$$

where $|C|$ indicates the total number of sentences in BookCorpus and f_w denotes the number of sentences containing the word w. Thus, the evaluation result of coherence can be obtained by the ensemble of the scores from all the pattern evaluators:

$$S_{coh}(I) = \sum_{j=1}^{M} \mathrm{NISF}(Y_j) \cdot \log P_\theta(Y_j|Y_{\backslash j}) \tag{8}$$

3.2.2 Consistency

Consistency aims to evaluate whether the generated text is consistent to the content prefix (Celikyilmaz et al., 2020; Rashkin et al., 2020). We devise two symmetric pattern evaluators $E_{X\to Y}$ and $E_{Y\to X}$ to evaluate the consistency between the content prefix and the generated text as follows:

$$f_{X\to Y}(I) = X\,\texttt{[M]}, g_{X\to Y}(I) = Y_{\backslash X} \tag{9}$$

$$f_{Y\to X}(I) = \texttt{[M]}\,Y_{\backslash X}, g_{Y\to X}(I) = X \tag{10}$$

where $Y_{\backslash X}$ denotes the remaining part of the generated text without the prefix. Similar to coherence, we still adopt the log probability of the pre-trained model as the pattern evaluator's score and weight them with normalized inverse sentence frequency to obtain the final result of consistency:

$$S_{cons}(I) = \mathrm{NISF}(Y_{\backslash X}) \cdot \log P_\theta(Y_{\backslash X}|X\,\texttt{[M]}) + \mathrm{NISF}(X) \cdot \log P_\theta(X|\,\texttt{[M]}\,Y_{\backslash X}) \tag{11}$$

3.2.3 Attribute Relevance

Attribute relevance aims to measure whether the generated text satisfies the attribute label (Dathathri et al., 2020). To probe the relevance between generated texts and attribute labels, we first introduce a verbalizer $v(\cdot)$ which maps all the attribute labels a in the attribute set $\mathcal{A}$ to the corresponding words (Schick and Schütze, 2021a). Then, we design the pattern evaluators $E_j = (f_j, g_j)(1 \le j \le N_{AR})$ where $f_j(\cdot)$ adds prompts and a mask token to the generated text, and $g_j(\cdot)$ is set to be a verbalizer:

$$f_j(I) = \mathrm{Concat}(\mathrm{Prompt}_j, \texttt{[M]}, Y) \tag{12}$$

$$g_j(I) = v_j(a) \tag{13}$$

where Concat$(\cdot)$ indicates the concatenation of the prompt, the mask token, and the generated text in some order. We give an example for the pattern design of attribute relevance which is also shown in Figure 1. In this example, the attribute is set to be the sentiment $\mathcal{A} = \{$Positive,Negative$\}$, while the patterns are designed as $f(I) =$ "Y It was `[M]`." and $g(I) = v$(Positive/Negative) $=$ good/bad.

Inspired by the existing works (Schick and Schütze, 2021a), we use the generation probability of the corresponding label word over all the label words as the score of the pattern evaluator:

$$s_j(I) = \frac{P_\theta(v_j(a)|f_j(I))}{\sum_{a' \in \mathcal{A}} P_\theta(v_j(a')|f_j(I))} \tag{14}$$

Based on the assumption that the pattern evaluator is adequate to measure the data sample if the words of all the attribute labels are easily generated, we devise the unnormalized weighted score of each evaluator as the sum of generation probabilities over all the attribute labels:

$$w_j(I) = \sum_{a' \in \mathcal{A}} P_\theta(v_j(a')|f_j(I)) \tag{15}$$

$$\beta_j(I) = \frac{w_j(I)}{\sum_{k=1}^{N_{AR}} w_k(I)} \tag{16}$$

Similarly, the evaluation result of attribute relevance can be acquired by the weighted sum of all the pattern evaluators' scores:

$$S_{AR}(I) = \sum_{j=1}^{N_{AR}} \beta_j(I) \cdot s_j(I) \tag{17}$$

Task	#Prefixes	#Labels	#Models	#Samples	#Ratings (per sample)	Length	Krippendorff's α
Sentiment	15	2	4	360	5	54.2	0.626
Topic	20	4	4	960	5	55.7	0.622

Table 1: Statistics of the evaluation set, including the number of the prefixes / attribute labels / generation models / samples / ratings (per sample), the average length of each sample and Krippendorff's α.

4 Experiment

4.1 Datasets

Since there is no standard benchmark dataset for evaluating controlled text generation, we construct an evaluation set to measure the correlation between automatic metrics and human judgments.

Task: We choose sentiment-controlled and topic-controlled text generation as the benchmark tasks, which are widely used in the existing works (Dathathri et al., 2020; Chan et al., 2021). These two tasks require the models to generate texts conditioned on the given prefixes and sentiment / topic labels, respectively. In the task of sentiment-controlled text generation, we follow PPLM (Dathathri et al., 2020) and CoCon (Chan et al., 2021) to adopt 15 prefixes and 2 sentiment labels (i.e., positive and negative). As for topic-controlled text generation, we follow CoCon (Chan et al., 2021) to adopt 20 prefixes and 4 topic labels (i.e., computers, politics, religion, and science).

Generation Models: We consider various generation models including CTRL (Keskar et al., 2019), PPLM (Dathathri et al., 2020), GeDi (Krause et al., 2020), and CoCon (Chan et al., 2021). These representative models support both the sentiment-controlled and topic-controlled text generation tasks, and cover different levels of generation abilities. We make these models generate 3 different samples for each unique pair of prefixes and attribute labels. We set the maximum length of generated texts to be 80 and remove the last sentence if it is not complete. We directly use the generation results if they have been released by the original papers. Otherwise, we run the original codes to obtain the generation results.

Human Annotation: We collect human ratings on the generated texts from Amazon Mechanical Turk (AMT). Each survey of AMT contains a prefix, an attribute label, and five generated texts including (a) four generated texts from the above four models respectively, and (b) one negative sample which is constructed by perturbing (e.g. sentence shuffling and dropping) another sample from the evaluation set (Guan et al., 2021). We ask annotators to rate these texts with a 1-5 Likert scale for each aspect. To control the annotation quality, we discard the submissions if the annotator assigns a higher rating to the negative sample than other texts. We ensure that each generated text contains 5 valid ratings for each aspect, where the average value of valid ratings is used as the human judgments. We also calculate Krippendorff's α (Krippendorff, 2018) to show the agreement of human ratings, which is 0.626 / 0.622 for sentiment-controlled / topic-controlled text generation tasks, respectively.

The statistics of the evaluation set are shown in Table 1.

Task	#Seed Prompts	#Prompts	#Verbalizers	#Evaluators
Sentiment	3	24	3	72
Topic	4	32	1	32

Table 2: Statistics of the pattern evaluators in attribute relevance. The number of evaluators is obtained by multiplying the number of prompts and verbalizers.

4.2 Implementation Details

We choose PEGASUS (Zhang et al., 2020a) as our base model in the overall result and also explore other pre-trained models in §4.8. The hyper-parameters of Transformer blocks are the same as PEGASUS-large with 568M parameters. As for the pattern evaluators in attribute relevance involving prompts and verbalizers which need to be additionally designed, we follow BARTScore (Yuan et al., 2021) to first adopt manually devised seed prompts and verbalizers in the existing works (Schick and Schütze, 2021a,b), and then collect paraphrases to automatically expand our evaluator set. The statistics of pattern evaluators in attribute relevance are presented in Table 2. More details about the specific design of prompts and verbalizers are included in Appendix A.

4.3 Baselines

We choose several state-of-the-art reference-free metrics as our baselines:

Perplexity (PPL) (Brown et al., 1992): This method calculates the perplexity of generated texts

Task	Sentiment						Topic					
Aspect	Coherence			Consistency			Coherence			Consistency		
Metric	r	ρ	τ	r	ρ	τ	r	ρ	τ	r	ρ	τ

Table 4: Pearson (r), Spearman (ρ), and Kendall (τ) correlations of attribute relevance in sentiment-controlled and topic-controlled text generation. Note that the baselines which are not trained on attribute-annotated corpora can hardly measure the relevance between generated texts and attribute labels, thereby causing low correlations.

with a language model. We use GPT (Radford et al., 2018) and PEGASUS (Zhang et al., 2020a) as the base models since GPT is commonly used in the existing works (Dathathri et al., 2020) and PEGASUS is our base model. They are denoted as **PPL-GPT** and **PPL-PEGASUS**, respectively.

Discriminator Score (DisScore) (Kannan and Vinyals, 2017; Chan et al., 2021): This method trains a discriminator with different objectives. We adopt the IMDB movie review dataset (Maas et al., 2011) / HuffPost News category dataset[2] for sentiment-controlled / topic-controlled text generation tasks, respectively. For coherence and consistency, the discriminator is trained to distinguish human-written texts from manually constructed negative samples, where the ratio of positive and negative samples is 1:1. For attribute relevance, it is trained based on the sentiment / topic classification task, respectively (Chan et al., 2021). Both the sentiment and topic discriminators are implemented based on BERT (Devlin et al., 2019) and they achieve 94.15% / 91.54% on the corresponding test set, respectively.

UNION (Guan and Huang, 2020): This method is a self-supervised metric which is trained to distinguish human-written texts from the automatically perturbed negative samples with well-designed negative sampling strategies and multi-task learning. We use the same datasets as the discriminator score to train UNION.

BLEURT (Sellam et al., 2020): This method is a supervised metric which is pre-trained on synthetic examples and then fine-tuned to fit human ratings. We used the same instruction in §4.1 to additionally annotate the generated texts to construct the training set for BLEURT, whose amount is the same as the evaluation set. There is no overlap between BLEURT's training set and the evaluation set.

BARTScore (Yuan et al., 2021): This method utilizes the generation probabilities of BART (Lewis et al., 2020) to measure the relationship among sources, hypotheses, and references. Since this metric simultaneously contains referenced and reference-free parts, we only use the reference-free score in our experiments. We also use PEGASUS (Zhang et al., 2020a) as the base model for a fair comparison, which is denoted as **BARTScore-PEGASUS**.

4.4 Overall Result

We follow the existing work (Guan and Huang, 2020; Yuan et al., 2021) to adopt Pearson (r), Spearman (ρ), and Kendall (τ) correlation coefficients between automatic metrics and human judgments

---

[2] `https://www.kaggle.com/rmisra/news-category-dataset`

to measure the performance of different metrics.

The overall results on sentiment-controlled and topic-controlled text generation are shown in Table 3 and 4. We can observe that CTRLEval outperforms other baselines with a large margin, indicating the effectiveness of our metric on different evaluation aspects. In Table 4, unsupervised baselines can hardly measure the relevance between generated texts and attribute labels because they only provide a task-agnostic score which is weakly relevant to this specific aspect. For comparison, our metric, which supports the evaluation for different aspects of generated texts via the design of text infilling tasks, can obtain much better performance and even outperform the supervised baselines.

4.5 Ablation Study

Metric	Aspect		
	Coherence	Consistency	Attr. Rel.
CTRLEval (Ours)	**0.2403**	**0.2342**	**0.5189**
Weight of Pattern Evaluators (w/o β)			
w/ mean$(\cdot)$	0.2295	0.1927	0.5091
w/ max$(\cdot)$	0.2323	0.1772	0.5170
w/ min$(\cdot)$	0.1518	0.1559	0.4153
Pattern Function (w/o $f\&g$)			
w/ PPL-GPT-PF	0.2041	0.2169	0.4376
w/ BARTScore-PF	0.1236	0.1843	0.3972

Table 5: Pearson correlation of ablation models in topic-controlled text generation.

To further investigate the effect of each module, we conduct ablation studies on the weight of pattern evaluators and the design of pattern functions. For the weight of evaluators, we use the mean, maximum and minimum values of all the evaluators as the final result rather than the weighted sum based on the factor β. As for the design of pattern functions, we fix the base model and replace our input and output patterns ($f\&g$) with those of PPL-GPT (Radford et al., 2018) and BARTScore (Yuan et al., 2021). The pattern functions of these ablation models are not designed for text infilling tasks. Both of them remove the mask token in the input pattern, and PPL-GPT additionally places the input pattern at the beginning of the output pattern.

The results in Table 5 show that each module in our metric contributes to the final performance. As for the weight of evaluators, we can observe that our weight factor performs better than common aggregation functions especially in consistency, indicating the necessity of the well-designed ensemble method when the number of pattern evaluators is small. Also, our pattern functions outperform those of other baselines, thereby showing the effectiveness of text infilling tasks which can fully utilize pre-trained models in an unsupervised setting.

4.6 Analysis on Generalization Ability

Generalization ability is essential for automatic metrics to evaluate open-ended text generation models. In this section, we will test whether our metric can be generalizable to measure the generated texts faced with model drift and quality drift.

4.6.1 Model Drift

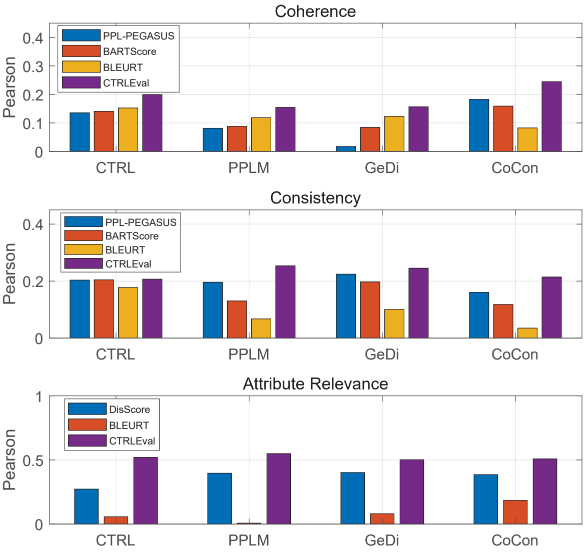

Figure 2: Pearson correlation on the generated results from four generation models in the task of topic-controlled text generation.

To measure whether CTRLEval is reliable to assess the generated results of different models, we split the evaluation set into four subsets based on the generation model and calculate Pearson correlation between each metric and human judgments.

The results in Figure 2 show that our metric can outperform other baselines on the generated texts of all the generation models. Simultaneously, CTRLEval can achieve stable performance with smaller variances when evaluating different generation models, indicating that our metric can generalize to the model drift better.

4.6.2 Quality Drift

To evaluate the generalization ability of CTRLEval on the generated texts with different qualities, we follow the existing work (Sellam et al., 2020; Guan

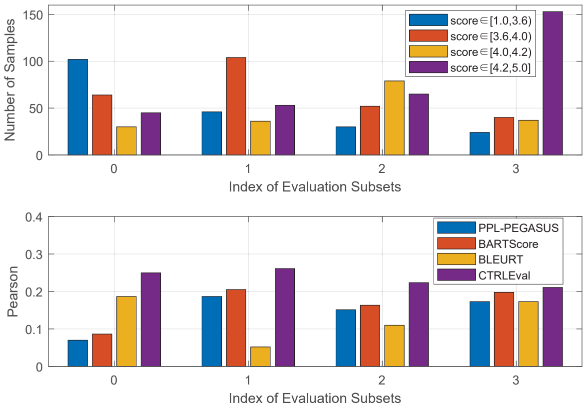

Figure 3: **Top**: The number of samples with different coherence scores in the four biased evaluation subsets. **Bottom**: Pearson correlation of different metrics on the biased evaluation subsets.

and Huang, 2020) to construct four biased subsets based on the coherence score of topic-controlled text generation. We first sort all the samples in the evaluation set and use the quartiles to split them into four subsets with the index from 0 to 3. Then, we create four biased subsets. For the j^{th} subset, we sampled the generated texts which belong to the original i^{th} subset with a probability of $\frac{1}{|j-i|+1}$ where $i, j = 0, 1, 2, 3$. Thus, the four biased subsets have different distributions of generated texts with different qualities, as shown in Figure 3.

We then calculate the Pearson correlation between each metric and human judgments. The results in Figure 3 show that CTRLEval has higher correlations than the baselines on the evaluation subsets with different qualities. Also, our metric can achieve more stable performance on different subsets, which shows our better generalization ability to deal with quality drift.

4.7 Analysis on the Number of Evaluators

To investigate how the number of pattern evaluators affects the performance, we randomly sample the evaluators 20 times when evaluating attribute relevance in topic-controlled text generation, and illustrate mean values and standard deviations of each number of evaluators in Figure 4.

Figure 4 shows that as the number of evaluators increases, the mean value of our performance can be persistently improved while the standard deviation is gradually reduced. This demonstrates the necessity of devising multiple pattern evaluators for each aspect, which can alleviate the bias brought by the pattern design. The comparison between the pattern functions of CTRLEval and other baselines indicates our superior performance on all the numbers of evaluators.

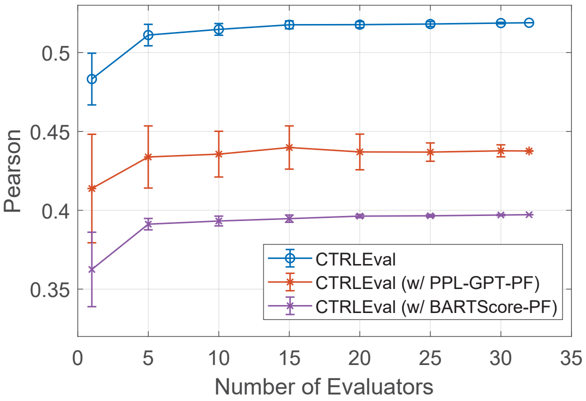

Figure 4: Pearson correlation of the models with different numbers of evaluators.

4.8 Analysis on Base Model

Base Model	#Param	Aspect		
		Coherence	Consistency	Attr. Rel.
PEGASUS	568M	0.3044	0.2235	**0.2111**
BART	400M	**0.3123**	0.1650	0.1951
T5	770M	0.2930	**0.2350**	0.2075

Table 6: Kendall correlation of CTRLEval with different base models in sentiment-controlled text generation. #Param means the number of parameters.

Since our method can adapt to different pre-trained models whose pre-training task is text infilling, we additionally choose BART (Lewis et al., 2020) and T5 (Raffel et al., 2020) as our base model, and present the results in Table 6.

Table 6 shows that PEGASUS and T5 obtain comparable performance on all the evaluation aspects, which indicates that our well-designed text infilling tasks can be transferable to T5 without considerable modification. As for BART which performs worse on consistency and attribute relevance, we conjecture that the fewer parameters and the form of pre-training tasks may limit the performance. Since the pre-training task of BART is to generate the complete text rather than only the masked part of the input text, it may not be good at the evaluation involving a short span of texts, such as the prefix in the evaluation of consistency and the label word in attribute relevance.

We also provide the analysis on the number of parameters in Appendix B and the case study in Appendix C.

5 Discussion

Extension to More Control Variables: In this paper, we evaluate the relationship between generated texts and two control variables (including content prefixes and attribute labels) via consistency and attribute relevance, respectively. We can also extend our metric to other control variables by designing additional pattern evaluators to measure the relationship between generated texts and each variable, respectively. We will further investigate the extensibility of our metric in the future work.

Design of Pattern Evaluators: With the rapid development of prompt tuning, recent works have proposed new methods on the design of prompts and verbalizers (Gao et al., 2021; Lester et al., 2021), which provide alternatives to our metric in attribute relevance. Also, the weight factor of each evaluator can be set as diversity metrics (Hashimoto et al., 2019) besides NISF in coherence and consistency. We will leave the exploration of more settings on pattern evaluators as the future work.

6 Conclusion

We present an unsupervised reference-free metric called CTRLEval for evaluating controlled text generation. This metric formulates the evaluation of different aspects into multiple text infilling tasks, and utilizes the ensemble of generation probabilities from a pre-trained model in different tasks as the evaluation result. Experimental results indicate that CTRLEval obtains higher correlations with human judgments and shows better generalization ability for addressing model drift and quality drift.

This work was supported by the National Science Foundation for Distinguished Young Scholars (with No. 62125604) and the NSFC projects (Key project with No. 61936010 and regular project with No. 61876096). This work was also supported by the Guoqiang Institute of Tsinghua University, with Grant No. 2019GQG1 and 2020GQG0005.

Ethics Statement

We construct an evaluation set for evaluating controlled text generation. The data samples in this set are all from the existing works with open-source codes, model checkpoints, and generated results. We directly use the generated results if the authors have released them. Otherwise, we adopt the same setting as the original papers to make these models generate texts. We do not apply extra selection strategies to the generated results.

We resort to Amazon Mechanical Turk (AMT) for the annotation of this evaluation set. We do not invade the privacy or collect personal information of annotators. We pay each annotator \$0.06 for each survey including four generated texts and one negative sample. The payment is determined based on the length of data samples. We additionally ask annotators to check whether there is a potential ethical problem in the data, and remove these problematic data in the evaluation set. After annotation on AMT, we manually review all the annotated samples from an ethical perspective. However, we admit that there may still exist unpredictable bias in this evaluation set.

A Pattern Evaluator for Attribute Relevance

We first choose the prompts and verbalizers which have been shown to work well in the existing works on few-shot text classification (Schick and Schütze, 2021a; Gao et al., 2021) and generation (Schick and Schütze, 2021b) as the seed prompts and verbalizers. Then, we expand our prompt set with the following rules: 1) Switching the order of generated texts, prompts, and mask tokens; 2) Collecting the paraphrases of seed prompts just as BARTScore (Yuan et al., 2021) does. All the prompts and verbalizers which are used in our experiments are shown in Table 8.

B Analysis on the Number of Parameters

Base Model	#Param	Aspect		
		Coherence	Consistency	Attr. Rel.
T5-small	60M	0.2389	0.1495	0.1765
T5-base	220M	0.2847	0.2053	0.1867
T5-large	770M	**0.2930**	**0.2350**	**0.2075**

Table 7: Kendall correlation of CTRLEval with T5-small, T5-base, and T5-large in sentiment-controlled text generation. #Param means the number of parameters.

We further conduct experiments on the base model with different numbers of parameters. Since the authors of PEGASUS (Zhang et al., 2020a) do not release the model checkpoint of PEGASUS-base, we choose T5-small, T5-base and T5-large (Raffel et al., 2020) as our base models respectively, and present the results in Table 7. The results show that larger numbers of parameters can benefit the model performance while degrading the computation efficiency.

C Case Study

To intuitively show how our metric works in the evaluation of controlled text generation, we provide some cases on the three evaluation aspects, including coherence (Figure 6), consistency (Figure 6), and attribute relevance (Figure 7). Since the range of various metrics is always different, it may be less meaningful to directly compare the absolute value of each metric. Thus, we follow the existing works (Guan and Huang, 2020; Liu et al., 2021b) to conduct a pairwise comparison on different samples.

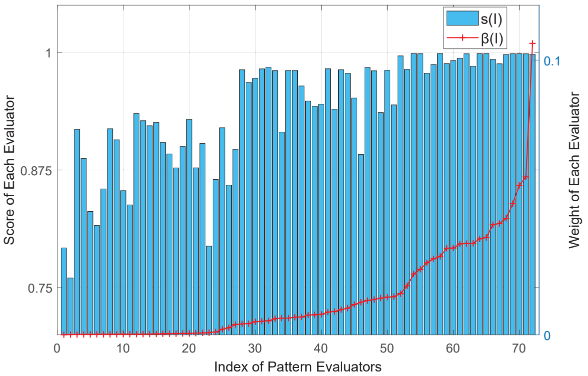

Figure 5: The score and weight of each evaluator for evaluating attribute relevance of the second sample in Figure 7.

The results in Figure 6 and 7 show that our metric can give accordant preferences with human judgments, indicating the effectiveness of our metric on all three evaluation aspects. To further show how each pattern evaluator works in the overall evaluation result, we take the second sample in Figure 7 as an example and visualize the weight $\beta(I)$ and score $s(I)$ in Figure 5. We can observe that most of the pattern evaluators assign high scores to this sample which agree with the human judgment. Simultaneously, the weight factor automatically reduces the effect of low-quality evaluators which also plays an important role in the final evaluation result.

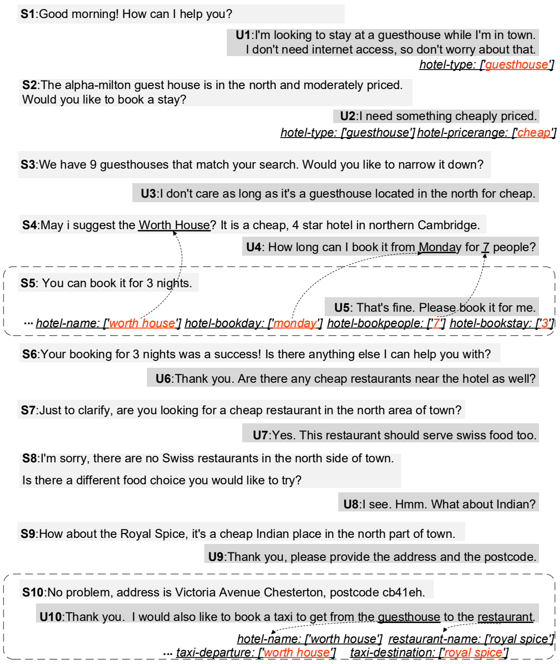
Abstract

In dialogue state tracking, dialogue history is a crucial material, and its utilization varies between different models. However, no matter how the dialogue history is used, each existing model uses its own consistent dialogue history during the entire state tracking process, regardless of which slot is updated. Apparently, it requires different dialogue history to update different slots in different turns. Therefore, using consistent dialogue contents may lead to insufficient or redundant information for different slots, which affects the overall performance. To address this problem, we devise DiCoS-DST to dynamically select the relevant dialogue contents corresponding to each slot for state updating. Specifically, it first retrieves turn-level utterances of dialogue history and evaluates their relevance to the slot from a combination of three perspectives: (1) its explicit connection to the slot name; (2) its relevance to the current turn dialogue; (3) Implicit Mention Oriented Reasoning. Then these perspectives are combined to yield a decision, and only the selected dialogue contents are fed into State Generator, which explicitly minimizes the distracting information passed to the downstream state prediction. Experimental results show that our approach achieves new state-of-the-art performance on MultiWOZ 2.1 and MultiWOZ 2.2, and achieves superior performance on multiple mainstream benchmark datasets (including Sim-M, Sim-R, and DSTC2).[1]



S1:Good morning! How can I help you?

U1:I'm looking to stay at a guesthouse while I'm in town. I don't need internet access, so don't worry about that.

hotel-type: ['guesthouse']

S2:The alpha-milton guest house is in the north and moderately priced. Would you like to book a stay?

U2:I need something cheaply priced.

hotel-type: ['guesthouse'] hotel-pricerange: ['cheap']

S3:We have 9 guesthouses that match your search. Would you like to narrow it down?

U3:I don't care as long as it's a guesthouse located in the north for cheap.

S4:May i suggest the Worth House? It is a cheap, 4 star hotel in northern Cambridge.

U4: How long can I book it from Monday for 7 people?

S5: You can book it for 3 nights.

U5: That's fine. Please book it for me.

··· *hotel-name: ['worth house'] hotel-bookday: ['monday'] hotel-bookpeople: ['7'] hotel-bookstay: ['3']*

S6:Your booking for 3 nights was a success! Is there anything else I can help you with?

U6:Thank you. Are there any cheap restaurants near the hotel as well?

S7:Just to clarify, are you looking for a cheap restaurant in the north area of town?

U7:Yes. This restaurant should serve swiss food too.

S8:I'm sorry, there are no Swiss restaurants in the north side of town. Is there a different food choice you would like to try?

U8:I see. Hmm. What about Indian?

S9:How about the Royal Spice, it's a cheap Indian place in the north part of town.

U9:Thank you, please provide the address and the postcode.

S10:No problem, address is Victoria Avenue Chesterton, postcode cb41eh.

U10:Thank you. I would also like to book a taxi to get from the guesthouse to the restaurant.

hotel-name: ['worth house'] restaurant-name: ['royal spice']

Figure 1: An example of multi-domain dialogues. Utterances at the left and the right sides are from system and user, respectively. Each red slot value in the figure indicates that it is updated in its turn.

1 Introduction

Task-oriented dialogue systems have recently attracted growing attention and achieved substantial progress. Dialogue state tracking (DST) is a core component, where it is responsible for interpreting user goals and intents and feeding downstream policy learning in dialogue management. The common practice treats it as a problem of compacting the dialogue content into a series of slot-value pairs that represent information about the user goals updated until the current turn. For example, in Figure 1, the dialogue state at turn 2 is {(“$hotel-type$”, “$guesthouse$”), (“$hotel-pricerange$”, “$cheap$”)}.

In dialogue state tracking, dialogue history is a crucial source material. Recently, granularity has been proposed to quantify the utilization of dialogue history(Yang et al., 2021). In DST, the definition of granularity is the number of dialogue turns spanning from a certain dialogue state in the dialogue to the current dialogue state. Traditional DST models usually determine dialogue

Volume 1: Long Papers, pages 2320 - 2332

states by considering only utterances at the current turn (i.e., $\mathrm{granularity} = 1$), while recent researches attempt to utilize partial history (i.e., $\mathrm{granularity} = k,\ k < T$) or introduce all dialogue history information into the prediction (i.e., $\mathrm{granularity} = T$). However, no matter what granularity is used, we find that each model uses a constant granularity it determines, regardless of which slot is being updated. Apparently, it requires different granularity for different slots in different turns. For example, in Figure 1, the granularity required for slot “$hotel-name$”, “$hotel-bookday$”, and “$hotel - bookpeople$” in turn 5 is 2, while slot “$hotel - bookstay$” in turn 5 requires a granularity of 1. Therefore, using a constant granularity may lead to insufficient input for updating some slots, while for others, redundant while confusing contents can become distracting information to pose a hindrance, which affects the overall performance.

Furtherly, granularity means directly working on all dialogue contents from a particular turn to the current turn, regardless of the fact that there are still dialogue contents that are not relevant to the slot. Therefore, if it is possible to break the limitation of granularity and to dynamically select relevant dialogue contents corresponding to each slot, the selected dialogue contents as input will explicitly minimize distracting information being passed to the downstream state prediction.

To achieve this goal, we propose a DiCoS-DST to fully exploit the utterances and elaborately select the relevant dialogue contents corresponding to each slot for state updating. Specifically, we retrieve turn-level utterances of dialogue history and evaluate their relevance to the slot from a combination of three perspectives. First, we devise an SN-DH module to touch on the relation of the dialogue and the slot name, which straightforward reflects the relevance. Second, we propose a CT-DH module to explore the dependency between each turn in the dialogue history and the current turn dialogue. The intuition behind this design is that the current turn dialogue is crucial. If any previous turn is strongly related to the current turn dialogue, it can be considered useful as dependency information for slot updating. Third, we propose an Implicit Mention Oriented Reasoning module to tackle the implicit mention (i.e., coreferences) problem that commonly exists in complex dialogues. Specifically, we build a novel graph neural network (GNN) to explicitly facilitate reasoning over the turns of dialogue and all slot-value pairs for better exploitation of the coreferential relation information. After the evaluation of these three modules, we leverage a gate mechanism to combine these perspectives and yield a decision. Finally, the selected dialogue contents are fed into State Generator to enhance their interaction, form a new contextualized sequence representation, and generate a value using a hybrid method.

We evaluate the effectiveness of our model on most mainstream benchmark datasets on task-oriented dialogue. Experimental results show that our proposed DiCoS-DST achieves new state-of-the-art performance on both two versions of the most actively studied dataset: MultiWOZ 2.1 (Eric et al., 2019) and MultiWOZ 2.2 (Zang et al., 2020) with joint goal accuracy of 61.02% and 61.13%. In particular, the joint goal accuracy on MultiWOZ 2.2 outperforms the previous state-of-the-art by 3.09%. In addition, DiCoS-DST also achieves new state-of-the-art performance on Sim-M and Sim-R (Shah et al., 2018) and competitive performance on DSTC2 (Henderson et al., 2014).

Our contributions in this work are three folds:

- We propose a Multi-Perspective Dialogue Collaborative Selector module to dynamically select relevant dialogue contents corresponding to each slot from a combination of three perspectives. This module can explicitly filter the distracting information being passed to the downstream state prediction.
- We propose Implicit Mention Oriented Reasoning and implement it by building a GNN to explicitly facilitate reasoning and exploit the coreferential relation information in complex dialogues.
- Our DiCoS-DST model achieves new state-of-the-art performance on the MultiWOZ 2.1, MultiWOZ 2.2, Sim-M, and Sim-R datasets.

2 Related Work

There has been a plethora of research on dialogue state tracking. Traditional dialogue state trackers relied on a separate Spoken Language Understanding (SLU) module (Thomson and Young, 2010; Wang and Lemon, 2013) to extract relevant information. In recent years, neural network models are proposed for further improvements. One way to classify DST models is whether they use dialogue

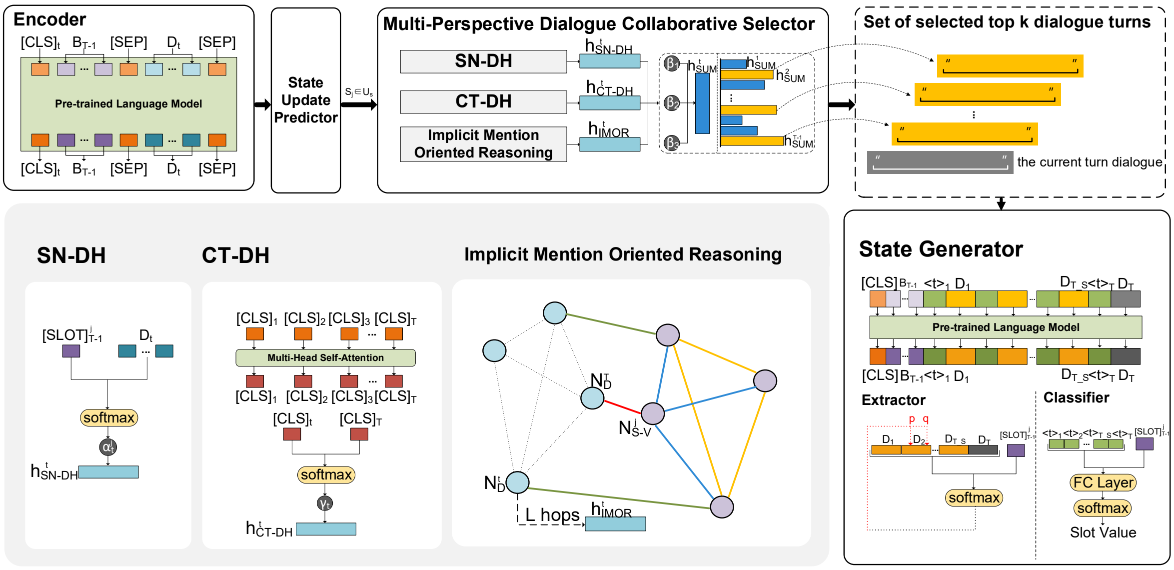

Figure 2: The architecture of the proposed DiCoS-DST model. The gray area in the lower left part of the figure shows the internal structure of the three modules in Multi-Perspective Dialogue Collaborative Selector.

history. Some DST models obtain each slot value in the dialogue state by inquiring about a part or all of the dialogue history (Xu and Hu, 2018; Lei et al., 2018; Goel et al., 2019; Ren et al., 2019; Shan et al., 2020; Zhang et al., 2020; Chen et al., 2020; Guo et al., 2021), while the others use the current turn dialogue to predict the dialogue state (Mrkšić et al., 2017; Kim et al., 2020; Heck et al., 2020; Zhu et al., 2020). Recently, (Yang et al., 2021) first proposed the granularity in DST to quantify the use of dialogue history. Its experimental results show that different models on different datasets have different optimal granularity (not always using the entire dialogue history). However, no matter what granularity is used, each model uses a constant granularity it determines, regardless of which slot is updated.

On the other hand, dialogue state tracking and machine reading comprehension (MRC) have similarities in many aspects (Gao et al., 2020). Recently, Multi-hop Reading Comprehension (MHRC) has been a challenging topic. For cases in MHRC datasets, one question is usually provided with several lexically related paragraphs, which contain many confusing contexts. To deal with this situation, cascaded models (Qiu et al., 2019; Groeneveld et al., 2020; Tu et al., 2020; Wu et al., 2021) that are composed of a reader and a retriever are often used. They retrieve the most relevant evidence paragraphs first and perform multi-hop reasoning on retrieved contexts thereafter. The mechanism of dialogue selection before state generation in our work is partially inspired by the paragraph retrieval in multi-hop reading comprehension.

3 Approach

The architecture of DiCoS-DST is illustrated in Figure 2. DiCoS-DST consists of Encoder, State Update Predictor, Multi-Perspective Dialogue Collaborative Selector, and State Generator. Here we first define the problem setting in our work. We define the number of the current turn as T. The task is to predict the dialogue state at each turn t $(t \leq T)$, which is defined as $\mathcal{B}_t = \{(S^j, V^j_t)|1 \leq j \leq J\}$, where S^j is the slot name, V^j_t is the corresponding slot value, and J is the total number of slots. For the sake of simplicity, we omit the superscript T in the variables in the next sections.

3.1 Encoder

We employ the representation of the previous turn dialogue state B_{T-1} concatenated to the representation of each turn dialogue utterances D_t as input: $E_t = [\text{CLS}]_t \oplus B_{T-1} \oplus [\text{SEP}] \oplus D_t$, $(1 \leq t \leq T)$, where $[\text{CLS}]_t$ is a special token added in front of every turn input. The representation of the previous turn dialogue state is $B_{T-1} = B^1_{T-1} \oplus \ldots \oplus B^J_{T-1}$. The representation of each slot's state $B^j_{T-1} = [\text{SLOT}]^j_{T-1} \oplus S_j \oplus [\text{VALUE}]^j_{T-1} \oplus V^j_{T-1}$, where $[\text{SLOT}]^j_{T-1}$ and $[\text{VALUE}]^j_{T-1}$ are special tokens that represent the slot name and the slot value at turn $T-1$, respectively. We donate the representation of the dialogue at turn t as $D_t = R_t \oplus ; \oplus U_t \oplus$ [SEP], where R_t is the system response and U_t is the user utterance. ; is a special token used to mark the boundary between R_t and U_t, and [SEP] is a special token used to mark the end of a dialogue turn.

Then a pre-trained language model (PrLM) will be adopted to obtain contextualized representation for the concatenated input sequence E_t.

3.2 State Update Predictor

We attach a two-way classification module to the top of the Encoder output. It predicts which slots require to be updated in the current turn. The subsequent modules will only process the selected slots, while the other slots will directly inherit the slot values from the previous turn.

We inject this module because whether a slot requires to be updated indicates whether the current turn dialogue is significant for this slot. For CT-DH of the subsequent Multi-Perspective Collaborative Selector, the great importance of the current turn dialogue is a prerequisite. A more detailed explanation will be given in Section 3.3.

We employ the same mechanism as (Guo et al., 2021) to train the module and to predict the state operation. We sketch the prediction process as follows:

$$\mathrm{SUP}(S_j) = \begin{cases} \text{update}, & \text{if Total\_}score_j > \delta \\ \text{inherit}, & \text{otherwise} \end{cases} \tag{1}$$

We define the set of the selected slot indices as $\mathbf{U}_s = \{j | \mathrm{SUP}(S_j) = \text{update}\}$.

3.3 Multi-Perspective Dialogue Collaborative Selector

For each slot S_j ($j \in \mathbf{U}_s$) selected to be updated, SN-DH, CT-DH, and Implicit Mention Oriented Reasoning modules are proposed to evaluate dialogue relevance and aggregate representations from three perspectives. Then a gated fusion mechanism is implemented to perform the dialogue selection.

SN-DH SN-DH (Slot Name - Dialogue History) aims to explore the correlation between slot names and each turn of the dialogue history. For slot S_j, the slot name is straightforward explicit information. Therefore, the correlation with the slot name directly reflects the importance of the dialogue turn. We take the slot name presentation $[\mathrm{SLOT}]^j_{T-1}$ as the attention to the t-th turn dialogue representation D_t. The output $\boldsymbol{\alpha}^j_t = \mathrm{softmax}(D_t([\mathrm{SLOT}]^j_{T-1})^\intercal)$ represents the correlation between each position of D_t and the j-th slot name at turn t. Then we get the aggregated dialogue representation $h^t_{\mathrm{SN-DH}} = (\boldsymbol{\alpha}^j_t)^\intercal D_t$, which will participate in the subsequent fusion as the embedding of the t-th turn dialogue in this perspective.

CT-DH As aforementioned, a slot that needs to be updated in the current turn means that the current turn dialogue is most relevant to this slot. In this case, if the dialogue content of any other turn contains the information that the current turn dialogue highly depends on, it can also be considered useful. Based on this consideration, we devise a CT-DH (Current Turn - Dialogue History) module to explore this association. Specifically, we build a multi-head self-attention (MHSA) layer on top of the [CLS] tokens generated from different turns of dialogue to enhance inter-turn interaction. The MHSA layer is defined as:

$$head_i = \mathrm{Attention}(QW_i^Q, KW_i^K, VW_i^V) \tag{2}$$

$$Multihead = (head_i \oplus \ldots \oplus head_n)W^O \tag{3}$$

$$I = \mathrm{MHSA}([\mathrm{CLS}]_1 \oplus \ldots \oplus [\mathrm{CLS}]_T) \tag{4}$$

where Q, K, and V are linear projections from [CLS] embeddings of each turn of dialogue, representing attention queries, key and values.

We then append an attention layer between the output representation of the current turn dialogue and each turn of dialogue history to capture interactions between them:

$$\boldsymbol{\gamma}_t = \mathrm{Attention}([\mathrm{CLS}]_t, [\mathrm{CLS}]_T) \tag{5}$$

$$h^t_{\mathrm{CT-DH}} = \boldsymbol{\gamma}_t[\mathrm{CLS}]_T + [\mathrm{CLS}]_t \tag{6}$$

$h^t_{\mathrm{CT-DH}}$ will participate in the subsequent fusion as an aggregated representation of the t-th dialogue in this perspective.

Implicit Mention Oriented Reasoning Handling a complex dialogue usually requires addressing implicit mentions (i.e., coreferences). As shown in Figure 1, in turn 10, the restaurant is not referred to explicitly upon ordering a taxi within the same dialogue turn. Instead, it is present in the value of another slot. Therefore, SN-DH and CT-DH are difficult to deal with this case due to their mechanisms. To tackle this problem, we build a graph neural network (GNN) model to explicitly facilitate reasoning over the turns of dialogue and all slot-value pairs for better exploitation of the coreferential relation. As illustrated in Figure 3, the nodes in the graph include two types: N_D for each turn dialogue and N_{S-V} for each slot-value pair. They are initialized with the MHSA output representation $[\text{CLS}]_t$ and $W_{S-V}([\text{SLOT}]^z_{T-1} \oplus [\text{VALUE}]^z_{T-1})$ $(1 \leq z \leq J)$, respectively. Then we design four types of edges to build the connections among graph nodes:

1) Add an edge between N^j_{S-V} and N^T_D (red line in Figure 3). As aforementioned, the slot S_j will be updated. This edge is to establish the connection between the slot to be updated and the current turn dialogue;

2) Add an edge between N^j_{S-V} and N^z_{S-V} $(z \neq j)$ (blue line in Figure 3). These edges are to establish connections between the slot to be updated and other slots;

3) Add an edge between N^z_{S-V} $(z \neq j)$ and $N^{t_z}_D$. t_z is the turn when the most up-to-date value of S_z is updated (green line in Figure 3). These edges are to establish connections between each slot and the turn of dialogue in which its latest slot value was updated;

4) Add an edge between $N^{z_1}_{S-V}$ and $N^{z_2}_{S-V}$ (S_{z_1} and S_{z_2} belong to the same domain) (yellow line in Figure 3). These edges are to establish connections between slots that belong to the same domain.

The motivation for this design is that we first explore the relation between the slot to be updated and other slot-value pairs based on the current turn dialogue. Then we use other slot-value pairs as media to establish relations to their corresponding dialogue turns. We add the fourth type of edges to represent the auxiliary relationship of slots that belong to the same domain.

We use multi-relational GCN with gating mechanism as in (De Cao et al., 2019; Tu et al., 2019). We define h^0_i represents initial node embedding from N_D or N_{S-V}. The calculation of node embedding after one hop can be formulated as:

$$h^{l+1}_i = \sigma(u^l_i) \odot g^l_i + h^l_i \odot (1 - g^l_i) \tag{7}$$

$$u^l_i = f_s(h^l_i) + \sum_{r \in \mathcal{R}} \frac{1}{|\mathcal{N}^r_i|} \sum_{n \in \mathcal{N}^r_i} f_r(h^l_n) \tag{8}$$

$$g^l_i = \text{sigmoid}(f_g([u^l_i; h^l_i])) \tag{9}$$

$\mathcal{N}^r_i$ is the neighbors of node i with edge type r, $\mathcal{R}$ is the set of all edge types, and h^l_n is the node representation of node n in layer l. $|\cdot|$ indicates the size of the neighboring set. Each of f_r, f_s, f_g can be implemented with an MLP. Gate control g^l_i is a vector consisting of values between 0 and 1 to control the amount information from computed update u^l_i or from the original h^l_i. Function σ denotes a non-linear activation function.

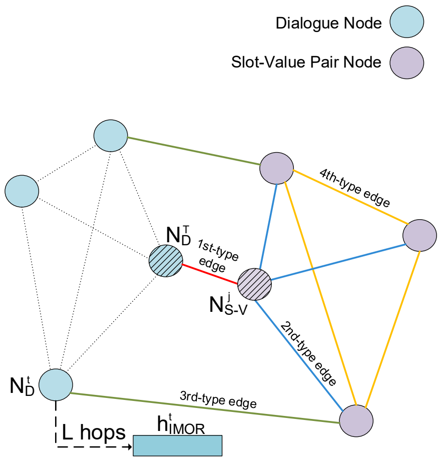

Figure 3: Diagram of the graph neural network. The dashed connection between the dialogue nodes does not actually exist. We draw them to show that using the dialogue representation output by MHSA already includes the contextual interactions between the dialogues.

After the message passes on the graph with L hops, we take the final representation of the t-th turn dialogue node N^t_D as the aggregated representation h^t_{IMOR} in this perspective.

Gating Fusion and Collaborative Selection The representations $h^t_{\text{SN-DH}}$, $h^t_{\text{CT-DH}}$, and h^t_{IMOR} of the t-th turn dialogue enter this module for fusion and ranking. To balance the information from multiple perspectives, we leverage a gate mechanism to compute a weight to decide how much information from each perspective should be combined. It is defined as follows:

$$\beta_1 = \sigma_1(W_{\beta_1} \tanh(W_1 h^t_{\text{SN-DH}})) \tag{10}$$

$$\beta_2 = \sigma_2(W_{\beta_2} \tanh(W_2 h^t_{\text{CT-DH}})) \tag{11}$$

$$\beta_3 = \sigma_3(W_{\beta_3} \tanh(W_3 h^t_{\text{IMOR}})) \tag{12}$$

$$h^t_{\text{sum}} = \beta_1 h^t_{\text{SN-DH}} + \beta_2 h^t_{\text{CT-DH}} + \beta_3 h^t_{\text{IMOR}} \tag{13}$$

After the fusion, an MLP layer is followed, and then we take the dialogues of the top k ranked turns as the selected dialogue contents.

It is worth mentioning that, unlike the state update predictor, since there is no ground-truth label of the dialogue turns that should be selected corresponding to each slot, we take this module and the following state generator as a whole and train it under the supervision of the final dialogue state label. We mark each selected dialogue turn to make the gradient of the state generator losses only backpropagate to the marked turns to ensure the effectiveness of supervision.

3.4 State Generator

The selected dialogue content will be utilized to jointly update the dialogue state.

Cascaded Context Refinement After acquiring a nearly noise-free set $\mathbf{U}_D$ of selected dialogue turns, we consider that directly using their representations as inputs may ignore the cross attention between them since they are used as a whole. As a result, we concatenate these dialogue utterances together to form a new input sequence $C = [\text{CLS}] \oplus B_{T-1} \oplus \langle t \rangle_1 \oplus D_1 \oplus \ldots \oplus \langle t \rangle_{T\_S} \oplus D_{T\_S} \oplus \langle t \rangle_T \oplus D_T$ $(T\_S = |\mathbf{U}_D|)$.

Especially, we inject an indicator token "$\langle t \rangle$" before each turn of dialogue utterance to get aggregated turn embeddings for the subsequent classification-based state prediction. Then we feed this sequence into a single PrLM to obtain the contextualized output representation.

Slot Value Generation We first attempt to obtain the value using the extractive method from representation $C_{\text{E}} = D_1 \oplus D_2 \oplus \ldots \oplus D_{T\_S} \oplus D_T$:

$$p = \text{softmax}(W_s C_{\text{E}}([\text{SLOT}]^j_{T-1})^\intercal) \quad (14)$$

$$q = \text{softmax}(W_e C_{\text{E}}([\text{SLOT}]^j_{T-1})^\intercal) \quad (15)$$

The position of the maximum value in p and q will be the start and end predictions of the slot value. If this prediction does not belong to the candidate value set of S_j, we use the representation of $C_{\text{C}} = \langle t \rangle_1 \oplus \langle t \rangle_2 \oplus \ldots \oplus \langle t \rangle_{T\_S} \oplus \langle t \rangle_T$ to get the distribution and choose the candidate slot value corresponding to the maximum value:

$$y = \text{softmax}(W_{\text{C}} C_{\text{C}}([\text{SLOT}]^j_{T-1})^\intercal) \quad (16)$$

We define the training objectives of two methods as cross-entropy loss:

$$L_{\text{ext}} = -\frac{1}{|\mathbf{U}_s|} \sum_j^{|\mathbf{U}_s|} (p \log \hat{p} + q \log \hat{q}) \quad (17)$$

$$L_{\text{cls}} = -\frac{1}{|\mathbf{U}_s|} \sum_j^{|\mathbf{U}_s|} y \log \hat{y} \quad (18)$$

where $\hat{p}$ and $\hat{q}$ are the targets indicating the proportion of all possible start and end, and $\hat{y}$ is the target indicating the probability of candidate values.

4 Experiments

4.1 Datasets and Metrics

We conduct experiments on most of the mainstream benchmark datasets on task-oriented dialogue, including MultiWOZ 2.1, MultiWOZ 2.2, Sim-R, Sim-M, and DSTC2. MultiWOZ 2.1 and MultiWOZ 2.2 are two versions of a large-scale multi-domain task-oriented dialogue dataset. It is a fully-labeled collection of human-human written dialogues spanning over multiple domains and topics. Sim-M and Sim-R are multi-turn dialogue datasets in the movie and restaurant domains, respectively. DSTC2 is collected in the restaurant domain.

We use joint goal accuracy and slot accuracy as evaluation metrics. Joint goal accuracy refers to the accuracy of the dialogue state in each turn. Slot accuracy only considers slot-level accuracy.

4.2 Baseline Models

We compare the performance of DiCoS-DST with the following baselines: TRADE encodes the dialogue and decodes the value using a copy-augmented decoder (Wu et al., 2019). BERT-DST generates language representations suitable for scalable DST (Chao and Lane, 2019). DST+LU presents an approach for multi-task learning of language understanding and DST (Rastogi et al., 2018). TripPy extracts values from the dialogue context by three copy mechanisms (Heck et al., 2020). DSS-DST consists of the slot selector based on the current turn dialogue, and the slot value generator based on the dialogue history (Guo et al., 2021). Seq2Seq-DU employs two BERT-based encoders to respectively encode the utterances and the descriptions of schemas (Feng et al., 2021). Pegasus-DST applies a span prediction-based pretraining objective designed for text summarization to DST (Zhao et al., 2021). DST-as-Prompting uses schema-driven prompting to provide task-aware history encoding (Lee et al., 2021).

4.3 Implementation Details

We employ a pre-trained ALBERT-large-uncased model (Lan et al., 2019) for the encoder. The hidden size of the encoder d is 1024. We use AdamW optimizer (Loshchilov and Hutter, 2018) and set the warmup proportion to 0.01 and L2 weight decay of 0.01. We set the peak learning rate of State Update Predictor the same as in DSS-DST and the peak learning rate of the other modules to 0.0001. We set the dropout (Srivastava et al., 2014) rate

Table 3: Ablation study with joint goal accuracy (%). Each performance in this table represents the test results after the model was retrained with the corresponding module removed. "- State Update Predictor" means that all slots are updated in each turn. "-Multi-Perspective Dialogue Collaborative Selector" means that using the entire dialogue history without selection. "-Cascaded Context Refinement" means that directly using the representation of selected turns from the dialogue selector without context refinement.

to 0.1. We utilize word dropout (Bowman et al., 2016) with the probability of 0.1. We set L to 3. The max sequence length for all inputs is fixed to 256. During training the Multi-Perspective Dialogue Collaborative Selector, we use the ground truth selected slots instead of the predicted ones. We report the mean joint goal accuracy over 10 different random seeds to reduce statistical errors.

4.4 Main Results

Table 1 shows the performance of our DiCoS-DST and other baselines. Our model achieves state-of-the-art performance on MultiWOZ 2.1 and MultiWOZ 2.2 with joint goal accuracy of 61.02% and 61.13%. In particular, the joint goal accuracy on MultiWOZ 2.2 outperforms the previous state-of-the-art by 3.09%. Besides, despite the sparsity of experimental results on Sim-M and Sim-R, our model still achieves state-of-the-art performance on these two datasets. On DSTC2, the performance of our model is also competitive. Among our models, DiCoS-DST ($k = 2$) performs the best on all datasets. Especially, DiCoS-DST ($k = 2$) and DiCoS-DST ($k = 1$) perform better than DiCoS-DST ($k = 3$). We conjecture that selecting two turns from the dialogue history may be sufficient, and introducing more turns may confuse the model.

4.5 Ablation Study

Different PrLMs We employ different pre-trained language models with different scales as the backbone for training and testing on MultiWOZ 2.2. Table 2 shows that the joint goal accuracy of other encoders decreases in varying degrees compared with ALBERT (large). The joint goal accuracy of BERT(base) decreases by 1.62%, but still outperforms the previous state-of-the-art performance on MultiWOZ 2.2. This demonstrates that our model achieves consistent performance gain in all fair

Table 7: Domain-specific results on MultiWOZ 2.2.

comparison environments with other methods.

Effect of Core Components To explore the effectiveness of core components, we conduct an ablation study of them on MultiWOZ 2.2. As shown in Table 3, we observe that the performance degrades by 2.65% for joint goal accuracy when the State Update Predictor is removed. It is worth mentioning that this performance still outperforms the previous state-of-the-art performance, which demonstrates that the large performance gain of DiCoS-DST over other baselines comes from its dialogue selection. This is also supported by the observation that the performance of the model without the Multi-Perspective Dialogue Collaborative Selection module drops drastically (degrades by 6.19% for joint goal accuracy). In addition, when we remove the Cascaded Context Refinement module, we lose 1.38%, indicating the usefulness of interaction between different dialogue turns.

Separate Perspective and Combinations We explore the performance of each separate perspective and their various combinations. When a perspective needs to be masked, we set their corresponding gating weights to 0. It can be observed in Table 4 that the SN-DH module has the greatest impact on performance, and the most effective combination of perspectives is the combination of SN-DH and CT-DH. Despite the simplicity of the mechanism of SN-DH, the association with the slot name straightforward reflects the importance of the dialogue. To solve the common problem of coreferences in complex dialogues, the Implicit Mention Oriented Reasoning module improves the performance close enough to the CT-DH.

Graph Edges Ablation We investigate the effect of the different edges in the GNN. As shown in Table 5, the performance degradation is relatively obvious when the first, second, and third types of edges are removed separately. It indicates that the majority of the connections are indeed to construct the reasoning logic, while the correlation of the same domain's slots plays an auxiliary role. In addition, we design two comparative experiments. First, we start naively by fully connecting all dialogue nodes to enhance the interaction among dialogue turns. However, this change does not give a clear benefit. This is mostly because the initialization of the dialogue nodes using the dialogue representation output by MHSA already includes the contextual interactions between the dialogues. Second, we add a third type of edges between each slot-value pair node and all dialogue nodes without distinguishing the correspondence. We observe that this change does harm to the performance (degrades by 1.09%). This reflects the importance of using other slots to explore their corresponding turns of dialogues when dealing with coreferences.

5 Analysis

5.1 Is It Beyond the Granularity?

DiCoS-DST filters out some distracting information by selecting relevant dialogues, but is it really beyond the granularity? To investigate it, we simulate the granularity and compare it with DiCoS-DST. Specifically, we use the maximum granularity (i.e., the number of dialogue turns spanning from the selected furthest dialogue turn to the current turn) and capture the corresponding dialogue contents as input to State Generator. As shown in Table 6, DiCoS-DST outperforms the granularity-based method by 1.46% ($k = 1$), 1.25% ($k = 2$), and 0.97% ($k = 3$), indicating that there is still redundant information in the dialogue contents determined by the granularity that confuses the model.

5.2 Domain-Specific Dialogue Requirements

Table 7 shows the domain-specific results when we set different values for k ($k = 0, 1, 2$). In $taxi$ and $train$ domains, the performance of the model decreases significantly when $k = 0$ compared to $k = 2$, implying that acquiring the values of the slots in these domains is highly dependent on the dialogue history. Nevertheless, there is no significant difference in the performance in $attraction$ domain when we set different values for k. This indicates that the values of the slots in this domain can usually be simply obtained from the current turn dialogue, instead of using the dialogue history or resolving coreferences.

6 Conclusion

We introduce an effective DiCoS-DST that dynamically selects the relevant dialogue contents corresponding to each slot from a combination of three perspectives. The dialogue collaborative selector module performs a comprehensive selection for each turn dialogue based on its relation to the slot name, its connection to the current turn dialogue, and the implicit mention oriented reasoning. Then only the selected dialogue contents are fed into State Generator, which explicitly minimizes the distracting information passed to the downstream state prediction. Our DiCoS-DST model achieves new state-of-the-art performance on the MultiWOZ benchmark, and achieves competitive performance on most other DST benchmark datasets. The potential relationship among the above perspectives is a promising research direction, and we will explore it for more than dialogue selection in the future.

Ethical Considerations

The claims in this paper match the experimental results. This work focuses on DST in task-oriented dialogue systems, and the improvements could have a positive impact on helping humans to complete goals more effectively in a more intelligent way of communication.

Abstract

Finetuning large pre-trained language models with a task-specific head has advanced the state-of-the-art on many natural language understanding benchmarks. However, models with a task-specific head require a lot of training data, making them susceptible to learning and exploiting dataset-specific superficial cues that do not generalize to other datasets. Prompting has reduced the data requirement by reusing the language model head and formatting the task input to match the pre-training objective. Therefore, it is expected that few-shot prompt-based models do not exploit superficial cues. This paper presents an empirical examination of whether few-shot prompt-based models also exploit superficial cues. Analyzing few-shot prompt-based models on MNLI, SNLI, HANS, and COPA has revealed that prompt-based models also exploit superficial cues. While the models perform well on instances with superficial cues, they often underperform or only marginally outperform random accuracy on instances without superficial cues.

1 Introduction

Finetuning large pre-trained language models with a task-specific head has achieved remarkable performance on many natural language benchmarks (Wang et al., 2018, 2019). However, the task-specific head introduces a lot of random task-specific parameters that require enormous finetuning data to attain optimal performance. The exposure to enormous data increases the potential for models to learn and exploit dataset-specific superficial cues that do not generalize to other datasets without superficial cues (Gururangan et al., 2018; Poliak et al., 2018; Sugawara et al., 2018; Niven and Kao, 2019; Schuster et al., 2019; Kavumba et al., 2019). For example, Niven and Kao (2019) found that task-specific head models exploit the presence of "not" in the input of argument reasoning comprehension dataset (Habernal et al., 2018) to achieve state-of-the-art accuracy, but drop to random accuracy when the superficial cue is neutralized. On the other hand, prompting reuses the pre-training language model head, introducing no random task-specific parameters. Thus, prompt-based models can achieve remarkable performance with only a few training examples (Brown et al., 2020; Schick and Schütze, 2021a,b; Gao et al., 2021; Le Scao and Rush, 2021). Hence, few-shot prompting lowers the potential for models to learn and exploit dataset-specific superficial cues.

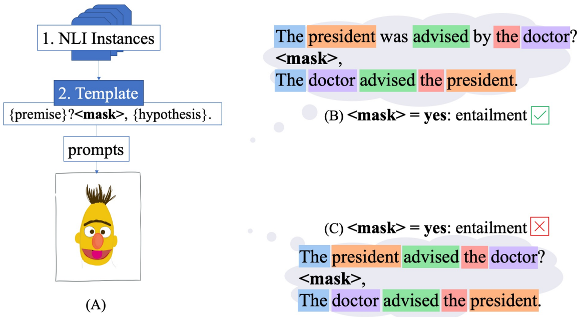

Figure 1: (A) shows a prompt-based model receiving natural language inference (NLI) prompts generated through a template. (B) Our analysis reveals that prompt-based models exploit superficial cues (highlighted lexical overlap) that are predictive of entailment relation between premise and hypothesis. (C) The model fails to generalize to instances were the superficial cues no longer predict entailment relation.

This work empirically investigates whether few-shot prompt-based models exploit superficial cues. Specifically, we ask: *Do few-shot prompt-based models exploit superficial cues?* To answer this question, we examine prompted-based models on two fundamental tasks of natural language understanding: natural language inference (NLI) and commonsense reasoning; comprehending natural language inference and commonsense are essential to make progress in natural language understanding (Bowman et al., 2015; Williams et al., 2018; Roemmele et al., 2011). We analyze the per-

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 2333 - 2352
May 22-27, 2022

formance of prompt-based models trained on the Stanford Natural Language Inference dataset (Bowman et al., 2015, SNLI), the Multi-Genre Natural Language Inference data (Williams et al., 2018, MNLI), and the Choice of Plausible Alternatives dataset (Roemmele et al., 2011, COPA) on instances with and without superficial cues.

To facilitate the analysis, we define two types of superficial cues that abstract away from the underlying tasks: *context* and *contextless* superficial cues, where the definition of the *context* depends on the task. For example, in natural language inference tasks, we define the premise as the *context*, while in multiple-choice tasks, we define the question as the *context*. Context superficial cues such as lexical overlap (Figure 1) coexist in the context (premise) and the hypothesis. In contrast, contextless superficial cues exist only in the hypothesis (in NLI) or in answer choices (in multiple-choice tasks). A dataset can contain either one or both types of superficial cues. Therefore, both types must be investigated to sufficiently answer whether a model can exploit superficial cues.

As a prerequisite, we reanalyze superficial cues in MNLI, SNLI, and COPA datasets to created evaluation sets that have and do not have superficial cues. We find that these datasets contain more superficial cues than previously known. Specifically, we find that 90.1% of MNLI matched instances contain *contextless superficial cues* in the hypothesis, while 71.9% SNLI contains *contextless superficial cues*. Additionally, we find that COPA contains not only contextless superficial cues (Kavumba et al., 2019), but 78.0% of the instances also contain *context superficial cues*.

Finally, we examine whether few-shot prompt-based models also rely on superficial cues to achieve remarkable performance on MNLI, SNLI, COPA, and the HANS dataset (McCoy et al., 2019). COPA experiments reveal that prompt-based models do not rely on contextless superficial cues for typical few-shot training sizes. However, the other empirical results show that prompt-based models heavily rely on superficial cues—failing to generalize to data without superficial cues (Figure 1).

In summary, our contributions are:

1. We propose to divide superficial cues into *context* and *contextless* superficial cues, which abstracts away from the underlying tasks (§ 3).
2. We established that the datasets of MNLI (§ 3.2), SNLI (§ 3.2) and COPA (§ 3.1) contain more superficial cues than previously known. We release analyzed datasets at `https://github.com/legalforce-research/prompt-models-clueless`.
3. We present the first investigation of the exploitation of superficial cues by prompt-based models, finding that prompt-based models also exploit superficial cues (§ 5).

2 Background

We will begin with a review of the necessary concepts required to understand the rest of the paper.

2.1 Prompting

Prompt-based finetuning has been demonstrated to be effective in few-shot setup (Brown et al., 2020; Schick and Schütze, 2021a,b; Gao et al., 2021; Le Scao and Rush, 2021). By reusing the pretraining language model head, prompting introduces no or only a few randomly initialized parameters. Prompting reformulates any task to match the pretraining objective. For example, consider the task of classifying the sentiment polarity of movie reviews using a masked language model such as BERT (Devlin et al., 2019). A review such as "*I liked the movie*" is converted to "*I liked the movie. It was [MASK]*". The model, then, fills [MASK] with words such as *{good, nice, bad, terrible}*, which are mapped to the task labels—positive or negative—through a verbalizer (Schick and Schütze, 2021a,b). In contrast, a task-specific classification head model directly predicts positive or negative sentiment. For an in-depth review, we will refer the interested reader to a survey by Liu et al. (2021).

2.2 Superficial Cues

Superficial cues can be described as linguistic or non-linguistic characteristics of instances that have nothing to do with the task itself but are tied to a specific task label. These characteristics include lexical overlap (McCoy et al., 2019), distinct words frequently appearing in the correct choices (Niven and Kao, 2019; Kavumba et al., 2019), and distinctive style of the correct choices (Trichelair et al., 2019). As a concrete example, consider a sentiment classification dataset whose negative sentiment instances contain "not"; for example, "I did not like the movie". Here, "not" is a superficial cue because it is predictive of the correct label.

2.3 Training Datasets

MNLI The Multi-Genre Natural Language Inference (Williams et al., 2018, MNLI) dataset is an important dataset of natural language inference which is also part of the SuperGLUE benchmark (Wang et al., 2019). Given a premise and a hypothesis, the task asks to pick one label from among three, {contradiction, neutral, entailment}. The test set of MNLI is divided into matched (in-domain instances) and mismatched (out-of-domain instances) subsets based on whether the domain of each test instance matches the training set domain.

SNLI The Stanford Natural Language Inference (Bowman et al., 2015, SNLI) is a popular natural language inference dataset with the same format as MNLI.

COPA The Choice of Plausible Alternatives (Roemmele et al., 2011, COPA) dataset is a popular multiple-choice commonsense dataset, which is also a part of the SuperGLUE benchmark. Given a premise and a question, the task is to select the most plausible cause or effect from the set of two candidates.

3 Superficial Cues in NLI and COPA

We investigate prompted-based models on two fundamental tasks of natural language understanding: natural language inference (NLI) and commonsense reasoning. As a prerequisite, we begin by creating test sets with and without superficial cues that we will subsequently use to investigate whether prompt-based models exploit superficial cues. We analyze and split test sets of English language datasets into subsets with and without superficial cues in the following subsections.

To facilitate easy analysis, we divide superficial cues into two categories: *context* superficial cues and *contextless* superficial cues, where the definition of *context* is task dependent. For example, in natural language inference tasks such as COPA, the *context* can be defined as the premise, while in multiple-choice tasks, the *context* can be defined as the question. Context superficial cues, such as lexical overlap found by McCoy et al. (2019) can only be exploited when the context is available in the input. On the other hand, contextless superficial cues, such as the occurrence of "not" in the correct answer choices found by Niven and Kao (2019), are those that are exploitable even in the absence of the context required to perform a task.

3.1 Context Superficial Cues

Natural Language Inference (NLI): NLI has a good dataset designed to test for contextless superficial cues. Specifically, the HANS dataset tests the models' ability to exploit three types of context superficial cues in NLI: *lexical overlap*, *subsequence*, and *constituent* McCoy et al. (2019). Therefore, we evaluate prompt-based models on the HANS dataset instead of splitting tests of MNLI and SNLI into instances with and without superficial cues.

COPA Eyeballing all instances to find common patterns that identify the correct answer choice, but are unrelated to the task, can be challenging and error-prone. To circumvent the need for manual examination, we propose to solve the task in a setup that encourages the model to solve the task using superficial cues. This setup is similar to providing only partial input (Gururangan et al., 2018; Poliak et al., 2018). Specifically, we randomly shuffle the words in the answer choices such that identifying the correct choice is mainly based on superficial cues in the question and the answer choice. For example, given the original instance;

Premise: The host cancelled the party. What was the CAUSE of this?
a) She worried she would catch the flu.
b) She was certain she had the flu. (correct)

The new answer choices for the new instance becomes:

a) She would she catch the worried flu.
b) She had was she the certain flu. (correct)

In this setting, we find that RoBERTa achieves an average accuracy of 78%, indicating the existence of context superficial cues. Following this result, we split the test set into a subset with superficial cues containing instances solved by the majority of models, and a subset without superficial cues, containing all the remaining instances.

3.2 Contextless Superficial Cues

Natural Language Inference To investigate contextless superficial cues in NLI, we train RoBERTa (Liu et al., 2019) with a classification head on only the hypothesis of MNLI and SNLI. This analysis is similar to the one done by Gururangan et al. (2018) using fastText (Joulin et al., 2017). If the model can not find contextless superficial cues in the hypothesis, it is expected to achieve random performance (33.3%). But, RoBERTa trained

Dataset	accuracy
Random	33.3
MNLI	90.1 ±0.1
MNLI-mm	90.0 ±0.2
SNLI	71.9 ±0.1

Table 1: Average accuracy on matched MNLI (MNLI) and mismatched MNLI (MNLI-mm), and SNLI for a head RoBERTa model trained on the hypothesis. MNLI and MNLI-mm results are for a model trained on MNLI and SNLI results are for a model trained on SNLI.

on MNLI achieve an average performance of 90.1% and 90.0% on matched and mismatched instances, respectively (Table 1), which is worse than previously known (53.9% matched and 52.3% mismatched (Gururangan et al., 2018)). On the test set of SNLI, RoBERTa trained on SNLI achieves an average accuracy of 71.9% (Table 1), which is 4.9 percentage points higher than previously known Gururangan et al. (2018). Following this result, we split the testing sets of MNLI and SNLI such that each test set has two subsets: instances with contextless superficial cues, containing all instances that the majority of models solved correctly, and instances without contextless superficial cues contain all the remaining instances.

COPA The test set of COPA has already been split into two subsets that have instances with contextless superficial cues and instances that do not have contextless superficial cues Kavumba et al. (2019). The subsets were constructed based on the performance of RoBERTa trained on answers only. Therefore we do not reanalyze COPA; instead, we will use the same publicly available subsets in our evaluation.

4 Experimental Setup

The goal of our experimental setup is to answer the following research question: Do prompt-based models exploit superficial cues? We decompose this question into two sub-questions: 1) Do prompt-based models exploit context superficial cues? 2) Do prompt-based models exploit contextless superficial cues?

Training Details For all our experiments, we use RoBERTa-large (355M parameters) because it is the widely used model in prompt-based fine-tuning (Schick and Schütze, 2021a; Gao et al., 2021; Le Scao and Rush, 2021). We build on the source code by Gao et al. (2021) [1] and Le Scao and Rush (2021) [2], and we load the pre-trained weights from HuggingFace (Wolf et al., 2019). We use the best-reported hyperparameters and templates (Appendix B) from Gao et al. (2021) on NLI. All NLI models are trained with 16 instances per label. We use the same partitions used by Gao et al. (2021). On COPA we use the best hyperparameters and templates (Appendix B) from Schick and Schütze (2021b); Le Scao and Rush (2021). We ran all experiments three times with different random seeds and report the average and standard deviation.

Evaluation The goal of our experimental evaluation is to answer the following question: Do prompt-based models exploit superficial cues? We answer this question by investigating whether the model exploits or relies on either context or contextless superficial cues. We train and evaluate our models on English datasets.

Context Superficial Cues To investigate whether models exploit context superficial cues, we train prompt-based models on MNLI, SNLI, and COPA. We evaluate NLI models on the HANS dataset that tests the models' ability to exploit three types of context superficial cues in NLI: *lexical overlap*, *subsequence*, and *constituent* McCoy et al. (2019). We report the average accuracy and standard deviation on the two subsets of the dataset: a subset where the superficial is informative (Entailment) and a subset where the superficial cues are uninformative (Non-entailment). A model that does not rely on context superficial cues is expected to perform comparably on both subsets.

Contextless Superficial Cues To investigate whether prompt-based models exploit contextless superficial cues, we train a prompt-based model on MNLI, SNLI, and COPA; and evaluate them on the corresponding test set of each dataset. Each test set consists of two subsets obtained and described in sections 3: a subset of instances with contextless superficial cues and a subset without contextless superficial cues. A model that does not rely on contextless superficial cues is expected to perform comparably on both subsets.

(a) w/ & w/o Context Cues

(b) w/ & w/o Contextless Cues

Figure 2: Average accuracy on instances with superficial cues (w/ cues) and without superficial cues (w/o cues) for prompt-based RoBERTa models trained on MNLI and SNLI. (a) shows results on the HANS dataset on three kinds of context superficial cues: lexical overlap (lexical), subsequence (subs), and constituent (consti). (b) shows results on instances with and without contextless superficial cues of matched MNLI (MNLI) and mismatched MNLI (MNLI-mm) for a model trained on MNLI; and evaluations results on SNLI for a model trained on SNLI.

5 Results

5.1 Exploiting Context Superficial Cues

Natural Language Inference (NLI) Figure 2a shows the results on the HANS dataset of the prompt-based model trained on MNLI (left) and SNLI (right), respectively. The results show that prompt-based RoBERTa trained on MNLI performs considerably well on instances with superficial cues, an overall average of 98.7%. However, the model only achieves an overall average accuracy of 7.4% on instances without context superficial cues, failing to reach random accuracy of 50%. This indicates that the prompt-based models trained on MNLI exploit superficial cues.

Similarly, figure 2a (right) shows that while RoBERTa performs considerably well on instances with superficial cues (overall average 91.3%), it fails to achieve the same performance on instances without superficial cues (overall average of 31.7%). [3] This result also leads to the same conclusion that the model exploits context superficial cues.

COPA Table 2 shows the results of the prompt-based RoBERTa trained on COPA and evaluated on the two subsets of COPA: with and without superficial cues. The results show RoBERTa performs well on instances with superficial cues but barely exceeds random accuracy (50%) on instances without superficial cues. This, too, indicates that the model exploit contextless superficial cues.

# Examples	*w/ cues*	*w/o cues*	Overall
8	83.0±0.5	55.7±1.4	78.1±0.3
16	81.6±1.9	57.9±1.0	77.3±1.4
32	82.4±2.0	53.5±0.5	77.1±1.5
64	84.4±1.4	53.8±4.1	78.9±1.2
96	87.0±1.7	57.9±4.1	81.7±0.8
100	87.9±1.7	54.2±1.9	81.7±1.2

Table 2: Average accuracy of few-shot prompt-based RoBERTa models on COPA instances with context superficial cues between the context and the answer choices; and instances without exploitable context superficial cues. Column "# Examples" shows the number of examples used for finetuning.

5.2 Exploiting Contextless Superficial Cues

NLI Figure 2b shows the results of prompt-based RoBERTa train on MNLI and SNLI and evaluated on the corresponding test set. The results show that the prompt-based model trained on MNLI performs considerably better on instances with superficial cues on both matched (69.5%) and mismatched (72.0%) instances. On instances without superficial cues we observe a gap of 30.9% and 30.5% on matched and mismatched instances, respectively. The high difference in performance indicates that the models exploit contextless superficial cues. For the model trained on SNLI and evaluated on SNLI subsets, we observe a gap of 15.1% between performance on instances with and without superficial cues (82.2% vs 67.1%). This also indicates that the model does exploit contextless superficial cues.

COPA Table 3 shows of the prompt-based RoBERTa trained on COPA and evaluated on the

[3] The high variance is similar to that reported by previous work studying head models (Bras et al., 2020).

# Examples	*w/ cues*	*w/o cues*	Overall
8	79.1±0.9	77.4±0.0	78.1±0.3
16	77.0±1.3	77.4±1.6	77.3±1.4
32	77.7±3.1	76.8±0.9	77.1±1.5
64	80.2±0.5	78.1±1.6	78.9±1.2
96	83.7±1.1	80.4±0.7	81.7±0.8
100	84.6±1.1	80.0±1.6	81.7±1.2

Table 3: Average accuracy of few-shot prompt-based RoBERTa models on COPA instances with contextless superficial cues (w/ cues) in the answer choices and instances without contextless superficial cues (w/o cues). Column "# Examples" shows the number of examples used for finetuning.

COPA subsets with and without superficial cues. The results show that the prompt-based model does not exploit superficial cues at a small enough training set (less or equal to 32 instances). However, increasing the size further increases the gap in performance between instances with and without contextless superficial cues. It is encouraging to note that the model does not exploit contextless superficial cues at sizes commonly used in few-shot settings.

6 Discussion

6.1 Predictions Errors

The results on natural language inference instances without superficial cues are worse than random performance. One wonders whether it is because the instances are hard. We look at some instances that the model fails to solve correctly. We show some of the instances in Table 4. The instances are simple enough for anyone that understands English. One question that immediately arises is; are prompt-based models sensitive to the meaning of the question?

6.2 Attention Visualization

To investigate whether prompt-based models are sensitive to meaning, we compare the attention weight across all twenty-four layers of RoBERTa-large for closely related instances that differ only in meaning and hence the labels. While there have been many questions that have been raised over the reliability of singly using attention weights for explanation (Wiegreffe and Pinter, 2019; Vig and Belinkov, 2019), here we use attention weights coupled with other results to gain more insights into the models' inner working. We are interested in knowing whether there is a huge change in attention weights responding to the change in meaning. For example, we take an instance with superficial cues, which lead to the correct prediction of the Entailment label:

Premise: The president was advised by the doctor.
Hypothesis: The doctor advised the president.
label: Entailment

And an instance without superficial cues:

Premise: The president advised the doctor.
Hypothesis: The doctor advised the president.
label: Non-Entailment

While the instances are completely different in meaning, the model predicts Entailment in both cases because of the superficial cue of high overlap. When we compare the attention maps for all the layers, we notice that there is barely any change in response to the change in the meaning of the sentences. Because of space limitation, we show attention maps only for the first two layers and the last layer (Figure 3). The attention maps for all the 24 layers are shown in Appendix E. The visualizations highlight the inability of the model to respond to the change in meaning. We investigate this further in the next section.

6.3 Sensitivity to Word Order in NLI

The visual attention analysis revealed that the model does not respond well to change in meaning. To investigate this at scale, we evaluate a model trained on input with correct word order and input with randomly shuffled word order. We will refer to input with correct word order as *meaningful* input and input with shuffled word order as *meaningless* input. Specifically, given an original test instance, we make it meaningless by randomly shuffling all the words in the instance while maintaining the English end of sentence punctuation mark if it exists in the original instance. We do this so we can preserve the same number of English sentences as the original instance while making them meaningless.

For example, given the original NLI instance:

Premise: The president was advised by the doctor.
Hypothesis: The doctor advised the president.
label: Entailment

The new instance becomes:

Premise: The doctor by the president advised was.

Premise	Hypothesis	Label	Prediction
The president advised the doctor	The doctor advised the president	N	E
The student saw the managers	The managers saw the student	N	E
The presidents encouraged the banker	The bank encouraged the president	N	E
The actors avoided the bankers	The bankers avoided the bankers	N	E
The managers saw the secretaries	The secretary saw the managers	N	E
The lawyers helped the judge	The judge helped the lawyers	N	E
The banker thanked the tourist	The tourist thanked the banker	N	E

Table 4: Some examples of instances without superficial cues from the HANS dataset that a prompt-based model trained on MNLI wrongly classify as entailment (E) because of superficial cues: high lexical overlap.

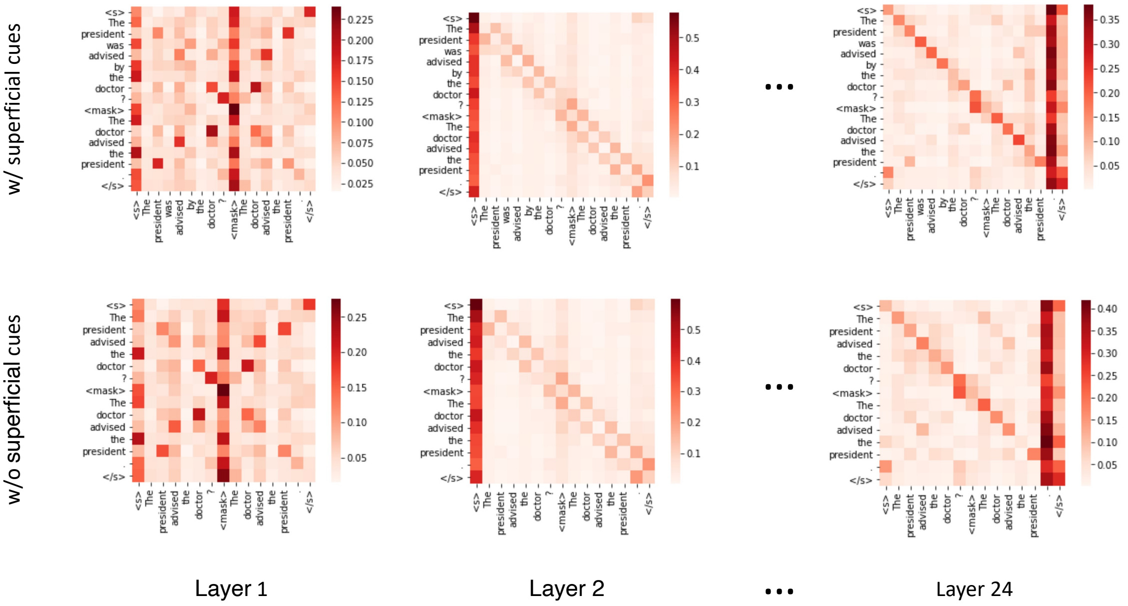

Figure 3: A comparison of prompt-based model attention maps on two natural language inference instances that have some words in common but have entirely different meanings. The first row attention maps are for an instance with superficial cues, and the second row attention maps are for an instance without superficial cues (Appendix E shows all layers).

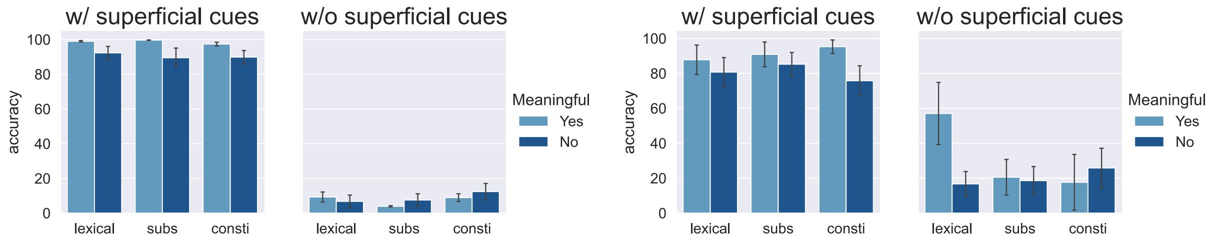
Hypothesis: The doctor the president advised.
label: Entailment

If the model is sensitive to meaning, we expect the performance on this meaningless input to drop to random performance because the model was trained on meaningful input.

Figure 4a and Figure 4b shows the results of prompt-based RoBERTa trained on MNLI and SNLI, respectively. The figures show the results of a prompt-based model trained on meaning-containing instances evaluated on the test set of instances whose meaning is preserved (Yes) and when the instances are made meaningless (No). The results show that when meaning is removed from the instances, the model barely changes its predictions, indicating that the model hardly relies on the meaning of the instances.

Future Work At this point, some questions still remain unanswered: (1) What are the specific superficial cues that the models exploit? This still remains a hard interpretability question. (2) Are there any prompts that discourage models from exploiting superficial cues? (3) Can incorporating task demonstrations without superficial cues mitigate against the reliance on superficial cues?



(a) MNLI (b) SNLI

Figure 4: The average accuracy of prompt-based RoBERTa trained on MNLI (a) and SNLI (b) instances with the correct word order ("Meaningful") when evaluated on HANS dataset when the input has the correct word order (Yes in legend) and when the word order is shuffled (No in legend).

7 Related Works

Few-shot Prompting Language model prompting was popularized by recent work of GPT-3 (Brown et al., 2020). Brown et al. (2020) showed that by using prompts and some task demonstrations, GPT-3 could perform a number of tasks in the few shot setup. Following this work, Schick and Schütze (2021a) showed that even much smaller language models such as RoBERTa-large could perform well when finetuned with prompts. The subsequent work (Schick and Schütze, 2021b) demonstrated that a smaller model could achieve similar performance to GPT-3 in a few shot setup once finetuned with prompts. Many works proposed better ways of generating prompts and answer keys (Gao et al., 2021; Le Scao and Rush, 2021). Our work develops on these works to gain more insights into model predictions. Specifically, we undertake the first investigation of whether prompt-based models exploit superficial cues.

Superficial Cues in Datasets Superficial cues have been analyzed across several natural language understanding datasets. Gururangan et al. (2018) analyzed contextless superficial cues—hypothesis only superficial cues—in the MNLI dataset and SNLI dataset using fastText (Joulin et al., 2017), finding that a little over half of MNLI contain superficial cues and 67% of SNLI contain superficial cues. We argue that these figures could be outdated. Hence, we reanalyze contextless superficial cues in MNLI and SNLI. McCoy et al. (2019) analyzed context superficial cues in MNLI, finding that lexical overlap is one superficial cue that can be exploited to correctly predict entailment labels. Following their analysis, they released the HANS dataset that has an equal number of instances with superficial cues and those without superficial cues. In this work, we use the HANS dataset to evaluate the models' ability to exploit superficial cues. Kavumba et al. (2019) analyzed contextless superficial cues in COPA using RoBERTa and productivity measures introduced by Niven and Kao (2019). However, they did not analyze context superficial cues. In this work, we analyze context superficial cues in COPA, and we use the contextless superficial cues from Kavumba et al. (2019).

Exploiting Superficial Cues in Head Language Models Head language models that use a task-specific head for a downstream task have been analyzed on their ability to exploit superficial cues in datasets. McCoy et al. (2019) found that head BERT (Devlin et al., 2019) exploits superficial cues on MNLI dataset. Similarly, Niven and Kao (2019) found that head BERT exploits superficial cues on the argument reasoning comprehension task and Kavumba et al. (2019) analyzed BERT and RoBERTa's ability to exploit superficial cues on the COPA dataset. While head models have been analyzed already, prompt-based models have not been analyzed yet. In this paper, we investigated whether prompt-based models also exploit superficial cues.

8 Conclusions

We presented the first analysis of whether prompt-based models exploit superficial cues. We found that prompt-based models exploit superficial cues and fail to generalize well to instances without superficial cues on MNLI, SNLI, COPA, and HANS. We, further, proposed to divide superficial cues into two: context and contextless superficial cues. Our analysis of MNLI, SNLI, and COPA has revealed more superficial cues than was previously known.

A Datasets

A.1 MNLI

The Multi-Genre Natural Language Inference (Williams et al., 2018, MNLI) dataset is an important dataset of natural language inference which is also part of the SuperGLUE benchmark (Wang et al., 2019). Given a premise, such as *"The Old One always comforted Ca'daan, except today."*, and a hypothesis, in this case, *"Ca'daan knew the Old One very well."* (neutral), a model is asked to pick one label from among three, {contradiction, neutral, entailment}. The test set of MNLI is divided into two subsets according to whether the domain of each test instance matches the domain of the training set: matched (in-domain instances) and mismatched (out-of-domain instances).

A.2 SNLI

The Stanford Natural Language Inference (Bowman et al., 2015, SNLI) is a popular natural language inference dataset with the same format as MNLI.

A.3 HANS Datasets

McCoy et al. (2019) identified three context superficial cues in MNLI: *lexical overlap*, *subsequence*, and *constituent*. These superficial cues are predictive of entailment label. Both *subsequence* and *constituent* superficial cues are special cases of lexical *lexical overlap*. Following this analysis, McCoy et al. (2019) created the HANS (Heuristic Analysis for NLI Systems) dataset, which includes instances with superficial cues—lexical overlap entails an entailment label and instances without superficial cues—lexical overlap does not necessarily mean it is an entailment label.

A.4 COPA

The Choice of Plausible Alternatives (Roemmele et al., 2011, COPA) dataset is a popular commonsense dataset that asks the model to select the most plausible answer choice from the set of two candidates, which is also a part of the SuperGLUE benchmark. For example, given a premise such as *"I tipped the bottle."* and a question that can either be the *cause* or *effect*, the model is asked to select the most plausible alternative from either *"The liquid in the bottle froze."* or *"The liquid in the bottle poured out."* (correct).

B Prompt Templates and Answer Keys

In the templates we show the part that is replaced with actual question input between two braces ({}), and we represent the mask token for a language model with <MASK>.

B.1 MNLI

We use the template and answer keys from (Gao et al., 2021).
Template:

`{premise}? <MASK>, {hypothesis}`

For the answer key that maps from model output to task labels we used:

`{yes: entailment, maybe: netural, No: contradiction}`

B.2 SNLI

We use the template and answer keys from (Gao et al., 2021).
Template:

`{premise}? <MASK>, {hypothesis}`

For the *answer key* that maps from model output to task labels we used:

`{yes: entailment, maybe: netural, No: contradiction}`

B.3 COPA

For COPA we use different templates from Schick and Schütze (2021b); Le Scao and Rush (2021) depending on the question type. COPA instances can have a *cause* or *effect* question.

For a *cause* question with a given *premise* and two possible causes; *choice1* and *choice2*. We use the template;

`"{choice1}" or "{choice2}"? {premise}, so <MASK>.`

and

`{choice1} or {choice2}? {premise}, so <MASK>.`

For an *effect* question with a given *premise* and two possible causes; *choice1* and *choice2*. We use the template;

`"{choice1}" or "{choice2}"? <MASK>, because {premise}.`

and

`{choice1} or {choice2}? <MASK>, because {premise}.`

For the answer key we use the identity function.

Train set	Cue Type	W/ Superficial Cues		W/O Superficial Cues	
		Meaningful	Meaningless	Meaningful	Meaningless
MNLI	lexical_overlap	99.0 ±0.4	92.3±3.7	9.3 ±2.9	6.8 ±3.7
	subsequence	99.6 ±0.1	89.5 ±5.6	3.9 ±0.3	7.6 ±3.6
	constituent	97.4 ±1.0	89.9 ±3.8	8.9 ±2.2	12.4 ±4.7
SNLI	lexical_overlap	87.8 ±8.4	80.7 ±8.3	57.0 ±17.8	16.7 ±7.1
	subsequence	90.9 ±7.1	85.2 ±6.7	20.6 ±10.2	18.6 ±8.1
	constituent	95.3 ±3.9	75.8 ±8.6	17.6 ±15.9	25.8 ±11.3

Table 5: Average accuracy on HANS Datasets for prompt-based RoBERTa models trained on meaningful MNLI and SNLI; and evaluated on instances whose meaning has been preserved (Meaningful) and instances whose meaning has been removed (Meaningless). The instances are further divided into instances with (W/) and without (W/O) context superficial cues

Dataset	w/ s. cues	w/o s. cues	Overall
MNLI	69.5±0.1	38.6±0.6	66.7±0.1
MNLI-mm	72.0±0.2	41.5±0.7	69.1±0.2
SNLI	82.2±0.9	67.1±1.0	78.0±0.9

Table 6: Results of of prompt-based RoBERTa on MNLI and SNLI instances with contextless superficial cues in the hypothesis and instances without contextless superficial cues.

C Training Details

All our experiments are run on a single NVIDIA Tesla T4 GPU with 16GB memory. All the models are trained in a few-shot setup. Thus they training only takes a few minutes to complete. We use a learning rate of 1e-5 for all our experiments.

D Numeric Results

For all the figures containing results—figure 2 and figure 4—we also include numeric results in table 5 and table 6—to show the exact values and standard deviations to make it easier to compare with future work.

E Attention Maps

This appendix shows the complete attention maps partially visualized in section 6.2.

The attention maps are for a instance with superficial cues below.

Premise: The president was advised by the doctor.
Hypothesis: The doctor advised the president.
label: Entailment

And an instance without superficial cues:

Premise: The president advised the doctor.
Hypothesis: The doctor advised the president.
label: Non-Entailment

To make it easier to compare the attention maps, we alternate the pages between the attention maps for an instance with and without superficial cues. Each page has six attention maps to make it easier to see all the points.

Abstract

Confidence estimation aims to quantify the confidence of the model prediction, providing an expectation of success. A well-calibrated confidence estimate enables accurate failure prediction and proper risk measurement when given noisy samples and out-of-distribution data in real-world settings. However, this task remains a severe challenge for neural machine translation (NMT), where probabilities from softmax distribution fail to describe when the model is probably mistaken. To address this problem, we propose an unsupervised confidence estimate learning jointly with the training of the NMT model. We explain confidence as how many hints the NMT model needs to make a correct prediction, and more hints indicate low confidence. Specifically, the NMT model is given the option to ask for hints to improve translation accuracy at the cost of some slight penalty. Then, we approximate their level of confidence by counting the number of hints the model uses. We demonstrate that our learned confidence estimate achieves high accuracy on extensive sentence/word-level quality estimation tasks. Analytical results verify that our confidence estimate can correctly assess underlying risk in two real-world scenarios: (1) discovering noisy samples and (2) detecting out-of-domain data. We further propose a novel confidence-based instance-specific label smoothing approach based on our learned confidence estimate, which outperforms standard label smoothing[1].

1 Introduction

Confidence estimation has become increasingly critical with the widespread deployment of deep neural networks in practice (Amodei et al., 2016). It aims to measure the model's confidence in the prediction, showing when it probably fails. A calibrated confidence estimate can accurately identify failure, further measuring the potential risk induced by noisy samples and out-of-distribution data prevalent in real scenarios (Nguyen and O'Connor, 2015; Snoek et al., 2019).

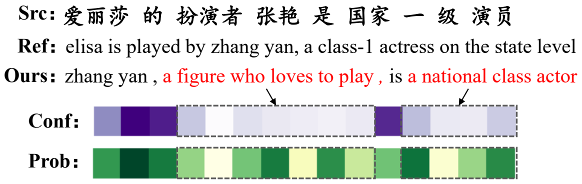

Figure 1: An example of generated probabilities and our learned confidence estimates. The phrases in red are wrong translations. The corresponding prediction probabilities and confidence estimates are outlined in dashed boxes. The dark color indicates a large value under two evaluations.

Unfortunately, neural machine translation (NMT) is reported to yield poor-calibrated confidence estimate (Kumar and Sarawagi, 2019; Wang et al., 2020), which is common in the application of modern neural networks (Guo et al., 2017). It implies that the probability a model assigns to a prediction is not reflective of its correctness. Even worse, the model often fails silently by providing high-probability predictions while being woefully mistaken (Hendrycks and Gimpel, 2017). We take Figure 1 as an example. The mistranslations are produced with high probabilities (dark green blocks in the dashed box), making it problematic to assess the quality based on prediction probability when having no access to references.

The confidence estimation on classification tasks is well-studied in the literature (Platt, 1999; Guo et al., 2017). Yet, researches on structured generation tasks like NMT is scarce. Existing researches only study the phenomenon that the generated probability in NMT cannot reflect the accuracy (Müller et al., 2019; Wang et al., 2020), while little is known about how to establish a well-calibrated confidence estimate to describe the predictive un-

certainty of the NMT model accurately.

To deal with this issue, we aim to learn the confidence estimate jointly with the training process in an unsupervised manner. Inspired by *Ask For Hints* (DeVries and Taylor, 2018), we explain confidence as how many hints the NMT model needs to make a correct prediction. Specifically, we design a scenario where ground truth is available for the NMT model as hints to deal with tricky translations. But each hint is given at the price of some penalty. Under this setting, the NMT model is encouraged to translate independently in most cases to avoid penalties but ask for hints to ensure a loss reduction when uncertain about the decision. More hints mean low confidence and vice versa. In practice, we design a confidence network, taking multi-layer hidden states of the decoder as inputs to predict the confidence estimate. Based on this, we further propose a novel confidence-based label smoothing approach, in which the translation more challenging to predict has more smoothing to its labels.

Recall the example in Figure 1. The first phrase "*a figure who loves to play*" is incorrect, resulting in a low confidence level under our estimation. We notice that the NMT model is also uncertain about the second expression "*a national class actor*", which is semantically related but has inaccurate wording. The translation accuracy largely agrees with our learned confidence rather than model probabilities.

We verify our confidence estimate as a well-calibrated metric on extensive sentence/word-level quality estimation tasks, which is proven to be more representative in predicting translation accuracy than existing unsupervised metrics (Fomicheva et al., 2020). Further analyses confirm that our confidence estimate can precisely detect potential risk caused by the distributional shift in two real-world settings: separating noisy samples and identifying out-of-domain data. The model needs more hints to predict fake or tricky translations in these cases, thus assigning them low confidence. Additionally, experimental results show the superiority of our confidence-based label smoothing over the standard label smoothing technique on different-scale translation tasks (WMT14 En⇒De, NIST Zh⇒En, WMT16 Ro⇒En, and IWSLT14 De⇒En).

The contributions of this paper are three-fold:

- We propose the learned confidence estimate to predict the confidence of the NMT output, which is simple to implement without any degradation on the translation performance.
- We prove our learned confidence estimate as a better indicator of translation accuracy on sentence/word-level quality estimation tasks. Furthermore, it enables precise assessment of risk when given noisy data with varying noise degrees and diverse out-of-domain datasets.
- We design a novel confidence-based label smoothing method to adaptively tune the mass of smoothing based on the learned confidence level, which is experimentally proven to surpass the standard label smoothing technique.

2 Background

In this section, we first briefly introduce a mainstream NMT framework, Transformer (Vaswani et al., 2017), with a focus on how to generate prediction probabilities. Then we present an analysis of the confidence miscalibration observed in NMT, which motivates our ideas discussed afterward.

2.1 Transformer-based NMT

The Transformer has a stacked encoder-decoder structure. When given a pair of parallel sentences $x = \{x_1, x_2, ...x_S\}$ and $y = \{y_1, y_2, ...y_T\}$, the encoder first transforms input to a sequence of continuous representations $\boldsymbol{h} = \{\boldsymbol{h_1^0}, \boldsymbol{h_2^0}, \boldsymbol{...h_S^0}\}$, which are then passed to the decoder.

The decoder is composed of a stack of N identical blocks, each of which includes self-attention, cross-lingual attention, and a fully connected feed-forward network. The outputs of l-th block h_t^l are fed to the successive block. At the t-th position, the model produces the translation probabilities p_t, a vocabulary-sized vector, based on outputs of the N-th layer:

$$p_t = \mathrm{softmax}(\boldsymbol{W}\boldsymbol{h_t^N} + b) \tag{1}$$

During training, the model is optimized by minimizing the cross entropy loss:

$$\mathcal{L}_{\mathrm{NMT}} = \sum_{t=1}^{T} -y_t \mathrm{log}(p_t) \tag{2}$$

where $\{\boldsymbol{W}, b\}$ are trainable parameters and y_t is denoted as a one-hot vector. During inference, we implement beam search by selecting high-probability tokens from generated probability for each step.

2.2 Confidence Miscalibration in NMT

Modern neural networks have been found to yield a miscalibrated confidence estimate (Guo et al.,

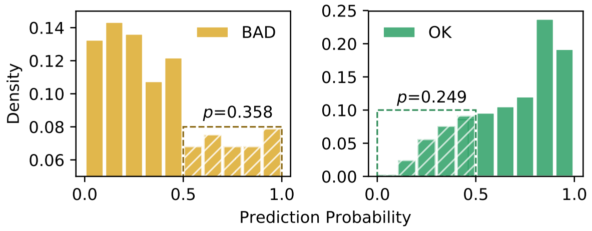

Figure 2: The density function of word probabilities predicted by the NMT model on OK and BAD translations. We outline the miscalibration with slash mark: *over-confident* (producing high probabilities for errors) and *under-confident* (generating low probabilities for right translations).

2017; Hendrycks and Gimpel, 2017). It means that the prediction probability, as used at each inference step, is not reflective of its accuracy. The problem is more complex for structured outputs in NMT. We cannot judge a translation as an error, even if it differs from the ground truth, as several semantically equivalent translations exist for the same source sentence. Thus we manually annotate each target word as OK or BAD on 200 Zh⇒En translations. Only definite mistakes are labeled as BAD, while other uncertain translations are overlooked.

Figure 2 reports the density function of prediction probabilities on OK and BAD translations. We observe severe miscalibration in NMT: *over-confident* problems account for 35.8% when the model outputs BAD translations, and 24.9% OK translations are produced with low probabilities. These issues make it challenging to identify model failure. It further drives us to establish an estimate to describe model confidence better.

3 Learning to Estimate Confidence

A well-calibrated confidence estimate should be able to tell when the NMT model probably fails. Ideally, we would like to learn a measure of confidence for each target-side translation, but this remains a thorny problem in the absence of ground truth for confidence estimate. Inspired by *Ask For Hints* (DeVries and Taylor, 2018) on the image classification task, we define confidence as how many hints the NMT model needs to produce the correct translation. More hints mean low confidence, and that is a high possibility of failure.

Motivation. We assume that the NMT model can ask for hints (look at ground-truth labels) during training, but each clue comes at the cost of a slight penalty. Intuitively, a good strategy is to independently make the predictions that the model is confident about and then ask for clues when the model is uncertain about the decision. Under this assumption, we approximate the confidence level of each translation by counting the number of hints used.

To enable the NMT model to ask for hints, we add a confidence estimation network (ConNet) in parallel with the original prediction branch, as shown in Figure 3. The ConNet takes hidden states of the decoder at t-th step ($\boldsymbol{h}_t$) as inputs and predicts a single scalar between 0 and 1.

$$c_t = \sigma(\boldsymbol{W}'\boldsymbol{h_t} + b') \tag{3}$$

where $\theta_c = \{W', b'\}$ are trainable parameters. $\sigma(\cdot)$ is the sigmoid function. If the model is confident that it can translate correctly, it should output c_t close to 1. Conversely, the model should output c_t close to 0 for more hints.

To offer the model "hints" during training, we adjust softmax prediction probabilities by interpolating the ground truth probability distribution y_t (denoted as a one-hot vector) into the original prediction. The degree of interpolation is decided by the generated confidence c_t:

$$p_t' = c_t \cdot p_t + (1 - c_t) \cdot y_t \tag{4}$$

The translation loss is calculated using modified prediction probabilities.

$$\mathcal{L}_{\text{NMT}} = \sum_{t=1}^{T} -y_t \log(p_t') \tag{5}$$

To prevent the model from minimizing the loss by always setting $c_t = 0$ (receiving all the ground truth), we add a log penalty to the loss function.

$$\mathcal{L}_{\text{Conf}} = \sum_{t=1}^{T} -\log(c_t) \tag{6}$$

The final loss is the sum of the translation loss and the confidence loss, which is weighted by the hyper-parameter λ:

$$\mathcal{L} = \mathcal{L}_{\text{NMT}} + \lambda \mathcal{L}_{\text{Conf}} \tag{7}$$

Under this setting, when $c \to 1$ (the model is quite confident), we can see that $p' \to p$ and $\mathcal{L}_{\text{Conf}} \to 0$, which is equal to a standard training procedure. In the case where $c \to 0$ (the model is quite unconfident), we see that $p' \to y$ (the model obtains correct labels). In this scenario, $\mathcal{L}_{\text{NMT}}$ would approach 0, but $\mathcal{L}_{\text{Conf}}$ becomes very large. Thus, the model can reduce the overall loss only when it successfully predicts which outputs are likely to be correct.

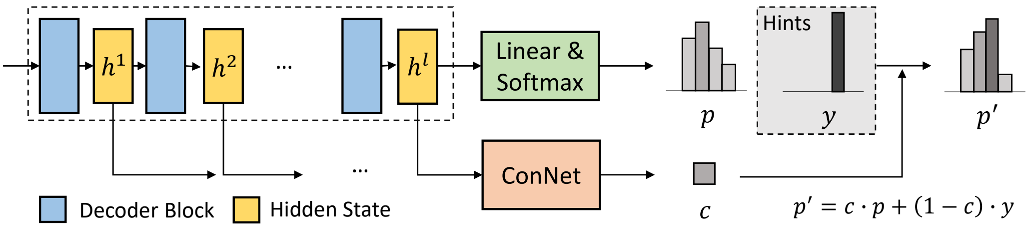

Figure 3: The overview of the framework. The NMT model is allowed to ask for hints (ground-truth translation) during training based on the confidence level predicted by the ConNet. During inference, we use the model prediction p to sample hypotheses. Each translation word comes with a corresponding confidence estimate.

Implementation Details. Due to the complexity of Transformer architecture, it requires several optimizations to prevent the confidence branch from degrading the performance of the translation branch.

Do not provide hints at the initial stage. The early model is fragile, which lays the groundwork for the following optimization. We find that affording hints at an early period leads to a significant performance drop. To this end, we propose to dynamically control the value of λ (as in Equation 7) by the training step (s) as:

$$\lambda(s) = \lambda_0 * e^{-s/\beta_0} \tag{8}$$

where λ_0 and β_0 control the initial value and the declining speed of λ. We expect the weight of confidence loss to be large at the beginning ($c \to 1$) and give hints during middle and later stages.

Do not use high-layer hidden states to predict confidence. We find that it would add much burden to the highest layer hidden state if used to predict translation and confidence simultaneously. So we suggest using low-layer hidden states for the confidence branch and leaving the translation branch unchanged (here, the decoder has 6 layers):

$$\boldsymbol{h}_t = \mathrm{AVE}(\boldsymbol{h}_t^1 + \boldsymbol{h}_t^2 + \boldsymbol{h}_t^3) \tag{9}$$

where h_t^l is the l-th layer hidden state in the decoder. Besides, other combinations of low-layer hidden states are alternative, i.e., $\boldsymbol{h}_t = \mathrm{AVE}(\boldsymbol{h}_t^1 + \boldsymbol{h}_t^3)$.

Do not let the model lazily learn complex examples. We encounter the situation where the model frequently requests hints rather than learning from difficulty. We follow DeVries and Taylor (2018) to give hints with 50% probability. In practice, we apply Equation 4 to only half of the batch.

Confidence-based Label Smoothing. Smoothing labels is a typical way to prevent the network from miscalibration (Müller et al., 2019). It has been used in many state-of-the-art models, which assigns a certain probability mass (ϵ_0) to other non-ground-truth labels (Szegedy et al., 2016). Here we attempt to employ our confidence estimate to improve smoothing. We propose a novel instance-specific confidence-based label smoothing technique, where predictions with greater confidence receive less label smoothing and vice versa. The amount of label smoothing applied to a prediction (ϵ_t) is proportional to its confidence level.

$$\epsilon_t = \epsilon_0 * e^{1 - \frac{c_t}{\hat{c}}}$$

where ϵ_0 is the fixed value for vanilla label smoothing, $\hat{c}$ is the batch-level average confidence level.

4 Experiments

This section first exhibits empirical studies on the Quality Estimation (QE) task, a primary application of confidence estimation. Then, we present experimental results of our confidence-based label smoothing, an extension of our confidence estimate to better smoothing in NMT.

4.1 Confidence-based Quality Estimation

To evaluate the ability of our confidence estimate on mistake prediction, we experiment on extensive sentence/word-level QE tasks. Supervised QE task requires large amounts of parallel data annotated with the human evaluation, which is labor-intensive and impractical for low-resource languages. Here, we propose to address QE in an unsupervised way along with the training of the NMT model.

4.1.1 Sentence-level Quality Estimation

We experiment on WMT2020 QE shared tasks[2], including high-resource language pairs (English-German and English-Chinese) and mid-resource language pairs (Estonian-English and Romanian-English). This task provides source language sentences, corresponding machine translations, and

---

[2] http://www.statmt.org/wmt20/quality-estimation-task.html

NMT models used to generate translation. Each translation is annotated with direct assessment (DA) by professional translators, ranging from 0-100, according to the perceived translation quality. We can evaluate the performance of QE in terms of Pearson's correlation with DA scores.

We compare our confidence estimate with four unsupervised QE metrics (Fomicheva et al., 2020):

- *TP*: the sentence-level translation probability normalized by length T.
- *Softmax-Ent*: the average entropy of softmax output distribution at each decoding step.
- *Sent-Std*: the standard deviation of word-level log-probability $p(y_1), ..., p(y_T)$.
- *D-TP*: the expectation for the set of TP scores by running K stochastic forward passes through the NMT model with model parameters $\hat{\theta}^k$ perturbed by Monte Carlo (MC) dropout (Gal and Ghahramani, 2016).

We also report two supervised QE models:

- *Predictor-Estimator* (Kim et al., 2017): a weak neural approach, which is usually set as the baseline system for supervised QE tasks.
- *BERT-BiRNN* (Kepler et al., 2019b): a strong QE model using a large-scale dataset for pre-training and quality labels for fine-tuning.

We propose four confidence-based metrics: (1) *Conf*: the sentence-level confidence estimate averaged by length, (2) *Sent-Std-Conf*: the standard deviation of word-level log-confidence $c_1, ..., c_T$, (3) *D-Conf*: similar to D-TP, we compute the expectation of Conf by running K forward passes through the NMT model, and (4) *D-Comb*: the combination of D-TP and D-Conf:

$$\text{D-Comb} = \frac{1}{K}\sum_{k=1}^{K}(\text{Conf}_{\hat{\theta}^k} + \text{TP}_{\hat{\theta}^k}) \qquad (10)$$

Note that our confidence estimate is produced together with translations. It is hard to let our model generate exact translations as provided by WMT, even with a similar configuration. Thus, we train our model on parallel sentences as used to train provided NMT models. Then, we employ force decoding on given translations to obtain existing unsupervised metrics and our estimations. We do not use any human judgment labels for supervision.

Methods	Mid-resource		High-resource	
	Et-En	Ro-En	En-De	En-Zh
TP	0.514	0.529	0.179	0.258
Softmax-Ent	0.535	0.526	0.144	0.257
Sent-Std	0.493	0.418	0.195	0.281
D-TP (K=30)	0.583	0.553	0.197	0.288
Conf	0.557	0.569	0.218	**0.293**
Sent-Std-Conf	0.494	0.482	**0.239**	0.293
D-Conf (K=30)	0.572	0.572	0.210	0.288
D-Comb (K=30)	**0.583**	**0.577**	0.198	0.288
PredEst ‡	0.477	0.685	0.145	0.190
BERT-BiRNN ‡	0.635	0.763	0.273	0.371

Table 1: Pearson's correlation between unsupervised QE indicators and DA scores. K is set following Wang et al. (2019). We reimplement the first four unsupervised QE metrics on our NMT model. The best results of unsupervised metrics are marked in bold. Results with ‡ are copies from Fomicheva et al. (2020).

Table 1 shows the Pearson's correlation with DA scores for the above QE indicators. We find that:

Our confidence-based metrics substantially surpass probability-based metrics (the first three lines in Table 1). Compared with dropout-based methods (D-TP), our metrics obtain comparable results on mid-resource datasets while yielding better performance on high-resource translation tasks. We note that the benefits brought from the MC dropout strategy are limited for our metrics, which is significant in probability-based methods. It also proves the stability of our confidence estimate. In addition, the predictive power of MC dropout comes at the cost of computation, as performing forward passes through the NMT model is time-consuming and impractical for the large-scale dataset.

Our approach outperforms PredEst, a weak supervised method, on three tasks and further narrows the gap on Ro-En. Though existing unsupervised QE methods still fall behind with the strong QE model (BERT-BiRNN), the exploration of unsupervised metrics is also meaningful for real-world deployment with the limited annotated dataset.

4.1.2 Word-level Quality Estimation

We also validate the effectiveness of our confidence estimate on QE tasks from a more fine-grained view. We randomly select 250 sentences from Zh⇒En NIST03 and obtain NMT translations. Two graduate students are asked to annotate each target word as either OK or BAD. We assess the performance of failure prediction with standard metrics, which are introduced in Appendix A.

Methods	Zh⇒En						En⇒De	De⇒En	Ro⇒En
	MT03	MT04	MT05	MT06	MT08	ALL			
Transformer w/o LS	48.77	48.50	47.45	46.65	35.93	45.50	26.98	34.27	29.71
+ Standard LS	49.14	48.48	50.53	47.44	36.23	45.83	27.40	34.52	30.03
+ Confidence-based LS	50.2*	48.57	50.91*	48.57*	37.38*	46.55*	27.75*	35.02*	30.82*

Table 2: Translation results (beam size 4) for standard label smoothing and our confidence-based label smoothing on NIST Zh⇒En, WMT14 En⇒De (using case-sensitive BLEU score for evaluation), IWSLT14 De⇒En, and WMT16 Ro⇒En. "$*$" indicates gains are statistically significant than Transformer w/o LS with $p < 0.05$.

Methods	AUROC↑	AUPR↑	EER↓	DET↓
MSP	72.59	97.49	32.30	31.22
MCDropout	86.52	99.23	20.80	20.76
Ours	85.89	99.07	20.40	19.90

Table 3: Word-level QE evaluated by the separation accuracy of OK and BAD translations in the Zh⇒En task. All values are shown in percentages. ↑ indicates higher scores are better, and ↓ indicates lower is better.

Experimental results are given in Table 3. We implement competitive failure prediction approaches, including Maximum Softmax Probability (MSP) (Hendrycks and Gimpel, 2017) and Monte Carlo Dropout (MCDropout) (Gal and Ghahramani, 2016). We find that our learned confidence estimate yields a better separation of OK and BAD translation than MSP. Compared with MCDropout, our metrics achieve competing performance with significant advantages on computational expenses.

Overall, the learned confidence estimate is a competitive indicator of translation precision compared with other unsupervised QE metrics. Moreover, the confidence branch added to the NMT system is a light component. It allows each translation to come with quality measurement without degradation of the translation accuracy. The performance with the confidence branch is in Appendix B.

4.2 Confidence-based Label Smoothing

We extend our confidence estimate to improve smoothing and experiment on different-scale translation tasks: WMT14 English-to-German (En⇒De), LDC Chinese-to-English (Zh⇒En)[3], WMT16 Romanian-to-English (Ro⇒En), and IWSLT14 German-to-English (De⇒En). We use the 4-gram BLEU (Papineni et al., 2002) to score the performance. More details about data processing and experimental settings are in Appendix C.

As shown in Table 2, our confidence-based label smoothing outperforms standard label smoothing by adaptively tuning the amount of each label smoothing. For Zh⇒En task, our method improves the performance over Transformer w/o LS by 1.05 BLEU, which also exceeds standard label smoothing by 0.72 BLEU. We find that improvements over standard label smoothing differ in other language pairs (0.35 BLEU in En⇒De, 0.5 BLEU in De⇒En, and 0.79 BLEU in Ro⇒En). It can be attributed to that the seriousness of miscalibration varies in different language pairs and datasets (Wang et al., 2020).

Experimental results with a larger search space (i.e. beam size=30) are also given in Appendix C to support the above findings.

5 Analysis

Confidence estimation is particularly critical in real-world deployment, where noisy samples and out-of-distribution data are prevalent (Snoek et al., 2019). Given those abnormal inputs, neural network models are prone to be highly confident in misclassification (Nguyen et al., 2015). Thus, we need an accurate confidence estimate to detect potential failures caused by odd inputs by assigning them low confidence. This section explores whether our confidence estimate can accurately measure risk under those two conditions.

5.1 Noisy Label Identification

We expect that the model requires more hints to fit noisy labels by predicting low confidence. To test this point, we experiment on the IWSLT14 De⇒En dataset containing 160k parallel sentences. We build several datasets with progressively increasing noisy samples by randomly replacing target-side words with others in the vocabulary. We train on each dataset with the same configuration and picture the learned confidence estimate in Figure 4.

The learned confidence estimate appears to make

Table 5: Comparison of the model probability and our confidence estimate on out-of-domain data detection tasks. We present the rate of unknown words (UNK) and average length of input sentences for each dataset (the average input length of in-domain dataset is 22.47). All scores are shown in percentages and the best results are highlighted in bold. ↑ indicates that higher scores are better, while ↓ indicates that lower scores are better.

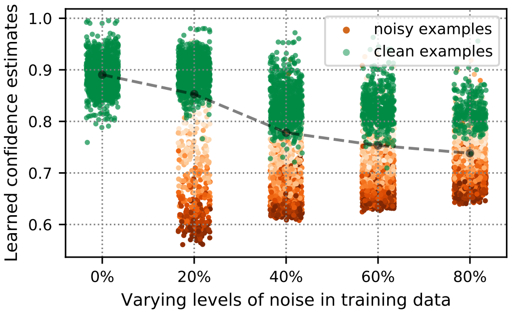

Figure 4: The learned confidence estimate on IWSLT14 De⇒En as varying levels of noisy labels. The shade of colors denotes how many words are corrupted in a sentence (dark orange means a high pollution rate). The dashed line shows averaged learned confidence estimate on the whole dataset.

reasonable assessments. (1) It predicts low confidence on noisy samples but high confidence on clean ones. Specifically, the confidence estimate is much lower as a higher pollution degree in one example (darker in color). (2) With increasing noises in the dataset, the NMT model becomes more uncertain about its decision accordingly. Large numbers of noises also raise a challenge for separating clean and noisy samples.

We also compare ours with the model probability by giving the accuracy of separating clean and noisy examples under varying pollution rates. We set clean data as the positive example and use evaluation metrics listed in Appendix A.

As shown in Table 4, our confidence estimate obtains better results in all cases, especially in a high noise rate. Our metric improves the area under the precision-recall curve (AUPR) from 64.15% to 76.76% and reduces the detection error (DET) from 13.41% to 8.13% at an 80% noise rate. It proves that our confidence estimate is more reliable for detecting potential risks induced by noisy data.

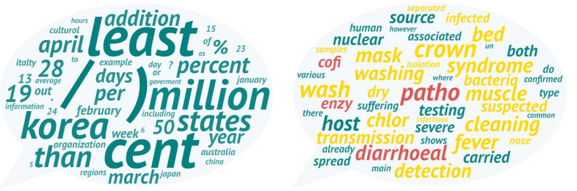
5.2 Out-of-Domain Data Detection

For our in-domain examples, we train an NMT model on the 2.1M LDC Zh⇒En news dataset and then sample 1k sentences from NIST2004 as the in-domain testbed. We select five out-of-domain datasets and extract 1k samples from each. Most of them are available for download on OPUS, specified in Appendix D. Regarding the unknown words (UNK) rate, the average length of input sentences, and domain diversity, the descending order based on distance with the in-domain dataset is WMT-news > Tanzil > Tico-19 > TED2013 > News-Commentary. Test sets closer to the in-domain dataset are intuitively harder to tell apart.

We use sentence-level posterior probability and confidence estimate of the translation to separate in- and out-of-domain data. Evaluation metrics are in Appendix A. Results are given in Table 5.

We find that our approach performs comparably with the probability-based method on datasets with distinct domains (WMT-news and Tanzil). But

(a) Rank by prediction probability



(b) Rank by our confidence estimate

Figure 5: Word clouds of the most confident/uncertain translations in the Tico-19 dataset ranked by (a) prediction probability and (b) learned confidence estimate. We divide tokens into three categories based on their frequencies. *High*: the most 3k frequent words, *Medium*: the most 3k-12k frequent words, *Low*: the other tokens.

when cross-domain knowledge is harder to detect (the last three lines in Table 5), our metric yields a better separation of in- and out-of-domain ones.

To better understand the behaviour of our confidence estimates on out-of-domain data, we visualize word clouds of the most confident/uncertain words ranked by model probability and our measurements on a medicine dataset (Tico-19) in Figure 5. The colors of words indicate their frequencies in the in-domain dataset.

Our metrics correctly separate in- and out-of-domain data from two aspects: (1) *word frequency*: the NMT model is certain about frequent words yet hesitates on rare words as seen in Figure 5(b). But colors in Figure 5(a) are relatively mixing. (2) *domain relation*: the most uncertain words ranked by our confidence estimate are domain-related, like "patho" and "syndrome", while the most confident words are domain-unrelated (e.g., punctuations and prepositions). This phenomenon cannot be seen in Figure 5(a), showing that probabilities from softmax fall short in representing model uncertainty for domain-shift data.

6 Related Work

The task of confidence estimation is crucial in real-world conditions, which helps failure prediction (Corbière et al., 2019) and out-of-distribution detection (Hendrycks and Gimpel, 2017; Snoek et al., 2019; Lee et al., 2018). This section reviews recent researches on confidence estimation and related applications on quality estimation for NMT.

6.1 Confidence Estimation for NMT

Only a few studies have investigated calibration in NMT. Müller et al. (2019) find that the NMT model is well-calibrated in training, which is proven severely miscalibrated in inference (Wang et al., 2020), especially when predicting the end of a sentence (Kumar and Sarawagi, 2019). Regarding the complex structures of NMT, the exploration for fixing miscalibration in NMT is scarce. Wang et al. (2019); Xiao et al. (2020) use Monte Carlo dropout to capture uncertainty in NMT, which is time-consuming and computationally expensive. Unlike them, we are the first to introduce learned confidence estimate into NMT. Our method is well-designed to adapt to Transformer architecture and NMT tasks, which is also simple but effective.

6.2 Quality Estimation for NMT

QE is to predict the quality of the translation provided by an MT system at test time without standard references. Recent supervised QE models are resource-heavy and require a large mass of annotated quality labels for training (Wang et al., 2018; Kepler et al., 2019a; Lu and Zhang, 2020), which is labor-consuming and unavailable for low-resource languages.

Exploring internal information from the NMT system to indicate translation quality is another alternative. Fomicheva et al. (2020) find that uncertainty quantification is competitive in predicting the translation quality, which is also complementary to supervised QE model (Wang et al., 2021). However, they rely on repeated Monte Carlo dropout (Gal and Ghahramani, 2016) to assess uncertainty at the high cost of computation. Our confidence estimate outperforms existing unsupervised QE metrics, which is also intuitive and easy to implement.

7 Conclusion

In this paper, we propose to learn confidence estimates for NMT jointly with the training process. We demonstrate that learned confidence can better indicate translation accuracy on extensive sentence/word-level QE tasks and precisely measures potential risk induced by noisy samples or out-of-domain data. We further extend the learned confidence estimate to improve smoothing, outperforming the standard label smoothing technique. As our confidence estimate outlines how much the model knows, we plan to apply our work to design a more suitable curriculum during training and post-edit low-confidence translations in the future.

A Evaluation Metrics

We let TP, FP, TN, and FN represent true positives, false positives, true negatives, and false negatives. We use the following metrics for evaluating the accuracy of word-level QE, noisy label identification, and out-of-domain detection:

- *AUROC*: the Area Under the Receiver Operating Characteristic (ROC) curve, which plots the relation between TPR and FPR.
- *AUPR*: the Area Under the Precision-Recall (PR) curve. The PR curve is made by plotting *precision* = TP/(TP+FP) and *recall* = TP/(TP+FN).
- *DET*: the Detection Error, which is the minimum possible misclassification probability over all possible threshold when separating positive and negative examples.
- *EER*: the Equal error rate. It is the error rate when the confidence threshold is located where FPR is the same with the false negative rate (FNR) = FN / (TP+FN).

We set OK translations in the word-level QE task, clean samples in the noisy data identification task, and in-domain samples in the out-of-domain data detection task as the positive example.

B Translation Results with the Confidence Branch

The confidence branch added to the NMT system is a light component. It allows each translation to come with quality measurement without degradation of the translation accuracy. Translation results with the confidence branch are given in Table 6.

We see that the added confidence branch does not affect the translation performance. Implementation details in section 3 are necessary for achieving this. For instance, if we use the highest hidden state to predict confidence and translation together, BLEU scores would dramatically decline with a larger beam size, the drop of which is more significant than that of the baseline model. For the En⇒De task, the change is from 27.31 (beam size 4) to 25.6 (beam size 100), while the baseline model even improves 0.5 BLEU further with a larger beam size 100.

C Confidence-based Label Smoothing

We experiment on different-scale translation tasks: WMT14 En⇒De, LDC Zh⇒En, WMT16 Ro⇒En, and IWSLT14 De⇒En.

Datasets. We tokenize the corpora by Moses (Koehn et al., 2007). Byte pair encoding (BPE) (Sennrich et al., 2016) is applied to all language pairs to construct a join 32k vocabulary except for Zh⇒En where the source and target languages are separately encoded.

For En⇒De, we train on 4.5M training samples. Newstest2013 and newstest2014 are set as validation and test sets. For Zh⇒En, we remove sentences of more than 50 words and collect 2.1M training samples. We use NIST 2002 as the validation set, NIST 2003-2006 (MT03-06), and 2008 (MT08) as the testbed. For Ro⇒En, we train on 0.61M training data and use newsdev2016 and newstest2016 as validation and test sets. For De⇒En, we train on its training set with 160k training samples and evaluate on its test set.

Settings. We implement the described model with fairseq[5] toolkit for training and evaluating. We follow Vaswani et al. (2017) to set the configurations of models with the `base` Transformer. The dropout rate of the residual connection is 0.1 except for Zh⇒En (0.3). The experiments last for 150k steps for Zh⇒En and En⇒De, 30k for small-scale De⇒En and Ro⇒En. We average the last ten checkpoints for evaluation and adopt beam search (beam size 4/30, length penalty 0.6). We set $\epsilon_{ls} = 0.1$ for the vanilla label smoothing.

The hyper-parameters λ_0 and β_0 (as seen Equation 8) control the initial value and declining speed of λ (as in Equation 7), which decides the number of hints the NMT model can receive. To ensure that no hints are available at the early stage of training, we set $\lambda_0 = 30$, $\beta_0 = 4.5 * 10^4$ for Zh⇒En and En⇒De, $\beta_0 = 1.2 * 10^4$ for De⇒En and Ro⇒En. We set $\epsilon_0 = 0.1$ (as seen in Equation 10) for all language pairs.

Results. A common setting with beam size=4 is given in Table 2 in the main body. Here, we experiment with a larger search space where being over-or under-confident further worsens model performance (Guo et al., 2017). The results with beam size=30 are listed in Table 7. For Zh⇒En task, our method yields +1.17 BLEU improvements

"$*$" indicates gains are statistically significant than Transformer w/o LS with $p < 0.05$.

over Transformer w/o LS, exceeding standard label smoothing by 0.58 BLEU scores. The performance gains can also be found in other language pairs, showing the effectiveness of our confidence-based label smoothing with a larger beam size.

D Out-of-domain Data Detection

We select five out-of-domain datasets for our tests (we extract 1k samples each), which are available for download on OPUS[4]. The datasets are:

- *WMT-News*: A parallel corpus of News Test Sets provided by WMT for training SMT[5], which is rich in content including sports, entertainment, politics, and so on.
- *Tanzil*: This is a collection of Quran translations compiled by the Tanzil project[6].
- *Tico-19*: This is a collection of translation memories from the Translation Initiative for COVID-19, which has many medical terms[7].
- *TED2013*: A corpus of TED talks subtitles provided by CASMACAT[8], which are about personal experiences in informal expression.
- *News-Commentary*: It is also a dataset provided by WMT[9], but the extracted test set is all about international politics.

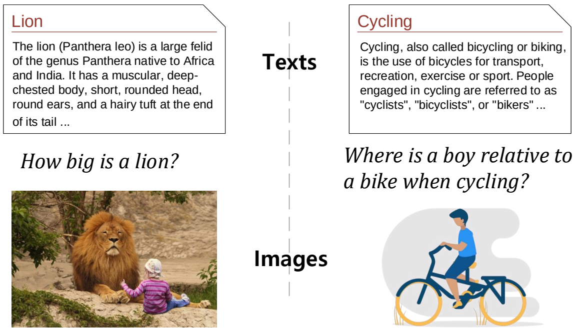
Abstract

Spatial commonsense, the knowledge about spatial position and relationship between objects (like *the relative size of a lion and a girl*, and *the position of a boy relative to a bicycle when cycling*), is an important part of commonsense knowledge. Although pretrained language models (PLMs) succeed in many NLP tasks, they are shown to be ineffective in spatial commonsense reasoning. Starting from the observation that images are more likely to exhibit spatial commonsense than texts, we explore whether models with visual signals learn more spatial commonsense than text-based PLMs. We propose a spatial commonsense benchmark that focuses on the relative scales of objects, and the positional relationship between people and objects under different actions. We probe PLMs and models with visual signals, including vision-language pretrained models and image synthesis models, on this benchmark, and find that image synthesis models are more capable of learning *accurate* and *consistent* spatial knowledge than other models. The spatial knowledge from image synthesis models also helps in natural language understanding tasks that require spatial commonsense. Code and data are available at `https://github.com/xxxiaol/spatial-commonsense`.

1 Introduction

Spatial perception, the ability to detect the spatial position and to infer the relationship between visual stimuli (Donnon et al., 2005; Saj and Barisnikov, 2015), is basic but important for human beings (Pellegrino et al., 1984). It is of everyday use, from understanding the surrounding environment, like *when seeing a woman sitting in a car with her hands on the steering wheel, we know she is probably driving*, to processing spatial information and performing reasoning, like *navigating through a dense forest*. We regard the knowledge needed in spatial perception as spatial commonsense. Humans start to develop spatial perception and acquire spatial commonsense from infancy, and apply the commonsense through lifetime (Kuipers et al., 1990; Poole et al., 2006).



The lion (Panthera leo) is a large felid of the genus Panthera native to Africa and India. It has a muscular, deep-chested body, short, rounded head, round ears, and a hairy tuft at the end of its tail ...

Cycling, also called bicycling or biking, is the use of bicycles for transport, recreation, exercise or sport. People engaged in cycling are referred to as "cyclists", "bicyclists", or "bikers" ...

Figure 1: Texts and images related to *lion* and *cycling*. Images exhibit more explicit spatial knowledge than texts.

Although text-based Pretrained Language Models (PLMs) achieve great performance on various commonsense reasoning tasks (Davison et al., 2019; Zhou et al., 2020), they are shown to be ineffective when dealing with spatial commonsense. Zhang et al. (2020) and Aroca-Ouellette et al. (2021) show that current PLMs lack the ability to reason about object scales. Bhagavatula et al. (2020) find that BERT (Devlin et al., 2019) underperforms on instances involving spatial locations. The struggle of PLMs with spatial commonsense is partly because spatial commonsense is rarely expressed explicitly in texts. We may write sentences like *lions are big animals*, but we seldom explicitly mention how big lions are; we also rarely write about the spatial relationship between a boy and a bicycle when he is cycling.

Spatial commonsense is exhibited in images more commonly (Cui et al., 2020). As shown in Figure 1, the two Wikipedia articles provide little

---

spatial information, but a picture of *a lion and a girl* provides a reference to the size of a lion; and a painting of *a boy riding a bicycle* depicts that he sits *on* the bicycle. Hence, a natural idea is to elicit spatial knowledge from models with visual signals.

We first study *whether models with visual signals learn more spatial knowledge than text-only models*. We select Vision-Language PreTrained Models (VL-PTMs) and Image Synthesis Models (ISMs) for investigation. VL-PTMs encode texts and images together, fusing their features to deal with downstream tasks. ISMs take texts as input, and generate images based on the texts. To evaluate the spatial commonsense in PLMs and models with visual signals, we design a benchmark that involves two subtasks: 1) comparing sizes and heights of different objects (like *a lion and a girl*), and 2) determining the positional relationship between a person and an object when a certain action happens (like *a boy's position when riding a bicycle*). The subtasks are designed to examine the model's capability to master two kinds of spatial commonsense: understanding spatial scales, and the relationship between surrounding objects and ourselves.

As shown in Figure 2, we probe models with text prompts on this benchmark. We feed text prompts with masks to PLMs and VL-PTMs, and take the possible word with the highest probability as their prediction. We probe ISMs in a similar way: we first feed the text prompts to ISMs and then evaluate the generated images. We evaluate the images with two methods: automatically comparing bounding boxes of objects and conducting human evaluation. Results show that models with visual signals learn more accurate spatial commonsense than PLMs.

Besides the performance comparison, we are also interested in *how is the quality of spatial commonsense learned by different models?* We investigate how consistent the spatial knowledge learnt by a model is, like whether it can manifest *a lion is larger than a girl* and *a girl is smaller than a lion* simultaneously; and to what extent models can generalize the knowledge when uncommon scenarios like *an enchantress lights the sparkler* appear. We observe that ISMs are capable of generating consistent spatial knowledge and the performance is robust in uncommon scenarios.

The following problem is *how to benefit natural language understanding tasks with the spatial knowledge from ISMs?* We investigate this in the question answering scenario. Take a question like *A boy is riding a bicycle. Is he on the bicycle?* We generate an image about the question context *a boy who is riding a bicycle* with a text prompt using ISMs, and feed both the question and the generated image into vision-language models to predict an answer. This framework outperforms strong question answering models pretrained on texts only. While this is a simplified scenario of spatial commonsense reasoning, it manifests a possible way to employ the spatial knowledge learned by ISMs in natural language understanding.

Motivated by the observation that images contain more spatial commonsense than texts, we 1) design a framework, including the data and probing methods, to compare the spatial reasoning ability of models with different modalities; 2) propose methods to evaluate the quality of learned spatial commonsense, and find that models with visual signals, especially ISMs, learn more *precise* and *robust* spatial knowledge than PLMs; and 3) demonstrate the improvement in spatial commonsense question answering with the help of visual models.

2 Related Works

2.1 Spatial Commonsense Reasoning

Object Scales. Bagherinezhad et al. (2016) build a dataset for objects' size comparison, and Elazar et al. (2019) provide distributional information about objects' lengths. Forbes and Choi (2017) also involve spatial comparison but are criticized for ill-defined comparison (Elazar et al., 2019). Aroca-Ouellette et al. (2021) design a physical reasoning dataset that requires not only spatial commonsense but also a complex reasoning process, which is extremely challenging for existing models. We choose the formulation of object comparison in pairs as this kind of knowledge is easy to be probed from different models.

Spatial Relationship. Collell et al. (2018) introduce a dataset of spatial templates for objects under different relations, but the spatial relations are represented as relative positions of bounding boxes, which are hard to express in language. Yatskar et al. (2016) extract statements of spatial relationship from object co-occurrences in MS-COCO (Lin et al., 2014). Mirzaee et al. (2021) design a textual spatial reasoning benchmark, and Johnson et al. (2017) and Hudson and Manning (2019) involve spatial reasoning in images, but they focus on logical reasoning rather than commonsense. Contrast

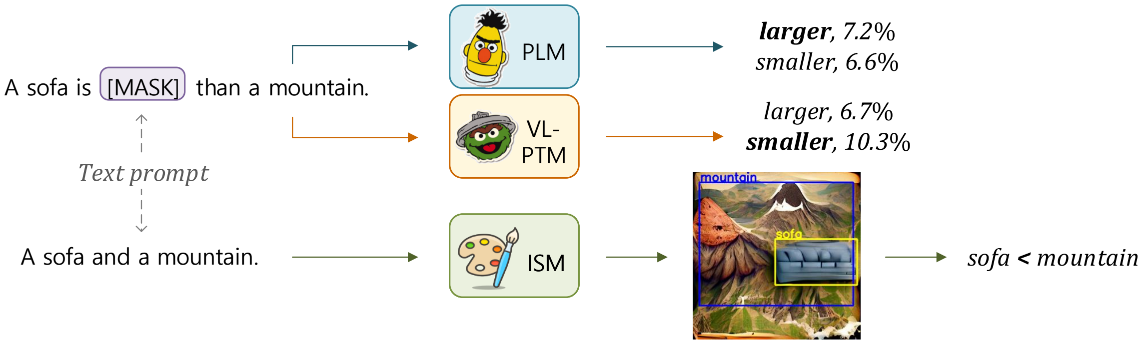

Figure 2: The probing process. We take the size comparison between $sofa$ and $mountain$ as an example.

to them, we build a dataset to describe the spatial relationship between people and objects in certain actions with preposition words.

2.2 Knowledge Probing

Early attempts in probing PLMs (Liu et al., 2019a; Hewitt and Manning, 2019) mainly train a classifier on the task of interest with the encoded representations. However, the probing performance is highly influenced by the probe design (Pimentel et al., 2020), thus is hard to reflect the ability of PLMs.

Recently, prompt-based methods (Petroni et al., 2019; Zhou et al., 2020) become more prevalent to study what knowledge PLMs already encode. PLMs take a prompt as input, and generate the continuation (for generative PLMs) or predict masked words (for discriminative PLMs). This does not need additional training, and only a small development set is used to choose optimal prompts and answers (Jiang et al., 2020). In this work, we probe PLMs and VL-PTMs with prompts. Prompt-based methods are also used in model training (Schick and Schütze, 2021; Zhou et al., 2021), while we focus on the knowledge already learned by models.

Basaj et al. (2021); Oleszkiewicz et al. (2021) try to apply the probing methods into the computer vision domain, but they focus on probing representations of visual models. In contrast, we probe ISMs by evaluating the generated images.

3 Benchmark Construction

3.1 Datasets

Size and Height. Inspired by the cognitive discovery (Hersh and Caramazza, 1976) that people tend to categorize objects scales into fuzzy sets, we select 25 common objects in daily life, and categorize them into 5 groups as shown in Table 1a to construct the dataset for size comparison. Typical objects in the former group are smaller than those in the latter group. We form 250 pairs of objects from different groups, like ⟨*ant, bird*⟩, where the first object is smaller than the second in commonsense. Models are asked to compare the size of objects in pairs. To avoid an imbalance of answer distribution, we also consider the reversed pairs like ⟨*bird, ant*⟩, so there are 500 instances in total.

	Size
1	ant, coin, nut, bullet, dice
2	bird, cup, shell, bottle, wallet
3	tyre, chair, microwave, dog, suitcase
4	human, sofa, bookshelf, tiger, bed
5	house, cinema, mountain, truck, plane

(a) Objects of different levels of sizes.

	Height
1	ant, insect, water drop, bullet, dice
2	bird, cup, shoe, bottle, mobile phone
3	table, chair, trash can, sofa, suitcase
4	human, horse, bookshelf, camel, door
5	apartment, theatre, giraffe, truck, street lamp

(b) Objects of different levels of heights.

Table 1: The dataset of object scales.

The dataset for comparing objects' heights is constructed similarly, as shown in Table 1b. We also form 500 instances with the objects. The comparison between objects is validated by 5 human annotators for both datasets.

Positional Relationship. The positional relationship dataset consists of human actions regarding objects and the most likely positional relation between the person and the object. We consider four types of positional relations: *above, below, inside, beside*, as they do not overlap with each other.

We select common objects, and write actions between people and the objects. The actions do *not* contain prepositions, like *sit on the chair*. Each ob-

Figure 3: Example of two positional relations between *man* and *car*.

ject is accompanied by two actions with different positional relations. Take Figure 3 as an example. The man is *beside* the car when washing the car, whereas he is *inside* the car when driving it. Therefore, the relation cannot be easily inferred from collocations between the person and the object. The dataset contains 224 instances, validated by 5 annotators.

3.2 Probing Tasks

We probe PLMs and VL-PTMs through masked word prediction. Given a text prompt with masks and a set of possible words, a model calculates the probability of each possible word filling the masked position. The word with the highest possibility is regarded as the prediction.

We also probe ISMs through text prompts. The input is a piece of descriptive text, and the output is the image generated by an ISM. We assess the image with two methods as described in 3.3.

PLMs are found to perform poorly in scenarios involving complex reasoning over spatial knowledge (Aroca-Ouellette et al., 2021), and we want to investigate whether they even fail in early stages, like whether they have learned spatial knowledge. So we probe models with simple tasks. In the subtask of size and height, the prompt for PLMs and VL-PTMs is in the form of O_a *is [MASK] than* O_b, where $\langle O_a, O_b \rangle$ is an object pair. The possible answer set is $\{larger, smaller\}$ for size and $\{taller, shorter\}$ for height. The prompt for ISMs is in the form of O_a *and* O_b, and the objects in generated images are compared for size and height.

In the subtask of positional relationship, the prompt for PLMs and VL-PTMs contains an event scenario and a masked token for the positional relationship, like *A woman washes the car. She is [MASK] the car.* The possible answer set is $\{above, below, inside, beside\}$. The prompt for ISMs describes the scenario only, like *A woman washes the car.*

3.3 ISM Evaluation

We assess the images generated by ISMs with two methods. We first use the spatial information of bounding boxes (referred to as ISM (Box)). For each object mentioned in the prompt, we select the classified bounding box with the highest confidence. To mitigate the effect of viewpoint (an object closer to the camera may appear larger in the image), we compute the average depth of the box as the object's depth. We use the object detector from Zhang et al. (2021), and the depth estimator from Godard et al. (2019). When probing the relative size, we compare $area \times depth^2$ of the two objects' boxes; and when probing the relative height, we compare $height \times depth$. When classifying positional relations, we use the mapping rules between spatial relations and image regions from Visual Dependency Grammar (VDG) (Elliott and Keller, 2013). We list the rules in Appendix A.1.

Some generated images are vague while object detection models are trained to process clear pictures, so a number of objects are not recognized. To precisely assess the generated images, we conduct human evaluation on all images (referred to as ISM (Human)). Annotators are asked to compare the size/height of the objects in the images (for the first subtask) and classify the positional relationship between the person and the object (for the second subtask). Each image is evaluated by two annotators, and the average performance is reported. Specifically, we report the accuracy and macro F1 between models' predictions and correct answers. Besides the performance of ISMs on the subset of recognized instances, we also report the performance on the full dataset, giving the unrecognized instances a random guess.

4 Probing Spatial Commonsense

4.1 Models

We take BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019b) as examples of text-only PLMs. For VL-PTMs, we choose VinVL (Zhang et al., 2021), which performs well in various vision-language tasks. It uses a transformer-based backbone and is pretrained on various vision-language datasets including image caption datasets, visual QA datasets, etc. As it preserves the masked word prediction objective like PLMs, it can also be probed with prompts. We choose VQGAN+CLIP[1]

(b) Comparing heights of objects. Both objects are recognized by the object detection model in 14% images and are recognized by humans in 82% images.

Table 2: Probing performance on object scales. The numbers are in percentages (%). The number before the slash (/) is the average performance of different folds, and the number after the slash is the standard deviation. The number out of parentheses is the performance on the whole dataset, and the number in parentheses indicates performance on the subset of instances where the generated images can be recognized by object detection models (§), and on the subset recognized by humans (†).

as a representative of ISMs. It uses CLIP (Radford et al., 2021) to guide VQGAN (Esser et al., 2021) to generate images that best match the given text. To make a fair comparison regarding model size, we select BERT-large, RoBERTa-large, and VinVL-large. We use VQGAN with codebook size $Z = 16384$ and downsampling factor $f = 16$, and CLIP with ViT-B/32 (Dosovitskiy et al., 2020) architecture. All four models are of similar sizes.

As language models are sensitive to the expressions in probing (Liu et al., 2021) (like changing an answer choice from *larger* to *bigger*, the predictions of BERT may differ a lot), we generate new prompts and answers based on those originally designed in the benchmark, and search for the optimal ones for PLMs and VL-PTMs. Similar to Jiang et al. (2020), we use back-translation to generate 10 candidates for prompts and answers, and filter out the repeated ones. To select prompts and answers, we split the dataset into 5 folds, where different folds do not share the same objects. For each run, one fold is used as the development set to choose the best candidate, and the model is probed on other folds with the chosen prompt. We report average performance of 5 runs.

Figure 4: Images generated by ISM in scale comparison. ✓means objects are successfully recognized by the object detection model or humans, and × means not.

4.2 Probing Results

Size and Height. Table 2 reports the probing performance of comparing the scales of objects. We also demonstrate probing results on RelativeSize (Bagherinezhad et al., 2016) in Appendix B. We observe that PLMs perform similarly. Even the best PLMs are slightly better than random guesses, indicating they are ineffective in predicting object scales. Although RoBERTa is trained on more texts and assumed to encode more knowledge, its performance is similar to BERT's. It shows that PLMs do not learn much spatial commonsense from texts even if the pretrained corpus greatly increases.

With the help of visual features in pretraining, VinVL greatly outperforms PLMs. ISM (Box), which simply compares bounding boxes in images generated by the ISM, also outperforms PLMs. Since only a small portion of instances are recognized with bounding boxes, if we only consider the predictions on these instances, the gap between ISM (Box) and PLMs is more than 15%. These

Model	**Acc** (avg. / σ)	**F1** (avg. / σ)
BERT	26.1 / 4.15	19.0 / 5.20
RoBERTa	31.0 / 15.4	20.1 / 9.29
VinVL	**56.1** / 7.09	**41.8** / 6.69
Model	**Acc**	**F1**
Best PLM§	31.0 (32.5)	20.1 (17.6)
VinVL§	**56.1** (**56.0**)	**41.8** (**36.0**)
ISM (Box)§	33.0 (42.5)	26.5 (26.1)
Best PLM†	31.0 (30.5)	20.1 (20.1)
VinVL†	56.1 (56.4)	41.8 (42.9)
ISM (Human)†	**73.4** (**75.4**)	**65.1** (**68.0**)

Table 3: Probing performance on positional relationship (%). The symbols are identical to those in Table 2. Both the person and the object are recognized with bounding boxes in 39% images and by humans in 93% images.

indicate that models with visual signals learn accurate spatial commonsense knowledge from images.

ISM (Box) outperforms VinVL on those recognizable instances (81.6 vs. 53.8), but the recognition ratio is admittedly low. We conduct human evaluation on the generated images for more precise assessment. More than 80% of images are recognized by humans and these images accurately reflect the spatial commonsense compared to PLMs and VinVL. [2] The gap between VinVL and ISM (Human) may be due to different ways of using visual signals in pretraining. A training objective of VinVL, and other VL-PTMs, is aligning text with image regions. The discriminative features of objects are amplified, while other features may not receive as much attention. For instance, the shape and color are the discriminative features of an *apple*, and its size is not that important in recognition. In image synthesis, models need to learn comprehensive knowledge of objects for reconstruction, and spatial knowledge may be learned implicitly in this process.

Figure 4 demonstrates images generated by the ISM given the prompts of object pairs. ISM grasps the main characteristics of the objects, including their scales. Some objects (like *theatre* at the bottom of the middle column) can be identified by humans but are difficult for the object detection model because they are obstructed by objects in the foreground. And some objects are generated in multiple fragments (like *plane* and *horse* in the right column), therefore cannot be recognized by either the object detection model or humans.

Model	Size		Height	
	Sym.	Trans.	Sym.	Trans.
Best PLM	37.5	71.9	25.9	73.1
VinVL	**43.5**	**95.0**	**43.0**	**93.2**
Best PLM†	36.6	72.2	26.1	72.3
VinVL†	44.4	**95.3**	32.2	**97.8**
ISM (Human)†	**82.5**	81.1	**83.2**	85.2

Table 4: The percentage (%) of predictions that meet consistency. Sym and Trans indicate symmetry and transitivity. † indicates performance on the subset of images recognized by humans.

Positional Relationship. The probing performance on positional relationship is shown in Table 3. VinVL outperforms PLMs more than 20%, and ISM (Human) outperforms PLMs more than 35%, suggesting that models with visual signals learn more knowledge of the scenarios, especially the positions of objects relative to people.

The gap between PLMs and ISM (Box) is smaller compared to the gap in the subtask of size and height. One reason is that the rules defined in VDG cannot perfectly reflect the true positional relationship in images. For example, the man is *beside* the car in the left image of Figure 3, but he will be regarded as *inside* the car by the rules, as the region of car covers the region of man.

Text-based PLMs tend to lean towards certain positional relations between a person and an object, without referring to the action. In 64% cases, RoBERTa chooses the same option for a ⟨*person, object*⟩ pair with different actions, while the proportion is 21% for VinVL, and 28% for ISM (Human).

5 Quality of Spatial Knowledge

5.1 Consistency

Models that master better spatial knowledge should be able to infer the relative scale of two objects from intermediate references. For example, if a model knows *a dog is larger than an ant* and *a sofa is larger than a dog*, it may learn *a sofa is larger than an ant*, even if it has not seen *sofa* and *ant* together. We inspect models on how consistent their probing results are.

The consistency is measured in two aspects: *symmetry* and *transitivity*. Symmetry implies that if a model predicts $A > B$, then it should also predict $B < A$, and vice versa: $A < B \implies B > A$. Here $>$ and $<$ are in terms of size or height. We enumerate the object pairs and count the percent-

---

[2] The agreement between annotators is more than 90%.

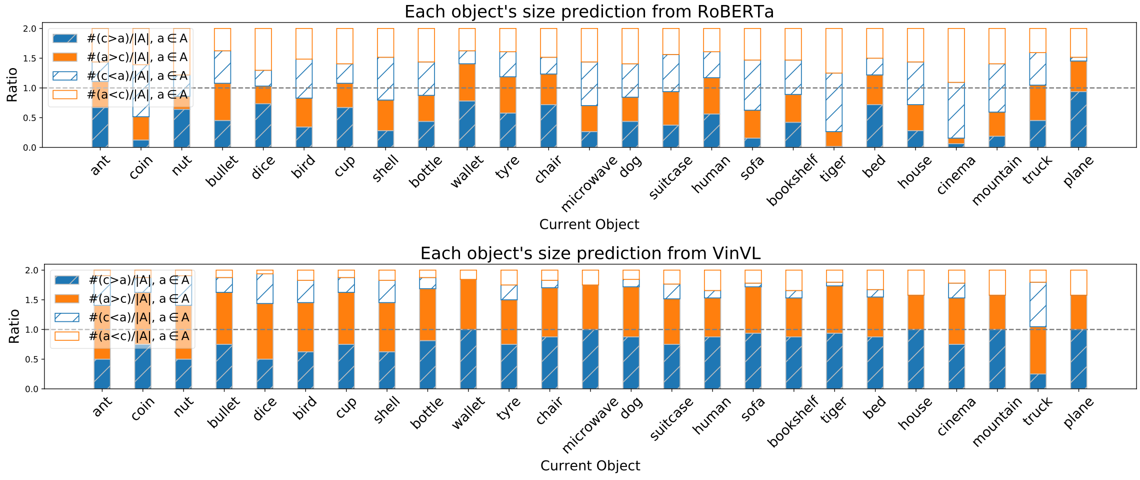

Figure 5: Predictions from RoBERTa and VinVL in the subtask of objects' sizes. c is the current object and A is the set of all other comparable objects. $\#(c > a)/|A|$ indicates the ratio of predicting the current object larger than others. As $c > a$ and $a > c$ should not appear simultaneously, the sum of the two solid bars is expected to be 1.

age of predictions that meet the symmetry criterion. Transitivity implies that if a model predicts $A > B$ and $B > C$, then it should predict $A > C$. It also works for $<$, $A < B \wedge B < C \implies A < C$. We enumerate the triples $\langle A, B, C\rangle$ where the predicted relation between $\langle A, B\rangle$ is identical to the prediction between $\langle B, C\rangle$, and count the percentage that the prediction between $\langle A, C\rangle$ meets the transitivity criterion. Note that we only evaluate whether the predictions are consistent with each other, regardless of the gold answers.

We evaluate the consistency of predictions from PLMs that perform the best in the probing tasks (RoBERTa for size and BERT for height), VinVL, and ISM (Human). The results are in Table 4.

VinVL outperforms the best PLM in both metrics, and the characteristics of them are similar: the transitive consistency is high, while the symmetric consistency is low. To further analyze this phenomenon, we exhibit each object's size predictions from RoBERTa and VinVL in Figure 5. The models exhibit different behaviors in recognizing object scales. As the objects (X-axis of Figure 5) are roughly listed from smaller to larger groups, the bottom blue bars are expected to follow a non-descending order from left to right, and the solid orange bars should be non-ascending. The predictions of VinVL are generally in line with this trend, while RoBERTa's predictions are disordered. For example, *ant* is predicted to be *larger than* other objects with high probability, and *cinema is larger than others* is unlikely to happen. On the other hand, if the model predictions are consistent, the two solid bars should sum to 1. However, the sum is far above 1 for most objects in VinVL's predictions. This bias towards words indicating the choice of *large* may come from the pretraining corpus. For example, *sofa* occurs twice as many times with words indicating large as with words indicating small in COCO (Lin et al., 2014), one of VinVL's pretraining datasets.

Model	**Acc** (avg. / σ)	**F1** (avg. / σ)
BERT	27.4 / 3.17	19.7 / 7.25
RoBERTa	29.5 / 16.0	20.1 / 9.90
VinVL	**58.1** / 1.97	**44.4** / 1.63
Model	**Acc**	**F1**
Best PLM†	29.5 (28.4)	20.1 (19.1)
VinVL†	58.1 (52.3)	44.4 (41.0)
ISM (Human)†	**66.5** (**74.8**)	**59.4** (**69.2**)

Table 5: Probing models on the generalized dataset of positional relationship. The symbols are identical to those in Table 2. The human recognition ratio is 81%.

ISM's predictions comply with the symmetry criterion, outperforming other models by 40%, while also having good transitive consistency. The knowledge probed from ISM is more consistent. Figure 6 exhibits the symmetric and transitive consistency of images generated by ISM. The consistency of scale knowledge makes the predictions more convincing, and gives models a chance to learn new comparisons between objects.

5.2 Generalizability

ISM may learn positional relations from training images directly. For example, *a boy riding a bi-*

(a) Two groups of generated images. Sizes of objects are consistent with each other.

(b) Two groups of generated images. Heights of objects meet the transitivity criterion.

Figure 6: Examples of the symmetric and transitive consistency of images generated by ISM.

cycle is a *common* scenario and may frequently exist in ISM's training set, so models can generate images more easily when being fed with the text prompts like *a boy rides a bicycle*. To further challenge ISM's capability, we make a generalized version of our original positional relationship dataset. It is designed to examine whether models are able to robustly reflect the spatial commonsense knowledge when facing *uncommon* scenarios.

A generalized scenario is built upon the original one by replacing the person and object in the text prompts. We select the new person and new object from the subterms of the original ones (those with *IsA* relation in ConceptNet (Speer et al., 2017), like *enchantress* is a *woman*). To ensure these newly constructed scenarios are not likely to appear in the training data of models, we search them in BookCorpus (Zhu et al., 2015) and remove the scenarios that have appeared. The newly generated scenarios are also validated by humans to ensure that they are reasonable.

Results of probing PLMs, VinVL, and ISM[3] on the generalized dataset are in Table 5. PLMs and VinVL achieve similar performance on both the generalized dataset and the original one, indicating that they behave robustly when facing uncommon scenarios. The performance gap between other models and ISM (Human) slightly narrows down, but ISM (Human) still outperforms VinVL more than 8%. Figure 7 exhibits images generated by ISM with the generalized prompts. Although it is difficult for ISM to generate unfamiliar objects, it is still capable of capturing the positional relations.

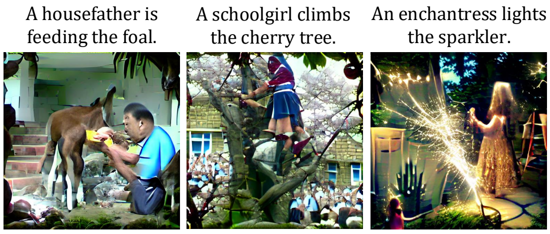

Figure 7: Images generated by ISM with the generalized prompts.

6 Solving Natural Language Questions

We investigate how to acquire spatial knowledge from ISMs and whether the knowledge is effective in natural language understanding scenarios. To our best knowledge, there is no appropriate task that focuses on spatial commonsense, so we create a toy task by transforming our probing benchmark into the form of question answering (QA).

Dataset. We construct a QA dataset of yes/no questions. Questions of objects' sizes are in the form of *Is* O_a *larger/smaller than* O_b*?* And questions of objects' heights are like *Is* O_a *taller/shorter than* O_b*?*, where O_a and O_b are two objects. Questions about positional relationship are accompanied with the action: for instance, *A man washes the car. Is the man inside the car?* To avoid bias in answer distribution, the numbers of *yes* and *no* are equal in gold answers. There are 500 questions for size, 500 for height, and 448 for positional relationship.

---

[3] We do not consider ISM (Box) because many new objects we used are unfamiliar to object detection models. Only 17% of the objects are in the object detection classes.

Model	Size		Height		PosRel	
	Acc	F1	Acc	F1	Acc	F1
UnifiedQA	51.3	38.5	58.4	52.8	56.7	48.1
ISM w/ VinVL	**52.4**	**43.8**	**59.4**	**54.3**	**59.8**	**58.7**

Table 6: Performance of answering commonsense questions. Accuracy (%) and macro F1 (%) are reported. PosRel refers to positional relationship.

Models. We use VinVL-base together with our image synthesis model VQGAN+CLIP to answer spatial commonsense questions. The VinVL here is finetuned on the VQA (Goyal et al., 2017) task. It takes images generated from ISM with textual prompts from questions, and predicts the answer based on the question and image together. Note that the VQA training corpus does not contain commonsense reasoning questions.

We choose UnifiedQA (Khashabi et al., 2020) as a text-based QA model for comparison. Based on the pretrained T5 model (Raffel et al., 2019), UnifiedQA is continually trained on various QA tasks, including three yes/no datasets. We use UnifiedQA-large, which is comparable with our synthesis and reasoning model (ISM w/ VinVL) in size.

Results. As shown in Table 6, ISM w/ VinVL outperforms UnifiedQA on all subtasks, showing that spatial knowledge from ISMs can be directly used by vision-language models without additional training. Although some images cannot be precisely recognized by object detection models, vision-language models may find regions that are related to the objects mentioned in questions, and make decisions based on the features of these regions. The results on the simple natural language task show that it is beneficial to tackle natural language tasks with vision-language methods, and ISMs can be *a bridge between the two modalities*. With the development of ISMs and object detection techniques, we believe the generated images will help more.

7 Conclusion

We propose a new spatial commonsense probing framework to investigate object scales and positional relationship knowledge in text-based pretrained models and models with visual signals. Experimental results show that models with visual signals, especially ISMs, learn more accurate and consistent spatial commonsense than text-only models. Integrating ISMs with visual reasoning models outperforms PLMs in answering spatial questions. This manifests the potential of using spatial knowledge from ISMs in natural language understanding tasks.

A Implementation Details

Relation	Definition
X *inside* Y	The entirety of region X overlaps with Y.
X *beside* Y	The angle between the centroid of X and the centroid of Y lies between 315° and 45° or 135° and 225°.
X *above* Y	The angle between X and Y lies between 225° and 315°.
X *below* Y	The angle between X and Y lies between 45° and 135°.

Table 7: Spatial relations between image regions in Visual Dependency Grammar (VDG).

A.1 Spatial Relations in Visual Dependency Grammar

We use the rules defined in Visual Dependency Grammar (Elliott and Keller, 2013) to determine the positional relationship between bounding boxes. The rules used are listed in Table 7. If two bounding boxes meet the *inside* standard, they will be predicted as *inside*. Otherwise, the angle between the centers of the boxes is calculated to determine whether the prediction is *above*, *below*, or *beside*.

A.2 Image Synthesis

We generate images of 512 × 512 pixels with text prompts. We use 1) VQGAN (Esser et al., 2021), which takes in a vector, and outputs a high-resolution image; and 2) CLIP (Radford et al., 2021), which can encode both text and images, and map them into a multi-modal embedding space. Image synthesis is the process of finding the optimal vector $\boldsymbol{v}$ inputted to VQGAN. In each iteration, the vector is fed into VQGAN to generate an image $img = \text{VQGAN}(\boldsymbol{v})$. CLIP encodes the image into $\boldsymbol{c} = \text{CLIP}(img)$, and encodes the text prompt into $\boldsymbol{t} = \text{CLIP}(text)$, respectively.

The optimization goal is to bring $\boldsymbol{c}$ and $\boldsymbol{t}$, the representation of the image and text encoded by CLIP closer. The vector $\boldsymbol{v}$ is randomly initialized and optimized for 600 iterations. We use Adam optimizer with a learning rate of 0.5. This process looks like a normal model "training", but here both VQGAN and CLIP are pretrained and their parameters are frozen; only the vector $\boldsymbol{v}$ is optimized from randomness for every prompt.

A.3 Prompt Candidates Generation

When probing PLMs, we follow Jiang et al. (2020) to generate prompt and answer candidates with back-translation. Manually designed prompts and answers are translated from English to German and then backward. It is used to construct candidates with similar meanings. We leverage the translation model designed in Ng et al. (2019).

Model	**Acc** (avg. / σ)	**F1** (avg. / σ)
BERT	49.0 / 4.11	43.7 / 8.25
RoBERTa	48.9 / 1.71	43.4 / 5.42
VinVL	**60.6** / 1.47	**51.2** / 2.22
Model	**Acc**	**F1**
Best PLM	49.0 (47.5)	43.7 (40.5)
VinVL	**60.6** (60.8)	51.2 (49.8)
ISM (Box)	58.5 (**71.5**)	**58.5** (**71.4**)
Best PLM	49.0 (48.5)	43.7 (43.5)
VinVL	60.6 (65.5)	51.2 (55.7)
ISM (Human)	**72.5** (**76.5**)	**71.8** (**75.7**)

Table 8: Probing performance on RelatizeSize. Accuracy and macro F1 are reported. The numbers are in percentages (%). In the last six lines, the first number is the performance on the whole dataset, and the number in parentheses indicates performance on the subset of instances where the generated images can be recognized by object detection models and humans, respectively. The standard deviation on different folds is represented with σ. Both objects are recognized with bounding boxes in 40% images and are recognized by humans in 85% images.

A.4 Computing Infrastructure

Experiments are conducted on NVIDIA GeForce RTX 3090 GPU. It takes 8 hours to generate 500 images on one GPU, and all other experiments can be executed in a few minutes.

B Probing Results on RelativeSize

RelativeSize (Bagherinezhad et al., 2016) is another dataset for comparing objects' sizes. Table 8 demonstrates the probing results on it. The results are consistent with those on our datasets: ISM probing, both evaluated with bounding boxes and evaluated by humans, outperforms PLM probing.

The methods used in Bagherinezhad et al. (2016) are all retrieval-based. They execute search engine queries and download images from Flickr to make the comparisons. So we do not compare with their results directly. However, it is worth noticing that our ISM probing is comparable to the image retrieval-based baseline (its accuracy is 72.4%). It exhibits that ISM learns sufficient knowledge from images.

Conditional Bilingual Mutual Information Based Adaptive Training for Neural Machine Translation

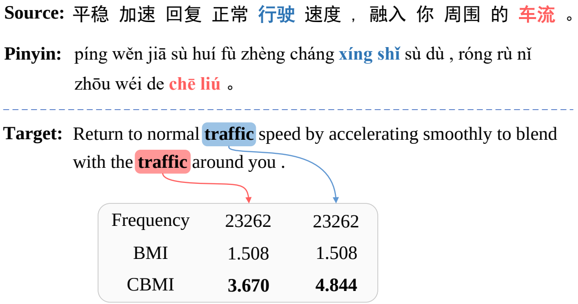
Abstract

Token-level adaptive training approaches can alleviate the token imbalance problem and thus improve neural machine translation, through re-weighting the losses of different target tokens based on specific statistical metrics (*e.g.,* token frequency or mutual information). Given that standard translation models make predictions on the condition of previous target contexts, we argue that the above statistical metrics ignore target context information and may assign inappropriate weights to target tokens. While one possible solution is to directly take target contexts into these statistical metrics, the target-context-aware statistical computing is extremely expensive, and the corresponding storage overhead is unrealistic. To solve the above issues, we propose a target-context-aware metric, named conditional bilingual mutual information (CBMI), which makes it feasible to supplement target context information for statistical metrics. Particularly, our CBMI can be formalized as the log quotient of the translation model probability and language model probability by decomposing the conditional joint distribution. Thus CBMI can be efficiently calculated during model training without any pre-specific statistical calculations and large storage overhead. Furthermore, we propose an effective adaptive training approach based on both the token- and sentence-level CBMI. Experimental results on WMT14 English-German and WMT19 Chinese-English tasks show our approach can significantly outperform the Transformer baseline and other related methods.

1 Introduction

Neural machine translation (NMT) (Bahdanau et al., 2014; Gehring et al., 2017; Vaswani et al., 2017; Meng and Zhang, 2019; Liu et al., 2021a,b) has made remarkable achievements in recent years. Generally, NMT models are trained to maximize the likelihood of the next target token given ground-truth tokens as inputs (Johansen and Juselius, 1990; Goodfellow et al., 2016). Due to the token imbalance phenomenon in natural language (Zipf, 1949), for an NMT model, the learning difficulties of different target tokens may be various. However, the vanilla NMT model equally weights the training losses of different target tokens, irrespective of their difficulties.



Source: 平稳 加速 回复 正常 行驶 速度 ， 融入 你 周围 的 车流 。

Pinyin: píng wěn jiā sù huí fù zhèng cháng **xíng shǐ** sù dù , róng rù nǐ zhōu wéi de **chē liú** 。

Target: Return to normal **traffic** speed by accelerating smoothly to blend with the **traffic** around you .

Frequency	23262	23262
BMI	1.508	1.508
CBMI	**3.670**	**4.844**

Figure 1: An example from the WMT19 Zh-En training set. Despite the different mappings from the source sentence, existing target-context-free metrics (*i.e.,* frequency and BMI) equally assess the two '*traffic*' tokens, while our CBMI can distinguish the different dependencies of the two tokens on the source sentence with the guidance of target contexts.

Recently, various adaptive training approaches (Gu et al., 2020; Xu et al., 2021) have been proposed to alleviate the above problem for NMT. Generally, these approaches re-weight the losses of different target tokens based on specific statistical metrics. For example, Gu et al. (2020) take the token frequency as an indicator and encourage the NMT model to focus more on low-frequency tokens. Xu et al. (2021) further propose the bilingual mutual information (BMI) to measure the word mapping diversity between bilinguals, and down-weight the tokens with relatively lower BMI values.

Despite their achievements, there are still limita-

May 22-27, 2022

tions in these adaptive training approaches. Given that the standard translation model autoregressively makes predictions on the condition of previous target contexts, we argue that the statistical metrics used in the above approaches ignore target context information and may assign inaccurate weights for target tokens. Specifically, although existing statistical metrics can reflect complex characteristics of target tokens (*e.g.,* mapping diversity), they fail to model how these properties vary across different target contexts. Secondly, for the identical target tokens in different positions of a target sentence (*e.g.,* two '*traffic*' tokens in the Figure 1), they may be mapped from different source-side tokens, but such target-context-free metrics cannot distinguish the above different mappings. In summary, it is necessary to incorporate target context information into the above statistical metrics. One possible solution is to directly take target context information into account and conduct target-context-aware statistical calculations. But in this way, the calculation cost and storage overhead will become huge and unrealistic[1]. Therefore, it is non-trivial to design a suitable target-context-aware statistical metric for adaptive training in the field of NMT.

In this paper, we aim to address the above issues in adaptive training methods. Firstly, we propose a novel target-context-aware metric, named **C**onditional **B**ilingual **M**utual **I**nformation (CBMI), to measure the importance of different target tokens by their dependence on the source sentence. Specifically, we calculate CBMI by the mutual information between a target token and its source sentence on the condition of its target contexts. With the aid of target-context-aware calculations, CBMI can easily model the various characteristics of target tokens under different target contexts, and of course can distinguish identical target tokens with different source mappings. Regarding the computational efficiency, through decomposing the conditional joint distribution in the aforementioned mutual information, our CBMI can be formalized as the log quotient of the translation model probability and language model probability[2]. Therefore, CBMI can be efficiently calculated during model training without any pre-specific statistical calculations and huge storage overhead, which makes it feasible to supplement target context information for statistical metrics. Subsequently, we design an adaptive training approach based on both the token- and sentence-level CBMI, which dynamically re-weights the training losses of the corresponding target tokens.

We evaluate our approach on the WMT14 English-German and WMT19 Chinese-English translation tasks. Experimental results on both datasets demonstrate that our approach can significantly outperform the Transformer baseline and other adaptive training methods. Further analyses reveal that CBMI can also reflect the adequacy of translation, and our CBMI-based adaptive training can improve translation adequacy meanwhile maintain fluency. The main contributions of this paper can be summarized as follows:

- We propose a novel target-context-aware metric, named CBMI, which can reflect the importance of target tokens for NMT models. Theoretical analysis and experimental results show that CBMI is computationally efficient, which makes it feasible to complement target context information in statistical metrics.
- We further propose an adaptive training approach based on both the token- and sentence-level CMBI, which dynamically re-weights the training losses of target tokens.
- Further analyses show that CBMI can also reflect the adequacy of translation, and CBMI-based adaptive training can improve translation adequacy meanwhile maintain fluency[3].

2 Background

2.1 Neural Machine Translation

An NMT model is designed to translate a source sentence with M tokens $\mathbf{x} = \{x_1, x_2, \ldots, x_M\}$ into a target sentence with N tokens $\mathbf{y} = \{y_1, y_2, \ldots, y_N\}$ by predicting the probability of each target token:

$$P(\mathbf{y}|\mathbf{x};\theta) = \prod_{j=1}^{N} p(y_j|\mathbf{y}_{<j}, \mathbf{x};\theta) \qquad (1)$$

where j is the index of each time step, $\mathbf{y}_{<j}$ is the target-side previous context for y_j, and θ is the model parameter.

---

[1] Take the vanilla BMI (Xu et al., 2021) as an example, to process the raw WMT14 En-De training data (about 1.5GB), it takes about 12 CPU hours and 2GB disk storage to save the BMI values. To make matters worse, the cost will increase dozens of times in target-context-aware statistical calculations.

[2] The detailed derivation process is shown in Equation (7). Please note that the language model is only used during training and thus does not affect the inference speed.

[3] The code is publicly available at: `https://github.com/songmzhang/CBMI`.

During training, NMT models are generally optimized with the cross-entropy (CE) loss:

$$\mathcal{L}_{\text{CE}}(\theta) = -\sum_{j=1}^{N} \log p(y_j|\mathbf{y}_{<j}, \mathbf{x}; \theta) \tag{2}$$

During inference, NMT models predict the probabilities of target tokens in an auto-regressive mode and generate hypotheses using heuristic search algorithms like beam search (Reddy, 1977).

2.2 Token-level Adaptive Training for NMT

Token-level adaptive training aims to alleviate the token imbalance problem for NMT models by re-weighting the training losses of target tokens. How to design a suitable weight adjustment strategy matters, which is we aim to improve in this paper. Formally, for the j-th target token and its adaptive weight w_j, the standard cross-entropy loss in Equation (2) is expanded to the following formula:

$$\mathcal{L}_{\text{ada}}(\theta) = -\sum_{j=1}^{N} w_j \log p(y_j|\mathbf{y}_{<j}, \mathbf{x}; \theta) \tag{3}$$

2.3 Mutual Information for NMT

Mutual information (MI) is a general metric in information theory (Shannon, 1948), which measures the mutual dependence between two random variables a and b as follows[4]:

$$\text{MI}(a; b) = \log\left(\frac{p(a, b)}{p(a) \cdot p(b)}\right) \tag{4}$$

Xu et al. (2021) propose token-level bilingual mutual information (BMI) to measure the word mapping diversity between bilinguals and further conduct BMI-based adaptive training for NMT. The BMI is formulated as:

$$\text{BMI}(\mathbf{x}; y_j) = \sum_{i=1}^{|\mathbf{x}|} \log\left(\frac{f(x_i, y_j)}{f(x_i) \cdot f(y_j)}\right) \tag{5}$$

where $f(\cdot)$ is an word frequency counter. Although BMI can reflect the bilingual mapping properties to some extent, it cannot correspondingly vary with the target context. However, simply introducing target-context-aware calculations into BMI would make the above statistical calculations unrealistic.

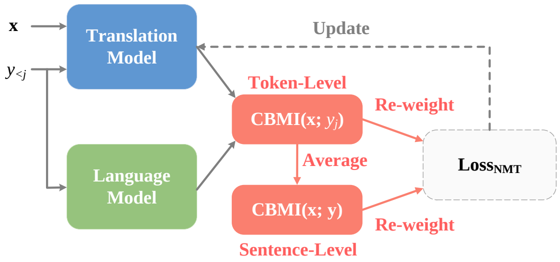

Figure 2: Overview of the training process of our method. For the target token y_j, we calculate its token-level CBMI by the translation model and the language model, and average all the token-level CBMI values in a sentence into the sentence-level CBMI. Then the two CBMI values with different granularities are combined to form the final training loss weight of the token y_j.

3 Approaches

In this section, we first introduce the definition of CBMI (Section 3.1). Then, we illustrate how to adjust the weights for the training losses of target tokens based on the token- and the sentence-level CBMI (Section 3.2). Figure 2 shows the overall training process of our approach.

3.1 Definition of CBMI

As mentioned above, it is necessary to incorporate target context information into the statistical metrics (*e.g.,* BMI) for adaptive training. However, it is impractical to directly conduct target-context-aware statistical computations due to the expensive computational costs and storage overhead. In this paper, we propose a new target-context-aware metric, named conditional bilingual mutual information (CBMI), to solve the above issues. Specifically, CBMI is calculated by the mutual information between each target token and its source sentence under the condition of previous target context. Formally, the CBMI of a target token y_j and its source sentence $\mathbf{x}$ is calculated as follow:

$$\begin{aligned}\text{CBMI}(\mathbf{x}; y_j) &= \text{MI}\left(\mathbf{x}; y_j|\mathbf{y}_{<j}\right) \\ &= \log\left(\frac{p(y_j, \mathbf{x}|\mathbf{y}_{<j})}{p(y_j|\mathbf{y}_{<j}) \cdot p(\mathbf{x}|\mathbf{y}_{<j})}\right)\end{aligned} \tag{6}$$

The original CBMI definition presented in the above equation still struggles in computation, thus we further simplify it by decomposing the condi-

---

[4] We use the point-wise MI here instead of the original expectation form, since we aim to calculate the mutual information between individual samples in this paper.

tional joint distribution:

$$
\begin{aligned}
\mathrm{CBMI}(\mathbf{x}; y_j) &= \log\left(\frac{p(y_j, \mathbf{x}|\mathbf{y}_{<j})}{p(y_j|\mathbf{y}_{<j}) \cdot p(\mathbf{x}|\mathbf{y}_{<j})}\right) \\
&= \log\left(\frac{p(y_j|\mathbf{x}, \mathbf{y}_{<j}) \cdot p(\mathbf{x}|\mathbf{y}_{<j})}{p(y_j|\mathbf{y}_{<j}) \cdot p(\mathbf{x}|\mathbf{y}_{<j})}\right) \\
&= \log\left(\frac{p(y_j|\mathbf{x}, \mathbf{y}_{<j})}{p(y_j|\mathbf{y}_{<j})}\right) \\
&= \log\left(\frac{p_{\mathrm{NMT}}(y_j)}{p_{\mathrm{LM}}(y_j)}\right)
\end{aligned}
\tag{7}
$$

where $p_{\mathrm{NMT}}(y_j)$ is the probability output by the NMT model, and $p_{\mathrm{LM}}(y_j)$ is the probability output by an additional target-side language model (LM). In this way, we formalize the complex target-context-aware calculation in Equation (6) as the log quotient of the NMT probability and LM probability. Based on the simplified Equation (7), CBMI can be computed in real time during the model training, thus enabling both target-context-aware and efficient computations. Considering the massive computation required by existing methods to perform the target-context-aware calculation, the LM in our CBMI only brings a modest computational cost in training and finally leads to better performance. We will give a detailed comparison of the calculation cost and storage overhead between our CBMI and existing approaches in Section 5.2.

3.2 CBMI-based Weight Adjustment

According to the definition, CBMI measures the mutual dependence between a target token and its corresponding source sentence on the condition of its context. Namely, target tokens with larger CBMI value rely more on the source-side information and less on the target historical translations, which is exactly in line with the goal of the adequacy translation model. Given that current NMT models tend to generate fluent but inadequate translations (Weng et al., 2020; Miao et al., 2021), we speculate that making the NMT models pay more attention to target tokens with larger CBMI values can improve translation adequacy and thus improve translation performance. Furthermore, we observe a phenomenon that if target sentences contain many words with small CBMI values, they generally do not match well with the corresponding source sentences. To alleviate the negative effect of these poorly matched sentence pairs, we average all the token-level CBMI values in a target sentence into a sentence-level CBMI and incorporate it into our approach. Consequently, we propose to dynamically adjust the training weight of each target token based on both the token- and sentence-level CBMI. For clarity, we use t to mark the 'token-level' intermediate variables and s to mark the 'sentence-level' ones in the following formulas.

Token-Level CBMI. The token-level CBMI can reflect the importance of target tokens for improving translation adequacy (*i.e.*, dependency of the source side information). Thus we amplify the weights of target tokens with larger token-level CBMI to make the NMT model pay more attention to them. Particularly, to reduce the variances and stabilize the distribution of the token-level CBMI in each target sentence, we firstly conduct intra-sentence normalization for the token-level CBMI $\mathrm{CBMI}^t(\mathbf{x}; y_j)$:

$$
\mathrm{CBMI}^t_{norm}(\mathbf{x}; y_j) = (\mathrm{CBMI}^t(\mathbf{x}; y_j) - \mu^t)/\sigma^t \tag{8}
$$

where μ^t, σ^t represent the mean values and the standard deviations of $\mathrm{CBMI}^t(\mathbf{x}; y_j)$ in each target sentence.

Then we scale the normalized CBMI value $\mathrm{CBMI}^t_{norm}(\mathbf{x}; y_j)$ to obtain the token-level training weight for y_j:

$$
w^t_j = \max\{0, scale^t \cdot \mathrm{CBMI}^t_{norm}(\mathbf{x}; y_j) + 1\} \tag{9}
$$

where $scale^t$ is a hyperparameter that controls the effect of $\mathrm{CBMI}^t_{norm}(\mathbf{x}; y_j)$.

Sentence-level CBMI. We average all the token-level CBMI values in a target sentence to form the sentence-level CBMI, which can further reflect the matching degree between the bilingual sentences in a sentence pair. To alleviate the negative effect of poorly matched sentence pairs and encourage the NMT model focus on well-matched sentences pairs, we up-weight the sentence pairs with larger sentence-level CBMI values and down-weight those sentence pairs with smaller sentence-level CBMI values. Specifically, the sentence-level CBMI between the source sentence $\mathbf{x}$ and the target sentence $\mathbf{y}$ can be derived from Equation (4) and represented as the arithmetic average of token-level CBMI values[5]:

---

[5] We divide the original sentence CBMI with its corresponding sentence length to reduce its variance.

$$\begin{aligned}\mathrm{CBMI}^s(\mathbf{x};\mathbf{y}) &= \frac{1}{|\mathbf{y}|}\log\left(\frac{p(\mathbf{x},\mathbf{y})}{p(\mathbf{x})\cdot p(\mathbf{y})}\right)\\ &= \frac{1}{|\mathbf{y}|}\log\left(\frac{p(\mathbf{y}|\mathbf{x})}{p(\mathbf{y})}\right)\\ &= \frac{1}{|\mathbf{y}|}\log\left(\frac{\prod_j p(y_j|\mathbf{x},\mathbf{y}_{<j})}{\prod_j p(y_j|\mathbf{y}_{<j})}\right)\\ &= \frac{1}{|\mathbf{y}|}\sum_j\log\left(\frac{p(y_j|\mathbf{x},\mathbf{y}_{<j})}{p(y_j|\mathbf{y}_{<j})}\right)\\ &= \frac{1}{|\mathbf{y}|}\sum_j \mathrm{CBMI}^t(\mathbf{x};y_j)\end{aligned} \tag{10}$$

Similarly, we conduct inter-sentence normalization for $\mathrm{CBMI}^s(\mathbf{x};\mathbf{y})$:

$$\mathrm{CBMI}^s_{norm}(\mathbf{x};\mathbf{y}) = (\mathrm{CBMI}^s(\mathbf{x};\mathbf{y}) - \mu^s)/\sigma^s \tag{11}$$

where μ^s, σ^s represent the mean values and the standard deviations of $\mathrm{CBMI}^s(\mathbf{x};\mathbf{y})$ in each mini-batch during training.

Subsequently, we also scale $\mathrm{CBMI}^s_{norm}(\mathbf{x};\mathbf{y})$ in Equation (11) with another hyperparameter $scale^s$ to obtain the sentence-level training weight:

$$w^s = \max\{0, scale^s \cdot \mathrm{CBMI}^s_{norm}(\mathbf{x};\mathbf{y}) + 1\} \tag{12}$$

Final Loss Weight. In our adaptive training approach, for the target token y_j, its final loss weight w_j in Equation (3) is the multiplication of the above two weights in Equation (9) and (12):

$$w_j = w^t_j \cdot w^s \tag{13}$$

4 Experiments

4.1 Datasets

We conduct experiments on two large-scale WMT tasks, *i.e.,* the WMT14 English to German (En-De) and WMT19 Chinese to English (Zh-En). For the En-De task, the training set contains 4.5M sentence pairs. The validation set and test set are newstest2013 and newstest2014, respectively. For the Zh-En task, the training set totally contains 20M sentence pairs and the validation set and test set are newstest2018 and newstest2019, respectively. Following previous work, we share the vocabulary for the En-De task and segment words into subwords using byte pair encoding (BPE) (Sennrich et al., 2016) with 32k merge operations for both datasets.

4.2 Implementation Details

Training. We implement baselines and our approach under $\text{Transformer}_{base}$ and Transformer_{big} settings based on the open-source toolkit fairseq (Ott et al., 2019) with mixed precision (Ott et al., 2018). We train all the translation models with the cross-entropy loss for 100k steps, and further finetune them with different adaptive training objectives for another 200k steps on both tasks. The target-side language model is a Transformer decoder without the cross-attention modules, which is trained synchronously with the translation model. The training data for the language model is the target-side monolingual data from the NMT training set. All the experiments are conducted on 8 NVIDIA Tesla V100 GPUs, and each batch on each GPU contains approximately 4096 tokens. We use Adam optimizer (Kingma and Ba, 2014) with 4000 warmup steps to optimize models. More training details are listed in Appendix B.

In our experiments, we have not been able to bring further improvement to our approach through simply enhancing the language model. Our conjecture is that stronger language models will generate sharper distribution, and will increase the variances of CBMI values when used as the denominator, resulting in detriment for NMT model training. We will leave this for the future work.

Evaluation. During inference, we set beam size to 4 and length penalty to 0.6 for both tasks. We use *multibleu.perl* to calculate case-sensitive BLEU for WMT14 En-De and *SacreBLEU*[6] to calculate case-sensitive BLEU for WMT19 Zh-En. We use the paired bootstrap resampling methods (Koehn, 2004) for the statistical significance test.

4.3 Hyperparameter Experiments.

In this section, we introduce the hyperparameter settings of our approach according to the performance on the validation set of the WMT14 En-De dataset, and we share the same hyperparameter settings with the WMT19 Zh-En dataset.

Scale Setting. The two hyperparameter $scale^t$ and $scale^s$ in Equation (9) and Equation (12) determine the effects of token-level and sentence-level CBMI. To investigate the effects of the two CBMI in different granularities, we firstly fix $scale^t$ to a moderate value, *i.e.*, 0.1, and tune $scale^s$ from 0.0 to 0.3 with the step of 0.05. The detailed results are shown in Figure 3. We observe that models perform better with larger $scale^s$, which conforms with our conjecture in Section 3.2 that well-matched sentence pairs contribute more to NMT models. Then

Table 1: BLEU scores (%) on two translation tasks. Each experiment runs over 3 times and we list the mean values and improvements in this table (full results including standard deviations are shown in Appendix A). '†' represents the results taken from the corresponding papers. Results with mark $*/**$ are statistically (Koehn, 2004) better than the most related method 'BMI-Adaptive' with $p < 0.05$ and $p < 0.01$.

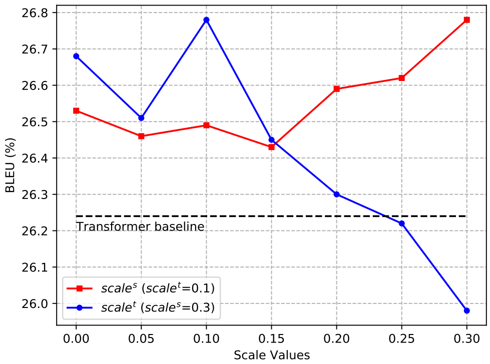

Figure 3: BLEU scores (%) on the validation set of WMT14 En-De with different $scale^t$ and $scale^s$ that defined in the Equation (9) and (12).

we fix $scale^s$ to 0.3 and tune $scale^t$ in a similar way. We find it better to keep $scale^t$ in a small range and too large value is harmful for models. We conjecture that over-focus on the high-CBMI tokens brings another imbalance for training and may hurt the models. Thus we set $scale^t$ to 0.1 in our following experiments.

4.4 Baseline Systems

We implement our approach based on the Transformer (Vaswani et al., 2017) and compare it with some mainstream adaptive training methods (detailed hyperparameter settings are provided in Appendix C).

Transformer. We follow the standard base/big model configurations (Vaswani et al., 2017) to implement our baseline systems.

Freq-Exponential. Gu et al. (2020) use monolingual token frequency to design an exponential weight function for token-level adaptive training:

$$w_j = A \cdot e^{-T \cdot Count(y_j)} + 1$$

where A and T are two hyperparameters to adjusting the distribution of weights.

Freq-Chi-Square. Gu et al. (2020) use the chi-square distribution to filter out extremely low frequency target tokens:

$$w_j = A \cdot Count(y_j)^2 e^{-T \cdot Count(y_j)} + 1$$

where A and T play the same roles as above.

BMI-adaptive. Xu et al. (2021) calculate BMI (in Equation (5)) during the data pre-processing stage and scale it for adaptive loss weights.

$$w_j = S \cdot \mathrm{BMI}(\mathbf{x}, y_j) + B \tag{14}$$

where S and B are hyperparameters to scale BMI to an appropriate range.

Focal Loss. Lin et al. (2017) propose the focal loss for objective detection tasks to solve the class imbalance problem. Here we introduce it into NMT.

$$\mathcal{L}_{fl} = -(1 - \alpha p)^{\gamma} \log p \tag{15}$$

where α and γ are hyperparameters to adjust the loss weight and p is the NMT predicted probability.

Anti-Focal Loss. Raunak et al. (2020) design an anti-focal loss function to solve the long-tailed problem in NMT by incorporating the inductive bias of inference into training.

$$\mathcal{L}_{afl} = -(1 + \alpha p)^{\gamma} \log p \tag{16}$$

where α and γ are similarly as the above focal loss.

Self-Paced Learning. Wan et al. (2020) calculate model confidence via Monte Carlo dropout sampling (Gal and Ghahramani, 2016) to measure the token difficulty and use it to re-weight the training losses of tokens.

Simple Fusion. Stahlberg et al. (2018) propose two simple strategies (i.e., PRENORM and POSTNORM) to fuse the NMT probabilities with the LM probablities and directly optimize the fusion during the NMT training process[7].

LM Prior. Baziotis et al. (2020) propose to distill the prior knowledge from LMs trained on rich-resource monolingual data to low-resource NMT models[8]:

$$\mathcal{L}_{lmp} = \mathcal{L}_{\mathrm{NMT}} + \lambda \cdot \mathcal{L}_{\mathrm{KL}}(p_{\mathrm{LM}} || p_{\mathrm{NMT}}; \tau) \tag{17}$$

where λ weights the distillation term and τ is the softmax temperature (Hinton et al., 2015).

4.5 Results

The overall results on two WMT tasks based on the Transformer$_{base}$ and Transformer$_{big}$ configurations are shown in Table 1. Under the Transformer$_{base}$ setting, CBMI-based adaptive training can respectively improve +0.91 and +0.85 BLEU scores on En-De and Zh-En tasks compared to the Transformer baseline. Compared to the most related yet target-context-free strategy 'BMI-adaptive', our CBMI-based adaptive training strategy can respectively yield significant improvements up to +0.46 and +0.44 BLEU scores on En-De and Zh-En, which demonstrate the significance of the target context for token assessment in token-level adaptive training. Compared with the best performing baseline 'Self-Paced Learning', our approach still outperforms it by +0.32 and +0.46 BLEU scores on the two tasks. Our conjecture is that CBMI not only reflects the model competence used in 'Self-Paced Learning' but also further incorporates the linguistic statistical information from the target-side LM, thus reflects more explicit translation property (*i.e.,* adequacy). However, other LM enhanced methods (*e.g.,* 'Simple Fusion' and 'LM Prior') bring limited improvement or even degradation to the NMT models when there is no extra data for the LMs, which further proves the utilization of the LM in our approach is more effective. Under the Transformer$_{big}$ setting, where the performances of existing methods are limited, our method can still bring the improvement of +0.81 and +0.82 BLEU scores on the En-De and Zh-En, which demonstrates the superiority of CBMI under stronger baselines.

5 Analysis

In this section, we provide in-depth analyses on the effectiveness of our CBMI and conduct experiments on the validation set of WMT14 En-De with the Transformer$_{base}$ model.

5.1 Effects of Different Levels of CBMI

We take the Transformer$_{base}$ as baseline, and then apply adaptive training based on the token-level CBMI, the sentence-level CBMI, and both of them, respectively. Results are listed in Table 2. We observe certain improvements (+0.29 and +0.44 BLEU scores) when separately applying the token- and sentence-level CBMI based approaches. It suggests that our CBMI can measure the token importance from different granularities, and up-weight

---

[7] The results in Table 1 are the higher ones between the two strategies.

[8] We did not use extra monolingual data for the LMs in 'Simple Fusion' and 'LM Prior' in our implementation for fair comparison.

Model	BLEU
Transformer$_{base}$	26.24
+ token-level CBMI	26.53 (+0.29)
+ sentence-level CBMI	26.68 (+0.44)
+ token- & sentence-level CBMI	**26.78 (+0.54)**

Table 2: BLEU scores (%) of CBMI at different granularities on the validation set of WMT14 En-De.

Method	Pre-process (hour)	#Params (M)	Train (hour)	Disk (GB)
Transformer$_{base}$	0	65	10	0
+ BMI	12	65	11	2.0
+ target context	$\approx 12\times$N	65	–	$\approx 2.0\times$N
+ CBMI	0	101	12	0

Table 3: The costs of calculation and storage of the BMI- and CBMI-based approaches on the WMT14 En-De (100k training steps). 'N' refers to the average length of target sentences.

Model	Adequacy	Fluency	Avg.
Transformer$_{base}$	4.25	4.69	4.47
+ CBMI-adaptive	**4.53***	**4.75**	**4.64**

Table 4: Human evaluation on adequacy and fluency. $*$ means the average Cohen's Kappa (Cohen, 1960) is higher than 0.6, which indicates substantial agreement between three annotators (Landis and Koch, 1977).

the important tokens or sentence pairs can improve translation quality. Furthermore, the combination of both the token- and sentence-level CBMI brings further improvement (+0.55 BLEU scores), which illustrates that the CBMI in different granularities are complementary and have cumulative gains.

5.2 Costs of Computing and Storage

In this section, we compare our CBMI-based approach with the BMI-based adaptive training in terms of the number of trainable parameters, the CPU computational costs of pre-processing, the GPU computational costs of training, and disk cost for storing intermediate variables. As shown in Table 3, the vanilla BMI-based approach requires additional 12 CPU hours to obtain the BMI values during the pre-processing stage, and about 2.0 GB of disk space to store these BMI values. To make matters worse, the costs of CPU calculation and disk storage will increase dozens of times (approximately equal to the average length of target sentences) when conducting the target-context-aware calculations for BMI. In contrast, our CBMI-based approach gets rid of the CPU computational costs, and thus has no additional storage overhead. Although we introduce an additional LM to calculate the CBMI values, it only brings a slight increase of model parameters and GPU calculation cost during model training. Particularly, our proposed method simply modifies the training loss of NMT, and thus has no effect on the inference speed. In short, our CBMI can be efficiently calculated during model training without any pre-specific statistical calculations and storage overhead, which makes it feasible to supplement target context information for statistical metrics.

5.3 Human Evaluation

To verify whether our CBMI measurement is indeed highly related to the translation adequacy of NMT models, as we conjectured in Section 3.2, we conduct the human evaluation in terms of adequacy and fluency. We randomly sample 100 sentences from the test set of WMT19 Zh-En and invite three annotators to evaluate the translation adequacy and fluency. Scores for both indexes are limited in [1,5]. For adequacy, '1' represents irrelevant to the source sentence and '5' represents semantically equal. For fluency, '1' means unintelligible and '5' means fluent and native. We finally average the scores from three annotators and list the results in Table 4. We observe that our approach significantly promotes the translation adequacy of the Transformer$_{base}$ baseline, and meanwhile slightly promotes the translation fluency. It indicates that the CBMI measurement is highly related to the adequacy of NMT models, and focusing more on the tokens with high CBMI can improve translation adequacy, and thus improve translation performance.

5.4 Prior Selection based on CBMI

Given that CBMI reflects the dependency between a target token and its source sentence on the condition of its target context, in this section, we explore whether CBMI can serve as an indicator for selecting an appropriate prior distribution to improve the NMT model. Prior distributions have been proved for their ability to provide additional knowledge for models (Baziotis et al., 2020; Li et al., 2020). Thus we try three generated distributions as prior distributions for NMT models, *i.e.*, the translation model distribution (TM prior), the language model distribution (LM prior), and the softmax normalized CBMI distribution (CBMI prior).

To verify the correctness of these prior distributions, we firstly calculate the top-1 accuracies of

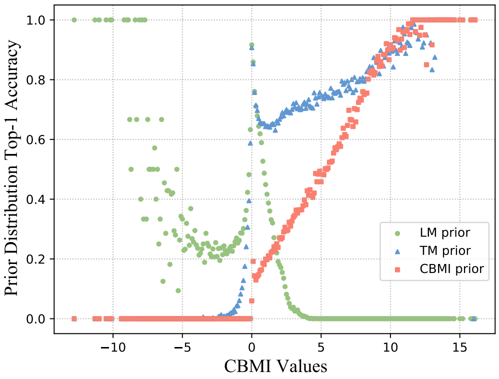

Figure 4: The most accurate prior distribution for tokens with different CBMI values. The LM prior (green circles) performs most accurate for tokens with lower CBMI values, the TM prior (blue triangles) performs best for tokens with moderate CBMI values, and the CBMI prior (red squares) performs best for tokens with higher CBMI values.

Prior Distribution	**BLEU**
$\text{Transformer}_{base}$	26.24
+ LM Prior	26.73 (+0.49)
+ TM Prior	26.61 (+0.37)
+ CBMI Prior	26.57 (+0.33)
+ Prior Selection	**26.75 (+0.51)**

Table 5: BLEU scores (%) on WMT14 En-De validation set for different prior distributions on all tokens.

these distributions according to different tokens and surprisingly observe that the accuracies are highly related to the CBMI values of tokens. As shown in Figure 4, the most accurate prior for target tokens with different CBMI values is not always consistent. Based on this observation, we further design a CBMI-based prior selection strategy to choose the best prior distribution for each token. The details of the selection strategy are seen in Appendix D.

As shown in Table 5, all these prior distributions can provide helpful guidance and enhance the baseline model. More importantly, the CBMI-based prior selection strategy can achieve a better performance compared with the single prior, demonstrating that CBMI also serves as an appropriate indicator for the translation prior selection. We will explore the more sophisticated CBMI-based prior selection strategy in the future work.

6 Related Work

Language Model Enhanced NMT. Exploiting the information in language models is a common solution to improve NMT models. In low-resource scenarios, LMs trained on extra monolingual data are usually more informative and thus used to fuse with NMT prediction (Gulcehre et al., 2015, 2017; Sriram et al., 2017; Stahlberg et al., 2018), provide prior knowledge for NMT models (Baziotis et al., 2020) and enhance representations of NMT (Clinchant et al., 2019; Zhu et al., 2020). In data augmentation methods, LMs are also widely used to generate contextual substitutions of words in sentences (Kobayashi, 2018; Wu et al., 2018; Gao et al., 2019). Differently, all the aforementioned methods rely on the LMs that are trained on extra data, while the LM in our method does not require extra data and also has no influence on the inference speed.

7 Conclusion

In this paper, we propose a target-context-aware metric for target tokens, named conditional bilingual mutual information (CBMI). Compared with previous statistical metrics, our CBMI only increases limited computational costs to incorporate the target context and provides a more suitable assessment for tokens. Furthermore, based on the token- and sentence-level CBMI, we design a CBMI-based adaptive training strategy to amply the contributions of the important tokens. Experimental results on two WMT tasks demonstrate the effectiveness of our proposed approach. Further analyses show that CBMI can improve translation adequacy and serve as an appropriate indicator for the translation prior selection.

A Complete Results

To prove the generality of the experimental results, we provide the complete results on two translation tasks which contain mean values and standard deviations in Table 6.

B Training Hyperparameters and Model Configurations

To assure the reproducibility of our experimental results, we provide the training details of our method and the model configurations in Table 7. The NMT models and LMs in our method use the same corpus and BPE vocabulary, so that they can generate two corresponding probability distributions for the same token and calculate its CBMI during training. Our LMs have the same model architecture and configuration with the NMT models' decoder except for the cross-attention module, yet we do not share their embedding layers for higher performance.

C Implementation Details for Baseline Systems

To make our experimental comparison more convincing, we present the details of hyperparameters involved in the baseline systems described in Section 4.4.

Freq-Exponential. Following the best hyperparameter setting in (Gu et al., 2020), we set A to 1.0 and T to 1.75 for the En-De task, and A to 1.0 and T to 0.35 for the Zh-En task.

Freq-Chi-Square. Similarly, we set A to 1.0 and T to 2.50 for the En-De task, and A to 1.0 and T to 1.75 for the Zh-En task according to (Gu et al., 2020).

BMI-adaptive. According to the settings in (Xu et al., 2021), we set S to 0.15 and B to 0.8 for the En-De task and S to 0.1 and B to 1.0 for the Zh-En task.

Focal Loss. As suggested in (Lin et al., 2017), we fix γ to 1.0 and search a α among [0.1, 0.5] which performs best on the validation sets of two tasks. Finally, we set α to 0.1 for both tasks.

Anti-Focal Loss. Similar with the settings in focal loss, we also fix γ to 1.0 and tune α for two tasks. Lastly, we also set α to 0.1 for both tasks.

LM Prior. We set the softmax temperature τ to 2.0 following the settings in (Baziotis et al., 2020) while λ to 0.1 according to the performances on the validation sets.

D Details for the Prior Selection Strategy

In our prior selection strategy, we firstly divide the target tokens in each mini-batch into three intervals according to their original CBMI values. Corresponding to the observation in Figure 4, we respectively apply the LM prior, the TM prior and

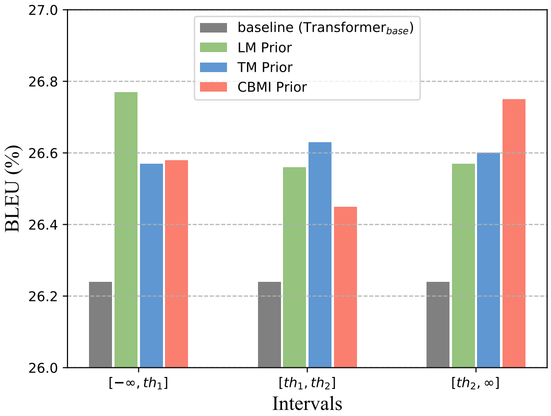

Figure 5: BLEU scores on the validation set of WMT14 En-De for different prior distributions on different CBMI intervals.

the CBMI prior on the tokens in the three intervals. Formally, the prior distribution $q(y_j)$ for target token y_j can be represented as follows:

$$q(y_j) = \begin{cases} q_{\text{LM}}, & \text{CBMI}(\mathbf{x}; y_j) \in [-\infty, th_1] \\ q_{\text{TM}}, & \text{CBMI}(\mathbf{x}; y_j) \in [th_1, th_2] \\ q_{\text{CBMI}}, & \text{CBMI}(\mathbf{x}; y_j) \in [th_2, \infty] \end{cases} \tag{18}$$

where th_1 and th_2 are two hyperparameters and empirically set to 0 and 8 according to the observations in Figure 4. q_{LM}, q_{TM}, q_{CBMI} represent the aforementioned three prior distributions.

Subsequently, we calculate the cross-entropy loss between the selected prior distribution and the model predicted distribution as an additional term and incorporate it with the original cross-entropy loss in Equation (2) to make up the new training objective:

$$\begin{aligned} \mathcal{L}(\theta) = & \mathcal{L}_{\text{CE}}(\theta) \\ & + \lambda \cdot \sum_{y=1}^{|\mathbf{y}|} -q(y_j) \log p(y_j | \mathbf{y}_{<j}, \mathbf{x}; \theta) \end{aligned} \tag{19}$$

where λ is a hyperparameter that controls the effect of prior distribution. In our experiments, we set λ to 0.1 according to the performances on the validation set.

To verify the reasonablility of the prior selection strategy, we compare the effects of the three priors on each single CBMI intervals in Figure 5. As we expected, the BLEU results also conform with the accuracy results in Figure 4, indicating that the most helpful prior distribution can be highly related to the CBMI values of tokens.

ClusterFormer: Neural Clustering Attention for Efficient and Effective Transformer

Abstract

Recently, a lot of research has been carried out to improve the efficiency of Transformer. Among them, the sparse pattern-based method is an important branch of efficient Transformers. However, some existing sparse methods usually use fixed patterns to select words, without considering similarities between words. Other sparse methods use clustering patterns to select words, but the clustering process is separate from the training process of the target task, which causes a decrease in effectiveness. To address these limitations, we design a neural clustering method, which can be seamlessly integrated into the Self-Attention Mechanism in Transformer. The clustering task and the target task are jointly trained and optimized to benefit each other, leading to significant effectiveness improvement. In addition, our method groups the words with strong dependencies into the same cluster and performs the attention mechanism for each cluster independently, which improves the efficiency. We verified our method on machine translation, text classification, natural language inference, and text matching tasks. Experimental results show that our method outperforms two typical sparse attention methods, Reformer and Routing Transformer while having a comparable or even better time and memory efficiency.

1 Introduction

Transformer (Vaswani et al., 2017) has been widely used and achieved state-of-the-art results in a variety of NLP tasks such as neural machine translation (Bahdanau et al., 2015), text classification, etc. Its good effectiveness benefits from its core component Self-Attention Mechanism which can capture global dependencies well. However, the large calculation and memory cost limit the further application of Transformer on long sequence tasks due to the complexity of $O(N^2d)$ of Self-Attention. As a result, many research works have been carried out to improve the efficiency of Transformer (Tay et al., 2020b). These efficient Transformers can be roughly divided into two categories: approximation-based (Tay et al., 2020a; Katharopoulos et al., 2020) and sparse pattern-based methods (Qiu et al., 2020; Ho et al., 2019; Beltagy et al., 2020; Liu et al., 2018).

Regarding approximation-based methods, some works are based on low-rank approximation (Tay et al., 2020a; Wang et al., 2020) while others are based on kernels (Katharopoulos et al., 2020; Choromanski et al., 2020). Specifically, Linformer (Wang et al., 2020) adopts a low-rank approximation idea and projects the length dimension of keys and values to a lower dimension ($N \to k$). This reduces the complexity to $O(Nkd)$. However, the projection matrix in this method requires that all input sequences must be filled to the same length N, which makes it cannot handle the variable-length sequence well. Linear Transformer (Katharopoulos et al., 2020) uses kernels and the associative property of matrix multiplication to linearize the softmax attention, which reduces the complexity to $O(Nd^2)$. However, the approximation error to the softmax matrix in Self-Attention can be large in some cases (Xiong et al., 2021).

Sparse pattern-based methods introduce *sparse patterns* into the attention mechanism and limit the number of key vectors that the query vector should pay attention to. Prior work (Child et al., 2019; Qiu et al., 2020; Ho et al., 2019; Beltagy et al., 2020; Liu et al., 2018) proposed to use *fixed* sparse patterns to improve the efficiency of Self-Attention. For example, Sparse Transformer (Child et al., 2019) restricts the query to focus only on keys that are nearby or at fixed intervals. Such fixed sparse patterns do not consider the similarity between the query and different keys, and directly filter keys according to their location, which re-

Volume 1: Long Papers, pages 2390 - 2402

sults in a degradation of the model effectiveness. More recently, the *clustering* sparse patterns are proposed. Reformer (Kitaev et al., 2020) and Routing Transformer (Roy et al., 2021) use Locality Sensitive Hashing (LSH) and K-Means algorithms, respectively, to divide the words in the sequence into different clusters, and then the attention operation is restricted within each cluster independently. In this way, they reduce the complexity to $O(N \log Nd)$ and $O(N\sqrt{N}d)$, respectively. However, in Reformer and Routing Transformer, both LSH and K-Means only play the role of cluster partitioning, but run separately from the attention network training. In addition, these two methods also have the problem of inconsistency in the similarity measure between the clustering and attention operation. LSH and K-Means respectively use the hash value obtained by random projections and the negative Euclidean distance as the similarity measure between the input vectors while the attention operations use the inner product. Therefore, such a sparse pattern idea often results in the reduced effectiveness.

To address the reduced effectiveness issue of many efficient Transformers, especially sparse pattern-based methods, we propose Neural Clustering Method to learn the sparse pattern of the Attention. It can be seamlessly integrated into neural networks for joint training and optimization. In our method, the cluster center (centroid) is updated by a weighted sum of all word hidden states. At the same time, the members of clusters are divided according to the subordinate matrix of the centroids and word hidden states. The optimization of the clustering loss can guide the representation of word hidden states while learning cluster centroids. The integration of the neural clustering method and attention training enables our Neural Clustering Attention to perform better than previous clustering-based sparse attention mechanisms. Our Neural Clustering Method is a general clustering method, in the sense that in addition to being integrated into the network of the specific task, it is can handle clustering tasks alone.

Our overall model is called ClusterFormer and it is obtained by replacing the Self-Attention Mechanism in Transformer with Neural Clustering Attention Mechanism. In order to validate the benefits of ClusterFormer, we have carried out comparison experiments of the efficiency and effectiveness respectively. For efficiency, we provide a detailed analysis about the time and memory on dataset 20NEWS of text classification. Results show that our model has a comparable or even better efficiency compared with two typical sparse attention models, Reformer and Routing Transformer. Especially, when the sequence length exceeds 2000, our model, Routing Transfomer and Reformer reduce the memory of Transformer by 53.8%, 60.8% and 31.8% while reducing the training time by 51.4%, 41.8% and 14.4%, respectively on GPU. For effectiveness, we test it on machine translation, text classification, natural language inference, and text matching tasks. Experimental results show that on all tasks, our model consistently outperforms Reformer and Routing Transformer. In particular, our method improves the accuracy by 15.6% and 7.2% on SciTail datasets of natural language inference task compared with Reformer and Routing Transformer, respectively.

The major contributions of our work are as follows:

- We propose a general end-to-end fuzzy clustering method based on neural network, named Neural Clustering Method, which can dynamically learn weights of each word and then update centroids by weighting all the input words along with the training of specific tasks.
- We design the Neural Clustering Attention Mechanism based on our proposed clustering method to refactor Self-Attention Mechanism. The experimental results show that our method has comparable efficiency and better effectiveness than typical sparse attention models.

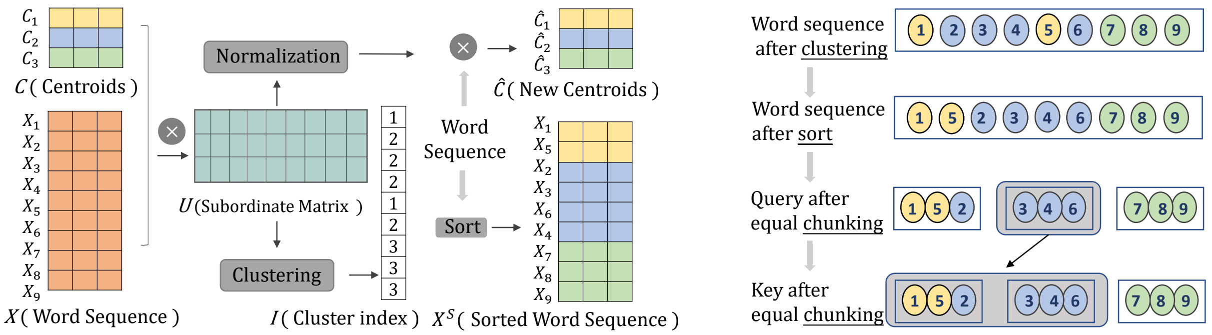
2 Related Work

2.1 Self-Attention Mechanism

The Self-Attention is the core component of Transformer (Vaswani et al., 2017). It extracts sequence features by processing the interaction of three sequence matrices Q, K, and V. Referring to the standard Transformer, its function can be written as follows:

$$\begin{gathered} Attention(Q,K,V) = Softmax(\frac{QK^T}{\sqrt{d}})V \\ Q,K,V = XW^Q, XW^K, XW^V \end{gathered} \tag{1}$$

where $X \in \mathbb{R}^{N \times d_{model}}$, Q, $K, V \in \mathbb{R}^{N \times d}$, $W^Q, W^V \in \mathbb{R}^{d_{model} \times d}$, N is the length of the se-



(a) Neural Clustering Method (b) Sorting and Chunking Operation

Figure 1: (a) is the Neural Clustering Method. Its main idea is to update centroids by weighting all the word hidden states and divide clusters according to the subordinate matrix. (b) is the sorting and chunking operations. It aims to make each cluster perform the attention mechanism in parallel.

quence, d_{model} is the dimensionality of the model, and d is the dimensionality of the attention head. In Self-Attention Mechanism, the interaction of Q and K gives the $N \times N$ attention (weight) matrix, and it leads to the complexity of $O(N^2 d)$, which has been one of the crucial limitation of Transformer.

2.2 Sparse variants of Transformer

Transformer has been developed into many variants to reduce the complexity of the attention mechanism. In these works, one of the main research directions is to use a sparse attention to substitute the quadratic-cost attention.

Some early works (Qiu et al., 2020; Ho et al., 2019; Beltagy et al., 2020) have been proposed to reduce the time complexity by restricting every query to focus only on keys that are nearby or at fixed intervals. This method fixes the sparsity pattern without considering the similarity between queries and keys, limiting its ability to assemble critical information from large contexts. Different from these works, our method attempts to automatically aggregate critical keys for each query based on dependency relationships.

Moreover, the clustering-pattern methods were used in Self-Attention to implement a sparse attention. For example, Reformer (Kitaev et al., 2020) and Routing Transformer (Roy et al., 2021) introduce Locality-Sensitive Hashing and K-Means algorithms, respectively, to reduce complexity to $O(N \log Nd)$ and $O(N\sqrt{N}d)$. However, in this kind of method, the clustering process and training process are separate, which is a limitation in improving effectiveness. Based on previous researches, we proposed a novel Neural Clustering Method, which can be seamlessly integrated into the network of specific tasks for joint training and optimization to improve effectiveness.

3 Model

In this section, we first introduce our Neural Clustering Method. Then, we introduce our Neural Clustering Attention Mechanism which combines our clustering method and the Self-Attention Mechanism.

3.1 Neural Clustering Method

As shown in Figure 1 (a), our clustering method takes word hidden states $X \in \mathbb{R}^{N \times d}$ and centroid hidden states $C \in \mathbb{R}^{k \times d}$ as inputs. C is initialized randomly in the first layer. Then, we can get the subordinate (similarity) matrix U between word vectors and centroid vectors. It can be defined as:

$$U_{ij} = \frac{exp(\phi(C_i, X_j W^C))}{\sum_{j=1}^{N} exp(\phi(C_i, X_j W^C))} \qquad (2)$$
$$1 \le i \le k \,, \quad 1 \le j \le N$$

where k is the number of clusters and N is the length of sequence. $W^C \in \mathbb{R}^{d_{model} \times d_{model}}$ is a parameter matrix. $\phi(\cdot)$ is a similarity measure function and it is the inner product operation in this scenario. X_j is the *j*-th row of matrix X and C_i is the *i*-th row of matrix C. The subordinate value $U_{ij} \in [0, 1]$ is the normalized similarity value between the *i*-th centroid vector and emphj-th word vector, and it represents the degree of the word X_j belonging to the centroid C_i.

Then, we get the updated centroids by weighting all the word hidden states. The corresponding formula is as follows:

$$\hat{C}_i = \sum_{j=1}^{N} U_{ij} X_j W^C \quad 1 \le i \le k \qquad (3)$$

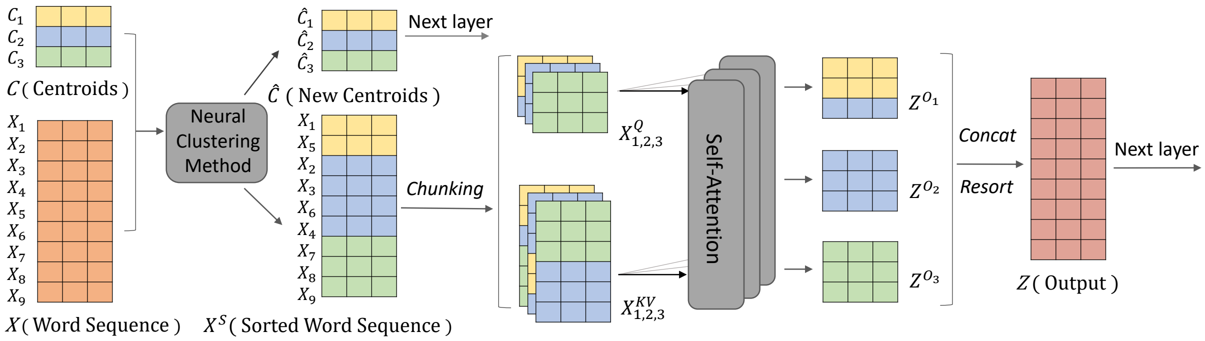


Figure 2: Neural Clustering Attention Mechanism. First, we group vectors with strong dependency into the same cluster and get a new word sequence X^S. Second, we carry out an equal chunking operation to get some block sequences, and then perform the attention within each cluster separately.

where i and j represent the index value of the centroid and word, respectively. Then we group the word vectors according to the subordinate matrix U, as follows:

$$I_j = Argmax(U_{:j}) \quad 1 \leq j \leq N \tag{4}$$

where $U_{:j}$ is the j-th column of the matrix U and function $Argmax(\cdot)$ assigns word hidden states to the corresponding cluster according to the maximum subordinate value. Therefore, $I \in \mathbb{R}^N$ represents the cluster index of all the word hidden states. Then, we sort the word vectors according to the cluster indexes I, as follows:

$$X^S,\, I^{'} = Sort(X, I) \tag{5}$$

where the function $Sort(\cdot)$ is used to arrange word hidden states belonging to the same cluster to adjacent positions in ascending order of cluster index. $X^S \in \mathbb{R}^{N\times d_{model}}$ is the sorted word vectors. $I^{'} \in \mathbb{R}^N$ is used to record the original positions of shuffled word hidden states in the sequence and will be used in Eq. 10. Through the above process, we get the grouped and sorted word hidden states X^S, as shown in Figure 1 (a).

Clustering Loss: Clustering Loss (L_1) is the mean of the negative similarity scores of word hidden states and their belonging centroids, and it will give guidance to learn the optimal clustering scheme. It is defined as follows:

$$L_1 = -\frac{1}{N}\sum_{j=1}^{N} \phi\left(X_j, \widehat{C}_{I_j}\right) \tag{6}$$

where X_j, $\widehat{C}_{I_j}$ represent the j-th word hidden state in the sequence and the updated centroid. The function $\phi(\cdot)$ is a similarity measure function and needs to be consistent with Eq. 2.

From the above analysis, our Neural Clustering Method is based on the soft clustering. There is a subordinate value between each pair of word vectors and centroid vectors, which can quantitatively describe the fuzzy relationship, so that the clustering can be carried out objectively and accurately. In addition, Neural Clustering Method is based on the neural network, which is easy to integrate into the network corresponding to the target task. The reconstruction of centroid vectors depends on all the word vectors and is based on the continuous optimization for the clustering objective function (as shown in Eq. 6) and the task-specific objective function to get better effectiveness.

In addition, we carried out a clustering comparison experiments between our method and traditional clustering methods and observed improvements of our method in effectiveness. See Appendix A for more details.

3.2 Neural Clustering Attention Mechanism

As described in Section 3.1, our Neural Clustering Method groups word vectors with strong dependency into the same cluster and outputs the sorted word vectors X^S. Then, we use different matrices to project X^S into matrix Q^S, K^S, and V^S, as follows:

$$Q^S, K^S, V^S = X^S W^Q, X^S W^K, X^S W^V \tag{7}$$

where W^Q, W^K and $W^V \in \mathbb{R}^{d_{model}\times d}$ are weight matrices. Q^S, K^S and V^S are matrices Query, Value and Key, respectively.

The number of members in each cluster may not be uniform, which makes it difficult for all clusters to perform the attention mechanism in parallel. For parallel computing, after arranging word hidden states in the same cluster to be in adjacent positions, we chunk them into equal blocks in order, as shown in Figure 1 (b) (essentially similar to the masking of Reformer). The process can be written as follows:

$$
\begin{aligned}
Q^{O_i} &= Q^S\Big((i-1)\left\lceil\frac{N}{k}\right\rceil : i\left\lceil\frac{N}{k}\right\rceil\Big] \\
K^{O_i} &= K^S\Big((i-2)\left\lceil\frac{N}{k}\right\rceil : i\left\lceil\frac{N}{k}\right\rceil\Big] \quad 1 \le i \le k
\end{aligned}
\tag{8}
$$

where $Q^{O_i} \in \mathbb{R}^{w\times d}$ and $K^{O_i} \in \mathbb{R}^{2w\times d}$ are the i-th Query block and Key block respectively. w ($w = \frac{N}{k}$) is the number of members in each block. Matrix V^{O_i} has operations similar to K^{O_i}. After chunking, Query contains one sequence block while Key and Value consist of two contiguous blocks, which corresponds to L_2 mentioned in Eq. 11. Each token in Query focuses on two blocks of tokens so that the query can cover the words in the same cluster as much as possible. Of course, it does not have to be 2, and can be adjusted.

Then, we perform the attention operation within the sequence block in parallel and concatenate the output of each block.

$$
\begin{aligned}
Z^{O_i} &= \mathit{Attention}(Q^{O_i}, K^{O_i}, V^{O_i}) \\
Z^{O} &= \mathit{Concat}(Z^{O_1}, ..., Z^{O_k}) \qquad 1 \le i \le k
\end{aligned}
\tag{9}
$$

where $Z^{O_i} \in \mathbb{R}^{w\times d}$ and $Z^O \in \mathbb{R}^{N\times d}$. Z^{O_i} is the output of the i-th sequence block after the attention operation.

Finally, we recover the shuffled sequence (output) to obtain the final result, as follows:

$$
Z = \mathit{Resort}(Z^O, I^{'}) \tag{10}
$$

where the function $\mathit{Resort}(\cdot)$ aims to recover shuffled sequence according to the original position record vector $I^{'}$ obtained from the Eq. 5. $Z \in \mathbb{R}^{N\times d}$ is the output of Neural Clustering Attention.

For the autoregressive modeling, we provide a Masked Neural Clustering Attention Mechanism to prevent the leftward information flow. More details can be found in Appendix B.

Centroid Sorting Loss: Centroid Sorting Loss (L_2) is the mean of the negative similarity scores of the adjacent centroid pairs. In Eq. 8, each token in Query block is expected to focus on two continuous blocks of tokens. L_2 makes word hidden states belonging to adjacent clusters are also close to each other. It is defined as follows:

$$
L_2 = -\frac{1}{k}\left(\left(\sum_{i=2}^{k}\phi\left(\widehat{C}_i, \widehat{C}_{i-1}\right)\right) + \phi\left(\widehat{C}_1, \widehat{C}_k\right)\right) \tag{11}
$$

where k is the number of centroids, $\widehat{C}_i$ is the i-th updated centroid, and the meaning of $\phi(\cdot)$ is consistent with Eq. 6.

In our method, Clustering Loss, Centroid Sorting Loss, and the loss of target tasks of the model are assigned different weights for joint optimization. More details can be found in Appendix C.

3.3 Analysis of Complexity

The complexity of Neural Clustering Attention Mechanism comes from two parts: (i) Neural Clustering Method. In this part, we need to calculate the subordinate matrix between centroid hidden states $C \in \mathbb{R}^{k\times d}$ and the word hidden states $X \in \mathbb{R}^{N\times d}$, referring to the Eq. 2, which leads to the complexity of $O(Nkd)$. (ii) Attention Mechanism. For this part, we compute attention within the Query block ($\in \mathbb{R}^{k\times w\times d}$) and Key block ($\in \mathbb{R}^{k\times 2w\times d}$), referring to the Eq. 9, which leads to the complexity of $O(kw^2d)$ where $w = \frac{N}{k}$. In summary, the overall complexity is $O(Nkd + kw^2d)$. When k is set to $\sqrt{N}$, the complexity is approximately $O(N\sqrt{N}d)$.

4 Experiments

In order to verify the effectiveness and efficiency of our method, we carried out the following tasks. We choose Transformer and its clustering-pattern variants (Reformer, Routing transformer) as baseline models. The implementations of the attention layer of Reformer and Routing transformer refer to the open source codes [1][2]. For a fair comparison, our proposed method and baseline models have the same architecture, except for the attention layer.

4.1 Machine Translation

We validate our model on IWSLT14 German-English and WMT14 English-German benchmarks, which have been widely used for machine translation tasks. For IWSLT14 De-En, it contains about 160K training sentence pairs and is pre-processed by using prepare-iwslt14en2de.sh [3]. For WMT14 En-De, it contains about 4.5 million training sentence pairs and it is pre-processed by using prepare-wmt14en2de.sh [4]. We use the BLEU score as the effectiveness evaluation metric. Some hyperparameters are set: the number of encoder and decoder

Table 2: Experimental results (Accuracy) on text classification tasks. "–" means that results are not reported.

layers L = 6, the number of centroids k = 3. The dimension of word embedding and model d_{model} = 512. Specifically, for IWSLT14, the number of heads is set to 4 and d_{ff} = 1024. For WMT14, the number of heads is set to 8 and d_{ff} = 2048.

As shown in Table 1, our method boosts effectiveness on both datasets. Specifically, the Tokenized BLEU score is improved by at least 1.5% compared with other models on IWSLT14 datasets. Compared with the latest models Reformer and Routing Transformer, ClusterFormer respectively has 2.6% and 7.4% improvement. Our method shows the same trend on WMT14 datasets. Especially, compared with Reformer and Routing Transformer, the Tokenized BLEU score of ClusterFormer respectively has 4.2% and 12.8% improvement and the sacreBLEU score respectively has 4.3% and 12.3% improvement.

4.2 Text Classification

We validate our model on five text classification tasks. CR (Hu and Liu, 2004): Customer reviews composed of positive or negative product reviews; MR (Pang and Lee, 2004): Movie reviews divided into positive and negative categories; SUBJ: Subjectivity dataset where the target is to classify a text as being subjective or objective; MPQA (Wiebe et al., 2005): Opinion polarity detection subtask. 20NEWS: A international standard dataset for text classification, text mining, and information retrieval research. The dataset collects about 20,000 newsgroup documents, divided into a collection of newsgroups on 20 different topics. Accuracy is used as the evaluation metric for these datasets. In addition, for all datasets, word embeddings are initialized by GloVe (Pennington et al., 2014) with 300-dimension. Some hyperparameters are set: The number of encoder layers L = 2, the dimension of model d = 300, the number of heads h = 4, and the number of centroids k is adjusted near the square root of the max length.

As shown in Table 2, ClusterFormer outperforms all baseline models and improves the test accuracy by at least 3.16%, 1.70% for CR and SUBJ datasets, respectively. In addition, on the MPQA dataset, ClusterFormer achieves a comparable result with MPSAN. We also carry out the text classification task on the long text dataset 20NEWS. The accuracy for the 20NEWS dataset increases at least 0.24% compared with other models. In addition, compared with the latest models Reformer and Routing Transformer, our model respectively has 6.1%, 3.8%, 1.6%, 2.0%, 2.6% and 10.0%, 4.9%, 2.0%, 11.3%, 3.1% improvement for CR, MR, SUBJ, MPQA and 20NEWS datasets.

4.3 Natural Language Inference (NLI) and Text Matching

In this section, we conduct Natural Language Inference tasks on SNIL, SciTail datasets, and Text Matching tasks on Quora, WikiQA datasets. SNLI (Bowman et al., 2015) is a benchmark dataset

Model	SNLI	SciTail	Quora	WikiQA	
				map	mrr
DELTA (Han et al., 2019)	80.7	–	–	–	–
Bigram-CNN (Yu et al., 2014)	–	–	–	0.619	0.628
Transformer† (Vaswani et al., 2017)	83.7	76.6	**85.4**	0.601	0.613
Reformer† (Kitaev et al., 2020)	78.6	67.3	74.3	0.587	0.603
Routing Transformer† (Roy et al., 2021)	76.3	72.6	81.5	0.560	0.574
ClusterFormer	**83.9**	**77.8**	**85.4**	**0.630**	**0.648**

Table 3: Experimental results on Neural Language Inference (NLI) and Text Matching tasks.

for natural language inference. There are 570k human-annotated sentence pairs with four labels. SciTail (Khot et al., 2018) is an entailment classification dataset constructed from science questions and answers. Quora Question Pairs is a dataset for paraphrase identification with two classes indicating whether one question is a paraphrase of the other. The evaluation metric for these three data sets is Accuracy. WikiQA (Yang et al., 2015) is a retrieval-based question answering dataset based on Wikipedia, which is composed of 20.4k/2.7k/6.2k (train/dev/test) samples. The mean average precision (MAP) and mean reciprocal rank (MRR) are used as the evaluation metrics. For SNIL and Quora datasets, word embeddings are initialized by GloVe (Pennington et al., 2014) with 300 dimensions. For the rest, we use random word embedding vectors with 300 dimensions. Some hyperparameters are set: $L = 1$, the number of heads $h = 6$ and the number of centroids $k = 3$.

As shown in Table 3, our model achieves the best results for most datasets. Specifically, the accuracy of our model is at least 1.6% higher than baseline models on the SciTail dataset. On WikiQA, our model improves the result by at least 1.8% and 3.2% in MAP and MRR evaluation metrics, respectively. Our model and Transformer have considerable effectiveness on SNLI and Quora datasets. In addition, compared with the latest models Reformer and Routing Transformer, our model has 6.7%, 15.6%, 14.9%, and 10.0%, 7.2%, 4.8% improvement for SNLI, SciTail, Quora datasets. For the WikiQA dataset, the score increases 7.3% and 7.5% by our model in MAP and MRR compared to Reformer. The score increases 12.5% and 13.0% compared to Routing Transformer.

4.4 The choice of clustering numbers k

In this section, we test the effect of different clustering numbers (k) on the effectiveness and efficiency. We test our model on the 20NEWS dataset of text classification tasks with a NVIDIA V100 (16GB) GPU. Some hyperparameters are set: the number of encoder layers L is 2, the dimension of the model d is 300, the batch size is 64, and the max sequence length N is 1500.

Model	Acc(%)	Memory(MiB)	Time (s)
Transformer	84.8	21268 (x)	263.5 (y)
Our (k=5)	84.9	10980 (1.48x)	197.9 (1.25y)
Our (k=10)	84.3	9312 (1.56x)	169.4 (1.36y)
Our (k=20)	**85.0**	8542 (1.60x)	153.6 (1.42y)
Our (k=30)	84.5	8282 (1.61x)	**147.6 (1.44y)**
Our (k=60)	84.3	8072 (1.62x)	150.4 (1.43y)
Our (k=100)	83.6	7920 (1.63x)	151.7 (1.42y)
Our (k=300)	83.6	**7830 (1.63x)**	170.0 (1.35y)
Our (k=500)	83.2	8444 (1.60x)	194.4 (1.26y)

Table 4: Experimental results of different clustering numbers k for ClusterFormer.

From Table 4, we can draw the following conclusions: (i) Accuracy of our model: In general, within a certain range during the growth of k, the performance of our model is relatively stable. When the value of k goes beyond a certain threshold, the performance of our model degrades; (ii) Memory cost of our model: As the number of centroids k increases, the memory cost of the model decreases first and then increases; (iii) Training time of our model: As the number of centroids k increases, the training time of the model also decreases first and then increases. Therefore, according to this law, our method can simultaneously gain both the effectiveness and efficiency of the model by determining an appropriate k value through finite experiments.

4.5 Ablation study for Clustering Losses

In this section, we provide an ablation experiment about the two kinds of clustering losses. We verify the effectiveness of the two loss modules by assigning different weight. Some hyperparameters

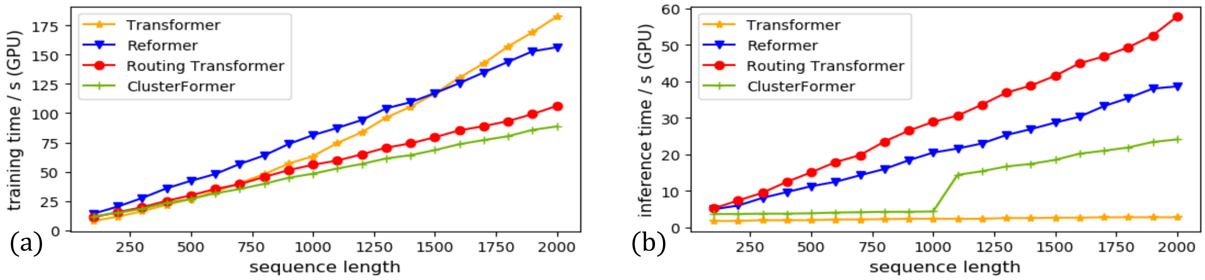

Figure 3: (a), (b) is the training and inference time versus the sequence length on GPU.

Datasets / Weight(L1/L2)	N/N	N/Y	Y/N	Y/Y
SciTail(Acc)	77.19	77.75	75.96	**78.32**
WikiQA(map)	0.612	0.620	0.619	**0.631**
WikiQA(mrr)	0.636	0.640	0.633	**0.648**

Table 5: Experimental results of Clustering Loss ablation. Specifically, 'N' represents the weight is zero and 'Y' represents the weight is non-zero.

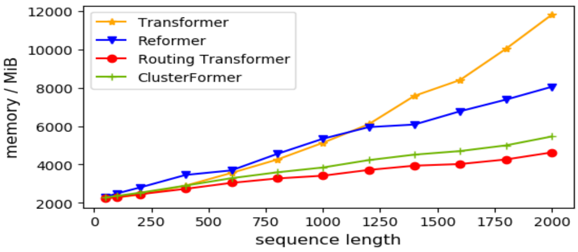

Figure 4: Memory cost versus the sequence length.

are set: the number of encoder layers L is 1, the dimension of model d is 300, the batch size is 128 and the max sequence length N is 500.

From Table 5, the experimental result shows that both L_1 and L_2 contribute to the performance. For example, on dataset SciTail, the accuracy with the best result is improved by 1.46% (acc) compared with the result without the two losses. On dataset WikiQA, the accuracy with the best result is improved by 3.10% (map), 1.89% (mrr) compared with the result without the two losses.

4.6 Time and Memory Analysis

In this section, we provide a comparison experiment on dataset 20NEWS about the time and memory cost for different models. About the dataset, its average sequence length is approximately 280 and the maximum sequence length exceeds 10,000. To compare time and memory cost, we set the range of sequence length N as (0, 2000] and batch size to 20. We test the memory and time cost on a NVIDIA V100 GPU. We take the time of 1000 steps forward propagation of the model as the inference time, and the time of 1000 steps forward and back propagation as the training time.

As shown in Figure 4, as the sentence length increases, both Routing Transformer and our model can significantly reduce memory cost compared to Transformer. When N exceeds 2000, our model, Routing Transfomer and Reformer reduce the memory by 53.8%, 60.8%, and 31.8%, respectively.

As shown in Figure 3, the training time of Transformer increases significantly with increasing sequence length, while our model and Routing Transformer have a relatively small increase on GPU devices. When N is 2000, our model, Routing Transfomer and Reformer reduce the training time by 51.4%, 41.8%, and 14.4%. However, the inference speed of these improvements is inferior compared with Transformer, which may be caused by the decrease of the model parallelism. The above analysis fully demonstrates the efficiency and effectiveness of our proposed Neural Clustering Mechanism.

5 Conclusion

In this paper, we propose a Neural Clustering Attention Mechanism to address the reduced effectiveness issue in sparse attention methods. This issue is mainly caused by the introduction of a sparse pattern that is separated from the target task or does not consider the similarity between words. In our method, we design a neural clustering algorithm to better capture critical pairs of dependencies. We integrate this clustering algorithm and the neural network to jointly train and optimize with specific tasks together to further contribute to the effectiveness and efficiency. The experimental results show that our model can achieve better effectiveness and a comparable or even better efficiency, compared with the latest typical sparse attention models, Reformer and Routing Transformer.

A Comparison experiment for clustering methods

In this section, we carry out the comparison experiment between the Neural Clustering Method and other clustering methods to verify the effectiveness of our clustering method.

Firstly, according to the division mode, we introduce the following two kinds of clustering methods.

Hard Clustering: Each element to be recognized is strictly divided into a certain cluster . It defines an *either/or relationship* $R \in \{0, 1\}$ between the element and clusters.

Soft Clustering (Fuzzy Clustering): Each element to be recognized is subordinate to all clusters (with different subordinate values). It defines a *fuzzy relationship* $U \in [0, 1]$ between the element and clusters.

Regarding the selection of the comparative clustering method, we chose the classic hard clustering algorithm K-means (used for Routing Transformer) and the soft clustering algorithm SOM, a competitive neural network. In addition, since Locality Sensitive Hashing (used for Reformer) cannot construct the loss function (no iteration condition), it cannot be used for the following clustering task on the MNIST dataset. In the experiment, we set the number of centroids k to 10, 50, 100, 200, and 300 respectively.

Data set	SOM	K-Means	Proposed method
MNIST(k=10)	59.8	59.2	**60.7**(+0.9, +1.5)
MNIST(k=50)	80.9	**82.5**	**82.5**(+1.6, +0)
MNIST(k=100)	87.8	87.7	**90.1**(+2.3, +2.4)
MNIST(k=200)	91.2	90.7	**91.8**(+0.6, +1.1)
MNIST(k=300)	93.1	92.0	**93.6**(+0.5, +1.6)

Table 6: Comparison of clustering accuracy of different clustering algorithms on MNIST task.

As shown in Table 6, our method consistently has the best effectiveness in experiments with different centroids. In particular, when the number of centroids exceeds 300, the accuracy of our method can reach 93.6, which improved the accuracy by 0.54% and 1.74% compared with SOM and K-Means, respectively. From the above analysis, we have confirmed that Neural Clustering Method is a general clustering method. It can also achieve better effectiveness compared with K-Means and SOM when handling clustering tasks alone.

B Masked Neural Clustering Attention Mechanism

For autoregressive modeling, we provide a Masked Neural Clustering Attention Mechanism to prevent the leftward information flow. We first obtain the original position indexes of the Q^{O_i}, K^{O_i} matrix. The formula is as follows:

$$\begin{aligned} I^{Q^{O_i}} &= I'\left((i-1)\left\lceil\frac{N}{k}\right\rceil : i\left\lceil\frac{N}{k}\right\rceil\right] \\ I^{K^{O_i}} &= I'\left((i-2)\left\lceil\frac{N}{k}\right\rceil : i\left\lceil\frac{N}{k}\right\rceil\right] \quad 1 \le i \le k \end{aligned} \tag{12}$$

where $I^{Q^{O_i}} \in \mathbb{R}^{w}$ and $I^{K^{O_i}} \in \mathbb{R}^{2w}$. $I^{Q^{O_i}}$ and $I^{K^{O_i}}$ are the original position indexes of the *i*-th sequence block Q^{O_i} and K^{O_i} respectively.

Then, we extend $I^{Q^{O_i}}$ in the second dimension to get $M^{Q^{O_i}} \in \mathbb{R}^{w\times 2w}$, and extend $I^{K^{O_i}}$ in the first dimension to get $M^{K^{O_i}} \in \mathbb{R}^{w\times 2w}$. Therefore, we can obtain a mask matrix M^{O_i} for the *i*-th sequence block by comparing these position indexes, as follows:

$$\begin{aligned} &M^{O_i}_{uv} = M^{K^{O_i}}_{uv} \ge M^{K^{O_i}}_{uv} \\ &1 \le i \le k\,, \quad 1 \le u \le w\,, \quad 1 \le v \le 2w \end{aligned} \tag{13}$$

where $M^{O_i} \in \mathbb{R}^{w\times 2w}$ is the mask matrix of the *i*-th block and the M^{O_i} is composed of either 0 or 1. $M^{O_i}_{uv}$ is the value of the *u*-th row and *v*-th column of the matrix M^{O_i}. Then, for each word in Query block, it will mask the words whose index value in Key block is greater than it according to mask matrix M^{O_i}, as follows:

$$\begin{aligned} &S^{O_i}_{uv} = \sum_{m=1}^{d} Q^{O_i}_{um} K^{O_i}_{vm} M^{O_i}_{uv} \\ &1 \le i \le k\,, \quad 1 \le u \le w\,, \quad 1 \le v \le 2w \end{aligned} \tag{14}$$

where $S^{O_i} \in \mathbb{R}^{w\times 2w}$ is the similarity matrix of the *i*-th sequence block. The subsequent operations are the same as Neural Clustering Attention Mechanism.

C Optimization of the multi-task learning for ClusterFormer

As shown in Figure 1, our model, ClusterFormer, consists of two joint training tasks, clustering tasks, and specific tasks of the model. Therefore, it contains the loss from the two tasks. The loss functions related to the clustering task are Clustering Loss (L_1) and Centroid Sorting Loss (L_2). Their equa-

Evaluation Metrics	Model/Length	2500	5000	7500	10000	15000	25000	35000	45000	55000
Memory(MiB)	Transformer	3271	7663	15519	–	–	–	–	–	–
	Reformer	2699	3807	4795	6067	9515	15867	–	–	–
	Routing Transformer	2129	2467	2841	3189	3779	5477	7451	9117	11397
	ClusterFormer	2257	2689	3165	3623	4435	6839	9647	12553	15695
Training Time(s)	Transformer	46.5	127.6	260.9	–	–	–	–	–	–
	Reformer	30.7	51.2	72.3	89.0	135.0	252.1	–	–	–
	Routing Transformer	24.8	38.5	58.5	69.8	114.9	207.2	343.4	490.1	684.6
	ClusterFormer	30.2	44.8	60.4	77.2	115.4	197.1	277.2	375.6	461.3

Table 7: Memory efficiency (measuring unit: MiB) and Training-time efficiency(measuring unit: second) of different methods under the ultra-long sequence condition. '-' represent memory cost exceeds the upper limit of the GPU device and the corresponding training time can not be provided.

tions are as follows:

$$L_1 = -\frac{1}{N}\sum_{j=1}^{N}\phi(X_j, \widehat{C}_{I_j})$$
$$L_2 = -\frac{1}{k}((\sum_{i=2}^{k}\phi(\widehat{C}_i, \widehat{C}_{i-1})) + \phi(\widehat{C}_1, \widehat{C}_k)) \tag{15}$$

where X and C are respectively word vectors and centroid vectors. N is the length of the input and k is the number of clusters. The loss function of a specific task (e.g., text classification) is formulated as follows:

$$L_3 = -\sum_{i=1}^{n} y_i log(\widehat{y_i}) + (1-y_i)log(1-\widehat{y_i}) \tag{16}$$

where $\widehat{y_i}$ is predictive value and y_i is the corresponding target value. Then, the overall loss function can be written as:

$$L_{total}(X, C, W, b) = \mu L_1 + \nu L_2 + \lambda L_3 \tag{17}$$

where C, W, and b are respectively centroid parameters, weight parameters, and bias parameters in ClusterFormer. μ, ν, and $\lambda \geq 0$ are non-negative coefficients, which are used to adjust the proportion of the importance of corresponding tasks.

Therefore, we can obtain the optimal parameters in the neural network by minimizing the loss function L_{total} through gradient descent, as follows:

$$c_i = c_i - \eta\frac{\partial L_{total}(X, C, W, b)}{\partial c_i} \quad 1 \leq i \leq k \times d_{model}$$
$$w_j = w_j - \eta\frac{\partial L_{total}(X, C, W, b)}{\partial w_j} \quad 1 \leq j \leq m$$
$$b_r = b_r - \eta\frac{\partial L_{total}(X, C, W, b)}{\partial b_r} \quad 1 \leq r \leq n \tag{18}$$

where c_i, w_i and b_i represent the element value of the corresponding vectors. d_{model} is the dimensionality of the model. m and n represent the number of weight and bias parameters, respectively. η is the learning rate. From the above, it can be seen that the update of centroid, weight, and bias parameters is the result of multi-task joint learning in ClusterFormer.

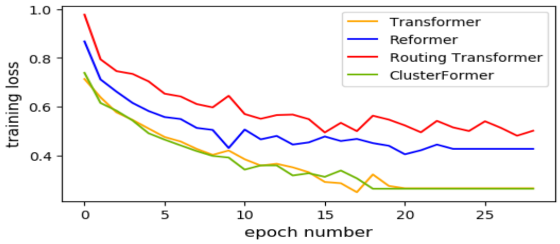

Figure 5: Comparison of training loss on SNLI dataset.

D Convergence Analysis

In this section, we provide a comparison experiment on the SNLI dataset about the convergence speed for standard Transformer and efficient Transformers during training, as shown in Figure 5. In our experiment, the epochs of different models to achieve convergence is: Transformer has 21 epochs, Reformer has 24 epochs Routing Transformer has 29 epochs and ClusterFormer has 19 epochs. Compared with Transformer, our model has a comparative convergence rate and is more stable. In addition, compared with the latest model Reformer and Routing Transformer, our model not only has a faster and more stable convergence speed, but also has better effectiveness.

E Comparison experiment of different methods under the ultra-long sequence condition

In this section, we have supplemented the experiment of time and memory cost in different methods on extremely long sequence tasks. We tested them on text classification of the 20NEWS dataset and trained them on a NVIDIA V100 GPU. We set the

Model	MNLI	QQP	QNLI	SST2	CoLA	STSB	MRPC	RTE	Average
Bert-Small-uncased	77.6/77.0	68.1/87.0	86.4	89.7	27.8	78.8/77.0	83.4/76.2	61.8	74.23
Pretrained ClusterFormer	75.21/75.7	83.1/86.9	82.5	88.3	34.2	82.7/82.4	85.2/77.7	60.3	**76.18**

Table 8: GLUE Dev results, the "Average" column represents the average of all datasets scores. F1 and accuracy scores are reported for QQP and MRPC. Spearman correlations are reported for STSB. Accuracy scores are reported for the other tasks.

number of centroids k to the square root of the max length and set the batch size to 2 (constrained by resources).

As shown in Table 7, we can see that our method has a better efficiency advantage on long sequences compared with Transformer. And as the sequence length increases, the advantage in memory and training time are even more significant.

F Pretraining experiment with the Neural Clustering Attention Mechanism

In this section, we pretrain a model with the Neural Clustering Attention Mechanism with two unsupervised tasks, masked language modeling (MLM) and next sentence prediction (NSP). The parameter settings of our pretraining model are similar to BERT-small-uncased. Some hyperparameters are set: the number of layers L is 4, the hidden size is 512, and the number of heads h is 8.

For downstream tasks, we use the General Language Understanding Evaluation (GLEU) benchmark which is a collection of diverse natural language understanding tasks. We use a batch size of 32 and fine-tune On a scale of 3 to 10 epochs over the data for all GLEU tasks. For each task, we selected the best fine-tuning learning rate (5e-5, 4e-5, 3e-5, and 2e-5) on the Dev set.

As shown in Table 8, experimental results demonstrate that our method can have a good performance improvement through Pretraining. Especially, compared with the Bert-Small-uncased, pretraining ClusterFormer respectively has 23.0%, 4.9% / 7.0%, and 2.2% / 2.0% improvement on CoLA, STSB, and MRPC datasets. The experimental results show that our model has the potential to do more NLP tasks including pretraining and non-pretraining tasks.

Bottom-Up Constituency Parsing and Nested Named Entity Recognition with Pointer Networks

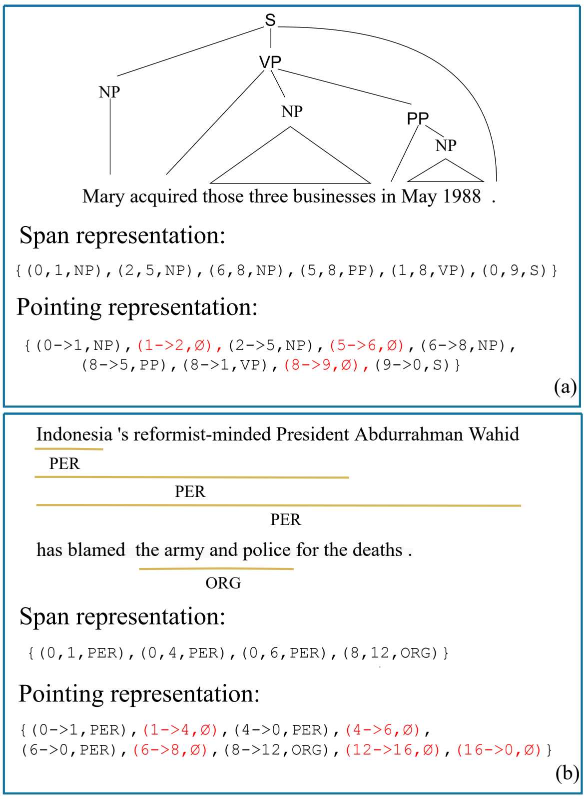
Songlin Yang, Kewei Tu*
School of Information Science and Technology, ShanghaiTech University
Shanghai Engineering Research Center of Intelligent Vision and Imaging
`{yangsl,tukw}@shanghaitech.edu.cn`

Abstract

Constituency parsing and nested named entity recognition (NER) are similar tasks since they both aim to predict a collection of nested and non-crossing spans. In this work, we cast nested NER to constituency parsing and propose a novel pointing mechanism for bottom-up parsing to tackle both tasks. The key idea is based on the observation that if we traverse a constituency tree in post-order, i.e., visiting a parent after its children, then two consecutively visited spans would share a boundary. Our model tracks the shared boundaries and predicts the next boundary at each step by leveraging a pointer network. As a result, it needs only linear steps to parse and thus is efficient. It also maintains a parsing configuration for structural consistency, i.e., always outputting valid trees. Experimentally, our model achieves the state-of-the-art performance on PTB among all BERT-based models (96.01 F1 score) and competitive performance on CTB7 in constituency parsing; and it also achieves strong performance on three benchmark datasets of nested NER: ACE2004, ACE2005, and GENIA [1].

1 Introduction

Constituency parsing is an important task in natural language processing, having many applications in downstream tasks, such as semantic role labeling (Fei et al., 2021), opinion mining (Xia et al., 2021), among others. Named entity recognition (NER) is a fundamental task in information extraction and nested NER has been receiving increasing attention due to its broader applications (Byrne, 2007).



Span representation:
`{(0,1,NP),(2,5,NP),(6,8,NP),(5,8,PP),(1,8,VP),(0,9,S)}`

Pointing representation:
`{(0->1,NP),(1->2,Ø),(2->5,NP),(5->6,Ø),(6->8,NP),(8->5,PP),(8->1,VP),(8->9,Ø),(9->0,S)}`

Indonesia 's reformist-minded President Abdurrahman Wahid has blamed the army and police for the deaths .

Span representation:
`{(0,1,PER),(0,4,PER),(0,6,PER),(8,12,ORG)}`

Pointing representation:
`{(0->1,PER),(1->4,Ø),(4->0,PER),(4->6,Ø),(6->0,PER),(6->8,Ø),(8->12,ORG),(12->16,Ø),(16->0,Ø)}`

Figure 1: (a) an example non-binary constituency tree. (b) an example sentence with nested named entities. We show the span and pointing representations.

Constituency parsing and nested NER are similar tasks since they both aim to predict a collection of nested and non-crossing spans (i.e., if two spans overlap, one must be a subspan of the other). Fig.1 shows example span representations of both tasks. The difference between the two tasks is that the collection of spans form a connected tree in constituency parsing, whereas they form several tree fragments in nested NER. However, we can add a node that spans the whole sentence to connect all tree fragments in nested NER to form a tree. Because of the similarity, there are some previous studies adapting methods from the constituency parsing literature to tackle nested NER (Finkel and Manning, 2009; Wang et al., 2018; Fu et al., 2021). In this work, we focus on constituency parsing, but our proposed method tackles nested NER as well.

The two main paradigms in constituency pars-

ing are span-based and transition-based methods. Span-based methods (Stern et al., 2017; Kitaev and Klein, 2018; Zhang et al., 2020; Xin et al., 2021, *inter alia)* decompose the score of a constituency tree into the scores of constituent spans and use chart-based algorithms for inference. Built upon powerful neural encoders, they have obtained state-of-the-art results. However, they suffer from the high inference time complexity of exact algorithms or error propagation of top-down approximate algorithms. In contrast, transition-based methods (Dyer et al., 2016; Cross and Huang, 2016; Liu and Zhang, 2017, *inter alia)* conduct a series of local actions (e.g., shift and reduce) to build the final parse in linear steps, so they enjoy lower parsing time complexities. However, they suffer from the error propagation and exposure bias problems.

Recently, Nguyen et al. (2021a) propose a sequence-to-sequence (seq2seq) model with pointer networks (Vinyals et al., 2015a). They cast constituency parsing to a top-down splitting problem. First, they use neural encoders to obtain span representations, similar to span-based methods. Then they feed input parent span representations into the neural decoder recursively following the order shown in Fig. 2(a)[2]—which amounts to pre-order traversal—to output a series of splitting points (i.e., boundaries) via pointer networks, so that each parent span is split into two child spans. Notably, Nguyen et al. (2020) propose a similar top-down pointing mechanism, but they design a chart-based parsing algorithm instead of adopting seq2seq modeling, and has been shown underperforming Nguyen et al. (2021a). Thanks to seq2seq modeling, Nguyen et al. (2021a)'s model achieves a competitive parsing performance with a lower parsing complexity compared with span-based methods.

However, their model has two main limitations. First, when generating each constituent, its subtree features cannot be exploited since its subspans have not been realized yet (Liu and Zhang, 2017). Thus it is difficult for the model to predict the splitting point of a long span due to a lack of its subtree information, which exacerbates the error propagation problem and undermines the parsing performance. Second, since each parent span can only be split into two, their parsing algorithm can only ouput binary trees, thus needing binarization.

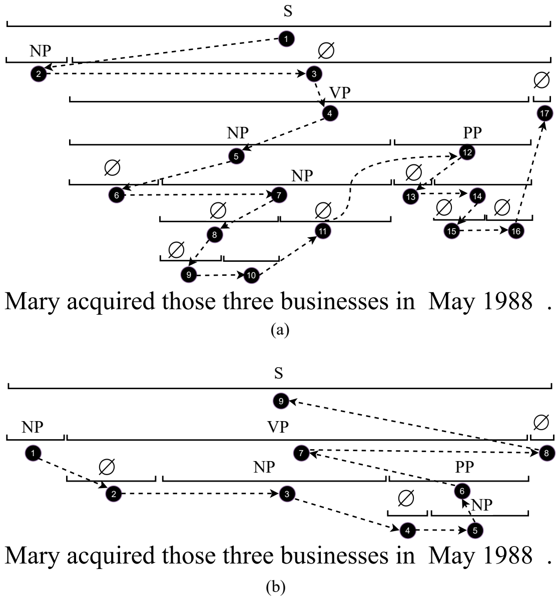

Figure 2: Illustration of pre-order and post-order traversal over the constituency tree shown in Figure 1(a). (a): pre-order traversal. (b): post-order traversal. We mark the generation order in the circles below spans and link two consecutively visited constituents by arrows. Note that in (a), binarization is assumed.

In this work, we devise a novel pointing mechanism for *bottom-up* parsing using (almost) the same seq2seq backbone as Nguyen et al. (2021a). Our model is able to overcome the two aforementioned limitations of Nguyen et al. (2021a). The main idea is based on the observation that if we traverse a constituency tree in post-order (i.e., visiting a parent after its children), two consecutively visited constituent spans would share a boundary. Fig. 2(b) shows an example: the right boundary of ❶ is also the left boundary of ❷ and the right boundary of ❺ is also the right boundary of ❻. Based on this observation, we propose to use a cursor to track the shared boundary boundaries and at each step, leverage a pointer network to predict the next boundary for generating the next constituent span and update the cursor to the right boundary of the new span. Our model generates one span at each step, thus needing only linear steps to parse a sentence, which is efficient. Besides, our model can leverage rich subtree features encoded in the neural decoder to generate parent constituent spans, which is especially helpful in predicting long spans. Finally, our model can output n-ary trees, enabling direct modeling of the original non-binary parse tree structures in treebanks and eliminating the need for binarization.

---

[2] Slightly different from the figure, they do not feed spans of length 1 into the decoder for obvious reasons.

We conduct experiments on the benchmarking PTB and CTB for constituency parsing. On PTB, we achieve the state-of-the-art performance (96.01 F1 score) among all BERT-based models. On CTB, we achieve competitive performance. We also apply our method to nested NER and conduct experiments on three benchmark datasets: ACE2004, ACE2005, and GENIA. Our method achieves comparable performance to many tailored methods of nested NER, beating previous parsing-based methods. Our contributions can be summarized as the following:

- We propose a novel pointing mechanism for bottom-up n-ary tree parsing in linear steps.
- Our model achieves the state-of-the-art result on PTB in constituency parsing. We further show its application in nested NER where it achieves competitive results.

2 Methods

2.1 Preprocessing

It is known that constituency parsing can be regarded as a top-down splitting problem where parent spans are recursively split into pairs of subspans (Stern et al., 2017; Shen et al., 2018; Nguyen et al., 2020, 2021a). However, this formulation can output binary trees. We make an extension to cast constituency parsing as top-down segmentation, i.e., parent spans are segmented into ≥ 2 subspans recursively, for the sake of outputting n-ary trees. To this end, we add some $\emptyset$ spans (we do not allow two adjacent $\emptyset$ spans to eliminate ambiguities) so that each span is either a bottommost span or can be segmented by its subspans. For instance, in Fig 2, ❸ is a bottom-most span, and ❼ can be segmented by ❷, ❸ and ❻. We always include the whole-sentence span in order to cast other tasks, e.g., nested NER, to constituency parsing. We also collapse unary chains to atomic labels in constituency parsing, e.g., `S->VP` $\rightarrow$ `S+VP`.

2.2 Parsing configuration

A problem of seq2seq constituency parsers is how to maintain structural consistency, i.e., outputting valid trees. To solve this problem, our pointing system maintains a *parsing configuration*, which is a quadruple (c, A, p, S) where:

- c: index of the cursor.
- A: set of indices of all candidate boundaries.
- p: the left boundary of the lastly created span, which is needed to maintain A.
- S: set of generated spans.

We can see from Fig. 3 that in the beginning, the cursor c lies at 0. At each step, c points to another boundary a from A to form a span $(\min(c, a), \max(c, a))$. There are two cases:

- $c < a$: a new bottom-most span is generated.
- $a < c$: several consecutive spans are merged into a larger span. It is worthy to note that we can merge $>= 2$ spans in a single step, which allows our model to perform n-ary tree parsing.

In the first case, the new bottom-most span can combine with the very previous span to form a larger span whose left boundary is p, so we push p back to A (except for the case that $p =$ `null`). In the later case, the very previous span is a subspan of the new span and thus p cannot be pushed back. In both cases, all indices $\min(c, a) \leq i < \max(c, a)$ are removed from A due to the post-order generation restriction; p is updated to $\min(c, a)$ and c is updated to $\max(c, a)$. The process stops when the whole-sentence span is generated. Table 1 formalises this process.

Oracle. The oracle pointing representations shown in Fig.1 can be generated by running a post-order traversal of the tree (e.g., Fig.2) and for each traversed span, pointing the cursor from its boundary shared with the previous span to its other boundary. If we do not allow two consecutive $\emptyset$ spans, the oracle is unique under our pointing system (we give a proof in Appendix A.1 by contradiction).

2.3 Model

Given a sentence $w = w_1, ..., x_n$, we add `<bos>` (beginning of sentence) as w_0 and `<eos>` (end of sentence) as w_{n+1}. The oracle is $\{q_i \rightarrow p_i, y_i\}_{i=1,\ldots,m}$, where y_i is the span label and we use $l_i = \min(q_i, p_i)$ and $r_i = \max(q_i, p_i)$ to denote the left and right boundary of the i-th span, respectively.

Encoder. We feed the sentence into BERT (Devlin et al., 2019) and for each word w_i, we use the last subtoken emebedding of the last layer as its dense representations x_i. Then we feed $x_0, \ldots, x_{n+1}$ into a three-layer bidirectional

Initial configuration	$(c, A, p, s) = (0, \{1, 2, \ldots, n\}, \texttt{null}, \emptyset)$		
Goal	$(0, n) \in S$		
Pointing action	Input	Output	Precondition
LEFT-POINT-a	(c, A, p, S)	$\Rightarrow (c, A \setminus \{a, \ldots, c-1\}, a, S \cup \{(a, c)\})$	$0 \leq a < c$
RIGHT-POINT-a	(c, A, p, S)	$\Rightarrow (a, A \cup \{p\} \setminus \{c, \ldots, a-1\}, c, S \cup \{(c, a)\})$	$c < a \leq n,$

Table 1: Description of the parsing configuration.

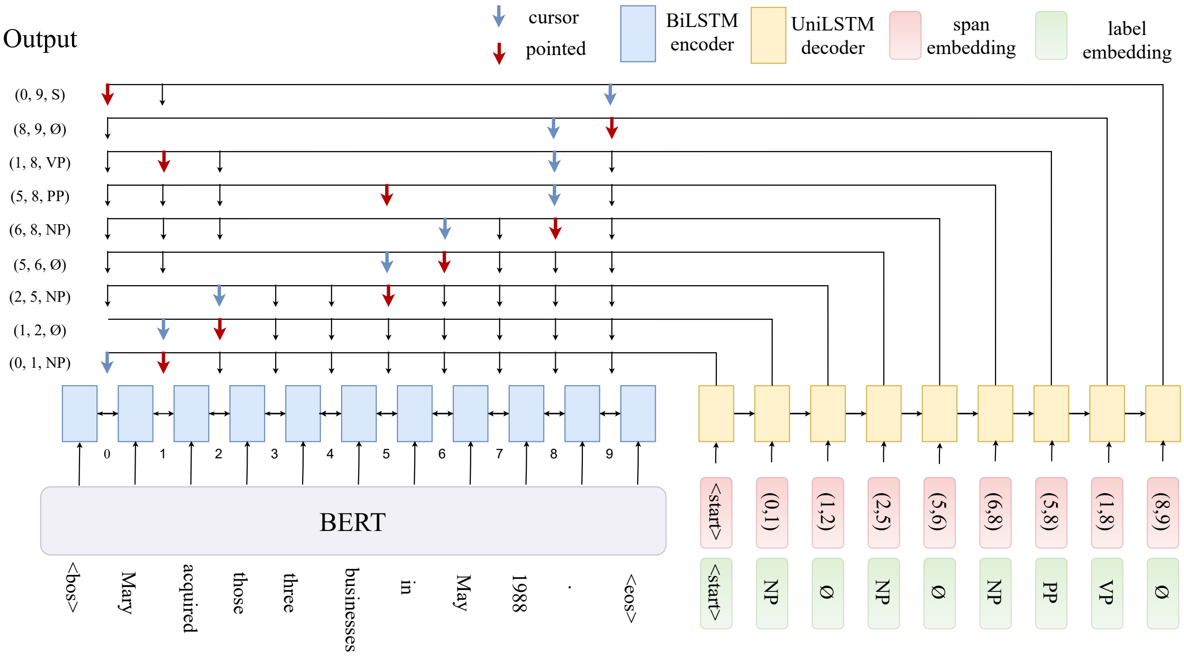

Figure 3: Demonstration of the generation process and the neural architecture. Black arrows point to candidate boundaries that are not selected in each step.

LSTM (Hochreiter and Schmidhuber, 1997) (BiLSTM) to obtain $c_0, \ldots, c_{n+1}$, where $c_i = [f_i; g_i]$ and f_i and g_i are the forward and backward hidden states of the last BiLSTM layer at position i respectively.

Boundary and span representation. We use fencepost representation (Cross and Huang, 2016; Stern et al., 2017) to encode the i-th boundary lying between x_i and x_{i+1}:

$$b_i = [f_i; g_{i+1}]$$

then we represent span (i, j) as:

$$h_{i,j} = \text{MLP}_{\text{span}}(b_j - b_i)$$

Decoder. We use a unidirectional one-layer LSTM network as the decoder:

$$d_t = \text{LSTM}(d_{t-1}, h_{l_{t-1}, r_{t-1}}; E_{y_{t-1}}), t \geq 2 \quad (1)$$

where d_t is the hidden state of the LSTM decoder at time step t, E is the label embedding matrix, ; is the concatenation operation. For the first step, we feed a randomly initialized trainable vector d_0 and a special `<START>` embedding into the decoder to obtain d_1.

Pointing score. We use a deep biaffine function (Dozat and Manning, 2017) to estimate the pointing score s_i^t of selecting the i-th boundary at time step t:

$$d'_t = \text{MLP}_{\text{cursor}}(d_t)$$
$$b'_i = \text{MLP}_{\text{point}}(b_i)$$
$$s_i^t = \left[b'_i; 1\right]^\top W_{\text{point}} d'_t$$

where $\text{MLP}_{\text{cursor}}$ and $\text{MLP}_{\text{point}}$ are multi-layer perceptrons (MLPs) that project decoder states and boundary representations into k-dimensional spaces, respectively; $W_{\text{point}} \in \mathcal{R}^{(k+1)\times(k)}$.

Label score. For a newly predicted span, we feed the concatenation of the span representation and the decoder state into another MLP to calculate the label score e^t:

$$\begin{aligned} H &= \text{MLP}_{\text{label}}([d^t; b_{r_t} - b_{l_t}]) \\ e^t &= HE^T \end{aligned}$$

Note that we reuse the label embedding matrix from Eq. 1 to facilitate parameter sharing.

Training objective. The training loss is decomposed into the pointing loss and the labeling loss:

$$\begin{aligned} L &= L_{\text{pointing}} + L_{\text{labeling}} \\ L_{\text{pointing}} &= -\sum_{t=1}^{m} \log \frac{\exp\{s^t_{p_t}\}}{\sum_{j=0}^{n} \exp\{s^t_j\}} \\ L_{\text{labeling}} &= -\sum_{t=1}^{m} \log \frac{\exp\{e^t_{y_t}\}}{\sum_{j=1}^{|L|} \exp\{e^t_j\}} \end{aligned}$$

where $|L|$ is the number of labels. Note that in the pointing loss we normalize over all boundaries instead of only accessible boundaries, because we find it performs better in our preliminary experiments.

Parsing. Our model follows the description in the previous subsection for parsing. For each time step t, it selects the highest-scoring accessible boundary to generate the span, then selects the highest-scoring label of the generated span, and updates the parsing configuration (Table 1).

3 Experiment setup

3.1 Data setup

Constituency parsing. We conduct experiments on Penn Treebank (PTB) 3.0 (Marcus et al., 1993) and Chinese Treebank (CTB) (Xue et al., 2005). Many previous researchers report that the results on CTB5.1 are unstable and of high variance (Zhang et al., 2020; Yang and Deng, 2020). So we follow the suggestion of Zhang et al. (2020) to conduct experiments on CTB7 instead of CTB5.1 for more robust evaluation as CTB7 has more test sentences and has a higher annotation quality. We use the standard data splits for both PTB and CTB.

Nested NER. We conduct experiments on three benchmark datasets: ACE2004 (Doddington et al., 2004), ACE2005 (Walker et al., 2006), and GENIA (Kim et al., 2003). We use the same data preprocessing as Shibuya and Hovy (2020) [3].

3.2 Evaluation

We report labeled recall/precision/F1 scores based on `EVALB` [4] for constituency parsing; span-level labeled recall/precision/F1 scores for nested NER. All reported results are averaged over three runs with different random seeds.

3.3 Implementation details

We use "bert-large-cased" (Devlin et al., 2019) for PTB, ACE2004 and ACE2005; "bert-chinese-based" for CTB; and "biobert-large-cased-v1.1" (Lee et al., 2020) for GENIA. We use no other external resources (e.g., predicted/gold POS tags, external static word embedding). The hidden size of LSTM is set to 1000 for both the encoder and the decoder. We add dropouts in LSTM/MLP layers. The dropout rate is set to 0.33. The hidden and output sizes of all MLPs are set to 500. The value of gradient clipping is set to 5. The number of training epochs is set to 10 for PTB, CTB, GENIA; 50 for ACE2004/2005. We use Adam (Kingma and Ba, 2015) as the optimizer with $\beta_1 = 0.9$ and $\beta_2 = 0.9$. The maximal learning rate is set to $5e-5$ for BERT and $2.5e - 3$ for all other components. We use the first 10% epochs to linearly warmup the learning rates of each components to their maximum value and gradually decay them to zero for the rest of epochs. We batch sentences of similar lengths to make full use of GPUs and the number of tokens in a single batch is set to 3000.

4 Main result

On both PTB and CTB, we find incorporating $E_{y_{t-1}}$ in Eq. 1 leads to a slightly inferior performance (-0.02 F1 score on PTB and -0.05 F1 score on CTB), so we report results without this input feature.

Table 2 shows the results on PTB test set. Our method achieves 96.01 F1 score, outperforming the method of Nguyen et al. (2021a) by 0.31 F1 and having the same worst-case $O(n^2)$ parsing time complexity as theirs [5]. It also outperforms all span-

---

[3] `https://github.com/yahshibu/nested-ner-tacl2020-transformers`

[4] `https://nlp.cs.nyu.edu/evalb`

[5] In their paper, they claim an $O(n)$ time complexity, which treats the complexity of a single pointing operation as O(1). This calculation, however, assumes full GPU parallelization. Without parallelization, their method has a worst-case $O(n^2)$ time complexity as ours.

Model	P	R	F
Kitaev et al. (2019) `[S]`	95.46	95.73	95.59

Model	P	R	F
Zhang et al. (2020) `[S]`	**91.73**	**91.38**	**91.55**
Ours `[Q]`	91.66	91.31	91.49

Table 3: Results on CTB7. All models use BERT as encoders.

based methods, obtaining the state-of-the-art performance among all BERT-based models while enjoying a lower parsing complexity.

Table 3 shows the results on CTB7. Our method obtains 91.49 F1 score, which is comparable to the method of Zhang et al. (2020) but has a lower complexity (worst-case $O(n^2)$ vs. $O(n^3)$).

Table 4 shows the results on three benchmark dataset on nested NER. We find that incorporating $E_{y_{t-1}}$ is important, leading to +0.67 F1 score and +0.52 F1 sore on ACE2004 and ACE2005, respectively. Although our method underperforms two recent state-of-the-art methods: Shen et al. (2021) and Tan et al. (2021), we find it has a competitive performance to other recent works (Wang et al., 2021; Yan et al., 2021; Fu et al., 2021). The most comparable one is the method of Fu et al. (2021), which belongs to parsing-based methods as ours. They adapt a span-based constituency parser to tackle nested NER using the CYK algorithm for training and inference. Our model outperforms theirs by 0.34 F1 and 0.13 F1 scores on ACE2004 and ACE2005 and has a similar performance to theirs on GENIA, meanwhile enjoying a lower inference complexity.

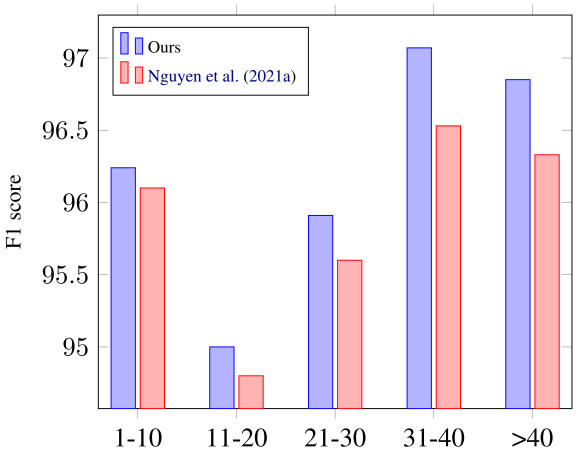

Figure 4: F1 scores against constituent span length on PTB test set.

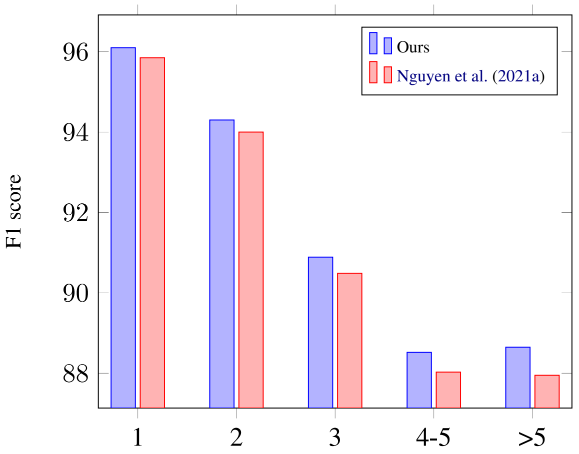

Figure 5: F1 scores on constituent nodes with different numbers of children on PTB test set.

5 Analysis

Error analysis. As we discussed previously, bottom-up parsing can make use of the subtree features when predicting parent spans, so it is expected to have higher F1 scores on longer spans. To verify this, we plot Fig. 4 to show the changes of F1 scores with different constituent span lengths on the PTB test set. We can see that our method consistently outperforms the method of (Nguyen et al., 2021a) on all span lengths, but our advantage is most prominent for spans of length >30, which verifies our conjecture. In Fig. 5, we can see that when a constituent has multiple children (>3), our method performs much better than that of (Nguyen et al., 2021a), which validates the benefit of *n-ary tree parsing*. An intuitive explanation of this benefit is that our method predicts n-ary branching structures in a single step, whereas theirs needs multiple steps, which is more error-prone.

Table 4: Results on ACE2004, ACE2005 and GENIA. All models use BERT as encoders.

Effect of beam search. We also tried beam search but observed very slight improvement or even worse performance (e.g., +0.05 F1 score on PTB and -0.03 F1 score on CTB when we use a beam size 20). Hence we report all results using greedy decoding for simplicity. This suggests that greedy decoding can yield near-optimal solutions, indicating that our model is less prone to the error propagation problem.

Effect of training loss. As discussed in Sec. 2.3, we find that explicitly considering the structural consistency constraints when normalizing is harmful (-0.12 F1 score on PTB, -0.10 F1 score on CTB). We speculate that not enforcing the constraints during training can help the model to learn the constraints implicitly, which is helpful for the model to generalize better on the unseen test set. Notably, Nguyen et al. (2021a) also adopt this strategy, i.e., normalizing over all boundaries.

Speed. Similar to Nguyen et al. (2021a), the training process (i.e., teacher forcing) can be fully parallelized without resorting to structured inference, which could be compute-intensive or hard to parallelize. On PTB, it takes only 4.5 hours to train the model using BERT as the encoder with a single Titan V GPU. As for parsing, our method has the same parsing complexity as Nguyen et al. (2021a), i.e., worst-case $O(n^2)$. Table 5 shows the speed comparison on parsing the PTB test set (we report values based on a single Titan V GPU and not using BERT as encoder following Nguyen et al. (2021a)). We report the average number of pointing actions in Appendix A.2.

System	Speed (Sents/s)	Speedup
Petrov and Klein (2007) (Berkeley)	6	1.0x
Zhu et al. (2013)(ZPar)	90	15.0x

6 Related Work

Constituency parsing. There are many methods to tackle constituency parsing, such as transition-based methods (Dyer et al., 2016; Cross and Huang, 2016; Liu and Zhang, 2017; Yang and Deng, 2020), span-based methods (Stern et al., 2017; Kitaev and Klein, 2018; Kitaev et al., 2019; Zhang et al., 2020; Wei et al., 2020; Nguyen et al., 2020; Xin et al., 2021), sequence-to-sequence (seq2seq)-based methods (Vinyals et al., 2015b; Fernández-González and Gómez-Rodríguez, 2020), sequence-labeling-based methods (Gómez-Rodríguez and Vilares, 2018; Vilares et al., 2019; Kitaev and Klein, 2020), among others.

Our work belongs to the category of seq2seq-based methods. Previous seq2seq models linearize constituency trees into bracket sequences (Vinyals et al., 2015b) or shift-reduce action sequences (Ma et al., 2017; Fernández-González and Gómez-Rodríguez, 2020). However, they may produce invalid outputs and their performance lags behind span-based methods. Recently, seq2seq models linearize constituency trees into sequences of spans in pre-order (Nguyen et al., 2021a) or in in-order (Wei et al., 2021). Our method generates sequences of spans in post-order instead, which has the advantage of utilizing rich subtree features and performing direct n-ary tree parsing.

Binarization is *de facto* in constituency parsing, but there is a recent trend toward n-ary parsing. Previous span-based methods adopt either explicit binarization (Zhang et al., 2020) or implicit binarization (Stern et al., 2017; Kitaev and Klein, 2018). Although the implicit binarization strategy eliminates the need for binarization in training, it can only output binary trees during decoding. Xin et al. (2021) propose an n-ary-aware span-based method by defining semi-Markov processes on each parent span so that the transition scores of adjacent sibling child-spans are explicitly considered in parsing. Fernández-González and Gómez-Rodríguez (2019); Yang and Deng (2020) propose novel transition systems to model n-ary trees. Our method outputs n-ary trees without the need for binarization via a novel pointing mechanism.

Parsing with pointer networks. Pointer Networks (Vinyals et al., 2015a) are introduced to the parsing literature by Ma et al. (2018) and quickly become popular in various parsing subtasks because they are flexible to predict various trees/graphs and can achieve very competitive performance. Ma et al. (2018) linearize a dependency tree in a top-down depth-first and inside-out manner and use a pointer network to predict the linearized dependency tree, which is then extended by Lin et al. (2019) to discourse parsing. Liu et al. (2019) add shortcuts between the decoder states of the previously generated parents/siblings to the current decoder states in both dependency and discourse parsing. Fernández-González and Gómez-Rodríguez (2019) propose a left-to-right dependency parser that predicts the heads of each word autoregressively, and later, they propose right-to-left and outside-in variants (Fernández-González and Gómez-Rodríguez, 2021a). They also adapt the left-to-right dependency parser to semantic dependency parsing (which predicts acyclic graphs instead of trees) (Fernández-González and Gómez-Rodríguez, 2020), discontinuous constituency parsing (by treating discontinuous constituency trees as augmented dependency trees) (Fernández-González and Gómez-Rodríguez, 2020), and joint dependency and constituency parsing (Fernández-González and Gómez-Rodríguez, 2020). They use a pointer network to reorder the sentence to reduce discontinuous constituency parsing to continuous constituency parsing (Fernández-González and Gómez-Rodríguez, 2021b). Nguyen et al. (2021a,b) cast (discourse) constituency/RST parsing as conditional splitting and use pointer networks to select the splitting points. Zhou et al. (2021) propose an action-pointer network for AMR parsing.

Nested NER. There are also many methods to tackle nested NER, such as hypergraph-based methods (Lu and Roth, 2015; Katiyar and Cardie, 2018; Wang and Lu, 2018), sequence-labeling-based methods (Shibuya and Hovy, 2020; Wang et al., 2021), parsing-based methods (Finkel and Manning, 2009; Wang et al., 2018; Fu et al., 2021), layered methods (Fisher and Vlachos, 2019; Wang et al., 2020; Luo and Zhao, 2020), span-based methods (Yu et al., 2020; Li et al., 2021), object-detection-based methods (Shen et al., 2021; Tan et al., 2021) etc.

Our work belongs to the category of parsing-based methods. Finkel and Manning (2009) insert named entities into a constituency tree and use a discriminative parser (Finkel et al., 2008) for learning and prediction. Wang et al. (2018) adapt a shift-reduce transition-based parser to output a constituency forest instead of a constituency tree for nested NER. Fu et al. (2021) adapt a span-based neural TreeCRF parser, treat nested named entities as the observed parts of a partially-observed constituency tree and develop a masked inside algorithm to marginalize all unobserved parts for maximizing the probability of the observed named entities. Our method has a better performance as well as a lower time complexity than Fu et al. (2021). Recently, Lou et al. (2022) extend the work of Fu et al. (2021), casting nested NER to lexicalized constituency parsing for leveraging headword information. They achieve a higher performance at the cost of a higher parsing complexity, i.e., $O(n^4)$.

7 Discussion and future work

In the deep learning era, global optimization on trees becomes less important in both training and decoding. Teng and Zhang (2018) show that a span-based model trained with a local span classification loss performs well in conjunction with CYK decoding. Wei et al. (2020); Nguyen et al. (2020) show that top-down greedy decoding performs comparably. In this work we have shown that greedy decoding works well. Thus it would also be a fruitful direction to design more powerful neural decoders which can leverage more subtree information and can maintain structural consistency. Also, it is a fruitful direction to devise more powerful span representations.

8 Conclusion

In this work we have presented a novel pointing mechanism and model for bottom-up constituency parsing, which allows n-ary tree parsing in linear steps. Experiments on multiple datasets show the effectiveness of our methods in both constituency parsing and nested NER.

A Appendix

A.1 Uniqueness of oracle

If there are two oracles o_1 and o_2 outputting the same tree. Their parsing configuration is (c_1, A_1, p_1, S_1) and (C_2, A_2, p_2, S_2), respectively. Assume that the first kth pointing actions of o_1 and o_2 are the same (so they share the same cursor c) and the $k+1$th action is $(c \to a_1, y_1)$ and $(c \to a_2, y_2)$ respectively. We enumerate all possibilities:

- $a_2 < c < a_1$, then (a_2, c) exists in S_2. c_1 would be updated to a_1, so thereafter the endpoint of the generated span is $\geq a_1$, thus (a_2, c) cannot exist in S_1 since $c < a_1$.
- $a_1 < c < a_2$, then (a_1, c) exists in S_2. Similar to the previous case, we can conclude that (a_1, c) cannot exist in S_1.
- $a_1 < a_2 < c$, then (a_2, c) exists in S_2, but $a_2 \notin A_1$ for all remaining steps, thus (a_2, c) cannot exist in S_1.
- $a_2 < a_1 < c$. This is similar to the previous case.
- $c < a_1 < a_2$, then (a_1, c) exists in S_1, but $a_1 \notin A_2$ for the remaining steps, thus (a_1, c) cannot exist in S_2.
- $c < a_2 < a_1$. This is similar to the previous case.

Hence there is exact one oracle and we have proved it by contradiction.

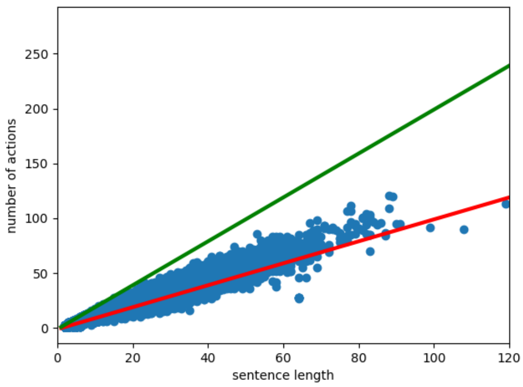

Figure 6: The number of actions with different sentence lengths in PTB

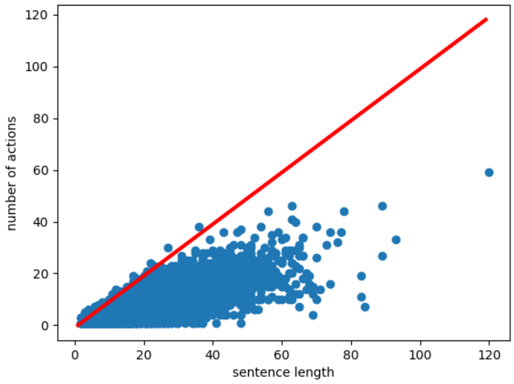

Figure 7: The number of actions with different sentence lengths in ACE2004

A.2 Number of actions

The system of Nguyen et al. (2021a) needs exact $n-1$ actions to parse a length-n sentence. While our model requires $2n-1$ actions in the worst case because we generate one span at each step and there are at most $2n-1$ spans if the corresponding constituency tree is a full binary tree. So there is a concern that our model needs twice time to parse. Empirically, since the constituency trees in the treebank are not full binary trees in most cases, we need less than $2n-1$ steps to parse. Fig. 6 shows the number of actions needed to parse with different sentence lengths in PTB training set. The red line is $y = x - 1$ and the green line is $y = 2x - 1$. In average, our method needs 1.13 actions per token, Nguyen et al. (2021a) needs 0.96 action per token. So, our method is around 20% slower than theirs. Fig. 7 shows the case in nested NER. We only need 0.40 action per token since the spans in nested NER is more *sparse* than that in constituency parsing. Our method is expectedly faster than other parsing-based methods in nested NER, such as the transition system of Wang and Lu (2018), which needs at least one action per word; and the span-based method of Fu et al. (2021), which needs cubic time for CYK parsing.

Redistributing Low-Frequency Words: Making the Most of Monolingual Data in Non-Autoregressive Translation

Abstract

Knowledge distillation (KD) is the preliminary step for training non-autoregressive translation (NAT) models, which eases the training of NAT models at the cost of losing important information for translating low-frequency words. In this work, we provide an appealing alternative for NAT – *monolingual KD*, which trains NAT student on external monolingual data with AT teacher trained on the original bilingual data. Monolingual KD is able to transfer both the knowledge of the original bilingual data (implicitly encoded in the trained AT teacher model) and that of the new monolingual data to the NAT student model. Extensive experiments on eight WMT benchmarks over two advanced NAT models show that monolingual KD consistently outperforms the standard KD by improving low-frequency word translation, without introducing any computational cost. Monolingual KD enjoys desirable expandability, which can be further enhanced (when given more computational budget) by combining with the standard KD, a reverse monolingual KD, or enlarging the scale of monolingual data. Extensive analyses demonstrate that these techniques can be used together profitably to further recall the useful information lost in the standard KD. Encouragingly, combining with standard KD, our approach achieves 30.4 and 34.1 BLEU points on the WMT14 English-German and German-English datasets, respectively. Our code and trained models are freely available at `https://github.com/alphadl/RLFW-NAT.mono`.

1 Introduction

Non-autoregressive translation (NAT, Gu et al. 2018) has been proposed to improve the decoding efficiency by predicting all tokens independently and simultaneously. However, the *independence assumption* prevents a model from properly capturing the highly multimodal distribution of target translations. In response to this problem, a sequence-level knowledge distillation (KD, Kim and Rush 2016) becomes the preliminary step for training NAT models, which produces more deterministic knowledge by reducing the translation modes of the bilingual data (Zhou et al., 2020).

Although the standard KD on original bilingual data eases the training of NAT models, distillation may lose some important information in the raw training data, leading to *more errors on predicting low-frequency words* (Ding et al., 2021c,b). To remedy this problem, Ding et al. (2021c) augmented NAT models the ability to learn lost knowledge from the raw bilingual data with an additional objective, and Ding et al. (2021b) first pre-trained NAT models on the raw training data and then fine-tuned them on the distilled training data. While previous studies mainly focus on recalling the lost information during the distillation of the original *bilingual* data, in this work we propose to improve the prediction of low-frequency words by redistributing them in the external *monolingual* data, which has the great potential to complement the original bilingual data on the word distribution.

Specifically, we leverage the monolingual data to perform KD (*monolingual KD*, §2.2), and train the NAT student model on the distilled monolingual data (Figure 1b). Monolingual KD provides appealing benefits. Firstly, the monolingual data and bilingual data in machine translation are generally complementary to each other (Zhang and Zong, 2016; Wu et al., 2019; Zhou and Keung, 2020; Siddhant et al., 2020; Jiao et al., 2021). Accordingly, monolingual KD is able to transfer both the knowledge of the bilingual data (implicitly encoded in the trained teacher model) and that of the monolingual data to the NAT student, without introducing additional computational cost. Secondly, the amount

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 2417 - 2426

of available monolingual data is several orders of magnitude larger than that of bilingual data, which offers monolingual KD the potential to further improve translation performance by exploiting more monolingual data.

Furthermore, we analyze the bilingual links in the bilingual and monolingual distilled data from two alignment directions (i.e. source-to-target and target-to-source). We found that the monolingual KD makes low-frequency source words aligned with targets more deterministically compared to bilingual KD, but both of them fail to align low-frequency words from target to source due to information loss. Starting from this finding, we propose reverse monolingual KD to recall more alignments for low-frequency target words. We then concatenate two kinds of monolingual distilled data (*bidirectional monolingual KD*, §2.3) to maintain advantages of deterministic knowledge and low-frequency information.

We validated our approach on several translation benchmarks across scales (WMT14 En↔De, WMT16 Ro↔En, WMT17 Zh↔En, and WMT19 En↔De) over two advanced NAT models: Mask Predict (Ghazvininejad et al., 2019) and Levenshtein (Gu et al., 2019). Experiments demonstrate the effectiveness and universality of our approach. Specifically, we have the following findings:

- Monolingual KD achieves better performance than the standard KD in all cases, and the proposed bidirectional monolingual KD can further improve performance by a large margin.

- Monolingual KD enjoys appealing expandability: enlarging the scale of monolingual data consistently improves performance until reaching the bottleneck of model capacity.

- Monolingual KD is complementary to the standard KD, and combining them obtains further improvement by alleviating two key issues of NAT, i.e., the multimodality problem and the low-frequency word translation problem.

The paper is an early step in exploring monolingual KD for NAT, which can narrow the performance gap between NAT models and the SOTA AT models. We hope the promising effect of monolingual KD on NAT can draw more interest and can make NAT a common translation framework.

2 Redistributing Low-Frequency Words

2.1 Preliminaries

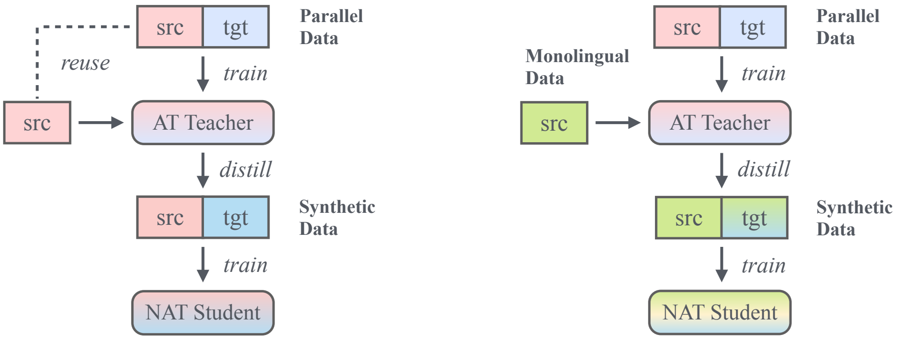
Non-Autoregressive Translation Recent years have seen a surge of interest in NAT (Gu et al., 2018), which can improve the decoding efficiency by predicting all tokens independently and simultaneously. Specifically, the probability of generating a target sentence $\mathbf{y}$ by given the source sentence $\mathbf{x}$ is computed as $p(\mathbf{y}|\mathbf{x}) = p_L(T|\mathbf{x};\theta)\prod_{t=1}^{T} p(\mathbf{y}_t|\mathbf{x};\theta)$, where T is the length of $\mathbf{y}$, which is predicted by a separate conditional distribution $p_L(\cdot)$. The parameters θ are trained to maximize the likelihood of a set of training examples according to $\mathcal{L}(\theta) = \arg\max_\theta \log p(\mathbf{y}|\mathbf{x};\theta)$. The conditional independence assumption prevents an NAT model from properly capturing the highly multimodal distribution of target translations (*multimodality problem*, Gu et al., 2018). As a result, the translation quality of NAT models often lags behind that of AT models (Vaswani et al., 2017).

Standard Knowledge Distillation Knowledge distillation is the preliminary step for training NAT models by reducing the modes in the original bilingual data, which makes NAT easily acquire more deterministic knowledge and achieve significant improvement (Zhou et al., 2020). Typically, a sequence-level KD (Kim and Rush, 2016) is employed for NAT training, as shown in Figure 1a.

2.2 Monolingual Knowledge Distillation

Different Distributions of Source Words To empirically reveal the difference on word distribution between bilingual and monolingual data, we visualize the overall word distributions, as plotted in Figure 2. We can observe the significant difference between bilingual and monolingual data in the low-frequency part, which indicates that the words that occur less in the bilingual data are not necessarily low-frequent in the external monolingual data. Starting from the observation, we propose to exploit external monolingual data to offer more useful information for predicting low-frequent words in bilingual data, which are generally lost in the standard knowledge distillation.

Our Approach Researches and competitions have shown that fully exploiting the monolingual data is at the core of achieving better generalization and accuracy for MT systems (Sennrich et al., 2016a; Zhang and Zong, 2016; Barrault et al.,



(a) Standard KD (b) Monolingual KD

Figure 1: Illustration of (a) standard bilingual data KD and (b) the proposed monolingual KD. The main difference between the two KDs lies in constructing the distilled data by (a) reusing the source side of bilingual data, or (b) introducing a new monolingual data.

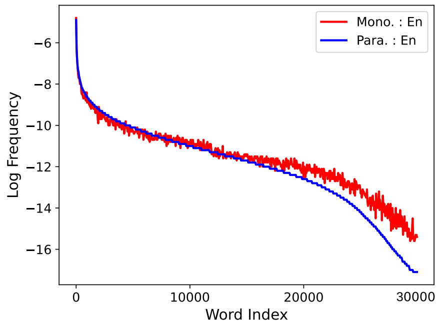


Figure 2: Word distributions of bilingual and monolingual English data on WMT14 En-De training data. Index is ranked by its frequency in bilingual data, where we normalize the frequency and report in log-scale.

2020). In this work we want to transfer the distribution of lost information, e.g. low-frequency words, from monolingual data to the NAT training. Figure 1b shows the pipeline of our proposed *Monolingual KD* for NAT, which differs from the *Standard KD* at how to construct the distilled data. Instead of reusing the source side of the original bilingual data, monolingual KD performs distillation on newly monolingual data, which eliminates the dependency on the original training data.

Intuitively, the monolingual KD can embed both the knowledge of the original bilingual data (implicitly encoded in the trained teacher model) and that of the newly introduced monolingual data. The comprehensive experiments in the following section provide empirical support for our hypothesis. In addition, the complementarity between the bilingual and monolingual data makes explicitly combining *Standard KD* and *Monlingual KD* can further improve model performance.

Data	$s \mapsto t$ LFW Links			$t \mapsto s$ LFW Links		
	R	**P**	**F1**	**R**	**P**	**F1**
Raw	66.4	81.9	73.3	72.3	80.6	76.2
$\overrightarrow{\text{KD}}_{\text{B}}$	73.4	89.2	80.5	69.9	79.1	74.2
$\overrightarrow{\text{KD}}_{\text{M}}$	75.1	87.7	80.9	70.8	81.4	75.7
$\overleftarrow{\text{KD}}_{\text{M}}$	63.7	80.2	71.0	**81.4**	**86.2**	**83.7**
$\overleftrightarrow{\text{KD}}_{\text{M}}$	**75.7**	**89.6**	**82.1**	80.5	79.4	79.9

Table 1: Evaluation of aligned links between source- and target-side low-frequency words on WMT14 En-De training data. "$\overrightarrow{\text{KD}}$" denotes the standard KD on source-language data, and "$\overleftarrow{\text{KD}}$" denotes reverse KD on target-language data. The subscripts $_{\text{B}}$ and $_{\text{M}}$ represent Bilingual and Monolingual distilled data.

2.3 Bidirectional Monolingual KD

Recalling Low-Frequency Target Words KD simplifies the training data by replacing low-frequency target words with high-frequency ones (Zhou et al., 2020; Ding et al., 2021c). This is able to facilitate easier aligning source words to target ones, resulting in high bilingual coverage (Jiao et al., 2020). Inspired by the low-frequency word (LFW) links analysis (Ding et al., 2021b), we borrow this LFW analysis to show the necessity of leveraging both the source- and target-side monolingual data. Concretely, we follow (Ding et al., 2021b) to evaluate the links of low-frequency words aligning from source to target ($s \mapsto t$) with three metrics: Recall (R) represents how many low-frequency source words can be aligned to targets; Precision (P) means how many aligned low-frequency links are correct according to human evaluation. F1 is the harmonic mean between precision and recall. Similarly, we can analyze in an opposite direction ($t \mapsto s$) by considering the links of low-frequency target words.

Table 1 lists the results. Comparing with the standard $\overrightarrow{\text{KD}}_{\text{B}}$, the forward monolingual KD ($\overrightarrow{\text{KD}}_{\text{M}}$ in Section 2.2) achieves better alignment quality of $s \mapsto t$ LFW links (F1: 80.9 vs. 80.5) by aligning more low-frequency source words (R: 75.1 vs. 73.4). The backward monolingual KD ($\overleftarrow{\text{KD}}_{\text{M}}$) can complementarily produce better alignment of low-frequency target words ($t \mapsto s$ LFW links). As we expected, combining the two types of distilled data ($\overleftrightarrow{\text{KD}}_{\text{M}}$) can produce better alignments for both low-frequency source (F1: 82.1 vs. 80.5) and target words (F1: 79.9 vs. 74.2).

Our Approach (*Bid. Monolingual KD*) Based on the above observations, we propose to train NAT models on bidirectional monolingual data by concatenating two kinds of distilled data. Like back-translation (Edunov et al., 2018), the reverse monolingual distillation $\overleftarrow{\text{KD}}_{\text{M}}$ is to synthesize the source sentences by a backward AT teacher, which is trained in the reverse direction of the original bilingual data. The mixture of the source-original and target-original synthetic datasets (i.e. $\overleftrightarrow{\text{KD}}_{\text{M}}$) is used to train the final NAT model. We expect that the better alignments of LFW links can lead to overall improvement of translation performance.

3 Experiments

3.1 Experimental Setup

Bilingual Data We conducted experiments on two widely-used NAT benchmarks: WMT14 English-German and WMT16 English-Romanian tasks, which consist of 4.5M and 0.6M sentence pairs respectively. To prove the universality of our approach on large-scale data, we also validated on WMT17 English-Chinese and WMT19 English-German tasks, which consist of 20.6M and 36.8M sentence pairs respectively. We shared the source and target vocabularies, except for En↔Zh data. We split the training data into subword units using byte pair encoding (BPE) (Sennrich et al., 2016b) with 32K merge operations, forming a vocabulary of 37k, 32k, 33k/48k and 44k for WMT14 En↔De, WMT16 En↔Ro, WMT17 En↔Zh and WMT19 En↔De respectively. We used case-sensitive token-BLEU (Papineni et al., 2002) to measure the translation quality (except for En-Zh, we used sacre-BLEU (Post, 2018)), and *sign-test* (Collins et al., 2005) for statistical significance test.

Task	Lang.	Bilingual data		Monolingual Data	
		# Sent.	# Word	# Sent.	# Word
W14	En	4.5M	127.7M	4.5M	138.6M

W16	En	0.6M	16.1M	0.6M	16.5M
	Ro		16.7M		17.3M
W17	En	20.6M	535.7M	20.6M	591.5M
	Zh		487.6M	18.4M	540.1M
W19	En	36.8M	881.0M	36.8M	937.3M
	De		911.0M		867.6M

Table 2: Data statistics of parallel and monolingual data. For fair comparison, the monolingual data has the same size with the corresponding bilingual data.

Monolingual Data We closely followed previous works to randomly sample monolingual data from publicly available News Crawl corpus[1] for the WMT tasks (Sennrich et al., 2016a; Wu et al., 2019). We randomly sampled English and German data from News Crawl 2007∼2020, and randomly sampled Romanian data from News Crawl 2015. For Chinese monolingual data, we used News Crawl 2008∼2020, News Commendary v16 and XMU data. For fair comparison, the monolingual data generally has the same size as corresponding bilingual data, as listed in Table 2.

Model Training We validated our approach on two state-of-the-art NAT models:

- *MaskPredict* [MaskT, Ghazvininejad et al. 2019] that uses the conditional masked language model (Devlin et al., 2019) to iteratively generate the target sequence from the masked input. We followed its optimal settings to keep the iteration number be 10 and length beam be 5.

- *Levenshtein Transformer* [LevT, Gu et al. 2019] that introduces three steps: deletion, placeholder prediction and token prediction, and the decoding iterations adaptively depends on certain conditions. We followed their setting and reproduced their reported results.

We trained both BASE and BIG Transformer (Vaswani et al., 2017) as the *AT teachers* for both standard and monolingual KD. For BIG models, we adopted *large-batch training* (i.e. 458K to-

$\overleftarrow{\text{KD}}_\text{M}$	24.9	-0.5	24.5	-1.1
$\overleftrightarrow{\text{KD}}_\text{M}$	26.6	+1.2	26.7	+1.1
$\overrightarrow{\text{KD}}_\text{M}$+$\overrightarrow{\text{KD}}_\text{B}$	26.7	+1.3	26.8	+1.2
$\overleftarrow{\text{KD}}_\text{M}$+$\overrightarrow{\text{KD}}_\text{B}$	26.6	+1.2	26.5	+0.9
$\overleftrightarrow{\text{KD}}_\text{M}$+$\overrightarrow{\text{KD}}_\text{B}$	27.1	+1.7	27.3	+1.7

Table 3: BLEU scores of different monolingual distillation strategies. "+$\overrightarrow{\text{KD}}_\text{B}$" means concatenating two sets of distilled data for model training, and "△" denotes improvement/decline over $\overrightarrow{\text{KD}}_\text{B}$. We used the same AT teacher and trained all models for the same steps.

kens/batch) to optimize the performance (Ott et al., 2018). The En↔Ro tasks employed Transformer-BASE as the teacher, and the other tasks used Transformer-BIG as the teacher. We also used *large-batch* (i.e. 480K tokens/batch) to train NAT models with Adam optimizer (Kingma and Ba, 2015). The learning rate warms up to 1×10^{-7} for 10K steps, and then decays for 60k steps with the cosine schedule (Ro↔En models only need 4K and 21K steps, respectively). Following the common practices (Ghazvininejad et al., 2019; Kasai et al., 2020), we evaluate the performance on an ensemble of 5 best checkpoints (ranked by validation BLEU) to avoid stochasticity.

3.2 Ablation Study on Monolingual KD

In this section, we evaluated the impact of different components of the monolingual KD on WMT14 En-De validation sets.

Impact of Distillation Strategy Table 3 lists the results of different distillation strategies. The forward monolingual KD ("$\overrightarrow{\text{KD}}_\text{M}$") consistently outperforms its standard counterpart ("$\overrightarrow{\text{KD}}_\text{B}$") (i.e. 25.8 vs. 25.4, and 26.2 vs. 25.6), which we attribute to the advantage of monolingual KD on exploiting both the original bilingual data knowledge (implicitly encoded in the trained AT teacher model) and the new monolingual data knowledge. Concatenating forward- and reverse-KD ($\overleftrightarrow{\text{KD}}_\text{M}$) can further improve the NAT performance, which is consistent with the findings in Table 1.

We also investigated whether monolingual KD is complementary to standard KD (i.e. "+ $\overrightarrow{\text{KD}}_\text{B}$" column). As seen, standard KD consistently improves translation performance across monolingual KD variants. Another interesting finding is that although reverse monolingual KD ($\overleftarrow{\text{KD}}_\text{M}$) significantly underperforms its forward counterpart ($\overrightarrow{\text{KD}}_\text{M}$) when used alone, they achieve comparable performance when using together with standard KD. We discuss in details how the two KD models complement each other in Section 3.4.

Sampling	$\overleftrightarrow{\text{KD}}_\text{M}$		**+** $\overrightarrow{\text{KD}}_\text{B}$	
	MaskT	**LevT**	**MaskT**	**LevT**
RANDOM	26.6	26.7	27.1	27.3
LOW-FREQ	26.4	26.6	26.9	27.1
LM-SEL	26.9	26.8	27.4	27.5

Table 4: Impact of monolingual data sampling.

Impact of Monolingual Data Sampling Some researchers may doubt that our approach heavily depends on the sampled monolingual data. To dispel the doubt, we investigated whether our model is robust to the selected monolingual data by varying the sampling strategies. Specifically, we conducted experiments on the full set of monolingual data from News Crawl 2007∼2020, which consist of 243M English and 351M German sentences. We compared with two representative approaches that sampled data with different priors: (1) LOW-FREQ samples difficult examples containing low-frequency words (Fadaee and Monz, 2018); (2) LM-SEL selects high quality examples with language model (Moore and Lewis, 2010).

As listed in Table 4, the difference of three sampling strategies w.r.t BLEU is not significant under the significance test $p < 0.05$ (Collins et al., 2005), demonstrating that *our approach is robust to the monolingual data sampling*. For the simplicity and robust applicability of our approach across different scenarios, we used RANDOM sampling as the default strategy in the following experiments.

3.3 Main Results

NAT Benchmarks Table 5 lists the results on the WMT14 En↔De and WMT16 En↔Ro benchmarks. Encouragingly, the conclusions in Section 3.2 hold across language pairs, demonstrating the effectiveness and universality of our approach. We also compared the performance against several

previous competitive NAT models. Although the results are not directly comparable since we used additional monolingual data, our approach improves previous SOTA BLEU on the NAT benchmarks. Notably, our data-level approaches neither modify model architecture nor add extra training loss, thus does not increase any latency ("Speed"), maintaining the intrinsic advantages of NAT models. The main side-effect of our approach is the increased training time for training an additional AT teacher model to build distilled data in the reverse direction. Fortunately, we can eliminate the side-effect by using only the monolingual KD ("Mono. KD"), which still consistently outperforms the standard KD without introducing any computation cost.

Larger-Scale WMT Benchmarks To verify the effectiveness of our method across different data sizes, we further experimented on two widely-used large-scale MT benchmarks, i.e. WMT17 En↔Zh and WMT19 En↔De. As listed in Table 6, our bidi-

rectional monolingual KD outperforms standard KD by averagely +1.9 and +2.3 BLEU points on En↔Zh and En↔De datasets, respectively, demonstrating the robustness and effectiveness of our monolingual KD approach. By combining with standard KD, our methods can achieve further +1.8 and +0.9 BLEU improvements.

3.4 Analysis

In this section, we provide some insights into how monolingual KD works. We report the results on WMT14 En-De data using Mask-Predict.

Monolingual KD Reduces Complexity of Training Data by Improving Low-Frequency Word Alignment We first present data-level qualitative analyses to study how monolingual KD complements bilingual KD. Zhou et al. (2020) revealed that standard KD improves NAT models by reducing the complexity of original bilingual data. Along this thread, we used the data complexity metric to measure different distilled datasets. Formally, the translation uncertainty of a source sentence x can be operationalized as conditional entropy:

$$\begin{aligned}\mathcal{H}(\mathbf{Y}|\mathbf{X}=\mathrm{x}) &= -\sum_{y\in Y} p(\mathrm{y}|\mathrm{x})\log p(\mathrm{y}|\mathrm{x}) \\ &\approx \sum_{t=1}^{T_x} \mathcal{H}(y|x=x_t),\end{aligned}$$

where T_x denotes the length of the source sentence, x and y represent a word in the source and target vocabularies, respectively.

We run *fast-align* on each parallel corpus to obtain word alignment. For fair comparison, we sampled the subsets (i.e. 4.5M) of "$\overleftrightarrow{\text{KD}}_{\text{M}}$" and "$\overleftrightarrow{\text{KD}}_{\text{M}}+\overrightarrow{\text{KD}}_{\text{B}}$" to perform complexity computation. As seen in Table 7, standard KD significantly reduces the data complexity compared to that of the bilingual data (1.95 vs. 3.67), and monolingual KD reduces even more data complexity. Additionally, the data complexity can be further reduced by combining with standard KD.

Data	WMT14 En-De			WMT14 De-En

$\overrightarrow{\text{KD}}_{\text{B}}$	82.4	78.2	68.4	83.7	79.6	69.9
$\overrightarrow{\text{KD}}_{\text{M}}$	82.9	78.4	69.5	83.9	80.1	71.2
$+\overrightarrow{\text{KD}}_{\text{B}}$	83.1	78.7	70.8	84.3	80.5	72.1
$\overleftrightarrow{\text{KD}}_{\text{M}}$	84.1	79.1	72.7	85.0	80.9	73.4
$+\overrightarrow{\text{KD}}_{\text{B}}$	84.6	79.7	73.6	85.2	81.4	75.2

Table 8: Accuracy of word translation. Darker color denotes more improvement over standard KD. "H/M/L" represent high/medium/low frequency words, which are estimated on the source sentences of bilingual data.

Monolingual KD Mainly Improves Low-Frequency Word Translation We first followed Ding et al. (2021c) to measure the translation accuracy of words with different frequencies, as shown in Table 8. The improvements over low-frequency words are the major reason for the performance gains, where the monolingual KD and bidirectional monolingual KD outperform the standard KD by averagely +1.2% and +3.9%, respectively. These findings confirm our hypothesis that monolingual KD can improve the translation of low-frequency words by redistributing them in the new monolingual data. Combining with standard KD can further improve the accuracy of translating low-frequency words, which reconfirms our hypothesis on the complementarity between the two KD methods on low-frequency words.

3.5 Further Exploiting Monolingual Data

In this section, we provide some potential directions to further improve NAT performance by making the most of monolingual data.

Exploiting Monolingual Data at Scale One strength of monolingual KD is the potential to exploit more monolingual data to further improve translation performance. To validate our claim, we scaled the size of monolingual data by {2×, 5×, 10×}, which are randomly sampled from the full set of monolingual data. As shown in Table 9,

Mono	WMT14 En-De		WMT14 De-En	
Size	MaskT	LevT	MaskT	LevT
		Bidirectional Monolingual KD		
1×	29.1	29.5	32.6	33.6
2×	29.7	30.1	33.1	33.9
5×	**30.6**	**30.9**	**33.9**	**34.5**
10×	30.4	30.8	33.3	34.4
		Combining with Standard KD

	✓	×	31.8	28.2
	✓	✓	31.8	30.5

Table 10: Applying monolingual KD for AT teacher and/or NAT student on WMT14 En-De test set. Raw data (for AT) and $\overleftrightarrow{\text{KD}}_\text{B}$ (for NAT) are used by default.

enlarging the monolingual data consistently improves the BLEU scores, while this trend does not hold when further scaling the monolingual data (i.e. 10×). One possible reason is that the limited capacity of NAT-base models cannot fully exploit the large data, which suggests future exploration of larger NAT architectures.

Augmenting AT Teacher with Monolingual KD An alternative to exploit monolingual data is to strength the AT teacher with monolingual KD, as listed in Table 10. Applying monolingual KD for AT teacher is less effective than using it for NAT training, which we attribute to the information loss when transferred from AT teacher to NAT student. Applying monolingual KD to both AT teacher and NAT student can further improve the NAT performance, at the cost of more computational cost.

4 Related Work

To bridge the performance gap, a number of recent efforts have explored, including model architectures (Ghazvininejad et al., 2019; Gu et al., 2019; Ding et al., 2020; Guo et al., 2020), training objectives and methods (Shao et al., 2019; Ghazvininejad et al., 2020; Ding et al., 2021a). Another thread of work focus on understanding and improving distillation training for NAT (Zhou et al., 2020; Ding et al., 2021c,b; Huang et al., 2022).

Sequence-level KD (Kim and Rush, 2016) is a preliminary step for training NAT models to reduce the intrinsic uncertainty and learning difficulty (Zhou et al., 2020; Ren et al., 2020). Recent studies have revealed that KD reduces the modes (i.e. multiple lexical choices for a source word) in the original data by re-weighting the training examples (Furlanello et al., 2018; Tang et al., 2020), at the cost of losing some important information, leading to more errors on predicting low-frequency words (Ding et al., 2021c). In response to this problem, Ding et al. (2021b) proposed to rejuvenate low-frequency words by pretraining NAT models on the raw bilingual data. In this study, we attempt to solve this problem from a different perspective – rediscovering low-frequency words from external monolingual data, which can simultaneously exploit the knowledge of bilingual data (implicitly encoded in the parameters of AT teacher).

Closely related to our work, Zhou and Keung (2020) improved NAT models by augmenting source-side monolingual data. Their work can be regarded as a special case of our approach (i.e. "*Mono. KD + Standard KD*" in Section 3.3), and our work has several more contributions. Firstly, we demonstrated the effectiveness of using only monolingual KD for NAT models, which can achieve better performance than the standard KD without introducing any computational cost. Secondly, we proposed a novel bidirectional monolingual KD to exploit both the source-side and target-side monolingual data. Finally, we provide insights into how monolingual KD complements the standard KD.

5 Conclusion

In this work, we propose a simple, effective and scalable approach – *monolingual KD* to redistribute the low-frequency words in the bilingual data using external monolingual data. Monolingual KD consistently outperforms the standard KD with more translation accuracy of low-frequency words, which attribute to its strength of exploiting both the knowledge of the original bilingual data (implicitly encoded in the parameters of AT teacher) and that of the new monolingual data.

Monolingual KD enjoys appealing expandability, and can be further enhanced by (1) combining with a reverse monolingual KD to recall more alignments for low-frequency target words; (2) combining with the standard KD to explicitly combine both types of complementary knowledge; (3) enlarging the scale of monolingual data that is cheap to acquire. Our study empirically indicates the potential to make NAT a practical translation system.

Future directions include designing advanced monolingual KD techniques and validating on larger-capacity NAT models (e.g. BIG setting) to strengthen the power of monolingual KD, and fully NAT models (Gu and Kong, 2021; Du et al., 2021) to show the universality of monolingual KD. Besides, it will be interesting to follow Liu et al. (2021) and Wang et al. (2022) to investigate the complementarity between our monolingual KD and pretrained language models to further enhance the NAT models.

Abstract

Higher-order methods for dependency parsing can partially but not fully address the issue that edges in dependency trees should be constructed at the text span/subtree level rather than word level. In this paper, we propose a new method for dependency parsing to address this issue. The proposed method constructs dependency trees by directly modeling span-span (in other words, subtree-subtree) relations. It consists of two modules: the *text span proposal module* which proposes candidate text spans, each of which represents a subtree in the dependency tree denoted by (root, start, end); and the *span linking module*, which constructs links between proposed spans. We use the machine reading comprehension (MRC) framework as the backbone to formalize the span linking module, where one span is used as query to extract the text span/subtree it should be linked to. The proposed method has the following merits: (1) it addresses the fundamental problem that edges in a dependency tree should be constructed between subtrees; (2) the MRC framework allows the method to retrieve missing spans in the span proposal stage, which leads to higher recall for eligible spans. Extensive experiments on the PTB, CTB and Universal Dependencies (UD) benchmarks demonstrate the effectiveness of the proposed method. [1] [2]

1 Introduction

Dependency parsing is a basic and fundamental task in natural language processing (NLP) (Eisner, 2000; Nivre, 2003; McDonald et al., 2005b). Among existing efforts for dependency parsers, graph-based models (McDonald et al., 2005a; Pei et al., 2015) are a widely used category of models, which cast the task as finding the optimal maximum spanning tree in the directed graph. Graph-based models provide a more global view than shift-reduce models (Zhang and Nivre, 2011; Chen and Manning, 2014), leading to better performances.

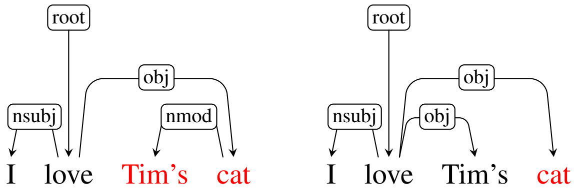

Figure 1: Two possible dependency trees for sentence “I love Tim's cat”. For the tree on the right hand side, if we look at the token-token level, ‘love" being linked to “cat" is correct. But at the subtree-subtree level, the linking is incorrect since the span/subtree behind “cat" is incorrect.

Graph-based methods are faced with a challenge: they construct dependency edges by using word pairs as basic units for modeling, which is insufficient because dependency parsing performs at the span/subtree level. For example, Figure 1 shows two possible dependency trees for the sentence “I love Tim's cat”. In both cases, at the token level, “love" is linked to “cat". If we only consider token-token relations, the second case of ‘love" being linked to “cat" is correct. But if we view the tree at the subtree-subtree level, the linking is incorrect since the span/subtree behind “cat" is incorrect. Although higher-order methods are able to alleviate this issue by aggregating information across adjacent edges, they can not fully address the issue. In nature, the token-token strategy can be viewed as a coarse simplification of the span-span (subtree-subtree) strategy, where the root token in the token-token strategy can be viewed as the **average** of all spans covering it. We would like an approach that directly models span-span relations using **exact** subtrees behind tokens, rather than the average of all spans covering it.

To address this challenge, in this work, we propose a model for dependency parsing that directly

operates at the span-span relation level. The proposed model consists of two modules: (1) the *text span proposal module* which proposes eligible candidate text spans, each of which represents a subtree in the dependency tree denoted by (root, start, end); (2) and the *span linking module*, which constructs links between proposed spans to form the final dependency tree. We use the machine reading comprehension (MRC) framework as the backbone to formalize the span linking module in an MRC setup, where one span is used as a query to extract the text span/subtree it should be linked to. In this way, the proposed model is able to directly model span-span relations and build the complete dependency tree in a bottom-up recursive manner.

The proposed model provides benefits in the following three aspects: (1) firstly, it naturally addresses the shortcoming of token-token modeling in vanilla graph-based approaches and directly performs at the span level; (2) with the MRC framework, the left-out spans in the span proposal stage can still be retrieved at the span linking stage, and thus the negative effect of unextracted spans can be alleviated; and (3) the MRC formalization allows us to take advantage of existing state-of-the-art MRC models, with which the model expressivity can be enhanced, leading to better performances.

We are able to achieve new SOTA performances on PTB, CTB and UD benchmarks, which demonstrate the effectiveness of the proposed method.

2 Related Work

Transition-based dependency parsing incrementally constructs a dependency tree from input words through a sequence of shift-reduce actions (Zhang and Nivre, 2011; Chen and Manning, 2014; Zhou et al., 2015; Dyer et al., 2015; Yuan et al., 2019; Han et al., 2019; Mohammadshahi and Henderson, 2020a). Graph-based dependency parsing searches through the space of all possible dependency trees for a tree that maximizes a specific score (Pei et al., 2015; Wang et al., 2018; Zhang et al., 2019).

Graph-based dependency parsing is first introduced by McDonald et al. (2005a,b). They formalized the task of dependency parsing as finding the maximum spanning tree (MST) in directed graphs and used the large margin objective (Crammer et al., 2006) to efficiently train the model. Zhang et al. (2016) introduced a probabilistic convolutional neural network (CNN) for graph-based dependency parsing to model third-order dependency information Wang and Chang (2016); Kiperwasser and Goldberg (2016) proposed to employ LSTMs as an encoder to extract features, which are then used to score dependencies between words. Zhang and Zhao (2015); Zhang et al. (2019); Wang and Tu (2020) integrated higher-order features across adjacent dependency edges to build the dependency tree. Ji et al. (2019) captured high-order dependency information by using graph neural networks. The biaffine approach (Dozat and Manning, 2016) is a particular kind of graph-based method improving upon vanilla scoring functions in graph-based dependency parsing. Ma et al. (2018) combined biaffine classifiers and pointer networks to build dependency trees in a top-down manner. Jia et al. (2020); Zhang et al. (2020) extended the biaffine approach to the conditional random field (CRF) framework. Mrini et al. (2020) incorporated label information into the self-attention structure (Vaswani et al., 2017b) for biaffine dependency parsing.

3 Method

3.1 Notations

Given a sequence of input tokens $\mathbf{s} = (w_0, w_1, ..., w_n)$, where n denotes the length of the sentence and w_0 is a dummy token representing the root of the sentence, we formalize the task of dependency parsing as finding the tree with the highest score among all possible trees rooted at w_0 .

$$\hat{T} = \arg\max_{T_{w_0}} \text{score}(T_{w_0}) \tag{1}$$

Each token w_i in the input sentence corresponds to a subtree T_{w_i} rooted at w_i within in the full tree T, and the subtree can be characterized by a text span, with the index of its leftmost token being $T_{w_i}.s$ in the original sequence, and the index of its rightmost token being $T_{w_i}.e$ in the original sequence. As shown in the first example of Figure 1, the span covered by the subtree T_{love} is the full sentence "I love Tim's cat", and the span covered by the subtree T_{cat} is "Tim's cat". Each directional arc $w_i \rightarrow w_j$ in T represents a parent-child relation between T_{w_i} and T_{w_j}, where T_{w_j} is a subtree of T_{w_i}. This implies that the text span covered by T_{w_j} is fully contained by the text span covered by T_{w_i}.

It is worth noting that the currently proposed paradigm can only handle the projective situation. We will get back to how to adjust the current paradigm to non-projective situation in Section 3.5.

Sentence: *root I love Tim's cat*	
Spans	**Links**
T_{root}: root I love Tim's cat	$T_{\text{root}} \rightarrow T_{\text{love}}$
T_{I}: I	$T_{\text{love}} \rightarrow T_{\text{I}}$
T_{love}: I love Tim's cat	$T_{\text{love}} \rightarrow T_{\text{cat}}$
$T_{\text{Tim's}}$: Tim's	$T_{\text{cat}} \rightarrow T_{\text{Tim's}}$
T_{cat}: Tim's cat	

Table 1: Spans and links for the left tree in Figure 1.

3.2 Scoring Function

With notations defined in the previous section, we now illustrate how to compute the score(T_{w_0}) in Eq.(1). Since we want to model the span-span relations inside a dependency tree, where the tree is composed by spans and the links between them, we formalize the scoring function as:

$$\begin{aligned} \text{score}(T_{w_0}) &= \sum_{i=1}^{n} \text{score}_{\text{span}}(T_{w_i}) \\ &+ \lambda \sum_{(w_i \rightarrow w_j) \in T_{w_0}} \text{score}_{\text{link}}(T_{w_i}, T_{w_j}) \end{aligned} \tag{2}$$

where score$_{\text{span}}(T_{w_i})$ represents how likely the subtree rooted at w_i covers the text span from $T.s$ to $T.e$. score$_{\text{link}}(T_{w_i}, T_{w_j})$ represents how likely tree T_{w_j} is a subtree of T_{w_i}, i.e. there is an arc from w_i to w_j, and λ is a hyper-parameter to balance score$_{\text{span}}$ and score$_{\text{link}}$. We will illustrate the details how to compute score$_{\text{span}}(T)$ and score$_{\text{link}}(T_1, T_2)$ in the following sections. Table 1 shows all the spans and links for the left tree in Figure 1.

3.3 Span Proposal Module

In this section, we introduce the span proposal module. This module gives each tree T_{w_i} a score score$_{\text{span}}(T_{w_i})$ in Eq.(2), which represents how likely the subtree rooted at w_i covers the text span from $T_{w_i}.s$ to $T_{w_i}.e$. The score can be decomposed into two components – the score for the left half span from w_i to $T_{w_i}.s$, and the score for the right half span from w_i to $T_{w_i}.e$, given by:

$$\begin{aligned} \text{score}_{\text{span}}(T_{w_i}) &= \text{score}_{\text{start}}(T_{w_i}.s|w_i) \\ &+ \text{score}_{\text{end}}(T_{w_i}.e|w_i) \end{aligned} \tag{3}$$

We propose to formalize score$_{\text{start}}(T_{w_i}.s|w_i)$ as the score for the text span starting at $T_{w_i}.s$, ending at w_i, by transforming the task to a text span extraction problem. Concretely, we use the biaffine function (Dozat and Manning, 2016) to score the text span by computing score$_{\text{start}}(j|i)$ – the score of the tree rooted at at w_i and staring at w_j:

$$\text{score}_{\text{start}}(j|i) = \mathbf{x}_i^\top U_{\text{start}} \mathbf{x}_j + \mathbf{w}_{\text{start}}^\top \mathbf{x}_j \tag{4}$$

where $U \in \mathbb{R}^{d \times d}$ and $\mathbf{w} \in \mathbb{R}^d$ are trainable parameters, $\mathbf{x}_i \in \mathbb{R}^d$ and $\mathbf{x}_j \in \mathbb{R}^d$ are token representations of w_i and w_j respectively. To obtain $\mathbf{x}_i$ and $\mathbf{x}_j$, we pass the sentence s to pretrained models such as BERT (Devlin et al., 2018). $\mathbf{x}_i$ and $\mathbf{x}_j$ are the last-layer representations output from BERT for w_i and w_j. We use the following loss to optimize the left-half span proposal module:

$$\mathcal{L}_{\text{span}}^{\text{start}} = -\sum_{i=1}^{n} \log \frac{\exp(\text{score}_{\text{start}}(T_{w_i}.s|i))}{\sum_{j=1}^{n} \exp(\text{score}_{\text{start}}(j|i))} \tag{5}$$

This objective enforces the model to find the correct span start $T_{w_i}.s$ for each word w_i. We ignore loss for w_0, the dummy root token.

score$_{\text{end}}(T_{w_i}.e|w_i)$ can be computed in the similar way, where the model extracts the text span rooted at index w_i and ending at $T_{w_i}.e$:

$$\text{score}_{\text{end}}(j|i) = \mathbf{x}_i^\top U_{\text{end}} \mathbf{x}_j + \mathbf{w}_{\text{end}}^\top \mathbf{x}_j \tag{6}$$

The loss to optimize the right-half span proposal module:

$$\mathcal{L}_{\text{span}}^{\text{end}} = -\sum_{i=1}^{n} \log \frac{\exp(\text{score}_{\text{end}}(T_{w_i}.e|i))}{\sum_{j=1}^{n} \exp(\text{score}_{\text{end}}(j|i))} \tag{7}$$

Using the left-half span score in Eq.(4) and the right-half span score in Eq.(6) to compute the full span score in Eq.(3), we are able to compute the score for any subtree, with text span starting at $T_{w_i}.s$, ending at $T_{w_i}.e$ and rooted at w_i.

3.4 Span Linking Module
