Abstract

Podcasts have shown a recent rise in popularity. Summarization of podcasts is of practical benefit to both content providers and consumers. It helps people quickly decide whether they will listen to a podcast and/or reduces the cognitive load of content providers to write summaries. Nevertheless, podcast summarization faces significant challenges including factual inconsistencies of summaries with respect to the inputs. The problem is exacerbated by speech disfluencies and recognition errors in transcripts of spoken language. In this paper, we explore a novel abstractive summarization method to alleviate these issues. Our approach learns to produce an abstractive summary while grounding summary segments in specific regions of the transcript to allow for full inspection of summary details. We conduct a series of analyses of the proposed approach on a large podcast dataset and show that the approach can achieve promising results. Grounded summaries bring clear benefits in locating the summary and transcript segments that contain inconsistent information, and hence improve summarization quality in terms of automatic and human evaluation.

1 Introduction

Podcasts are one of the most popular forms of new media. As of today, over 155 million people listen to a podcast every week (Christian, 2021). With the growing interest, there is an increased demand for textual summaries that foretell the content of podcasts. Those summaries help people decide, in a few seconds, if they will listen to a podcast or subscribe to the channel. They are helpful for users who want to find podcasts previously listened to. Furthermore, they can be re-purposed for social media posts or email marketing campaigns, enabling content creators to make their podcasts accessible to a larger audience.

It is desirable to generate *grounded* summaries from podcast transcripts, where spans of summary text are closely tethered to the original audio. Figure 1 provides an example of a grounded abstractive summary. When a user clicks on a summary segment, she will be directed to an audio clip that gives further detail of the conversational context. Grounded summaries give us a preview of notable podcast clips (Shalom, 2019) and they may further release summarization service providers from potential legal claims by directing users to the original audio. This is because, speech recognizers induce transcription errors and abstractive summarization models may hallucinate facts that are not entailed by the original (Kryscinski et al., 2020), both can cause podcast summaries to contain misleading or inaccurate information. With grounded summaries, users are able to frame, interpret, and place into context any system-generated summaries, thus reducing the barriers to deploy podcast summarization technology.

One may attempt to align summary text and podcast transcripts in a post-processing step to generate grounded summaries. Unfortunately, hallucinations do not allow for proper alignments as they are not found in the transcripts (Maynez et al., 2020). Hierarchical attention models may seem promising for this task (Liu and Lapata, 2019). However, the excessive length of the transcripts makes it difficult to produce attention distributions over the entire transcripts. Recent evidence suggests that attention weights are not reliable indicators of the relative importance of inputs (Jain and Wallace, 2019), thus it remains an open question whether attention can be used to find alignments between transcripts and summary segments.

In this paper, we seek to generate grounded summaries from podcast transcripts by exploring an *on-demand* abstractive summarizer. It mimics how a human might approach a lengthy transcript – the expert would identify a portion of the transcript that is deemed most important and relevant to the existing summary, use it as a ground to produce a new

Welcome to my podcast series a normal kind of all the Poetry from a normal Kind of Love is from my chapbook presentation. It was my presentation was called a normal kind of love and then I published it into a chap called a normal kind of love the chapbook all the poems that you will hear in this series are poems that can be found in that book and also my presentation that I have done in a few places around. Areaa normal Kind of Love is a presentation about domestic abuse is filled with poetry prose in music. So if you want to find out more about a normal kind of love, you can purchase the chat book on Amazon a normal kind of love the chat book by Ariana archery and also you can learn more about a normal Kind of Love on my author website at Ariana are cherry dot wordpress.com and up in the top menu. […]

And now I'm here on display naked and vulnerable for all of them to shame. I won't let them see me weep. I'm well let them call me by name. I'll hold on to my heart and seeing through my soul and love myself because even with no name with my spirit I am whole. Thank you for listening to a normal kind of love. It is in my hopes that it can help someone who is going through a similar situation with domestic abuse or violence or that if you know someone who is perhaps you can help them. It's a very sensitive situation, but I just want everyone to know no matter what it is possible to find a light. In the darkness, it just takes a lot of time a lot of careful planning a lot of compassion a lot of prayer and plenty of Hope and Faith but um always have faith that things will get better even if they don't seem very good right

Summary segments are grounded to chunks of the transcripts as a way of combating the errors that occur in transcript summarization.

The poem, "No Name" is from author, Ariana R Cherry's presentation, "A Normal Kind of Love," which is about domestic abuse. She has given the presentation in her home area to those who may be struggling with it or know someone who is.

Figure 1: An example of a *grounded* summary where spans of summary text are tethered to the original audio. The user can tap to hear the audio clip, thus interpreting a system-generated summary in context.

piece of the summary, and that process is repeated until the summary is finished. Our summarizer employs a novel regularization technique that enables it to visit portions of the transcript in chronological order, while allowing zigzags in order to produce a coherent summary. This has another implication. It implies that we may estimate what percentage of a podcast transcript is covered by the summary and thus adjust that when necessary.

Distinguishing our work from earlier research on extract-then-abstract methods (Hsu et al., 2018; Chen and Bansal, 2018; Gehrmann et al., 2018; Lebanoff et al., 2019; Jin et al., 2020; Pilault et al., 2020), we require selected transcript chunks to have high salience, but also those salient content must appear at the beginning of the selected chunks, so that the corresponding audio clips can provide good *jump-in points* for users to start listening. Our experiments are performed on a large podcast summarization dataset containing over 100,000 English podcasts (Clifton et al., 2020). We show that our proposed grounded summarizer can perform competitively or better than the state-of-the-art methods, including the recent methods that leverage large, pretrained models (Lewis et al., 2020; Beltagy et al., 2020) as judged by automatic metrics and human evaluation. Our contributions in this paper are as follows.

- We address the problem of podcast summarization by investigating an on-demand summarizer that produces grounded abstracts. The abstracts help users quickly decide if they will listen to the podcasts and offer a sampler of salient podcast clips. The on-demand summarizer does not need to encode the entire transcript, hence substantially reduces the GPU memory footprint.
- We conduct a series of analyses to gain insights into the impact of specific design decisions. They include how a transcript chunk should be defined, whether those transcript chunks overlap, to what extent the summary content is taken verbatim from selected chunks, and how the summary may be extended to cover more information.
- Through extensive experiments on a benchmark podcast dataset, we demonstrate the effectiveness of our proposed approach and show results that are comparable to human writer performance. The approach opens an avenue towards generating a new kind of abstractive summaries that allow users to verify the information consistency of summary parts against the original audio clips.[1]

2 Related Work

With the rapid rise of podcasts comes the need for automatic summarization of podcast transcriptions. While comparatively understudied, recent work has shown great progress. Clifton et al. (2020) present the Spotify dataset that was adopted in TREC 2020 for the podcast summarization task.[2] Our participating system in TREC 2020 focuses on identifying salient segments from transcripts and using them as input to an abstractive summarizer (Song et al., 2020). Reddy et al. (2021) develop classifiers to detect and eliminate extraneous marketing materials in podcasts to aid summarization. In this paper, we explore techniques that generate *grounded podcast summaries* where pieces of summary text are tied to short podcast clips.

---

[1] Our model and code have been made publicly available: `https://github.com/tencent-ailab/GrndPodcastSum`

[2] `https://trec.nist.gov/data/podcast2020.html`

One of the most serious problems of neural abstractive summarization is that the summaries can contain factually incorrect information and hallucinations (Falke et al., 2019; Kryscinski et al., 2020; Maynez et al., 2020; Lebanoff et al., 2020). Without grounded summarization, users have to listen to the full episodes to find connections between details of the summaries and the original podcasts. If successful, grounded summaries will benefit a number of summarization tasks where the input involves lengthy transcripts, including meetings (Li et al., 2019; Koay et al., 2020, 2021; Zhong et al., 2021), medical conversations (Liu and Chen, 2019), interviews (Zhu et al., 2021), livestreams (Cho et al., 2021) and more.

An extract-then-abstract strategy could be used to produce grounded abstractive summaries (Chen and Bansal, 2018; Gehrmann et al., 2018; Hsu et al., 2018; Jin et al., 2020; Pilault et al., 2020). Most of these approaches are tailored to written documents, e.g., news, Wikipedia, and scholarly articles. They extract sentences from the documents and use them as input to an abstractive summarization model to produce a summary. Nevertheless, transcripts of spoken language lack essential document structure such as sentence, paragraph and section boundaries, making it unclear how these approaches will perform on podcasts.

Attention provides another mechanism for aligning the summary and transcript segments. The use of sparse attention allows a summarization model to potentially scale to longer documents (Beltagy et al., 2020; Kitaev et al., 2020; Huang et al., 2021). Hierarchical Transformer encodes multiple paragraphs in a hierarchical manner to allow them to exchange information (Liu and Lapata, 2019; Fabbri et al., 2019; Chen and Yang, 2020). However, it is shown that attention weights are not reliable indicators of the relative importance of inputs, as alternative attention distributions would have yielded similar results (Jain and Wallace, 2019).

Our approach in this paper is to better align summary segments with chunks of the transcripts to allow easy tracing of inconsistent information. It features a generator that writes a summary from beginning to end, and a savvy selector that knows when to switch to a new transcript chunk and where to switch to. Differing from PG networks (See et al., 2017) and retrieval-augmented generation (Guu et al., 2020; Lewis et al., 2021), our selector places heavy emphasis on modeling and selection of transcript chunks. A desirable chunk is expected to be about 2 minutes long and places important information at the beginning to enable easy user verification. In the following section, we present details of the model implementation.

3 Our Approach

A major challenge facing podcast summarization is the dramatic length difference between source and target sequences. At a speaking rate of 122 words per minute for spontaneous speech (Polifroni et al., 1991), the full transcript of a 1-hour long episode contains roughly 7,000 words and that of a 1.5-hour long episode could reach 10,000 words. In contrast, a podcast summary is short, containing on average 61 words according to Manakul and Gales (2020). The ratio of their lengths could reach as high as 100-to-1, and this motivates our study of abstractive *grounded* summarization where summary segments are grounded to selected chunks of transcripts as a way of combating the inevitable errors that occur in podcast summarization.

Let $\mathbf{x}$ be the sequence of tokens in the source transcript and $\mathbf{y}$ be the sequence of tokens in the summary. These tokens share the same vocabulary $\mathcal{V}$. We use $\mathbf{x}_{\mathcal{C}}$ to denote a chunk of the transcript, and $\mathcal{C}$ gives the indices of tokens that belong to the chunk. The full transcript can be decomposed into a sequence of chunks, denoted by $\{\mathcal{C}_1, \cdots, \mathcal{C}_M\}$. The chunks may have varying sizes and overlap with each other; they are the grounds for generating a podcast summary. Our assumption is twofold. Firstly, we assume a summary segment is produced by conditioning on the previously generated tokens ($\mathbf{y}_{<j}$) and a specific chunk of the transcript. Secondly, there exists a function $\mathcal{G}(\mathbf{x}, \mathbf{y}_{<j})$ (Eq. (1)) that determines the most appropriate grounding chunk for generating all tokens of the segment. Particularly, when the entire transcript is treated as a single chunk, it reduces to the standard conditional generation model $p_\theta(y_j|\mathbf{y}_{<j}, \mathbf{x})$.

$$p(\mathbf{y}|\mathbf{x}) = \prod_{j=1}^{N} p_\theta(y_j|\mathbf{y}_{<j}, \mathcal{G}(\mathbf{x}, \mathbf{y}_{<j})) \qquad (1)$$

Thus, the crucial point is a coarse segmentation of the source transcript and an alignment between the transcript chunks and summary segments. In this work we use a sliding window to produce transcript chunks, with window size $\mathcal{W}$ and stride size

$\mathcal{S}$.[3] The sizes can be measured in terms of tokens. E.g., $\mathcal{W}$=256 and $\mathcal{S}$=128 tokens will produce a series of fixed-length chunks that overlap with each other. The rationale for using overlapping chunks is to find those that serve both as grounds for summary generation and good jump-in points for user verification. The sizes can also be measured by the number of sentences. E.g., $\mathcal{W}$=20 and $\mathcal{S}$=20 sentences produce a set of varying-length, non-overlapping chunks. In spoken language, a series of consecutive short sentences often indicates the content is relatively unimportant (Marge et al., 2010).

Given a summary segment $\widetilde{\mathbf{y}}$, we designate $\mathbf{x}_\mathcal{C}$ as a **grounding chunk** if it attains the highest score $\mathcal{S}(\mathbf{x}_\mathcal{C}, \widetilde{\mathbf{y}})$ (Eq. (2)). This position-biased coverage score favors the transcript chunk that covers summary bigrams and puts summary content at the beginning to aid humans in performing content verification. It measures the percentage of unique summary bigrams $\mathcal{B}(\widetilde{\mathbf{y}})$ covered by a chunk $\mathbf{x}_\mathcal{C}$. Particularly, $\mathbb{I}\,[b_k \in \mathbf{x}_\mathcal{C}]$ is an indicator that returns 1 if the bigram b_k appears in $\mathbf{x}_\mathcal{C}$ and 0 otherwise. Each bigram b_k has an associated weight w_k (Eq. (3)). If it appears in the first position of $\mathbf{x}_\mathcal{C}$ ($\texttt{pos}_k = 0$), it receives a weight of one. Otherwise, the weight is decayed according to the relative position of the bigram's first occurrence in the chunk ($\texttt{pos}_k$) and γ is a coefficient for the decay.[4]

$$\mathcal{S}(\mathbf{x}_\mathcal{C}, \widetilde{\mathbf{y}}) = \frac{1}{|\mathcal{B}(\widetilde{\mathbf{y}})|} \sum_{b_k \in \mathcal{B}(\widetilde{\mathbf{y}})} w_k \, \mathbb{I}\,[b_k \in \mathbf{x}_\mathcal{C}] \quad (2)$$

$$w_k = 1 - \gamma \frac{\texttt{pos}_k}{|\mathcal{C}|}; \quad \gamma \in [0, 1] \quad (3)$$

We proceed by training a neural encoder-decoder model to generate an abstractive summary from the grounding transcript chunks. Each segment of the summary (= sentence)[5] is generated conditioned on its grounding chunk $\mathbf{x}_\mathcal{C}$ and all the previously generated tokens $\mathbf{y}_{<j}$. The process starts from the first chunk of the transcript $\mathbf{x}_{\mathcal{C}_1}$. The encoder converts this grounding chunk into a sequence of hidden vectors $[\mathbf{h}_1^\mathcal{C}, \ldots, \mathbf{h}_m^\mathcal{C}]$ (Eq. (4)). The decoder predicts the next summary token y_j (Eq. (5)) and continues to do so until a "*switch point*" is detected. At this point the current summary segment is finished and the decoder is poised to select the next transcript chunk $\mathbf{x}_{\mathcal{C}_\text{new}}$ and generate a new summary segment from it. The decoding process finishes when a special symbol ([sep]) is predicted that indicates the end of the summary.

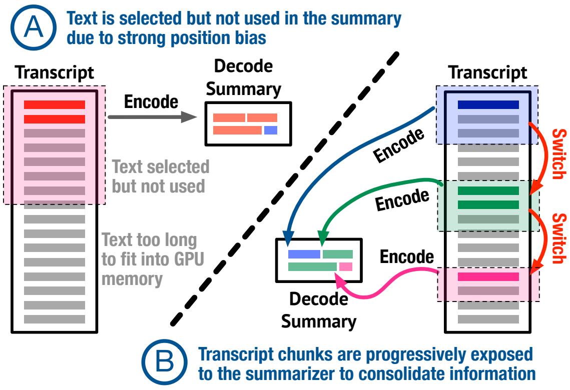

Figure 2: Strong position bias can cause the abstractor to use only content at the beginning of the input to generate a summary. By exposing the chunks progressively, our approach makes use of this characteristic to consolidate information from multiple transcript chunks.

$$[\mathbf{h}_1^\mathcal{C}, \ldots, \mathbf{h}_m^\mathcal{C}] = \texttt{Encode}(\mathbf{x}_\mathcal{C}) \quad (4)$$

$$y_j = \texttt{Decode}(\mathbf{y}_{<j}, [\mathbf{h}_1^\mathcal{C}, \ldots, \mathbf{h}_m^\mathcal{C}]) \quad (5)$$

$$\mathcal{G}(\mathbf{x}, \mathbf{y}_{<j}) = \begin{cases} \mathbf{x}_{\mathcal{C}_1}, & j = 1 \\ \mathbf{x}_{\mathcal{C}_\text{new}}, & j > 1 \ \texttt{\& switch} \\ \mathcal{G}(\mathbf{y}_{<j-1}), & j > 1 \ \texttt{\& no-switch} \end{cases}$$

There is a notable difference between our approach and most extract-then-abstract approaches that select important sentences from the document and provide them to the abstractor all-at-once. As illustrated in Figure 2, strong position bias causes the abstractor to use only content at the beginning of the input to generate a summary. By exposing the chunks progressively, our approach naturally makes use of this characteristic to consolidate information from multiple source chunks. It reduces the amount of computation necessary to train the encoder-decoder model, as only selected transcript chunks are encoded which is equal to the number of summary segments. Moreover, it is possible to encourage the summary to have a good coverage of the source content by specifying a minimal set of grounding chunks to be used for generation.

---

[3] Discourse segmentation is beyond the scope of this work. There is little to no data available to build a discourse segmentation tool and little existing work on discourse analysis of podcasts. We refer the reader to Joty et al. (2019) for recent advances in discourse processing research.

[4] If a summary segment cannot be mapped to a chunk using Eqs. (2-3), we perform the following: $\widetilde{\mathbf{y}}$ is assigned to the first chunk $\mathcal{C}_1$ if it is the first segment of the summary. Otherwise, $\widetilde{\mathbf{y}}$ is assigned to the same chunk as the previous summary segment to improve coherence. We require $\mathbf{x}_\mathcal{C}$ and $\widetilde{\mathbf{y}}$ to have a minimum of four shared bigrams (stopwords-only bigrams are excluded). Future work may consider aligning transcripts and summaries based on propositions (Ernst et al., 2020).

[5] We use sentences as summary segments; other sentence-like segments are possible in future work.

Regularizing Chunk Selection. Learning function $\mathcal{G}(\mathbf{x}, \mathbf{y}_{<j})$ that predicts a transcript chunk $\mathbf{x}_\mathcal{C}$ to switch to is crucial for success at inference time. Let there be M transcript chunks and N summary segments in a training instance. We define p_j^c to be the model probability that the c-th chunk is predicted as the ground for generating the j-th summary segment; c^* is the gold chunk obtained using Eq. (2-3). Our learning objective is a cross-entropy loss against the gold labels with a novel regularizing term $\mathcal{R}$ to enable chunks to be selected as per their original order in the transcript, while allowing zigzags to produce a coherent summary (Eq. (6-7)).

$$\mathcal{L}(\phi) = -\textstyle\sum_{j=1}^{N} \log p_j^{c^*} + \alpha\mathcal{R} \tag{6}$$

$$\mathcal{R} = \tfrac{1}{N} \textstyle\sum_{j=1}^{N} \sum_{c=1}^{M} \max(0, s_{j+1}^c - s_j^c) \tag{7}$$

Particularly, $s_j^c = \sum_{c'=1}^{c} p_j^{c'}$ denotes the sum of the probability assigned to all chunks up to the c-th position, in order to generate the j-th summary segment. We encourage $\sum_{c=1}^{M} \max(0, s_{j+1}^c - s_j^c)$ to be a small value so that if a chunk (up to the c-th position) is assigned to the j-th summary segment, it is unlikely to be assigned to the $(j+1)$-th segment. $\mathcal{R}$ is designed to regularize the loss and penalize violations; α is its coefficient which will be tuned on the validation set.

Given a partial summary $\mathbf{y}_{<j}$, selecting the next transcript chunk depends on two factors. Firstly, it should be a chunk that contains salient content at its beginning. We use $\mathcal{I}(\mathbf{x}_\mathcal{C})$ to denote the importance of the chunk. It is obtained by encoding the chunk into a vector $\mathbf{h}_{\mathbf{x}_\mathcal{C}}$ using RoBERTa (Liu et al., 2019), then apply a feedforward network to it to estimate the importance (Eq. (9)).[6]

$$p_j^c \propto \exp(\mathcal{I}(\mathbf{x}_\mathcal{C}) + \mathcal{R}(\mathbf{x}_\mathcal{C}, \mathbf{y}_{<j})) \tag{8}$$

$$\mathcal{I}(\mathbf{x}_\mathcal{C}) = \texttt{FFN}_1(\mathbf{h}_{\mathbf{x}_\mathcal{C}}) \tag{9}$$

$$\begin{aligned}\mathcal{R}(\mathbf{x}_\mathcal{C}, \mathbf{y}_{<j}) = {} & \texttt{FFN}_2([\mathbf{h}_{\mathbf{x}_\mathcal{C}} || \mathbf{h}_{\mathbf{y}_{<j}}]) \\ & + \texttt{LowRank}(\mathbf{h}_{\mathbf{x}_\mathcal{C}}^\top \mathbf{W}\, \mathbf{h}_{\mathbf{y}_{<j}})\end{aligned} \tag{10}$$

Secondly, the chunk may be relevant to the partial summary $\mathbf{y}_{<j}$. We define the relevance score $\mathcal{R}(\mathbf{x}_\mathcal{C}, \mathbf{y}_{<j})$ to capture two levels of interaction between the candidate chunk, represented by $\mathbf{h}_{\mathbf{x}_\mathcal{C}}$ and the last hidden state of the partial summary, represented by $\mathbf{h}_{\mathbf{y}_{<j}}$. Their linear interaction is captured by a feedforward network ($\texttt{FFN}_2$) and bilinear interaction is modelled by $\mathbf{h}_{\mathbf{x}_\mathcal{C}}^\top \mathbf{W}\, \mathbf{h}_{\mathbf{y}_{<j}}$ where a low-rank approximation is used: $\texttt{LowRank}(p^\top \mathbf{W} q) = (p^\top \mathbf{U})(\mathbf{V}^\top q)$. The score p_j^c is the likelihood that the c-th chunk is assigned to the j-th summary segment considering saliency and content relevancy.

Switch Point. A skilled writer pauses after writing down a sentence. We borrow that intuition to inform the construction of a switch-point predictor. The model combines the last hidden state of the summary sequence $\mathbf{h}_{\mathbf{y}_{<j}}$ and the embedding of the anticipated token $\mathbf{E}(y_j)$, and use a feedforward network $\texttt{FFN}_3$ to predict if the j-th decoding step corresponds to a "*switch point*" (Eq. (11)). During training, the last token of each summary sentence is a ground-truth switch point. At inference time, the model predicts a switch point if $p(\texttt{switch})$ exceeds a threshold, at which point we compute p_j^c to decide the next chunk. Note that the model may choose use the same transcript chunk after switching.

$$p(\texttt{switch}) = \sigma(\texttt{FFN}_3([\mathbf{h}_{\mathbf{y}_{<j}} || \mathbf{E}(y_j)])) \tag{11}$$

4 Podcast Data

With over 100,000 podcast episodes, the Spotify dataset (Clifton et al., 2020) is one of the largest corpora available for podcast search and summarization. It encompasses a wide range of topics: travel, business, sports, book reviews, mysteries, guided meditations, nutrition and weight loss, among others. Each episode is accompanied by an audio file, an automatic transcript generated by Google's Speech-to-Text API,[7] and metadata provided by the podcast creator. We do not use the audio data in this paper. Our summarizer takes as input a transcript and uses the creator-provided episode description as the reference summary.

Data Filtering. Episode descriptions provided by podcast creators show wide variations in quality. When noisy descriptions are used as reference summaries, they can cause a summarizer to hallucinate content. We conduct aggressive filtering of the training data to remove low-quality creator descriptions so as to maintain a balance between the amount of training examples available and quality of those examples. We clean up reference summaries on the token-, sentence- and summary-level.

---

[6] The parameters of $\texttt{FFN}_1$ are pretrained on an extraction task that favors chunks that contain summary content at the beginning. For each chunk, we compute its position-biased coverage score (Eq. (2)) against the entire summary. 1/4 of the chunks that yield the highest coverage scores are designated as positive instances, the remaining are negative instances. $\texttt{FFN}_1$ is thus pretrained as a binary classifier.

Creator Description	Tune in as Natalie and Jessica debate physical vs. chemical exfoliation options, and see what our ultimate verdict is on the best type and specific products we love!
hk_uu_podcast1	In this episode, Jessica and Natalie go head-to-head in the Great Exfoliation Debate! They each advocate their own type of exfoliator and try each other's products to see if they're worth the price difference. They also do a wine pairing and talk about the pros and cons of each of the products they tried.
UCF_NLP2	In this weeks episode, Jessica and Natalie go head-to-head in the great exfoliation debate. They each advocate for their own type of exfoliator, and then try each other's products for 10 minutes to see what they think. We also talk about the pros and cons of each type of product and recommend a wine to pair with this episode. Santa Julia Winemakers Reserve Mountain Blend .
cued_speechUniv2	In this episode of the Great Exfoliation Debate, Jessica and Natalie talk about their favorite types of exfoliators and the pros and cons of each of their favorite products. We also do a wine pairing and talk about the benefits and drawbacks of different types of chemical and physical exfoliation products.
GrndAbs-tn	Natalie and Jessica are back with another episode of Skincare Somali A's. This week we're talking about what we like to call the "Great Exfoliation Debate." We'll also be doing our wine pairing this week. Santa Julia Winemakers' Reserve Mountain Blend (2016)
GrndAbs-to	This week we are talking about what we like to call the "Great Exfoliation Debate." Because we've got two different points of view and we are going to Duke it out mano a mano this week. We will also of course do our wine pairing because we are your Somali A's and this week we're going with something a little bit more aggressive...a little bit bold.
GrndAbs-sn	In this episode, Natalie and Jessica debate the pros and cons of exfoliation. Exfoliation is this step in your skincare routine that is taking off all the dead skin cells on your face. And the point of Exfoliating is to reveal brighter, healthier skin while reducing the size of your pores. In this week's episode, we'll be discussing the pros, cons, and what we think is the best way to exfoliate your skin.
GrndAbs-so	Natalie and Jessica are back to debate the merits of exfoliation. This week, they are going mano a mano and will be debating the pros and cons of using exfoliating on your face. We will also do our wine pairing because we are your Somali A's and this week we're going with something a little bit more aggressive. We would like to recommend Santa Julia Winemakers' Reserve Mountain Blend. That is a Malbec and Cab Franc blend from 2016. It's just a bit of a middle of the road wine but super super tasty

Table 1: Grounded abstractive summaries (GrndAbs-*) demonstrate a high level of specificity compared to summaries without grounding. The latter contains more generic content. The segments of grounded summaries are tethered to specific transcripts chunks. If a listener finds the summary segment interesting, they can tap to hear the selected segment in context.

Tokens that correspond to URLs, email addresses, @mentions, #hashtags, and those excessively long tokens (>25 characters) are directly removed from the summaries. Each sentence in the summary is given a salience score that is the sum of IDF scores of its words. A low score (<10) indicates the sentence contains few informative words and it is thus removed from the summary. Finally, if, after sentence removal, the reference summary is too short or cannot be properly aligned to transcript chunks (§3), the instance is removed from the dataset.[8] This process filters out a substantial amount of low-quality reference summaries, yielding 40,302 episodes in the training set. The Spotify dataset has a standard test set of 1,027 episodes and 179 of them are set for human evaluation.

Baselines. Our baselines consist of three of the best performing systems in the TREC 2020 competition on podcast summarization. These systems were judged the best performing by both automatic metrics and human evaluation performed by NIST assessors. All systems make use of the BART-large model (Lewis et al., 2020). The model is tuned first on a news summarization dataset, i.e., CNN/DM or XSum, then fine-tuned on the podcast dataset. Due to the long length of the transcripts, Karlbom and Clifton (2020) describe a combined Longformer-BART model that replaces the BART attention layers with attentions of Longformer (Beltagy et al., 2020); their system is named hk_uu_podcast1. Song et al. (2020) develop an extractive module to select segments from transcripts, then integrate the extractor with BART abstractor to generate summaries (UCF_NLP2). Their baseline (UCF_NLP1) directly truncates the transcript to the first 1,024 tokens. Manakul and Gales (2020) develop a similar baseline (cued_speechUniv3) using the first 1,024 tokens. Further, they perform sentence filtering using a hierarchical attention model (cued_speechUniv1/2/4) and ensembles of models from different data shuffles and checkpoints (cued_speechUniv1/2). In this paper, our system is called GrndAbs for generating grounded abstracts. It has 4 options: -to, -tn, -so, -sn, indicating the sliding window is defined in terms of tokens (-t) or sentences (-s), overlapping (-o) or non-overlapping (-n). We obtain outputs from these competitive baselines and our system to examine both the successes and failures of these attempts.

5 Results and Analysis

Experimental Settings. Our encoder-decoder model uses BART-large as the base model before fine-tuning it on the podcast dataset. We use the AdamW (Loshchilov and Hutter, 2017) optimizer, where the momentum parameters are set to 0.9 and 0.999. The regularizing coefficient α is tuned on the validation set in the range of $\{0, 0.01, \underline{0.1}, 1\}$. For summary decoding, we use beam search with a beam size K=4 and a length penalty p=2. Our

---

[8] A summary is required to contain a minimum of 10 BPE tokens and have >2 shared bigrams with all of its grounding chunks. Only words whose IDF scores are greater than 1.2 are considered when computing sentence salience scores.

Run ID	R-1(%)	R-2(%)	R-L(%)	BertS(%)	BLEURT	SummL

GrndAbs-tn	**25.19**	50.58	**75.77**	**20.16**	4.07

Table 3: Human evaluation results. 25% of grounded abstractive summaries are rated as *Excellent* and 76% receive a rating of either *Excellent* (E) or *Good* (G).

sliding window, measured in terms of tokens or sentences, only contain whole sentences. We use the Byte-Pair Encoding (BPE) tokenizer with a vocabulary size $\mathcal{V}$=50,265. For transcripts and reference summaries, we use the SpaCy tool to segment them into sentences (model en_core_web_lg 2.2.5).

Example Summaries. In Table 1, we provide a direct comparison of system summaries. This podcast is hosted by Natalie and Jessica who call themselves "*Skincare Sommeliers.*" The episode is named "*The Great Exfoliation Debate.*" We find that grounded abstractive summaries (GrndAbs-*) have a higher level of specificity compared to summaries without grounding. Segments of grounded summaries are tied to specific transcripts chunks. If a listener finds a summary segment interesting, they can tap to hear the selected summary segment in context. Our baselines are highly competitive. Their summaries tend to contain more generic content. The description provided by podcast creators is relatively short and at times it does not directly summarize the episode. There are clear benefits in automatic summarization of podcasts, which can reduce the cognitive load and the time it takes for podcast creators to write the summary.

Automatic Metrics. In Table 2, we report results on the standard test set containing 1,027 podcast episodes. The metrics include ROUGE (Lin, 2004) variants that compare system summaries with creator descriptions based on n-gram overlap. Further, we experiment with recently developed metrics: BertScore (Zhang et al., 2020) and BLEURT (Sellam et al., 2020) that draw on deep neural representations to evaluate generated text. Our approach does not outperform the baselines in ROUGE evaluation against creator descriptions. However, the gap has been substantially reduced when more advanced metrics (BertScore and BLEURT) are considered. There are two possible explanations. First, grounded summaries are about 50% longer than plain abstractive summaries. Their average length is about 80 words per summary, yielding low precision scores. Second, the quality of creator descriptions can be poor. Jones et al. (2020) report only 40% of such descriptions are of Good or Excellent quality, indicating future work may consider creating high-quality ground-truth summaries. Among the four variants of our approach, we observe that their difference is not prominent. The token-based, non-overlapping windows (-tn) variant outperforms others in terms of R-1 and R-L. This system is used in subsequent experiments and analyses.

Human Evaluation. It is imperative to perform human evaluation given that creator-provided descriptions are of poor quality and ground-truth summaries are nonexistent. We follow the TREC guidelines to ask human evaluators to assign each summary to one of the four grades: *Excellent*, *Good*, *Fair* and *Poor*. The excellent summary will accurately conveys the most important content of the episode (topical content, genre, and participants). It should contain almost no redundant material, be coherent, comprehensible, and has no grammatical errors (Jones et al., 2020). We also asked the human evaluators to answer 8 yes/no questions re-

System	Q1: People Names	Q2: People Add Info	Q3: Main Topics	Q4: Podcast Format	Q5: Title Context	Q6: Summ Redund	Q7: Good English	Q8: Start/End Points
creator_description	60.08	50.19	80.81	59.61	57.00	16.28	88.76	60.16
hk_uu_podcast1	64.15	47.29	85.63	57.62	58.95	**10.85**	94.76	70.35
UCF_NLP2	67.38	51.55	87.02	63.57	62.52	14.40	**95.15**	71.71
cued_speechUniv2	69.12	50.67	87.98	64.73	63.62	12.87	94.93	**77.00**
GrndAbs-tn	**75.15**	**64.47**	**89.73**	**69.51**	**66.15**	17.09	94.55	73.35

Table 4: Average scores per human judgment of 179 testing summaries on 8 Yes/No questions. An assessor quickly skimmed the episode, and made judgments for each summary of the episode. "creator_description" represents the episode description. "cued_speechUniv2," "UCF_NLP2" and "hk_uu_podcast" are the top-3 teams in the Podcast Challenge. Our system "GrndAbs-tn" learns to produce abstractive summary while grounding summary segments in specific portions of the transcript to allow for full inspection of summary details.

Q1	Does the summary include **names of the main people** (hosts, guests, characters) involved or mentioned in the podcast?
Q2	Does the summary give any **additional information** about the people mentioned (such as their job titles, biographies, personal background, etc)?
Q3	Does the summary include the **main topic(s)** of the podcast?
Q4	Does the summary tell you anything about **the format of the podcast**; e.g. whether it's an interview, whether it's a chat between friends, a monologue, etc?
Q5	Does the summary give you **more context on the title** of the podcast?
Q6	Does the summary contain **redundant information**?
Q7	Is the summary written in **good English**?
Q8	Are the **start and end of the summary** good sentence and paragraph start and end points?

Table 5: There are 8 yes-or-no questions asked about the summary quality. An ideal summary should receive a "yes" (1) for all questions but Q6.

garding the quality of the summary as (Jones et al., 2020) suggested, those questions are shown in Table 5. We conduct these experiments on the test set containing 179 podcast episodes as (Jones et al., 2020) did, where each summary is evaluated by five Master workers recruited on the mechanical turk. As shown in Table 3, we find that humans prefer the lengthier grounded abstractive summaries, which substantially outperform all baselines. 25% of grounded abstractive summaries are rated as *Excellent* and 76% of them receive a rating of either *Excellent* or *Good*. Table 4 shows the results of the 8 questions. Comparing to previous best systems, our grounded abstractive summaries have a significant performance gain on retrieving important information including People Names(+6.03%), People Additional Information(+12.92%), Main Topics(+1.75%), Podcast Format(+4.78%) and Title related context(+2.47%) with slight redundancy.

Chunk Selection and Switch Point Prediction.

We are curious to know how well our system performs on predicting grounding chunks: $\mathcal{G}(\mathbf{x}, \mathbf{y}_{<j})$. In this study, we assume switch points are known and report results on the validation set. Our decoder starts from the first transcript chunk and predicts the next chunk at each switch point. We find that it achieves an accuracy of 86.02% on identifying ground-truth chunks. Next, we examine the performance of switch point prediction. On the validation set, we observe that the predictor achieves 98.75%, 84.95% and 91.33%, respectively, for precision, recall and F-score. Moreover, each summary has an average of 3.67 switch points. A majority of the time (92.42%) the model decides to use the current chunk to continue to decode the next summary segment. At a small percentage (7.58%) the model decides to find to a new grounding chunk. We find 1.24 unique grounding chunks per summary. The statistics suggest that identifying grounding chunks is crucial for summary generation.

Grounded Summaries. In Table 7, we measure the percentage of summary n-grams that appear in the transcripts (for all baselines) or grounding chunks (for our approach). While the distributions of unigrams are largely similar, we observe that grounded abstractive summaries tend to reuse more bigrams and trigrams of their grounding chunks. Moreover, for trigrams that are found in the grounding chunks, we find 70% of them tend to appear at the beginning – the front half of the chunks. These results suggest that the grounding chunks identified by our approach can provide effective support for summary generation.

What Made the Task Challenging?

We manually analyze a large amount of transcripts and their creator descriptions to identify the challenging points of podcast summarization in Table 8:

- Substantial lexical mismatch exists between the spoken and written form of descriptions. Speech recognition errors are abundant. E.g., "*by Hans Christian Andersen*" has been misrecognized into

Excellent	The summary accurately conveys all the most important attributes of the episode, which could include topical content, genre, and participants. In addition to giving an accurate representation of the content, it contains almost no redundant material which is not needed when deciding whether to listen. It is also coherent, comprehensible, and has no grammatical errors.
Good	The summary conveys most of the most important attributes and gives the reader a reasonable sense of what the episode contains with little redundant material which is not needed when deciding whether to listen. Occasional grammatical or coherence errors are acceptable.
Fair	The summary conveys some attributes of the content but gives the reader an imperfect or incomplete sense of what the episode contains. It may contain redundant material which is not needed when deciding whether to listen and may contain repetitions or broken sentences.
Bad	The summary does not convey any of the most important content items of the episode or gives the reader an incorrect or incomprehensible sense of what the episode contains. It may contain a large amount of redundant information that is not needed when deciding whether to listen to the episode.

Table 6: Guidelines for human evaluation of podcast summaries provided by TREC.

	1-gram	**2-gram**	**3-gram**
cued_speechUniv1	87.86	56.33	33.37
cued_speechUniv2	87.82	56.11	32.72
cued_speechUniv3	84.96	52.05	31.24
cued_speechUniv4	85.23	51.44	29.88
UCF_NLP1	83.96	49.89	28.61
UCF_NLP2	84.46	50.33	29.33
hk_uu_podcast1	86.94	56.12	35.55
GrndAbs-to	85.83	57.31	**39.03**
GrndAbs-tn	86.38	58.44	**40.38**
GrndAbs-so	86.52	59.76	**42.13**
GrndAbs-sn	86.80	60.55	**43.18**

Table 7: Percentage of summary 1/2/3-grams appearing in the transcripts (for all baselines) or grounding chunks (for our approach). We observe that grounded abstractive summaries tend to reuse bigrams and trigrams of their grounding chunks.

"*buy homes Christian Andersen.*"

- The creator descriptions are sometimes highly abstractive, do not always summarize the episode and contain teasers. E.g., "*A male perspective podcast to start a conversation...*" and "*Ever wondered how Ed Sheeran became famous.*"
- The transcripts contain advertising inserts, e.g., "*I need to tell you about our sponsor...*" and the same description is used for different episodes that causes confusion to the model, e.g., "*The goal of Daily Fortnite is to build a community...*"

6 Conclusion

In this paper, we investigate podcast summarization to produce textual summaries for podcast episodes that help listeners to understand why they might want to play those podcasts. We present a new kind of podcast summary where spans of summary text are tethered to the original audio to allow users to interpret system-generated abstracts in context. Experiments on a benchmark dataset demonstrates the utility of our proposed approach.

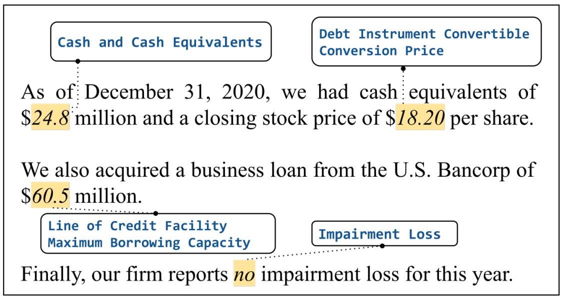
Abstract

Publicly traded companies are required to submit periodic reports with eXtensive Business Reporting Language (XBRL) word-level tags. Manually tagging the reports is tedious and costly. We, therefore, introduce XBRL tagging as a new entity extraction task for the financial domain and release FiNER-139, a dataset of 1.1M sentences with gold XBRL tags. Unlike typical entity extraction datasets, FiNER-139 uses a much larger label set of 139 entity types. Most annotated tokens are numeric, with the correct tag per token depending mostly on context, rather than the token itself. We show that subword fragmentation of numeric expressions harms BERT's performance, allowing word-level BILSTMs to perform better. To improve BERT's performance, we propose two simple and effective solutions that replace numeric expressions with pseudo-tokens reflecting original token shapes and numeric magnitudes. We also experiment with FIN-BERT, an existing BERT model for the financial domain, and release our own BERT (SEC-BERT), pre-trained on financial filings, which performs best. Through data and error analysis, we finally identify possible limitations to inspire future work on XBRL tagging.



As of December 31, 2020, we had cash equivalents of $24.8 million and a closing stock price of $18.20 per share.

We also acquired a business loan from the U.S. Bancorp of $60.5 million.

Finally, our firm reports no impairment loss for this year.

Figure 1: Sentences from FiNER-139, with XBRL tags on numeric and non-numeric tokens. XBRL tags are actually XML-based and most tagged tokens are numeric.

1 Introduction

Natural language processing (NLP) for finance is an emerging research area (Hahn et al., 2019; Chen et al., 2020; El-Haj et al., 2020). Financial data are mostly reported in tables,but substantial information can also be found in textual form, e.g., in company filings, analyst reports, and economic news. Such information is useful in numerous financial intelligence tasks, like stock market prediction (Chen et al., 2019; Yang et al., 2019), financial sentiment analysis (Malo et al., 2014; Wang et al., 2013; Akhtar et al., 2017), economic event detection (Ein-Dor et al., 2019; Jacobs et al., 2018; Zhai and Zhang, 2019), and causality analysis (Tabari et al., 2018; Izumi and Sakaji, 2019). In this work, we study how financial reports can be automatically enriched with word-level tags from the eXtensive Business Reporting Language (XBRL), a tedious and costly task not considered so far.[1]

To promote transparency among shareholders and potential investors, publicly traded companies are required to file periodic financial reports. These comprise multiple sections, including financial tables and text paragraphs, called *text notes*. In addition, legislation in the US, the UK, the EU and elsewhere requires the reports to be annotated with tags of XBRL, an XML-based language, to facilitate the processing of financial information. The annotation of tables can be easily achieved by using company-specific pre-tagged table templates, since the structure and contents of the tables in the reports of a particular company rarely change. On the other hand, the unstructured and dynamic nature of text notes (Figure 1) makes adding XBRL tags to them much more difficult. Hence, we focus on automatically tagging text notes. Tackling this task could facilitate the annotation of new and old reports (which may not include XBRL tags), e.g.,

by inspecting automatically suggested tags.

Towards this direction, we release FiNER-139, a new dataset of 1.1M sentences with gold XBRL tags, from annual and quarterly reports of publicly traded companies obtained from the US Securities and Exchange Commission (SEC). Unlike other entity extraction tasks, like named entity recognition (NER) or contract element extraction (Table 1), which typically require identifying entities of a small set of common types (e.g., persons, organizations), XBRL defines approx. 6k entity types. As a first step, we consider the 139 most frequent XBRL entity types, still a much larger label set than usual.

Another important difference from typical entity extraction is that most tagged tokens (~91%) in the text notes we consider are numeric, with the correct tag per token depending mostly on context, not the token itself (Figure 1). The abundance of numeric tokens also leads to a very high ratio of out-of-vocabulary (OOV) tokens, approx. 10.4% when using a custom WORD2VEC (Mikolov et al., 2013a) model trained on our corpus. When using subwords, e.g., in models like BERT (Devlin et al., 2019), there are no OOV tokens, but numeric expressions get excessively fragmented, making it difficult for the model to gather information from the fragments and correctly tag them all. In our experiments, this is evident by the slightly better performance of stacked BILSTMs (Graves et al., 2013; Lample et al., 2016) operating on word embeddings compared to BERT. The latter improves when using a CRF (Lafferty et al., 2001) layer, which helps avoid assigning nonsensical sequences of labels to the fragments (subwords) of numeric expressions.

To further improve BERT's performance, we propose two simple and effective solutions that replace numeric expressions with pseudo-tokens reflecting the original token shapes and magnitudes. We also experiment with FIN-BERT (Yang et al., 2020), an existing BERT model for the financial domain, and release our own family of BERT models, pre-trained on 200k financial filings, achieving the best overall performance.

Our key contributions are:

1. We introduce XBRL tagging, a new financial NLP task for a real-world need, and we release FiNER-139, the first XBRL tagging dataset.[2]
2. We provide extensive experiment BILSTMs and BERT with generic or in-domain pre-training, which establish strong baseline results for future work on FiNER-139.
3. We show that replacing numeric tokens with pseudo-tokens reflecting token shapes and magnitudes significantly boosts the performance of BERT-based models in this task.
4. We release a new family of BERT models (SEC-BERT, SEC-BERT-NUM, SEC-BERT-SHAPE) pre-trained on 200k financial filings that obtains the best results on FiNER-139.[3,4,5]

2 Related Work

Entity extraction: XBRL tagging differs from NER and other previous entity extraction tasks (Table 1), like contract element extraction (Chalkidis et al., 2019). Crucially, in XBRL tagging there is a much larger set of entity types (6k in full XBRL, 139 in FiNER-139), most tagged tokens are numeric (~91%), and the correct tag highly depends on context. In most NER datasets, numeric expressions are classified in generic entity types like 'amount' or 'date' (Bikel et al., 1999); this can often be achieved with regular expressions that look for common formats of numeric expressions, and the latter are often among the easiest entity types in NER datasets. By contrast, although it is easy to figure out that the first three highlighted expressions of Figure 1 are amounts, assigning them the correct XBRL tags requires carefully considering their context. Contract element extraction (Chalkidis et al., 2019) also requires considering the context of dates, amounts etc. to distinguish, for example, start dates from end dates, total amounts from other mentioned amounts, but the number of entity types in FiNER-139 is an order of magnitude larger (Table 1) and the full tag set of XBRL is even larger (6k).

[5] https://huggingface.co/nlpaueb/sec-bert-shape

Financial NER: Previous financial NER applications use at most 9 (generic) class labels. Salinas Alvarado et al. (2015) investigated NER in finance to recognize organizations, persons, locations, and miscellaneous entities on 8 manually annotated SEC financial agreements using CRFs. Francis et al. (2019) experimented with transfer learning by unfreezing different layers of a BILSTM with a CRF layer, pre-trained on invoices, to extract 9 entity types with distinct morphological patterns (e.g., IBAN, company name, date, total amount). Also, Hampton et al. (2015, 2016) applied a Maximum Entropy classifier, CRFs, and handcrafted rules to London Stock Exchange filings to detect 9 generic entity types (e.g., person, organization, location, money, date, percentages). Finally, Kumar et al. (2016) extended the work of Finkel et al. (2005) and built a financial entity recognizer of dates, numeric values, economic terms in SEC and non-SEC documents, using numerous handcrafted text features. By contrast, FiNER-139 uses a specialized set of 139 highly technical economic tags derived from the real-world need of XBRL tagging, and we employ no handcrafted features.

Numerical reasoning: Neural numerical reasoning studies how to represent numbers to solve numeracy tasks, e.g., compare numbers, understand mathematical operations mentioned in a text etc. Zhang et al. (2020) released NumBERT, a Transformer-based model that handles numerical reasoning tasks by representing numbers by their scientific notation and applying subword tokenization. On the other hand, GenBERT (Geva et al., 2020) uses the decimal notation and digit-by-digit tokenization of numbers. Both models attempt to deal with the problem that word-level tokenization often turns numeric tokens to OOVs (Thawani et al., 2021). This is important, because numerical reasoning requires modeling the exact value of each numeric token. In FiNER-139, the correct XBRL tags of numeric tokens depend much more on their contexts and token shapes than on their exact numeric values (Fig. 1). Hence, these methods are not directly relevant. GenBERT's digit-by-digit tokenization would also lead to excessive fragmentation, which we experimentally find to harm performance.

3 Task and Dataset

Traditionally, business filings were simply rendered in plain text. Thus, analysts and researchers needed to manually identify, copy, and paste each amount of interest (e.g., from filings to spreadsheets). With XBRL-tagged filings, identifying and extracting amounts of interest (e.g., to spreadsheets or databases) can be automated. More generally, XBRL facilitates the machine processing of financial documents. Hence, XBRL-tagged financial reports are required in several countries, as already noted (Section 1). However, manually tagging reports with XBRL tags is tedious and resource-intensive. Therefore, we release FiNER-139 to foster research towards automating XBRL tagging.

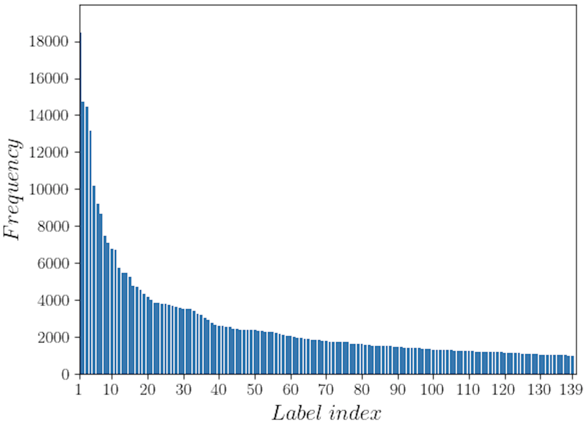

Figure 2: Frequency distribution of the 139 XBRL tags used in this work over the entire FiNER-139 dataset. Label indices shown instead of tag names to save space.

FiNER-139 was compiled from approx. 10k annual and quarterly English reports (filings) of publicly traded companies downloaded from SEC's EDGAR system.[6] The downloaded reports span a 5-year period, from 2016 to 2020. They are annotated with XBRL tags by professional auditors and describe the performance and projections of the companies. We used regular expressions to extract the text notes from the *Financial Statements Item* of each filing, which is the primary source of XBRL tags in annual and quarterly reports.

XBRL taxonomies have many different attributes, making XBRL tagging challenging even for humans (Baldwin et al., 2006; Hoitash and Hoitash, 2018). Furthermore, each jurisdiction has its own XBRL taxonomy. Since we work with US documents, our labels come from US-GAAP.[7] Since this is the first effort towards automatic XBRL tagging, we chose to work with the most essential and informative attribute, the *tag names*, which populate our label set. Also, since XBRL tags change periodically, we selected the 139 (out of 6,008) most frequent XBRL tags with at least 1,000 appearances in FiNER-139.

Dev	112,494	45.4 ± 35.9	1.7 ± 1.2
Test	108,378	46.5 ± 38.9	1.7 ± 1.1

Table 2: FiNER-139 statistics, using SPACY's tokenizer and the 139 tags of this work (± standard deviation).

The distribution of these tags seems to follow a power law (Figure 2), hence most of the 6k XBRL tags that we did not consider are very rare. We used the IOB2 annotation scheme to distinguish tokens at the beginning, inside, or outside of tagged expressions, which leads to 279 possible token labels.

We split the text notes into 1.8M sentences, the majority of which (~90%) contained no tags.[8] The sentences are also HTML-stripped, normalized, and lower-cased. To avoid conflating trivial and more difficult cases, we apply heuristic rules to discard sentences that can be easily flagged as almost certainly requiring no tagging; in a real-life setting, the heuristics, possibly further improved, would discard sentences that do not need to be processed by the tagger. The heuristic rules were created by inspecting the training subset and include regular expressions that look for amounts and other expressions that are typically annotated. Approx. 40% of the 1.8M sentences were removed, discarding only 1% of tagged ones. We split chronologically the remaining sentences into training, development, and test sets with an 80/10/10 ratio (Table 2).

4 Baseline Models

SPACY (Honnibal et al., 2020) is an open-source NLP library.[9] It includes an industrial NER that uses word-level Bloom embeddings (Serrà and Karatzoglou, 2017) and residual Convolutional Neural Networks (CNNs) (He et al., 2016). We trained SPACY's NER from scratch on FiNER-139.

BILSTM: This baseline uses a stacked bidirectional Long-Short Term Memory (LSTM) network (Graves et al., 2013; Lample et al., 2016) with residual connections. Each token t_i of a sentence S is mapped to an embedding and passed through the BILSTM stack to extract the corresponding contextualized embedding. A shared multinomial logistic regression (LR) layer operates on top of each contextualized embedding to predict the correct label. We use the WORD2VEC embeddings (Mikolov et al., 2013a,b) of Loukas et al. (2021).

BERT: This is similar to BILSTM, but now we fine-tune BERT-BASE (Devlin et al., 2019) to extract contextualized embeddings of subwords. Again, a multinomial LR layer operates on top of the contextualized embeddings to predict the correct label of the corresponding subword.

CRFs: In this case, we replace the LR layer of the previous two models with a Conditional Random Field (CRF) layer (Lafferty et al., 2001), which has been shown to be beneficial in several token labeling tasks (Huang et al., 2015; Lample et al., 2016; Chalkidis et al., 2020b).[10]

5 Baseline Results

We report micro-F_1 (μ-F_1) and macro-F_1 (m-F_1) at the entity level, i.e., if a gold tag annotates a multi-word span, a model gets credit only if it tags the exact same span. This allows comparing more easily methods that label words vs. subwords.

Table 3 shows that SPACY performs poorly, possibly due to the differences from typical token labeling tasks, i.e., the large amount of entity types, the abundance of numeric tokens, and the fact that in FiNER-139 the tagging decisions depend mostly on context. Interestingly enough, BILSTM (with word embeddings) performs slightly better than BERT. However, when a CRF layer is added, BERT achieves the best results, while the performance of BILSTM (with word embeddings) deteriorates significantly, contradicting previous studies.

Baseline methods	μ-F_1	m-F_1
SPACY (words)	48.6 ± 0.4	37.6 ± 0.2
BILSTM (words)	77.3 ± 0.6	73.8 ± 1.8
BILSTM (subwords)	71.3 ± 0.2	68.6 ± 0.2
BERT (subwords)	75.1 ± 1.1	72.6 ± 1.4
BILSTM (words) + CRF	69.4 ± 1.2	67.3 ± 1.6
BILSTM (subwords) + CRF	76.2 ± 0.2	73.4 ± 0.3
BERT (subwords) + CRF	**78.0** ± 0.5	**75.2** ± 0.6

Table 3: Entity-level μ-F_1 and m-F_1 (%, avg. of 3 runs with different random seeds, ± std. dev.) on test data.

We hypothesize that the inconsistent effect of CRFs is due to tokenization differences. When using BERT's subword tokenizer, there are more decisions that need to be all correct for a tagged span to be correct (one decision per subword) than when using word tokenization (one decision per word). Thus, it becomes more difficult for subword models to avoid nonsensical sequences of token labels,

---

[8] We use NLTK (Bird et al., 2009) for sentence splitting.

[9] We used SPACY v.2.3; see https://spacy.io/.

[10] We use a linear-chain CRF layer with log-likelihood optimization and Viterbi decoding.

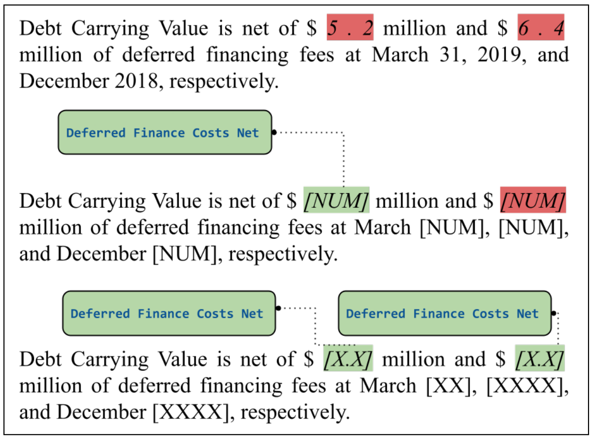
e.g., labeling two consecutive subwords as beginning and inside of different entity types, especially given the large set of 279 labels (Table 1). The **CRF** layer on top of subword models helps reduce the nonsensical sequences of labels.

On the other side, when using words as tokens, there are fewer opportunities for nonsensical label sequences, because there are fewer tokens. For instance, the average number of subwords and words per gold span is 2.53 and 1.04, respectively. Hence, it is easier for the **BILSTM** to avoid predicting nonsensical sequences of labels and the **CRF** layer on top of the **BILSTM** (with word embeddings) has less room to contribute and mainly introduces noise (e.g., it often assigns low probabilities to acceptable, but less frequent label sequences). With the **CRF** layer, the model tries to maximize both the confidence of the **BILSTM** for the predicted label of each word and the probability that the predicted sequence of labels is frequent. When the **BILSTM** on its own rarely predicts nonsensical sequences of labels, adding the **CRF** layer rewards commonly seen sequences of labels, even if they are not the correct labels, without reducing the already rare nonsensical sequences of labels.

To further support our hypothesis, we repeated the **BILSTM** experiments, but with subword (instead of word) embeddings, trained on the same vocabulary with **BERT**. Without the **CRF**, the subword **BILSTM** performs much worse than the word **BILSTM** (6 p.p drop in μ-F_1), because of the many more decisions and opportunities to predict nonsensical label sequences. The **CRF** layer substantially improves the performance of the subword **BILSTM** (4.9 p.p. increase in μ-F_1), as expected, though the word **BILSTM** (without **CRF**) is still better, because of the fewer opportunities for nonsensical predictions. A drawback of **CRF**s is that they significantly slow down the models both during training and inference, especially when using large label sets (Goldman and Goldberger, 2020), as in our case. Hence, although **BERT** with **CRF** was the best model in Table 3, we wished to improve **BERT**'s performance further without employing **CRF**s.

6 Fragmentation in BERT

In FiNER-139, the majority (91.2%) of the gold tagged spans are numeric expressions, which cannot all be included in **BERT**'s finite vocabulary; e.g., the token '`9,323.0`' is split into five subword units, ['`9`', '`##,`', '`##323`', '`##.`', '`##0`'], while the token '`12.78`' is split into ['`12`', '`##.`', '`##78`']. The excessive fragmentation of numeric expressions, when using subword tokenization, harms the performance of the subword-based models (Table 3), because it increases the probability of producing nonsensical sequences of labels, as already discussed. We, therefore, propose two simple and effective solutions to avoid the over-fragmentation of numbers.



Debt Carrying Value is net of $ *5 . 2* million and $ *6 . 4* million of deferred financing fees at March 31, 2019, and December 2018, respectively.

Debt Carrying Value is net of $ *[NUM]* million and $ *[NUM]* million of deferred financing fees at March [NUM], [NUM], and December [NUM], respectively.

Debt Carrying Value is net of $ *[X.X]* million and $ *[X.X]* million of deferred financing fees at March [XX], [XXXX], and December [XXXX], respectively.

Figure 3: **XBRL** tag predictions of **BERT** (top), **BERT** + [NUM] (middle), **BERT** + [SHAPE] (bottom) for the same sentence. **BERT** tags incorrectly the amounts in red. **BERT** + [NUM] and **BERT** + [SHAPE] tag them more successfully (green indicates correct tags).

BERT + [NUM]: We detect numbers using regular expressions and replace each one with a single [NUM] pseudo-token, which cannot be split. The pseudo-token is added to the **BERT** vocabulary, and its representation is learned during fine-tuning. This allows handling all numeric expressions in a uniform manner, disallowing their fragmentation.

BERT + [SHAPE]: We replace numbers with pseudo-tokens that cannot be split and represent the number's shape. For instance, '`53.2`' becomes '[XX.X]', and '`40,200.5`' becomes '[XX,XXX.X]'. We use 214 special tokens that cover all the number shapes of the training set. Again, the representations of the pseudo-tokens are fine-tuned, and numeric expressions (of known shapes) are no longer fragmented. The shape pseudo-tokens also capture information about each number's magnitude; the intuition is that numeric tokens of similar magnitudes may require similar **XBRL** tags. Figure 3 illustrates the use of [NUM] and [SHAPE] pseudo-tokens.

7 In-domain Pre-training

Driven by the recent findings that pre-training language models on specialized domains is beneficial for downstream tasks (Alsentzer et al., 2019; Belt-

Table 4: Entity-level micro-averaged P, R, F$_1$ ± std. dev. (3 runs) on the dev. and test data for BERT-based models.

agy et al., 2019; Yang et al., 2020; Chalkidis et al., 2020b), we explore this direction in our task which is derived from the financial domain.

FIN-BERT: We fine-tune FIN-BERT (Yang et al., 2020), which is pre-trained on a financial corpus from SEC documents, earnings call transcripts, and analyst reports.[11] The 30k subwords vocabulary of FIN-BERT is built from scratch from its pre-training corpus. Again, we utilize FIN-BERT with and without our numeric pseudo-tokens, whose representations are learned during fine-tuning.

SEC-BERT: We also release our own family of BERT models. Following the original setup of Devlin et al. (2019), we pre-trained BERT from scratch on EDGAR-CORPUS, a collection of financial documents released by Loukas et al. (2021). The resulting model, called SEC-BERT, has a newly created vocabulary of 30k subwords. To further examine the impact of the proposed [NUM] and [SHAPE] special tokens, we also pre-trained two additional BERT variants, SEC-BERT-NUM and SEC-BERT-SHAPE, on the same corpus, having replaced all numbers by [NUM] or [SHAPE] pseudo-tokens, respectively. In this case, the representations of the pseudo-tokens are learned during pre-training and they are updated during fine-tuning.

8 Improved BERT Results

Table 4 reports micro-averaged precision, recall, and F$_1$ on development and test data. As with Table 3, a LR layer is used on top of each embedding to predict the correct label, unless specified otherwise.

Focusing on the second zone, we observe that the [NUM] pseudo-token improves BERT's results, as expected, since it does not allow numeric expressions to be fragmented. The results of BERT + [NUM] are now comparable to those of BERT + CRF. Performance improves further when utilizing the shape pseudo-tokens (BERT + [SHAPE]), yielding 79.4 μ-F$_1$ and showing that information about each number's magnitude is valuable in XBRL tagging.

Interestingly, FIN-BERT (3rd zone) performs worse than BERT despite its pre-training on financial data. Similarly to BERT, this can be attributed to the fragmentation of numbers (2.5 subwords per gold tag span). Again, the proposed pseudo-tokens ([NUM], [SHAPE]) alleviate this problem and allow FIN-BERT to leverage its in-domain pre-training in order to finally surpass the corresponding BERT variants, achieving an 80.1 μ-F$_1$ test score.

Our new model, SEC-BERT (last zone), which is pre-trained on SEC reports, performs better than the existing BERT and FIN-BERT models, when no numeric pseudo-tokens are used. However, SEC-BERT is still worse than BERT with numeric pseudo-tokens (75.7 vs. 78.3 and 79.4 test μ-F$_1$), suffering from number fragmentation (2.4 subwords per gold tag span). SEC-BERT (without pseudo-tokens) also performs worse than the BILSTM with word embeddings (75.7 vs. 77.3 μ-F$_1$, cf. Table 3). However, when the proposed pseudo-tokens are used, SEC-BERT-NUM and SEC-BERT-SHAPE achieve the best overall performance, boosting the test μ-F$_1$ to 80.4 and 82.1, respectively. This indicates that learning to handle numeric expressions during model pre-training is a better strategy than trying to acquire this knowledge only during fine-tuning.

---

[11] We use the FINBERT-FINVOCAB-UNCASED version from https://github.com/yya518/FinBERT.

9 Additional Experiments

9.1 Subword pooling

An alternative way to bypass word fragmentation is to use subword pooling for each word. Ács et al. (2021) found that for NER tasks, it is better to use the *first* subword only, i.e., predict the label of an entire word from the contextualized embedding of its first subword only; they compared to several other methods, such as using only the *last* subword of each word, or combining the contextualized embeddings of all subwords with a self-attention mechanism. Given this finding, we conducted an ablation study and compare (i) our best model (SEC-BERT) with *first* subword pooling (denoted SEC-BERT-FIRST) to (ii) SEC-BERT with our special tokens (SEC-BERT-NUM, SEC-BERT-SHAPE), which avoid segmenting numeric tokens.

Table 5 shows that, in XBRL tagging, using the proposed special tokens is comparable (SEC-BERT-NUM) or better (SEC-BERT-SHAPE) than performing *first* pooling (SEC-BERT-FIRST). It might be worth trying other pooling strategies as well, like *last*-pooling or subword self-attention pooling. It's worth noting, however, that the latter will increase the training and inference times.

	μ-F$_1$	m-F$_1$
SEC-BERT	78.8 ± 0.1	72.6 ± 0.4
SEC-BERT-FIRST	79.9 ± 1.2	77.1 ± 1.7
SEC-BERT-NUM	80.4 ± 1.4	78.9 ± 1.3
SEC-BERT-SHAPE	**82.1** ± 0.1	**80.1** ± 0.2

Table 5: Entity-level μ-F$_1$ and m-F$_1$ (%, avg. of 3 runs with different random seeds, ± std. dev.) on test data using different ways to alleviate fragmentation.

9.2 Subword BILSTM with [NUM] and [SHAPE]

To further investigate the effectiveness of our pseudo-tokens, we incorporated them in the BILSTM operating on subword embeddings (3rd model of Table 3). Again, we replace each number by a single [NUM] pseudo-token or one of 214 [SHAPE] pseudo-tokens, for the two approaches, respectively. These replacements also happen when pretraining WORD2VEC subword embeddings; hence, an embedding is obtained for each pseudo-token.

Table 6 shows that BILSTM-NUM outperforms the BILSTM subword model. BILSTM-SHAPE further improves performance and is the best BILSTM subword model overall, surpassing the subword BILSTM with CRF, which was the best subword BILSTM model in Table 3. These results further support our hypothesis that the [NUM] and [SHAPE] pseudo-tokens help subword models successfully generalize over numeric expressions, with [SHAPE] being the best of the two approaches, while also avoiding the over-fragmentation of numbers.

	μ-F$_1$	m-F$_1$
BILSTM (subwords)	71.3 ± 0.2	68.6 ± 0.2
BILSTM (subwords) + CRF	76.2 ± 0.2	73.4 ± 0.3
BILSTM-NUM (subwords)	75.6 ± 0.3	72.7 ± 0.4
BILSTM-SHAPE (subwords)	**76.8** ± 0.2	**74.1** ± 0.3

Table 6: Entity-level μ-F$_1$ and m-F$_1$ (%, avg. of 3 runs with different random seeds, ± std. dev.) on test data for BILSTM models with [NUM] and [SHAPE] tokens.

9.3 A Business Use Case

Since XBRL tagging is derived from a real-world need, it is crucial to analyze the model's performance in a business use case. After consulting with experts of the financial domain, we concluded that one practical use case would be to use an XBRL tagger as a recommendation engine that would propose the k most probable XBRL tags for a specific token selected by the user. The idea is that an expert (e.g., accountant, auditor) knows beforehand the token(s) that should be annotated and the tagger would assist by helping identify the appropriate tags more quickly. Instead of having to select from several hundreds of XBRL tags, the expert would only have to inspect a short list of k proposed tags.

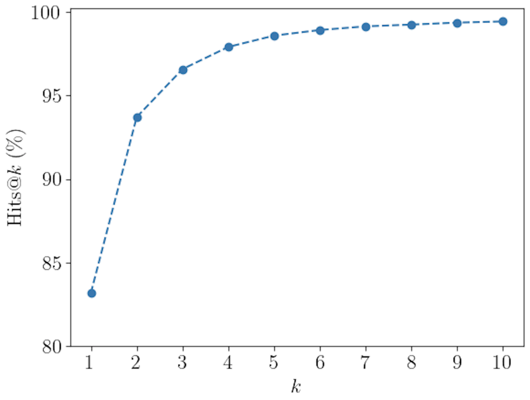

Figure 4: Hits@k results (%, avg. of 3 runs with different random seeds) on test data, for different k values. Standard deviations were very small and are omitted.

We evaluate our best model, SEC-BERT-SHAPE, in this use case using Hits@k. We use the model to return the k most probable XBRL tags for each token that needs to be annotated, now assuming that the tokens to be annotated are known. If the correct tag is among the top k, we increase the number of hits by one. Finally, we divide by the number of tokens to be annotated. Figure 4 shows the results for different values of k. The curve is steep for $k = 1$ to 5 and saturates as k approaches 10, where Hits@k is nearly perfect (99.4%). In practice, this means that a user would have to inspect 10 recommended XBRL tags instead of hundreds for each token to be annotated; and in most cases, the correct tag would be among the top 5 recommended ones.

9.4 Error Analysis

We also performed an exploratory data and error analysis to unveil the peculiarities of FiNER-139, extract new insights about it, and discover the limitations of our best model. Specifically, we manually inspected the errors of SEC-BERT-SHAPE in under-performing classes (where $F_1 < 50\%$) and identified three main sources of errors.

Specialized terminology: In this type of errors, the model is able to understand the general financial semantics, but does not fully comprehend highly technical details. For example, *Operating Lease Expense* amounts are sometimes missclassified as *Lease And Rental Expense*, i.e., the model manages to predict that these amounts are about expenses in general, but fails to identify the specific details that distinguish operating lease expenses from lease and rental expenses. Similarly, *Payments to Acquire Businesses (Net of Cash Acquired)* amounts are mostly misclassified as *Payments to Acquire Businesses (Gross)*. In this case, the model understands the notion of business acquisition, but fails to differentiate between net and gross payments.

Financial dates: Another interesting error type is the misclassification of financial dates. For example, tokens of the class *Debt Instrument Maturity Date* are mostly missclassified as not belonging to any entity at all (*'O'* tag). Given the previous type of errors, one would expect the model to missclassify these tokens as a different type of financial date, but this is not the case here. We suspect that errors of this type may be due to annotation inconsistencies by the financial experts.

Annotation inconsistencies: Even though the gold XBRL tags of FiNER-139 come from professional auditors, as required by the Securities & Exchange Commission (SEC) legislation, there are still some discrepancies. We provide an illustrative example in Figure 5. We believe that such inconsistencies are inevitable to occur and they are a part of the real-world nature of the problem.

> Excluding short-term leases, the Company's leases have initial terms ranging from **1** to **16** years, most of which include options the Company may elect to extend or renew the lease for **0.1** to **6** years, and some of which may include options to terminate the leases with notice periods of up to 1 year.

Figure 5: A manually inspected sentence from FiNER-139 showing some inconsistencies in the gold XBRL tags of the auditors. The green '1' is correctly annotated with the XBRL tag *Lessee Operating Lease Term Of Contract*. The red '16' should have also been annotated with the same tag, but is not, possibly because the annotator thought the (same) tag was obvious. The orange numbers '0.1' and '6' lack XBRL annotations; they should have both been annotated as *Lessee Operating Lease Renewal Term*. We can only speculate that the auditor might not have been aware that there is an XBRL tag for lease renewal terms, in which case the recommendation engine of Section 9.3 might have helped.

We hope that this analysis inspires future work on XBRL tagging. For example, the specialized terminology and financial date errors may be alleviated by adopting hierarchical classifiers (Chalkidis et al., 2020a; Manginas et al., 2020), which would first detect entities in coarse classes (e.g., expenses, dates) and would then try to classify the identified entities into finer classes (e.g., lease vs. rent expenses, instrument maturity dates vs. other types of dates). It would also be interesting to train classifiers towards detecting wrong (or missing) gold annotations, in order to help in quality assurance checks of XBRL-tagged documents.

10 Conclusions and Future Work

We introduced a new real-word NLP task from the financial domain, XBRL tagging, required by regulatory commissions worldwide. We released FiNER-139, a dataset of 1.1M sentences with XBRL tags. Unlike typical entity extraction tasks, FiNER-139 uses a much larger label set (139 tags), most tokens to be tagged are numeric, and the correct tag depends mostly on context rather than the tagged token. We experimented with several neural classifiers, showing that a BILSTM outperforms BERT due to the excessive numeric token fragmentation of the latter. We proposed two simple and effective solutions that use special tokens to generalize over the shapes and magnitudes of numeric expressions. We also experimented with FIN-BERT, an existing

BERT model for the financial domain, which also benefits from our special tokens. Finally, we pre-trained and released our own domain-specific BERT model, SEC-BERT, both with and without the special tokens, which achieves the best overall results with the special tokens, without costly CRF layers.

In future work, one could hire experts to re-annotate a subset of the dataset to measure human performance against the gold tags. Future work could also consider less frequent XBRL tags (few- and zero-shot learning) and exploit the hierarchical dependencies of XBRL tags, possibly with hierarchical classifiers, building upon our error analysis.

A Experimental Setup

For SPACY, we followed the recommended practices.[12] All other methods were implemented in TENSORFLOW.[13] Concerning BERT models, we used the implementation of HUGGINGFACE (Wolf et al., 2020). We also use Adam (Kingma and Ba, 2015), Glorot initialization (Glorot and Bengio, 2010), and the categorical cross-entropy loss.

Hyper-parameters were tuned on development data with Bayesian Optimization (Snoek et al., 2012) monitoring the development loss for 15 trials.[14] For the BILSTM encoders, we searched for $\{1, 2, 3\}$ hidden layers, $\{128, 200, 256\}$ hidden units, $\{1e\text{-}3, 2e\text{-}3, 3e\text{-}3, 4e\text{-}3, 5e\text{-}3\}$ learning rate, and $\{0.1, 0.2, 0.3\}$ dropout. We trained for 30 epochs using early stopping with patience 4. For BERT, we used grid-search to select the optimal learning rate from $\{1e\text{-}5, 2e\text{-}5, 3e\text{-}5, 4e\text{-}5, 5e\text{-}5\}$, fine-tuning for 10 epochs, using early stopping with patience 2. All final hyper-parameters are shown in Table 7. Training was performed mainly on a DGX station with 4 NVIDIA V100 GPUs and an Intel Xeon CPU E5-2698 v4 @ 2.20GHz.

	Params	*L*	*U*	P_{drop}	*LR*
BILSTM (words)	21M	2	128	0.1	1e-3
BILSTM (subwords)	8M	1	256	0.2	1e-3
BILSTM (words) + CRF	21M	2	128	0.1	1e-3
BILSTM (subwords) + CRF	8M	1	256	0.2	1e-3
BILSTM-NUM (subwords)	1M	1	256	0.2	1e-3

SEC-BERT-NUM	110M	-	-	-	1e-5
SEC-BERT-SHAPE	110M	-	-	-	1e-5

Table 7: Number of total parameters (*Params*) and the best hyper-parameter values for each method; i.e., number of recurrent layers (L), number of recurrent units (U), dropout probability P_{drop}, learning rate (LR).

B Additional Results

Table 8 shows micro-averaged Precision, Recall, and F1 for the development and test data, using all baseline methods. The macro-averaged scores are similar and we omit them for brevity. Using a logistic regression (LR) classification layer, BILSTM (words) surpasses BERT both in Precision and F1 score. However, when using a CRF layer on top, BERT outperforms BILSTM (words) in all measures.

Table 9 shows the micro-averaged Precision, Recall, and F_1 for the development and test data using the BILSTM models operating on subwords with the proposed tokenizations. [NUM] and [SHAPE] tokens help the model to bypass the word fragmentation problem, increasing its scores in all metrics.

Abstract

Contrastive learning has achieved impressive success in generation tasks to militate the "exposure bias" problem and discriminatively exploit the different quality of references. Existing works mostly focus on contrastive learning on the instance-level without discriminating the contribution of each word, while keywords are the gist of the text and dominant the constrained mapping relationships. Hence, in this work, we propose a hierarchical contrastive learning mechanism, which can unify hybrid granularities semantic meaning in the input text. Concretely, we first propose a keyword graph via contrastive correlations of positive-negative pairs to iteratively polish the keyword representations. Then, we construct intra-contrasts within instance-level and keyword-level, where we assume words are sampled nodes from a sentence distribution. Finally, to bridge the gap between independent contrast levels and tackle the common contrast vanishing problem, we propose an inter-contrast mechanism that measures the discrepancy between contrastive keyword nodes respectively to the instance distribution. Experiments demonstrate that our model outperforms competitive baselines on paraphrasing, dialogue generation, and storytelling tasks.

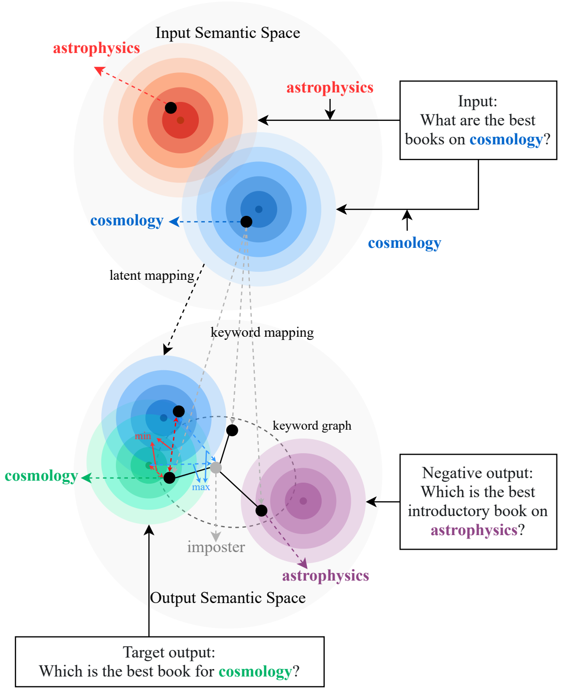

Figure 1: The semantic meaning of the sentence "what are the best books on cosmology?" would be greatly changed if the keyword "cosmology" is changed to "astrophysic".

1 Introduction

Generation tasks such as storytelling, paraphrasing, and dialogue generation aim at learning a certain correlation between text pairs that maps an arbitrary-length input to another arbitrary-length output. Traditional methods are mostly trained with "teacher forcing" and lead to an "exposure bias" problem (Schmidt, 2019). Incorporating the generation method with contrastive learning achieved impressive performance on tackling such issues, which takes an extra consideration of synthetic negative samples contrastively (Lee et al., 2021).

Existing contrastive mechanisms are mainly focused on the instance level (Lee et al., 2021; Cai et al., 2020). However, word-level information is also of great importance. Take the case shown in the upper part of Figure 1 for example, the keyword covers the gist of the input text and determines the embedding space of the text. The text representation will be significantly affected if adding a slight perturbation on the keyword, *i.e.,* changing "cosmology" to "astrophysics". In addition, as shown on the bottom part, under some circumstances, it is too easy for the model to do the classification since the semantic gap between contrastive pairs is huge. Thus, the model fails to distinguish the actual discrepancy, which causes a "contrast vanishing"

problem at both instance-level and keyword-level.

Based on the above motivation, in this paper, we propose a hierarchical contrastive learning method built on top of the classic CVAE structure. We choose CVAE due to its ability in modeling global properties such as syntactic, semantic, and discourse coherence (Li et al., 2015; Yu et al., 2020). We first learn different granularity representations through two independent contrast, *i.e.,* instance-level and keyword-level. Specifically, we use the universal and classic TextRank (Mihalcea and Tarau, 2004) method to extract keywords from each text, which contain the most important information and need to be highlighted. On the instance-level, we treat the keyword in the input text as an additional condition for a better prior semantic distribution. Then, we utilize Kullback–Leibler divergence (Kullback and Leibler, 1951) to reduce the distance between prior distribution and positive posterior distribution, and increase the distance with the negative posterior distribution. While on the keyword-level, we propose a keyword graph via contrastive correlations of positive-negative pairs to learn informative and accurate keyword representations. By treating the keyword in the output text as an anchor, the imposter keyword is produced by neighboring nodes of the anchor keyword and forms the keyword-level contrast, where the similarity between the imposter keyword and the anchor keyword is poorer than the positive keyword.

To unify individual intra-contrasts and tackle the "contrast vanishing" problem in independent contrastive granularities, we leverage an inter-contrast, the Mahalanobis contrast, to investigate the contrastive enhancement based on the Mahalanobis distance (De Maesschalck et al., 2000), a measure of the distance between a point and a distribution, between the instance distribution and the keyword representation. Concretely, we ensure the distance from the anchor instance distribution to the ground-truth keyword vector is closer than to the imposter keyword vector. The Mahalanobis contrast plays an intermediate role that joins the different granularities contrast via incorporating the distribution of instance with the representation of its crucial part, and makes up a more comprehensive keyword-driven hierarchical contrastive mechanism, so as to ameliorate the generated results.

We empirically show that our model outperforms CVAE and other baselines significantly on three generation tasks: paraphrasing, dialogue generation, and storytelling.

Our contributions can be summarized as follows:

- To our best knowledge, we are the first to propose an inter-level contrastive learning method, which unifies instance-level and keyword-level contrasts in the CVAE framework.
- We propose three contrastive learning measurements: KL divergence for semantic distribution, cosine distance for points, and Mahalanobis distance for points with distribution.
- We introduce a global keyword graph to obtain polished keyword representations and construct imposter keywords for contrastive learning.

2 Related Work

2.1 Contrastive Learning

Contrastive learning is used to learn representations by teaching the model which data points are similar or not. Due to the excellent performance on self-supervised and semi-supervised learning, it has been widely used in natural language processing (NLP). Firstly, Mikolov et al. (2013) proposed to predict neighboring words from context with noise-contrastive estimation. Then, based on word representations, contrastive learning for sentence has been utilized to learn semantic representations. Lee et al. (2021) generated positive and negative examples by adding perturbations to the hidden states. Cai et al. (2020) augmented contrastive dialogue learning with group-wise dual sampling. Moreover, contrastive learning has also been utilized in caption generation (Mao et al., 2016), summarization (Liu and Liu, 2021) and machine translation (Yang et al., 2019). Our work differs from previous works in focusing on hierarchical contrastive learning on hybrid granularities.

2.2 Mahalanobis Distance

The Mahalanobis distance is a measure of the distance between a point and a distribution (De Maesschalck et al., 2000). The distance is zero if the point is on the distribution. Recently, Mahalanobis distance is popularly applied to the NLP tasks (Tran et al., 2019). Podolskiy et al. (2021) showed that while Transformer is capable of constructing homogeneous representations of in-domain utterances, the Mahalanobis distance captures geometrical disparity from out of domain utterances. Further, Ren et al. (2021) considered that the raw density from deep generative models may fail at out-of-domain detection and proposed to fix this using a likelihood ratio between two generative models as a confidence score.

2.3 Conditional Variational Auto-Encoder

Variational autoencoder (VAE) was proposed by Kingma and Welling (2013), and has been widely used in various tasks such as headline generation (Li et al., 2021), dialogue generation (Serban et al., 2017) and story generation (Yu et al., 2020). Based on VAE, a more advanced model, Conditional VAE (CVAE), was proposed to generate diverse images conditioned on certain attributes, which was also applied to generate diverse outputs in NLP tasks (Zhao et al., 2017; Qiu et al., 2019). Existing works concentrate on generating diverse outputs, and we take one step further to utilize prior and posterior latent distribution to compare positive and negative samples, which helps to learn more accurate semantic information.

3 Method

3.1 Background

VAE: Variational auto-encoder (VAE) is a typical encoder-decoder structural model with certain types of latent variables. Given an input x, VAE models the latent variable z through the prior distribution $p_\theta(z)$, and the observed data x is reconstructed by the generative distribution $p_\theta(x|z)$ which is the likelihood function that generates x conditioned on z. Since z is unknown, it should be estimated according to the given data x as $p_\theta(z|x)$. While the posterior density $p_\theta(z|x) = p_\theta(x|z)p_\theta(z)/p_\theta(x)$ is intractable, VAE introduces a recognition posterior distribution $q_\phi(z|x)$ approximates to the true posterior $p_\theta(z|x)$. Thus, VAE is trained by optimizing the lower bound on the marginal likelihood of data x as:

$$\begin{aligned} logp_\theta(x) \geq \mathbb{E}_{z\sim q_\phi(z|x)}[logp_\theta(x|z)] \\ -D_{KL}(q_\phi(z|x)||p_\theta(z)), \end{aligned} \tag{1}$$

where D_{KL} is the Kullback–Leibler divergence.

CVAE: The conditional variational auto-encoder (CVAE) is the supervised version of VAE with an additional output variable. Giving a dataset $\{x_i, y_i\}_{i=1}^N$ consisting of N samples, CVAE is trained to maximize the conditional log-likelihood, and the variational lower bound of the model is written as follows:

$$\begin{aligned} logp_\theta(y|x) \geq \mathbb{E}_{z\sim q_\phi(z|x,y)}[logp(y|x,z)] \\ -D_{KL}(q_\phi(z|x,y)||p_\theta(z|x)). \end{aligned} \tag{2}$$

Assuming the type of latent variable obeys Gaussian distribution, the first right-hand side term can be approximated by drawing samples $\{z_i\}_{i=1}^N$ from the recognition posterior distribution $q_\phi(z|x,y)$, where $z \sim N(\mu, \sigma^2 I)$, and then objective of the CVAE with Gaussian distribution can be written as:

$$\begin{aligned} \mathcal{L}_{cvae}(x,y;\theta,\phi) = -\frac{1}{N}\sum_{i=1}^{N} logp_\theta(y|x,z_i) \\ +D_{KL}(q_\phi(z|x,y)||p_\theta(z|x)), \end{aligned} \tag{3}$$

where $z_i = g_\phi(x, y, \epsilon_i)$, $\epsilon_i \sim \mathcal{N}(0, I)$. The distribution $q_\phi(z|x,y)$ is reparameterized with a differentiable function g_ϕ, which enables the model trainable via stochastic gradient descent.

Inspired by Wu et al. (2019), we add keyword u as an additional condition to the prior distribution to control the generation process, which turns the $p_\theta(z|x)$ in Equaton 3 into $p_\theta(z|x,u)$.

3.2 Hierarchical Contrastive Learning

In this section, we introduce our hierarchical contrastive learning method, which is comprised of three parts: instance-level contrast based on KL divergence (sec.3.2.1), keyword-level contrast based on keyword graph (sec.3.2.2), and inter-contrast: Mahalanobis contrast (sec.3.2.3).

3.2.1 Instance-level Contrastive Learning

To tackle the "exposure bias" problem and discriminatively exploit the different quality of references, instance-level contrastive learning is introduced to learn discrepancies of targets. Specifically, in addition to the observed input data x and positive output y^+, a negative output y^- is added to construct a contrastive pair $\{(x, y^+), (x, y^-)\}$. In this case, the prior distribution $p_\theta(z|x)$ is learned from a prior network, which is denoted as $f_\theta(x)$. The approximate posteriors $q_\phi(z|x,y^+)$ and $q_\phi(z|x,y^-)$ are learned from a posterior network and represented as $f_\phi(x,y^+)$ and $f_\phi(x,y^-)$, respectively. The objective here is to make the distance between a prior distribution and positive posterior distribution closer than with the negative posterior distribution. Thus, the instance-level contrastive loss function can be written as:

$$\mathcal{L}_{ins} = -\mathbb{E}_{f_\phi}[log(1 - \frac{e^{h(f_\phi(x,y^+),f_\theta(x))/\tau}}{\sum_{y^*\in Y} e^{h(f_\phi(x,y^*),f_\theta(x))/\tau}})],$$

where the $y^* \in Y$ can be positive sample y^+ or negative sample y^-, and the τ is a temperature

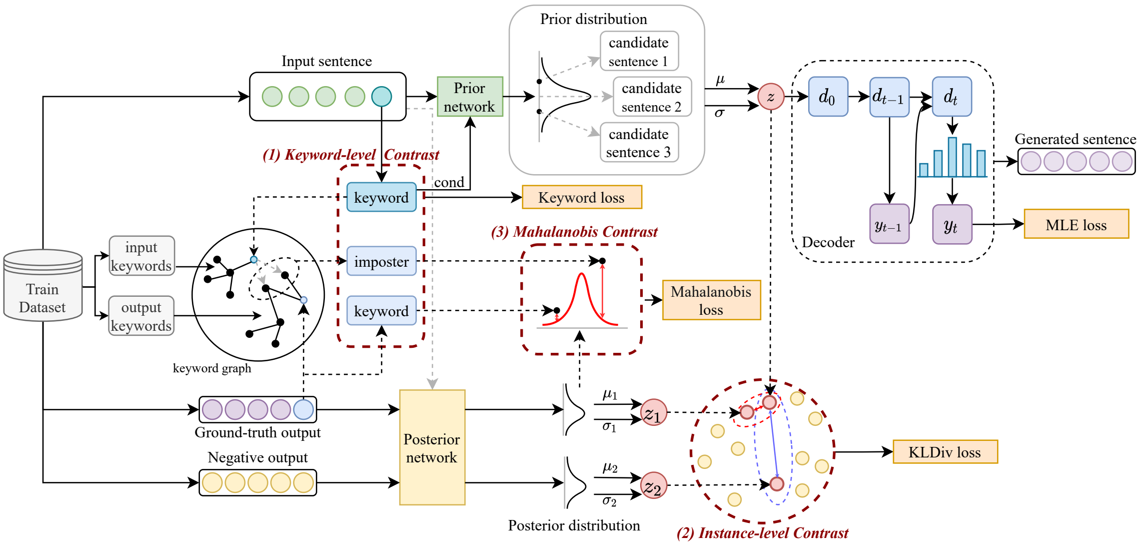

Figure 2: The architecture of hierarchical contrastive learning, which consists of three parts: (1) Keyword-level contrast from keyword graph; (2) Instance-level contrast based on KL divergence for semantic distribution; and (3) Mahalanobis contrast between instance-level and keyword-level.

parameter to control push and pull force. The function $h(\cdot)$ denotes the distance between elements, which is set as Kullback–Leibler divergence (Kullback and Leibler, 1951) in instance-level contrast, $D_{KL}(f_\phi(x, y^*)||f_\theta(x))$, to measure the difference between two distributions.

3.2.2 Keyword-level Contrastive Learning

Since the instance-level contrast focuses on learning high-level information and fails to discriminate the contribution of each word, we incorporate it with a keyword-level contrast to pay more attention to the specific keyword.

Keyword Graph: Given an input-output text pair (x, y), keywords k_x, k_y can be extracted from x and y, respectively. For an input text x_i with keyword $k_{x,i}$, input texts that contain the same keyword are gathered into a cluster $C_i = \{x_j\}_{j=1}^n, k_{x,j} \in x_j$, where n is the number of texts in C_i. Each text $x_j \in C_i$ has a positive-negative output text pair $\{(y_j^+, y_j^-)\}$ containing a positive output keyword $k_{y,j}^+$ and a negative one $k_{y,j}^-$, respectively. Thus, spreading to the entire cluster C_i, for the output text y_i, there exists positive relations $r_{i,j}^+$ between its keyword $k_{y,i}$ and each of the surrounded positive keywords $\{k_{y,j}^+\}_{j=1}^n$. Likewise, negative relations $r_{i,j}^-$ correlates the output keyword $k_{y,i}$ and the surrounded negative ones $\{k_{y,j}^-\}_{j=1}^n$.

Based on these keywords as nodes and their relations as edges (Chen et al., 2021), the keyword graph $\mathcal{G}_k$ is constructed. Each node representation h_i^0 is initialized as the average BERT embedding (Devlin et al., 2018) of texts in the cluster C_i with the same corresponding keyword $k_{x,i}$. Then, the relation edge r_{ij}^0 that connects node i and node j is learned via a feedforward layer $r_{ij}^0 = \text{FFN}([h_i^0; h_j^0])$.

Then, the representations of nodes and relation edges are iteratively updated with their connected nodes via the graph attention (GAT) layer and the feed-forward (FFN) layer. In the t-th iteration, we first update each edge representation by paying attention to the connected nodes, denoted as:

$$\beta_{r*}^t = \text{softmax}(\frac{(r_{ij}^t W_p)(h_*^t W_h)^T}{\sqrt{d}}), \tag{4}$$

$$p_{ij}^t = \beta_{ri}^t h_i^t + \beta_{rj}^t h_j^t, \tag{5}$$

$$r_{ij}^{t+1} = \text{FFN}(r_{ij}^t + p_{ij}^t), \tag{6}$$

where h_*^t can be h_i^t or h_j^t.

Then, based on the obtained edge representation r_{ij}^{t+1}, we update the node representations considering both the related nodes and relation edges by the graph attention layer, $\text{GAT}(h_i^t, h_j^t, r_{ij}^t)$, which is designed as:

$$e_{ij}^t = \frac{(h_i^t W_q)(h_j^t W_k + r_{ij}^{t+1} W_r)^T}{\sqrt{d}}, \tag{7}$$

$$\alpha_{ij}^t = \frac{exp(e_{ij}^t)}{\sum_{l \in N_i} exp(e_{il}^t)}, \tag{8}$$

$$u_i^t = \sum_{j \in N_i} \alpha_{ij}^t (h_j^t W_v + r_{ij}^{t+1}), \tag{9}$$

where W_q, W_k, W_r and W_v are all learnable parameters, and the α_{ij}^t is the attention weight between h_i^t and h_j^t. Besides, to avoid gradient vanishing after several iterations, a residual connection is added to the output u_i^t and the updated node representations h_i^{t+1} is obtained. In this way, the new representation of each keyword node consists of the relation dependency information from neighbor nodes N_i. We take the node representations from the last iteration as the final keyword representations, denoted as u for brevity.

Keyword-level Contrast: The keyword-level contrastive learning arises from input keywords against positive output keywords and negative impostor keywords. The input keyword u_{in} is extracted from the input text as an anchor, and the output keyword u_{out} is extracted from ground-truth output text. While the impostor keyword is calculated from the negative neighbours of the output keyword u_{out}, written as $u_{imp} = \sum_i W_i u_i$, where u_i is the representation of keyword node which is obtained by the keyword graph learning procedure described above. In this way, with the help of neighbour nodes in the graph, we can obtain a more indistinguishable and difficult negative sample. The loss of keyword level contrastive learning thus can be written as:

$$\mathcal{L}_{keyword} = -\mathbb{E}[log \frac{e^{h(u_{in}, u_{out})/\tau}}{\sum_{u_* \in U} e^{h(u_{in}, u_*)/\tau}}], \quad (10)$$

where $u_* \in U$ denotes the positive output keyword u_{out} or imposter keyword u_{imp}. In keyword-level contrast, $h(\cdot)$ utilizes cosine similarity to calculate the distance between points.

3.2.3 Mahalanobis Contrastive Learning

Note that there exists a space gap between the instance-level contrast and the keyword-level contrast, which disturbs the completeness of this hierarchical contrastive architecture. Besides, the contrastive values vanish when the distance metric is hard to measure the actual discrepancy between positive and negative merely in instance distributions or in keyword representations. To mitigate such problems, we design a Mahalanobis contrastive mechanism to correlate the instance distribution and keyword representation, where the objective is to minimize the margin between the output keyword u_{out} and the posterior semantic distribution $q_\phi(z|x,y) \triangleq f_\phi(x,y)$ and maximize the margin between the imposter keyword u_{imp} and the posterior distribution $f_\phi(x,y)$:

$$\mathcal{L}_{ma} = -\mathbb{E}_{f_\phi}[log(1 - \frac{e^{h(f_\phi(x,y), u_{out})/\tau}}{\sum_{u_* \in U} e^{h(f_\phi(x,y), u_*)/\tau}})], \quad (11)$$

where $u_* \in U$ can be the positive output keyword u_{out} or negative imposter keyword u_{imp}. In Mahalanobis contrast, $h(\cdot)$ utilizes Mahalanobis distance (De Maesschalck et al., 2000) to measure the similarity from keyword point to the instance distribution. In the univariate Gaussian case, $z \sim p(z|x,y) = N(\mu, \sigma^2)$, then the $h(f_\phi(x,y), u_*) \triangleq D_{MA}(p_\theta(z|x,y)||u_*) = (u_* - \mu)\sigma^2 I(u_* - \mu)$.

Finally, we equip the CVAE model with the proposed hierarchical contrastive learning framework to unify hybrid granularities by adding $\mathcal{L}_{ins}$, $\mathcal{L}_{keyword}$ and $\mathcal{L}_{ma}$ to the reconstructed loss of Equation 3.

4 Experiment

4.1 Tasks and Datasets

We conduct experiments on three public datasets QQP, Douban, RocStories for paraphrasing, dialogue generation, and storytelling task, respectively. The details of the datasets are as follows:

Dialogue (Douban) Douban (Cai et al., 2020) consists of Chinese daily conversations between pairs of speakers, collected from a popular social network website, Douban group[1]. The dataset contains 218,039/10,000/10,000 context-response pairs for training/validation/test, with an average of 3.94 turns per context and 38.32 characters per utterance. We concatenate historical dialogues and turn it into a single-turn dialogue training corpus.

Paraphrasing (QQP) QQP (Iyer et al., 2017; Wang et al., 2019) is a dataset published by the community question-answering website Quora on whether a pair of questions is semantically consistent. To adapt it to the contrastive learning task, we only keep question pairs that have positive and negative rewriting for the same input. Thus, there remain 44,949 samples in the dataset, which are split into training/validation/test sets of 40,441/2,254/2,254 samples.

Storytelling (RocStories) RocStories consists of 98,163 high-quality hand-crafted stories, which capture causal and temporal commonsense relations of daily events (Mostafazadeh et al., 2016).

Table 1: Automatic evaluation results on (a) QQP for paraphrasing, (b) Douban for dialogue generation, and (c) RocStories for storytelling. The best results in each group are highlighted with **bold**.

Each story paragraph contains 5 sentences with an average of 43 words. Following the previous work Yu et al. (2021), we split the dataset into 8:1:1 for training, validation, and test.

For the above three datasets, in order to construct different levels of contrastive learning, we performed the same preprocessing of extracting keywords. We utilize the TextRank model (Mihalcea and Tarau, 2004) to extract keywords from each input and output sample, respectively. Besides, the vocabulary size of both datasets is the same as BERT (Devlin et al., 2018) setting.

4.2 Implementation Details

Our experiments are implemented in Tensorflow (Abadi et al., 2016) on an NVIDIA Tesla P100 GPU. For our model and all baselines, we follow the same setting as described below. We pad or cut the input to 100, 20, 100 words for dialogue generation, paraphrasing, and storytelling, respectively. The truncation length is decided based on the observation that there is no significant improvement when increasing input length. The minimum decoding step is 5, and the maximum step is 20 for all tasks. Experiments were performed with a batch size of 256, and we use Adam optimizer (Kingma and Ba, 2015) as our optimizing algorithm. During the test stage, the beam-search size is set to 4 for all methods and the checkpoint with the smallest validation loss is chosen. Note that for better performance, our model is built based on BERT, and the decoding process is the same as Transformer (Vaswani et al., 2017). Finally, due to the limitation of time and memory, small settings are used in the pre-training baselines.

4.3 Compared Baselines

We compare our method against several traditional generation models, pretrained-based generation models, and contrastive learning models.

Traditional generation models: (1) **CVAE** (Zhao et al., 2017) generates sentences based on latent variables, sampling from potential semantic distribution. (2) **Seq2Seq** (Sutskever et al., 2014) is a sequence-to-sequence framework combined with attention mechanism and pointer network. (3) **Transformer** (Vaswani et al., 2017) is an abstractive method based solely on attention mechanisms.

Models	BLEU-1	BLEU-2	BLEU-3	BLEU-4	Extrema	Average	Greedy
ours	**0.6430**	**0.3517**	**0.1845**	**0.1153**	**0.6701**	**0.8495**	**0.8661**
w/o graph	0.6295	0.3333	0.1675	0.1001	0.6685	0.8455	0.8647
w/o keyword	0.5764	0.2993	0.1499	0.0892	0.6673	0.8450	0.8539
w/o MA	0.6013	0.3208	0.1628	0.0981	0.6605	0.8436	0.8524

Table 2: Ablation results on dataset QQP.

Pretrained-based generation models: (4) **Seq2Seq-DU** (Feng et al., 2021) is concerned with dialogue state tracking in a task-oriented dialogue system. (5) **DialoGPT** (Zhang et al., 2020) proposes a large, tunable neural conversational response generation model trained on more conversation-like exchanges. (6) **BERT-GEN** (Devlin et al., 2018) augments Seq2Seq with BERT as the encoder. (7) **T5** (Raffel et al., 2020) introduces a unified framework that converts all text-based language problems into a text-to-text format.

Contrastive learning methods: (8) **Group-wise** (Cai et al., 2020) augments contrastive dialogue learning with group-wise dual sampling. (9) **T5-CLAPS** (Lee et al., 2021) generates negative and positive samples for contrastive learning by adding small and large perturbations, respectively.

4.4 Evaluation Metrics

To evaluate the performance of our model against baselines, we adopt the following metrics widely used in existing studies.

BLEU We utilize BLEU score (Papineni et al., 2002) to measure word overlap between the generated text and the ground-truth. Specifically, following the conventional setting of (Gu et al., 2019), we adopt BLEU-1$\sim$4 scores under the smoothing techniques (smoothing 7).

Embedding To evaluate our model more comprehensively, we also capture the semantic matching degrees between the bag-of-words (BOW) embeddings of generated text and reference (Gu et al., 2019). Particularly we adopt three metrics: 1) *Extrema*, cosine similarity between the largest extreme values among the word embeddings in the two texts; 2) *Average*, cosine similarity between the averaged word embeddings of generated text and reference; 3) *Greedy*, greedily matching words in the two texts based on cosine similarities.

4.5 Experimental Results

4.5.1 Overall Performance

Automatic Evaluation The experimental results ars summarized in Table 1. The upper part lists the effects of traditional generation methods such as `Seq2Seq` and `Transformer`, and the lower part shows the latest pretrained-based methods including `DialoGPT` and `T5`. Overall, pretrained-based methods generally outperform traditional methods, and this also proves the effectiveness of the pretrained language model on the generation tasks. Secondly, we can find that the performance is significantly improved after adding contrast learning. Finally, our method outperforms `T5-CLAPS` by 2.7%, 3.6% on QQP, by 20.3%, 24.9% on Douban, and by 3.9%, 6.3% on RocStories in terms of BLEU-1, BLEU-2, respectively, which proves the superiority of our model.

	Flu	Mean	Diff
Seq2Seq-DU	2.03	2.12	1.76
DialoGPT	2.18	2.04	1.97
T5-CLAPS	2.24	2.16	2.19
Ours	**2.51**$^{\blacktriangle}$	**2.45**$^{\blacktriangle}$	**2.43**$^{\blacktriangle}$

Table 3: Fluency (Flu), Meaningfulness (Mean), and Differential (Diff) comparison by human evaluation. $^{\blacktriangle}$shows the statistical significance tested by a two tailed paired t-test.

Human Evaluation We also assessed system performance by eliciting human judgments on 100 randomly selected test instances on QQP dataset. Three annotators are asked to rate paraphrasing questions generated by `T5-CLAPS`, `DialoGPT`, `Seq2Seq-DU`, and our model according to Fluency (Flu), Meaningfulness (Mean), and Differential (Diff). The rating score ranges from 1 to 3, with 3 being the best. Table 3 lists the average scores of each model, showing that our model outperforms other baselines among all metrics, which indicates that our model generates paraphrasing sentences more readable successfully. The kappa statistics are 0.53, 0.61, and 0.56 for fluency, meaningfulness, and differential, respectively, which indicates the moderate agreement between annotators.

4.5.2 Ablation Study

We conduct ablation tests to assess the importance of the keyword graph architecture (`w/o graph`), keyword (`w/o keyword`), as well as the Maha-

Input text: What one exercise will help me lose belly fat?

Reference paraphrasing text: How do i remove belly fat?

Keyword extracted by TextRank: belly fat

Generated text 1: What is the best exercise way to lose belly fat?

Keyword from random-selected: disposable

Generated text 2: Can one-off exercise lose belly fat?

Seq2Seq-DU: What are the best ways to lose weight?

DialoGPT: Which exercise helps to lose weight?

T5-CLAPS: How can I lose weight?

Table 4: Case study to verify the influence of sampling different keywords. The texts in red and blue indicate the parts corresponding to the extracted keyword and random-selected keyword, respectively.

lanobis contrast (`w/o MA contrast`), and the results are shown in Table 2. Concretely, after removing the keywords (w/o keyword), using only instance-level contrastive, the effect of our model is greatly reduced by about 10.4%, which illustrates the desirability of considering the contributions of words in a sentence. On this basis, adding keyword contrastive learning with removing the keyword graph, the effect of the model has been improved but is still lower than our model by 2.1%. This shows that keywords are indeed conducive to capturing important information, and it also illustrates the significance of a keyword graph. Finally, the experiment of removing the Mahalanobis contrastive loss indicates that only with granularity independent contrast is not sufficient, and the Mahalanobis contrast plays a critical intermediate role.

4.5.3 Visualization of Different Levels of Contrastive Learning

To study the hierarchical contrastive learning, we visualize the vectors of keyword, input text, positive and negative output text on randomly sampled cases from QQP dataset, as shown in Figure 3. For visualization purposes, we reduce the dimension of the latent vector with t-SNE (Maaten and Hinton, 2008). It can be observed that the input sentence representation is located close to the keyword, which shows that the keyword, as the most important information in the sentence, determines the semantic distribution. Moreover, in contrastive learning, it can be seen that after training, the position of the input sentence is close to the positive samples and far away from the negative samples. This suggests that contrastive learning can correct the semantic distribution.

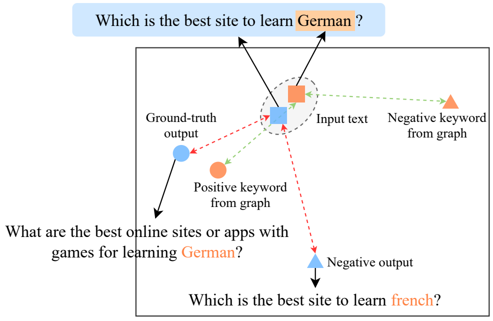

Figure 3: Visualization of contrastive learning. The square, circle and triangle represents the input text, positive output sample, and negative output sample, respectively. Blue represents the sentence, and yellow represents the keyword.

4.5.4 Analysis of Different Keywords

We finally investigate the influence of sampling different keywords. As shown in Table 4, for an input question, we provide keywords extracted by TextRank and randomly-selected keywords as the condition to control the semantic distribution and examine the quality of the generated text. As the most important information unit, different keywords lead to different semantic distributions and will result in different generated texts. The more properly the keywords are selected, the more accurately the sentences will be generated. When utilizing the keywords extracted by TextRank as a condition, the information “belly fat” is focused during the generation of paraphrasing questions, and the generated sentences are more accurate. On the contrary, after adding the random-selected keyword “disposable”, the generated question emphasizes “one-off exercise”, which brings incorrect information.

We also compare our model with several baselines in Table 4. Most baselines can generate fluent questions in this case. However, they focus on “lose weight”, and miss the significant information “belly fat”. Based on the above analysis, we can observe that keywords can emphasize and protect the highlight information in sentences, and affect the semantic distribution of as a condition.

5 Conclusion

In this paper, we propose a hierarchical contrastive learning mechanism, which consists of intra-contrasts within instance-level and keyword-level and inter-contrast with Mahalanobis contrast. The experimental results yield significant out-performance over baselines when applied in the CVAE framework. In the future, we aim to extend the contrastive learning mechanism to different basic models, and will explore contrastive learning methods based on external knowledge.

7 Ethics Impact

In this paper, we propose an inter-level contrastive learning method, which unifies instance-level and keyword-level contrasts in the CVAE framework. The positive impact lies in that it can help improve the capability of generation models on paraphrasing, dialogue generation, and storytelling tasks. The negative impact may be that the generation process of the system is not fully controllable, so it is possible to generate inaccurate or unreasonable content in some extreme cases. Hence, extra processing steps might be needed if this method were to be used in scenarios where high accuracy is required.

EPT-X: An Expression-Pointer Transformer model that generates eXplanations for numbers

Abstract

In this paper, we propose a neural model EPT-X (Expression-Pointer Transformer with Explanations), which utilizes natural language explanations to solve an algebraic word problem. To enhance the explainability of the encoding process of a neural model, EPT-X adopts the concepts of plausibility and faithfulness which are drawn from math word problem solving strategies by humans. A plausible explanation is one that includes contextual information for the numbers and variables that appear in a given math word problem. A faithful explanation is one that accurately represents the reasoning process behind the model's solution equation. The EPT-X model yields an average baseline performance of 69.59% on our PEN dataset and produces explanations with quality that is comparable to human output. The contribution of this work is two-fold. (1) EPT-X model: An explainable neural model that sets a baseline for algebraic word problem solving task, in terms of model's correctness, plausibility, and faithfulness. (2) New dataset: We release a novel dataset PEN (Problems with Explanations for Numbers), which expands the existing datasets by attaching explanations to each number/variable.

1 Introduction

Algebraic word problem solving is a challenging task for understanding natural language. As shown in Table 1, a model needs to interpret a word problem into a solution equation to solve the problem. Recent neural approaches have employed encoder-decoder architecture to tackle this task and achieved remarkable answer correctness (Huang et al., 2018; Chiang and Chen, 2019; Amini et al., 2019; Kim et al., 2020; Ki et al., 2020): ranging from 65% to 84% depending on datasets. So, as the model delivers a plausible answer, researchers have a firm belief that an encoder component of a neural model can comprehend the problem correctly. However, this belief has less been verified due to the opaqueness of an encoder. Thus, this paper aims to design an architecture that reveals how it understands a given word problem.

Q. Tom has 12 coins in quarters and nickels. Their value is \$2.20. How many coins of each type does he have?	
Solution Equation	$x + y = 12,\ 0.25x + 0.05y = 2.20$ $(\because x = 8, y = 4)$
Explanation	12 = the total number of coins 2.20 = the total value of coins x = the number of quarters y = the number of nickels

Table 1: An example algebraic word problem

Our novel model, Expression-Pointer Transformer with Explanations (EPT-X), is inspired by some pedagogical studies about human strategies on understanding an algebraic word problem (Conway and Polya, 1985; Jitendra et al., 2007; Montague, 2008; Jitendra and Star, 2012). In classrooms, teachers ask students to make an explanation or a diagram that depicts the role of each number written in the problem. Then, students use these explanations for numbers to build a correct equation. That is, understanding a problem produces explanations that satisfy the following two criteria. (1) *plausibility*: A plausible explanation is one that includes contextual information for the numbers and variables that appear in a given math word problem. Especially, as humans recognize each number/variable individually, the explanations should reveal what each number or variable represents in the context of the given problem. (2) *faithfulness*: A faithful explanation is one that accurately represents the reasoning process behind the model's solution equation (Jacovi and Goldberg, 2020). In other words, they should imply a reason behind selecting operators or operands.

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 4442 - 4458
May 22-27, 2022 ©2022 Association for Computational Linguistics

To reflect these two criteria in EPT-X, we adopt a two-phase architecture: (1) explaining numbers/variables and (2) building solution equations.

Though Ling et al. (2017) attempted to generate explanations, this work is different from ours in that their model focused on explaining the decoding process. So, they have less explored the above two criteria. In contrast, this paper attempts to explain how the model understands the given word problem by modifying an encoder component of a neural model. As humans successfully solve word problems by explaining their understanding, we expect our EPT-X model to achieve a good performance in terms of three criteria: *correctness* of equations, *plausibility* of explanations, and *faithfulness* of explanations. Through several analyses, our paper shows the following two contributions:

1. *EPT-X model:* We propose a baseline model that can generate explanations and solve algebraic word problems, in terms of correctness, plausibility, and faithfulness.
2. *New dataset:* We release a novel dataset PEN (Problems with Explanations for Numbers), which expands the existing datasets by attaching explanations to each number/variable.

2 Related work

Correctness: Researchers have attempted to build a model that solves word problems. Early attempts used hand-crafted features collected by experts to make a model understand a word problem (Kushman et al., 2014; Roy and Roth, 2015; Koncel-Kedziorski et al., 2015; Zhou et al., 2015; Upadhyay et al., 2016; Roy and Roth, 2017). Although researchers can interpret these models using the features, extending these studies to other datasets is limited as designing features is labor-intensive. On the other hand, recent studies have employed neural models (Wang et al., 2017; Huang et al., 2018; Chiang and Chen, 2019; Amini et al., 2019; Kim et al., 2020; Ki et al., 2020) and achieved answer correctness ranging from 62% to 84%. Though their extensibility is better than hand-crafted features, it becomes harder to interpret how a neural model understands a word problem.

Plausibility: To make a neural model that explains its reasoning process, Ling et al. (2017) built a model that outputs both a computation process and a rationale behind the process. Though their model generated a natural language phrase that explains a computation step in advance, the model is not enough to meet the plausibility criterion because of two issues. First, it is not guaranteed whether their model explains all numbers and variables required to solve the problem. As they focused more on explaining the model's computation, their model often skips explaining its understanding of numbers and variables stated in a problem. Second, it is not confirmed whether their model generates rationale comparable to that of humans. Though they measured their quality of rationale using BLEU-4 (Papineni et al., 2002), the reported score of 27.2 is somewhat low and not compared with any human-level performance. We suspect that this low-quality explanation affected the low correctness of their model: 36.4%. Therefore, it is worthwhile to build a new model that fulfills the plausibility criterion.

Faithfulness: As far as we know, studies on solving algebraic word problems have not measured the faithfulness of a generated explanation. Existing studies so far measured the quality of explanations using plausibility only. Following Jacovi and Goldberg (2020), we define faithful explanation as one that accurately represents the reasoning process behind the model's solution equation. Humans expect an explanation to be faithful. However, a model can generate an explanation that may not be related to the equations (Jacovi and Goldberg, 2020); it can generate random plausible sentences independently from the process of generating solution equations. Therefore, measuring faithfulness is meaningful in that a highly faithful explanation reflects a solution equation generation process that is expected by human problem solvers.

3 The EPT-X Model

The proposed model, Expression-Pointer Transformer with Explanations (EPT-X)[1], is a variant of Expression-Pointer Transformer (EPT; Kim et al. 2020), which is state-of-the-art *correctness* model. Figure 1 depicts the two phases EPT-X model. (1) *Plausibility*: In phase 1, EPT-X receives a problem text as an input and generates explanations for each number/variable. The number of variables is also predicted in this phase. (2) *Faithfulness*: In phase 2, EPT-X receives both the original problem and the generated explanations as inputs and then builds an equation using EPT. To jointly train these two phases, we add up the loss functions for the number

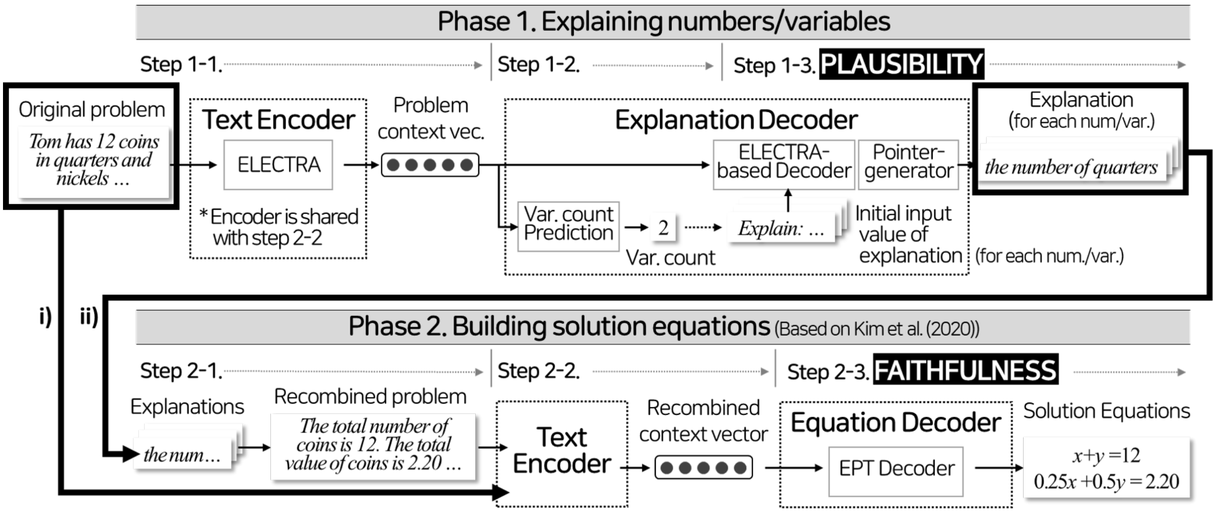

Figure 1: The two-phase pipeline of generating explanations and equations in our EPT-X model. i) shows the original problem input, and ii) shows the explanations which are recombined at Step 2-1.

of variables, explanations, and equations; all three use smoothed cross-entropy (Szegedy et al., 2016) with $\alpha = 0.01$.

3.1 Phase 1. Explaining numbers/variables

Phase 1 is a three-step procedure for generating explanations as shown in the top part of Figure 1. Phase 1 contains two components: text encoder and explanation decoder.

Step 1-1. Compute problem text vectors The text encoder receives a natural language problem as an input and computes problem context vectors. To utilize world knowledge in the computation process, we used ELECTRA (Clark et al., 2020), a pre-trained language model. After applying the text encoder, we obtain the problem context vector $\mathbf{w}_s$ for each token w_s in the given problem.

Step 1-2. Predict the number of variables Using the problem context vectors, EPT-X predicts the number of required variables N to solve the given problem. Using the first token's problem context vector $\mathbf{w}_0$, we compute the probability distribution of N as follows:

$$P(N) = \mathrm{softmax}\left(\mathrm{FF}_{n1}\left(\mathrm{ReLU}\left(\mathrm{FF}_{n2}(\mathbf{w}_0)\right)\right)\right),$$

where $\mathrm{FF}(\cdot)$ indicates the feed-forward layer. We set the maximum number of variables to 9.

Step 1-3. Generating plausible explanations The explanation decoder then produces explanations using problem context vectors as memories. The decoder uses a Transformer (Vaswani et al., 2017) decoder and a pointer-generator network (See et al., 2017). Before predicting the next explanation token x_{t+1}, the Transformer decoder computes a hidden state $\mathbf{h}_t$ based on the problem context vectors $\mathbf{w}_s$ and previously generated explanation tokens $x_1, \cdots, x_t$. To utilize world knowledge in generating explanations, we adopt Rothe et al. (2020) and use ELECTRA (Clark et al., 2020) as the initial weight.

The pointer-generator head receives the computed $\mathbf{h}_t$ and predicts the next token. Let p_g, P_v, and P_c be the probability of using the generated word, the probability of generating from the vocabulary, and the probability of copying from the problem, respectively. Then, the next token x_{t+1} is predicted as follows:

$$\begin{aligned} x_{t+1} &= \arg\max_{\omega} p_g P_v(\omega) + (1-p_g) P_c(\omega), \\ p_g &= \sigma\left(\mathrm{FF}_g\left(\mathbf{w}_t^* \oplus \mathbf{h}_t \oplus \mathrm{E}(x_{t-1})\right)\right), \\ P_v(\omega) &= \mathrm{softmax}\left(\mathrm{FF}_v(\mathbf{h}_t)\right), \\ P_c(\omega) &= \textstyle\sum_{w_s : w_s = \omega} \mathrm{attn}(\mathbf{w}_s, \mathbf{h}_t), \\ \mathbf{w}_t^* &= \textstyle\sum_{w_s} \mathrm{attn}(\mathbf{w}_s, \mathbf{h}_t), \end{aligned}$$

where $\sigma(\cdot)$, $\mathrm{E}(\cdot)$, and $\mathrm{attn}(\cdot)$ indicate the sigmoid, embedding, and single-head attention scoring function, respectively. And $\oplus$ indicates concatenation of vectors.

Plausibility of explanation is implemented during this stage by generating an explanation for each number/variable separately. We use unique initial input values for all numbers and variables. This method has been used in other studies to bind the decoder to a specific context (Raffel et al., 2020;

Keskar et al., 2019). For numbers, instead of using the initial input value '`[CLS]`' of the Transformer decoder, we use the input "`[CLS]` explain: *context* `[SEP]`," where the *context* part depends on the number or variable. For the numbers, we use a window of tokens that are near the given number token. For example, if the window size is three, we use three tokens placed before and after the given token. For variables, we use the variable index because variables do not appear in the problem. So, for example, the initial input value of the nth variable becomes "`[CLS]` explain: variable n `[SEP]`."

3.2 Phase 2. Building solution equations

Phase 2 is a three-step procedure for producing equations as shown in the bottom part of Figure 1. Phase 2 uses the same text encoder from Phase 1.

Step 2-1. Recombine explanations Inspired by human paraphrasing strategies (Conway and Polya, 1985; Gagnon and Maccini, 2001; Montague, 2008), EPT-X paraphrases the original problem by recombining its understanding. First, the model places each explanation and the corresponding number token value into a sentence: "*explanation* is a number *value*." for numbers and "What is *explanation*?" for variables. Then, EPT-X creates a recombined problem by concatenating these paraphrased sentences. We randomly recombined one of the reference explanations in the training process as EPT-X may not generate explanations ideally.

Step 2-2. Compute recombined context vectors The text encoder once again receives both the original problem and the recombined problem as inputs and computes the recombined context vectors $\mathbf{r}_i$ for each input token r_i. We designed EPT-X to use both problems for two reasons. First, using the original problem can avoid information loss. Second, using the recombined problem can make the equation decoder exploit the information of explanations. We arrange these two problems into the text encoder as follows: "`[CLS]` *original* `[SEP]` *recombined* `[SEP]`."

Step 2-3. Generate equations faithfully The equation decoder then produces equations using the recombined context vectors as memories. Following the EPT model (Kim et al., 2020), the decoder produces equations using expression tokens, each of which is a tuple of an operator and relevant operands. So, the equation decoder predicts the next jth expression as follows. First, the decoder receives expression tokens generated so far and converts them into embedding vectors $\mathbf{v}_k$ $(k = 0, \cdots, j-1)$. Then, using these embedding vectors $\mathbf{v}_k$ and recombined context vectors $\mathbf{r}_i$, the decoder builds an equation context vector $\mathbf{q}_j$ for the next expression. Lastly, the decoder simultaneously predicts the next operator and its required operands using $\mathbf{q}_j$. Thus, when we translate expressions into an equation, we can compute an answer to a problem.

The faithfulness of explanation is implemented during this stage by using explanations as the input data source. We change the input format of numbers and variables in EPT's equation decoder to use explanations. Originally, EPT used different types of vectors to input them: the encoder's hidden state for each known number and the decoder's hidden state for each unknown variable. However, in EPT-X, we guide the model to utilize the information from the explanation when writing an equation. As all numbers and variables appear in the recombined problem, EPT-X uses the vector $\mathbf{r}_i$ corresponding to each number/variable.

4 The PEN dataset

We release 'Problems with Explanations for Numbers' (PEN)[2], an algebraic word problem dataset with problem texts, equations, and explanations of numbers/variables for each problem to train and evaluate EPT-X. As existing datasets for algebraic word problems do not contain explanations, we provided explanations on the existing three benchmark datasets on solving algebraic word problems[3]: ALG514 (Kushman et al., 2014), DRAW-1K (Upadhyay and Chang, 2017), and MAWPS (Koncel-Kedziorski et al., 2016). The following sections introduce the two stages of building PEN: preparation for correcting errors and annotation for collecting explanations.

4.1 Preparation: correcting errors

We corrected the errors and organized the data in three steps. In the first step, we revised the problems' typos, grammatical errors, and logical flaws. For example, we found a problem asking

---

[2] `http://github.com/snucclab/pen`

[3] Though we considered using AQuA-RAT (Ling et al., 2017), which includes rationale about computation, we found that using it is intractable since we have to re-collect explanations for numbers and variables in most problems.

	Train	Dev.	Test	Total
Problems	2,581	365	365	3,581
Explanations	36,261	4,569	4,719	45,549
Words/Prob.	31.01	30.81	30.91	30.98
Num/Prob.	4.22	4.09	4.21	4.20
Var/Prob.	1.36	1.35	1.39	1.36
Words/Expl.	7.73	7.76	7.72	7.73

Table 2: Statistics of PEN dataset

about 'Senators' after telling a story about 'the House of Representatives.' So we replaced the out-of-context term with the other one. Second, we extracted numeric words from the modified text using WordNet (Fellbaum, 1998); Arabic numerals, fractions, ordinals, and their synonyms were extracted. Third, to normalize equations, we re-formulated them according to nine source formulas organized by Mayer (1981) and four formulas organized by Carpenter et al. (1996).

Among 3,886 problems from the three datasets, we corrected 3,581 problems in the PEN dataset. We excluded 305 problems because they are (1) exact duplicates of others (303 problems)[4] or (2) not an algebra problem (2 problems)[5]. After excluding 305 problems, we further revised incorrect equations: 62 of the 3,581 problems (1.73%).

4.2 Annotation: collecting explanations

When collecting natural language explanations, the explanations can be irrelevant to the given problem without any guidelines. Thus, we instructed our workers to follow eight rules, including "Use at least one word appearing in the problem text when writing an explanation." Moreover, we make workers obey the rules consistently using a web-based system. Details about all eight rules and the web-based system are illustrated in Appendix A.

Fourteen skilled workers provided explanations for numbers and variables in a problem. Before assigning workloads, we split the entire dataset into training (80%), development (10%), and test (10%) sets. Then, we collected multiple explanations for each problem; 3 for training set and 4 for the other. Table 2 shows the statistics of the PEN dataset. PEN has 45,549 explanations, and the average number of words in an explanation is 7.73.

5 Experimental setup

To verify whether the EPT-X model can solve an algebraic problem correctly while generating plausible and faithful explanations, we conduct three types of analyses: model performance analysis, quantitative error analysis, and qualitative output analysis. This section illustrates each analysis and further implementation details.

5.1 Model performance analysis

The model performance analysis measures the model's correctness, which is the percentage of correctly answered problems on the PEN dataset. We regard an answer to be correct only if the answer values of all the variables in the problem are paired and solved correctly. For example, Table 1 shows that a correct answer contains two variables and answer values of $x = 8$ and $y = 4$. Existing studies regarded $x = 4$, $y = 8$ to be a correct solution(Kushman et al., 2014; Kim et al., 2020; Lee and Gweon, 2020). However, in the context of generating explanations along with solutions, different explanations are generated with different variables (Conway and Polya, 1985; Montague, 2008). Therefore, we enforce a stricter constraint that requires that a variable should be matched with a correct answer value.

Using the correctness, we compare the EPT-X model with two previous inexplainable models (EPT (Kim et al., 2020), GEO (Lee and Gweon, 2020)) and human performance. The EPT is a model that generates one expression at a time and uses pointers instead of classifiers, and it achieved state-of-the-art accuracy on MAWPS and DRAW datasets. The GEO is a model that mixes encoder and decoder outputs before predicting a token, and it achieved state-of-the-art accuracy on DRAW and ALG514 datasets. To establish a human performance baseline, our research team manually checked for the answer correctness of the original datasets of ALG514, DRAW, and MAWPS. We found that 62 of the 3581 problems were incorrectly solved, thus yielding a human baseline performance of 98%.

5.2 Quantitative error analysis

We conduct four types of error analyses to understand the possible cause of EPT-X solution errors:

---

[4] Since we manually corrected errors and flaws in each problem and combined three different datasets, some problems become exact duplicates of other problems.

[5] These problems cannot be solved with a multivariate equation alone: problems about least common multiples or counting the number of cases.

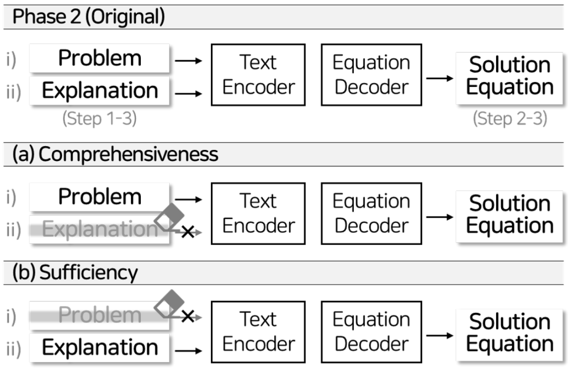

Figure 2: Two methods on measuring faithfulness, inspired by DeYoung et al. (2020)

plausibility test, faithfulness test, faithfulness control test, and error propagation test. Through these four types of analyses, we show how the generated explanations by the EPT-X model can be used to understand the equation generation process.

5.2.1 Plausibility test

To test the plausibility of explanations, we used BLEU-4 (Papineni et al., 2002), ROUGE-L (Lin, 2004), CIDEr (Vedantam et al., 2015), and BLEURT (Sellam et al., 2020). These metrics can measure the extent of similarity between a generated explanation and the reference explanation in the dataset.

Using the above four metrics, we compare the EPT-X model with a baseline model and human performance. First, we compare EPT-X with a baseline model which only contains Phase 1 (P1-only). This model can generate an explanation for each number/variable but cannot solve a word problem. Second, we compared EPT-X with human performance. While collecting explanations for each number/variable, we collected four sets of explanations. Of these four, one set is randomly set aside to serve as a hypothesis sentence and the other three as reference sentences when measuring human performance.

5.2.2 Faithfulness test

To measure the faithfulness of EPT-X, we used two metrics: sufficiency and comprehensiveness (DeYoung et al., 2020). First, in our context, *comprehensiveness* means "were explanations (Step 1-3) needed to produce the solution equation (Step 2-3)?". Figure 2 (a) shows the measurement setup for comprehensiveness. Specifically, we examined the amount of change between the two output solution equations: the equation from the original Phase 2 setup and the equation that is generated with only the problem text for the input of Phase 2. Since the output equation is not a single prediction as in DeYoung et al. (2020), we measured the change in the solution equations using tree edit distance (Zhang and Shasha, 1989).

Secondly, in our context, *sufficiency* means "do explanations (Step 1-3) contain enough information to produce solution equation (Step 2-3)?". Figure 2 (b) shows the measurement setup for sufficiency. Here, we examined the amount of change between the two output solution equations: the equation from the original Phase 2 setup and the equation that is generated with only the generated explanation. Similar to the comprehensiveness measure, the difference in equations was also computed using tree edit distance.

To provide a statistical baseline for interpreting the two metrics of comprehensiveness and sufficiency, we adopted a bootstrapping method (Koehn, 2004). We sampled 500 bootstrapped samples (each sample has 50 problems) to estimate the population distribution of each metric. After the estimation, we conducted hypothesis testing for each metric. For comprehensiveness $\mathcal{C}$, we set the following hypothesis $H_A : \mathcal{C} > 1$ as we expect to observe changes in equations when using only the problem input compared to using both problem and explanation input. For sufficiency $\mathcal{S}$, we set the following hypothesis $H_A : \mathcal{S} < 1$ as we expect to observe no change in equations when only using the explanation input.

5.2.3 Faithfulness control test

To examine a trade-off relationship between correctness and faithfulness, we train and analyze two variants of EPT-X, whose faithfulness is controlled. The first model is an inherently *faithful* model (EPT-XF) that uses only the explanation, but not the original problem, as an input to Phase 2. As EPT-XF entirely depends on the explanation to generate a solution equation, the model passes the test of faithfulness by definition. The second model is an inherently *unfaithful* model (EPT-XU) that uses only the original problem, but not the explanation from phase 1, as an input to Phase 2. As EPT-XU ignores the explanation input, the model fails the test of faithfulness by definition. Implementation details on these two models are explained in Appendix B.

5.2.4 Error propagation test

To examine how the quality of explanation affects the model's correctness, we used two models, EPT-X and EPT-XF. Both models employ a two-phase architecture, thus they are prone to errors in both phases. For the error propagation test, we examine how the performance of Phase 1 (plausibility) affects the end-task performance (correctness). Note that testing EPT-X may not reveal the errors that are solely propagated from the generated explanation because EPT-X also uses the original problem as an input. Therefore, EPT-XF performance was also measured in order to examine the impact of errors from the generated explanation only.

We measured the amount of error propagation in the two models, EPT-X and EPT-XF, by comparing correctness under two conditions: control and experiment. Under the control condition, the models build solution equations based on explanations generated by themselves. On the other hand, under the experiment condition, they build solution equations based on the gold standard explanations. Then, we measure the change of correctness between these two conditions for each model. Here, we expect that the change to reveal the proportion of problems affected by errors that are propagated from Phase 1.

5.3 Qualitative output analysis

The explanations generated by EPT-X were analyzed qualitatively using two methods. First, to measure the quality of the generated explanation itself, we manually labeled the quality in the PEN's development set using two criteria: (1) *plausibility* and (2) *faithfulness*. Human coders were asked to label an explanation to be plausible when the explanation and the original problem text are coherent in meaning. And for faithfulness, we asked human coders to build a solution equation using only the explanation produced from the EPT-X model. If the generated solution equation is identical to the EPT-X generated solution equation, the explanation is labeled to be faithful.

Second, to find the primary cause of errors when generating an explanation, we manually classified errors in EPT-X's explanations. The errors were categorized by comparing the generated explanation with the gold-standard explanation. We also used the PEN development set for this analysis.

		Dev.	Test
Human		98.35	98.35
Baselines:	EPT	77.26	74.52
	GEO	63.01	62.47
Proposed:	EPT-X	72.88	69.59

Table 3: Correctness of EPT-X on PEN dataset

5.4 Implementation Details

We describe three major implementation details used for training EPT-X: encoder, optimizer, and training epochs. For the text encoder component, EPT-X uses the base version of ELECTRA (Clark et al., 2020). We fixed its embedding and tied the embedding with the weights of FF_v in the explanation decoder to preserve the world knowledge in the embedding and to stabilize the training procedure. For the optimizer, we used LAMB (You et al., 2020) with a learning rate of 0.00176, which was found from a grid search on the development set. Finally, for the training epochs, we trained EPT-X for 500 epochs. Appendix C lists additional details of the model, including hardware, software, libraries, hyper-parameters, and random seeds.

6 Result and Discussion

The result of three analyses reveals that the EPT-X can generate an equation correctly based on a plausible and faithful explanation. First, Section 6.1 presents the result of the model performance analysis, which shows that EPT-X can achieve correctness 5% lower than previous inexplainable models. Second, Section 6.2 shows the result of error analysis, which reveals that many of EPT-X's errors are due to insufficient explanations. And lastly, Section 6.3 shows the result of qualitative analysis, which reveals three types of errors found in the explanation generation process of EPT-X.

6.1 Model performance analysis

The model performance analysis shows that EPT-X generates equations with 69.59% accuracy on the PEN dataset, despite being a two-phase model. Table 3 shows that adding the explanation generation functionality decreases the accuracy by approximately 5%, compared to state-of-the-art model EPT [6]. We suspect that this performance

---

[6] The results on the whole dataset is reported in this section, whereas results on each subset are reported in Appendix D.

		BLEU	ROUGE	CIDEr	BLEURT
Dev:	Human	57.16	78.66	343.0	71.44
	P1-Only	60.26	78.02	346.7	69.11
	EPT-X	60.07	77.99	347.1	69.61
Test:	Human	55.69	78.28	347.3	71.51
	P1-Only	59.32	77.99	342.9	69.69
	EPT-X	60.49	78.34	341.5	69.59

Table 4: Plausibility of EPT-X on PEN dataset

	Dev.	Test	H_A
Comprehensiveness	5.97^{**}	6.56^{**}	$(\mathcal{C} > 1)$
Sufficiency	1.20	1.19	$(\mathcal{S} < 1)$

* $p < 0.05$, ** $p < 0.01$

Table 5: Mean faithfulness of EPT-X on PEN dataset

drop is due to propagation of the errors in the generated explanations. Regardless, the results of EPT-X are meaningful since the model automatically generates explanations of problems without too much decrease in correctness. The difference of 5% is quite promising compared to that of the previous explainable model (Ling et al., 2017), about 40%, although a direct comparison is not possible due to differences in datasets.

6.2 Quantitative error analysis

6.2.1 Plausibility test

EPT-X achieved plausibility scores that are comparable to humans and the P1-only model, as shown in Table 4. The differences in plausibility scores between EPT-X and the other two baselines range between 1 to 2 points. This result indicates that EPT-X can select proper words to generate an explanation. In fact, BLEU-4 score of 60 is promising compared to Ling et al. (2017) (27.2). Given that EPT-X achieved human-level performance in terms of plausibility, but not for correctness, we explored the faithfulness metric to examine additional causes for the low model performance.

6.2.2 Faithfulness test

The results of the faithfulness test showed two characteristics of the explanation output of EPT-X. In terms of comprehensiveness, the generated explanation contains some information required to generate a solution equation, as evidenced by Table 2. Here, we observe that EPT-X passed the comprehensiveness test for the 99% confidence level. That is, compared to using both inputs in Phase 2, forcing EPT-X to use only the original problem input made EPT-X generate a different solution equation. This result suggests that the generated explanation provides information, which is not provided by the original problem but contributes to generating a solution equation.

		Dev.	Test
Proposed:	EPT-X	72.88	69.59
Variants:	EPT-XF	66.03	62.19
	EPT-XU	76.16	73.70

Table 6: Result of faithfulness control test

Meanwhile, in terms of sufficiency, the generated explanation may not provide sufficient numeric information to generate a solution equation. Table 2 shows that EPT-X failed the sufficiency test under the confidence level of 95%. That is, EPT-X generates different solution equations when it only receives the generated explanation as input in Phase 2. So, the explanation generated in Phase 1 does not contain sufficient information, which is contained in the original problem, to generate a solution equation.

6.2.3 Faithfulness control test

As the generated explanation fails to capture some information from the original problem, the correctness may change when we control the faithfulness of a model. Specifically, the control test shows that there is a trade-off between faithfulness and correctness; as faithfulness increases, the correctness decreases. Table 6 shows that the most faithful model EPT-XF achieves the lowest correctness score, which is 6% lower than EPT-X. Conversely, the most unfaithful model EPT-XU achieves the highest correctness score, which is 4% greater than EPT-X. Thus, the results of the faithfulness test and the faithfulness control test imply that in order to achieve a higher correctness score, we should verify whether the explanation contains “sufficient" information to build a correct equation.

6.2.4 Error propagation analysis

The error propagation test shows that the generated explanation does not contain sufficient information to build a correct equation for some problems. Table 7 shows that both EPT-X and EPT-XF can outperform the EPT model by 8% when using a gold standard explanation as an input. However,

		Generated	Gold	Change
Dev.:	EPT-XF	66.03	83.29	+17.26
	EPT-X	72.88	86.03	+13.15
Test:	EPT-XF	62.19	85.20	+23.01
	EPT-X	69.59	85.21	+15.62

Table 7: Result of error propagation test of explanation

using explanations generated by the EPT-X model may decrease the correctness by more than 15%. That is, more than 15% of errors are due to information loss in Phase 1.

6.3 Qualitative output analysis

Quality of explanations: The qualitative analysis showed that the quality of the generated explanations could be improved given that information required for solving word problems is missing. When we manually labeled the generated explanations for plausibility, 167 of 365 problems (45.8%) were labeled as plausible. Thus, the majority of the explanations are insufficient or contain incorrect information to generate a correct equation. Similarly, when we manually labeled the generated explanations for faithfulness, 201 of 365 problems (55.1%) were labeled as faithful. That is, when the same yet insufficient explanations were used to generate equations, the equations generated by EPT-X and humans were different.

Three categories of errors: Additional qualitative analysis found three possible causes for the EPT-X errors. Here, we will briefly discuss the causes, and the detailed examples are illustrated in Appendix E. First, when a problem mentions several entities with similar properties (e.g., Heather's weight and Emily's weight), the difference between entities is ignored in the encoder (69 of 118 incorrect problems; 58.5%). This error implies that the context window used in Step 1-3 may not be big enough to distinguish two different entities. Second, if a problem provides multiple situations related to an entity (e.g., outward trip versus return trip), assigning a corresponding number to the correct situation fails in the encoding process. Detailed explanations of situations of a word problem were often omitted in the encoder (57 of 118 problems; 48.3%). Third, when a problem contains some irrelevant numbers, which are not used in solving the problem (e.g., year), sometimes an explanation for an irrelevant number was generated instead of the relevant one in the encoding process (32 of 118 problems; 27.1%). The second and third error types imply that sharing the encoder in Phases 1 and 2 might have caused confusion. The goal of the encoder in Phase 1 was to provide a detailed explanation of a given number, whereas the goal in Phase 2 was to build an equation, which involves ignoring some details to build an abstraction in the form of an equation.

7 Conclusion

This study proposed a novel neural model EPT-X, Expression Pointer Transformer with Explanations, which generates explanations along with solution equations. The EPT-X model was designed to address two criteria of *plausibility* and *faithfulness* when generating an explanation. To address plausibility, the model generates explanations for each number/variable in the solution equation separately. And to address faithfulness, the model produces equations based on the information in the generated explanation. In addition to EPT-X, we release a new dataset, Problem with Explanations for Numbers (PEN), which extends existing three algebraic word problem datasets by augmenting explanations for numbers/variables. Using the PEN dataset, we conducted three analyses. The model performance analysis revealed that EPT-X could produce a correct equation with 69.59% accuracy. The quantitative error analysis showed that the EPT-X model could produce a plausible albeit insufficient explanation. Lastly, the qualitative output analysis identified three categories of errors made when generating explanations. Despite the insufficiency of explanations generated by the EPT-X model, our work is significant in that we demonstrated the possibility of generating explanations while solving an algebraic word problem. For future work, we plan to improve the correctness and faithfulness of EPT-X to enhance the existing state-of-the-art model.

Please enter a description of numbers and variables below.

Numbers in the problem

It takes a boat 4 hours to travel 24 miles down a river and 6 hours to return upstream to its starting point. What is the rate of the current in the river?

DistanceTimeRate 4 × downstream = 24
DistanceTimeRate 6 × upstream = 24
RateUpstream boat - river = upstream
RateDownstream boat + river = downstream

No description is required for this item.

It takes a boat 4 hours to travel 24 miles down a river and 6 hours to return upstream to its starting point. What is the rate of the current in the river?

DistanceTimeRate 4[Time] × downstream = 24
DistanceTimeRate 6 × upstream = 24
RateUpstream boat - river = upstream
RateDownstream boat + river = downstream

"4" means the number of hours of traveling down a river

Variables

It takes a boat 4 hours to travel 24 miles down a river and 6 hours to return upstream to its starting point. What is the rate of the current in the river?

DistanceTimeRate 4 × downstream = 24
DistanceTimeRate 6 × upstream = 24
RateUpstream boat[Boat] - river = upstream
RateDownstream boat[Boat] + river = downstream

"boat" means the rate of the boat in still water

It takes a boat 4 hours to travel 24 miles down a river and 6 hours to return upstream to its starting point. What is the rate of the current in the river?

DistanceTimeRate 4 × downstream = 24
DistanceTimeRate 6 × upstream = 24
RateUpstream boat - river[Current] = upstream
RateDownstream boat + river[Current] = downstream

"river" means the rate of the current in the river

Figure 3: A screenshot of the system used for annotating explanations on the PEN dataset

A Annotating explanations for PEN dataset

This section describes the detailed process of annotating explanations. Using a web-based system shown in Figure 3, coders inputted a natural language explanation for each number/variable. To provide situational information for each number/variable, we highlighted text snippets and equations related to the target number/variable. Based on the given information, the coder needed to complete the following sentence: "*number* means ..."

As the coders input natural language explanations, a coder's explanation may not be coherent with the given word problem. To make the explanation coherent with the problem, we used two strategies: rules and validation. For the rules, we instructed the coders to follow the eight rules below:

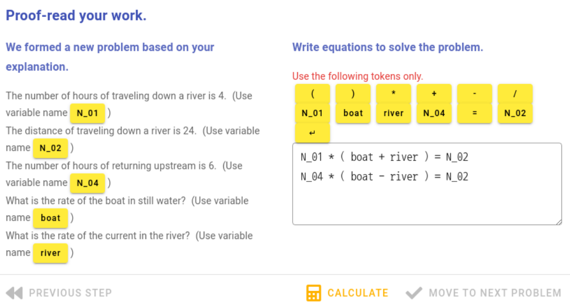
Rule 1. Please write an explanation of the situation that the number/variable denotes, using the words appearing in the text.

Rule 2. Each explanation is a simple noun phrase that has 3 to 25 words. Try to be concise.

Rule 3. Use at least one word appearing in the problem text when writing an explanation.

Rule 4. Do not use the same explanation for different objects.

Rule 5. You should be able to formulate equations for solving the problem, using your explanations only.



Proof-read your work.

We formed a new problem based on your explanation.

The number of hours of traveling down a river is 4. (Use variable name N_01)
The distance of traveling down a river is 24. (Use variable name N_02)
The number of hours of returning upstream is 6. (Use variable name N_04)
What is the rate of the boat in still water? (Use variable name boat)
What is the rate of the current in the river? (Use variable name river)

Write equations to solve the problem.

Use the following tokens only.

```
N_01 * ( boat + river ) = N_02
N_04 * ( boat - river ) = N_02
```

Figure 4: A screenshot of the system used for validating explanations on the PEN dataset

Rule 6. We suggest writing a difference A-B as "the value of A minus B."

Rule 7. We suggest writing a ratio A/B as "the ratio of A to B."

Rule 8. We suggest writing a numerator[denominator] of A/B as "the numerator[denominator] of the ratio of A to B."

Moreover, to assist the coders in obeying the eight rules, the system consistently checked whether the coders followed the rules. If one of the first four rules is broken, the system mandates the coder to obey the broken rule before proceeding to the next problem. For the other four rules, the system shows hints to make the coder manually verify the rules.

For the validation, we asked coders to validate their work by solving a problem reconstructed from the annotated explanations. For example, Figure 4 shows that the system synthesizes a problem by concatenating a coder's explanations and requests the coder to solve the synthesized problem. The coder can proceed to the next problem if an answer to the synthesized problem is the same as the original problem.

B Two variants of EPT-X

To investigate how the faithfulness of a model affects its correctness, we designed two variants of EPT-X: EPT-XF and EPT-XU. The following paragraphs illustrate each model.

EPT-XF is an inherently faithful variant of EPT-X. This model utilizes only the recombined problem in Step 2-2. So, the text encoder receives the following input in Step 2-2: "`[CLS]` *recombined problem* `[SEP]`." As the recombined problem contains information required in Step 2-3, the

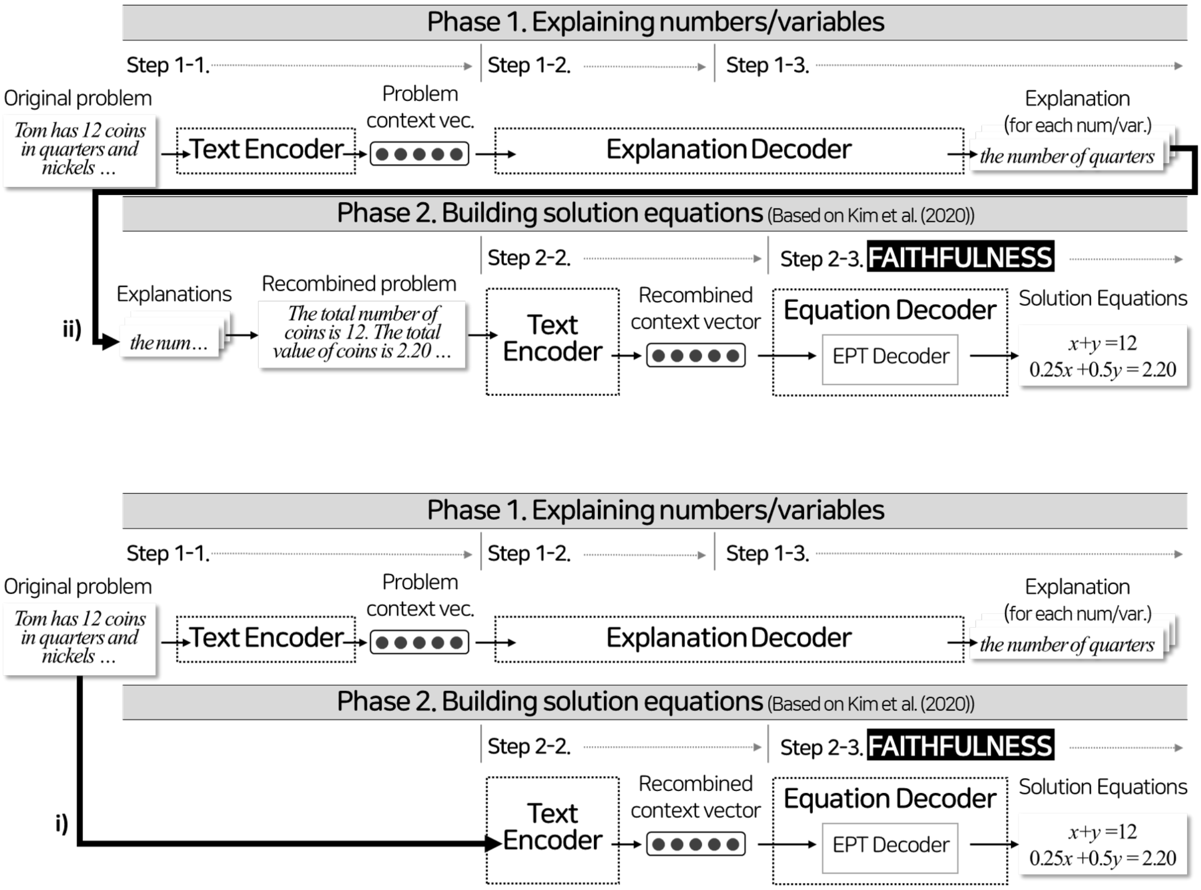


Figure 5: Two variants of EPT-X model: EPT-XF (top) and EPT-XU (bottom).

Model	Datasets				# of
	PEN	ALG	DRAW	MAWPS	Param.
EPT	.00088	.00176	.00176	.00125	122M
EPT-X	.00176	.00176	.00176	.00088	263M
EPT-XF	.00176	.00088	.00088	.00176	263M
EPT-XU	.00176	.00125	.00176	.00125	263M

Table 8: Selected learning rates and training information for the EPT and EPT-X model. Best rates are selected using the development split on PEN and DRAW dataset, and fold 0 split for the others.

other steps are unchanged. Note that, in this model, the model is more prone to errors in the generated explanation since the equation decoder solely depends on the output of the explanation decoder.

EPT-XU is an inherently unfaithful variant of EPT-X. This model utilizes only the original problem in Step 2-2. So, the text encoder receives the following input in Step 2-2: "`[CLS]` *original problem* `[SEP]` X_0 X_1 $\cdots$ X_N `[SEP]`" where N is the predicted number of variables from Step 1-2. We concatenated 'X_0 X_1 $\cdots$ X_N' in order to keep Step 2-3 unchanged. Step 2-3 requires vectors representing either a written number or a required variable to predict an operand. However, if we remove the recombined problem from the input of Step 2-2, the output of Step 2-2 could not provide such vectors, especially for the variables. Thus, for each variable, the list of variables is added to produce a vector value that Step 2-3 can use. And, for each number, the vector corresponding to the number written in the original text is used in Step 2-3 as the EPT model did.

C Implementation details

In this section, we describe the implementation details of EPT-X.

- Hardware:

  CPU: AMD Ryzen Threadripper 3970X
  GPU: GeForce RTX 3090, four cards
  Memory: 192GB

- Software:

  OS: Ubuntu 20.04.2 LTS (kernel 5.4.0-80)
  CUDA: 11.1
  Graphic Driver: 460.73.01
  Python: 3.8.10 (with virtualenv)

- Python libraries:

  PyTorch 1.8.1+cu111
  transformers 4.6.1 (for ELECTRA)
  torch-optimizer 0.1.0 (for LAMB)
  ray 1.3.0 (for hyperparameter search with ray[tune])
  bleurt `git+https://github.com/google-research/bleurt` Commit `c6f2375` (Oct 15th, 2021; for BLEURT)
  tensorflow 2.7.0 (for BLEURT)
  numpy 1.21.0
  scipy 1.7.0
  sympy 1.8
  pycocoevalcap 1.2
  pycocotools 2.0.2
  zss 1.2.0

- Hyperparameters and options for EPT-X:

  text encoder: google/electra-base-discriminator. We fixed the embedding layer to preserve the world knowledge in the embedding and to stabilize the training procedure.
  explanation decoder: Following (Rothe et al., 2020), we inserted randomly initialized cross-attention layers in an ELECTRA model of google/electra-base-discriminator.
  equation decoder: 6 layers of Transformer decoder. We tied weights across these layers.
  training epoch: 500
  optimizer: LAMB (You et al., 2020) with $\beta_1 = 0.9$, $\beta_2 = 0.999$, and $\epsilon = 10^{-12}$.
  learning rate: To find the best learing rate for each dataset and model, we conducted grid-search. Among the possible learning rates in $\{0.00088, 0.00125, 0.00176, 0.0025\}$, we selected a model with the highest answer correctness. For P1-Only models, we used EPT-X's learning rate. Table 8 shows the selected learning rates. Also, we applied linear warm-up for 10 epochs and linear decay for the rest of the epochs.

Sufficiency	0.69^{+}	1.74	1.55
Comprehensive.	4.83^{**}	9.57^{**}	10.33^{**}

$^{+}\ p < 0.1$, $^{*}\ p < 0.05$, $^{**}\ p < 0.01$

Table 12: Mean faithfulness of EPT-X on PEN's subsets

window size in Step 1-3: 3 tokens
batch size: 16 problems per batch
BLEURT checkpoint: BLEURT-20-D6

To ensure the reproducibility of our experiment, we used separate random number generators with seed '1' in the following places:

- Code where building mini-batches for training
- Code where selecting gold set explanations randomly for training Phase 2
- Code where inputting gold set explanations for the error propagation analysis

D Result of correctness, plausibility, and faithfulness on subsets

Correctness: The PEN dataset contains three subsets corresponding to each benchmark dataset: ALG514, DRAW, and MAWPS. To make the performance on these datasets be compatible with previous benchmarks, we retained duplicated problems in these subsets. Table 9 also shows the statistics of these three subsets. DRAW is the most difficult subset to generate explanations since its explanation is the longest (8.32 words) among the three subsets while its text is the shortest (32.70 words). Likewise, MAWPS is the easiest subset among the three subsets.

For each subset, we conducted the same comparative analysis to evaluate EPT-X. Tables 10 to 12 shows the EPT-X's performance on these subsets. Note that as we manually corrected problems and equations in PEN, the results cannot be directly compared with previous state-of-the-art models.

Table 10 reveals that EPT-X's correctness is comparable to the inexplainable models when generating explanations is simple. On the simplest subset MAWPS, EPT-X achieved answer correctness of 84.57%, which is 4% lower than to EPT (88.7%). Similarly, on the most difficult subset DRAW, EPT-X achieved an answer correctness of 56.0%, which is 7.5% lower than EPT (63.5%). As we discussed in Section 6, this performance decrease may be due to error propagation. On a subset whose explanation is difficult to generate (such as DRAW or ALG514), the chance of generating incorrect explanation increases. So, EPT-X can be swayed by wrong explanations considering the model's dependency on explanation.

Plausibility: Table 11 illustrates that EPT-X's plausibility scores are comparable to humans. On

Case 1. Encoder is confused an entity with others (69 of 118 problems)

Q. The Sears tower in Chicago is 1450 feet tall. The John Hancock center in Chicago is 1127 feet tall. Suppose you are asked to build a small-scale replica of each. If you make the Sears tower 3 meter tall, what would be the approximate height of the John Hancock replica?

Gold-standard	**EPT-X**
“How tall **Sears tower** is" is 1127.	“The height of the **Sears tower** in meter" is 1127.
“How tall **Hancock center** is" is 1450.	“The height of the **Sears tower** in meter" is 1450.
“Height of the **Sears tower replica**" is 3.	“The height of the **Sears tower**" is 3.
What[x_0] is “the height of Hancock replica?"	What[x_0] is “the height of the Sears tower?"
	What[x_1] is “the height of John Hancock center?"
Equation: $1127/1450 = 3/x_0$	**Equation:** $x_1 = 3 \times (1127 + 1450)$

Case 2. Encoder forgets to explain detailed situations (57 of 118 problems)

Q. Juan drives to work. Because of traffic conditions, he averages 22 miles per hour. He returns home, averaging 32 miles per hour. The total travel time is 2.25 hours. Write and solve an equation to find the time Juan spends driving to work.

Gold-standard	**EPT-X**
“The speed of Juan **driving to work**" is 22.	“The speed of Juan" is 22.
“The speed **returning home**" is 32.	“The speed of Juan"" is 32.
“The total travel time" is 2.25.	“The total travel time"" is 2.25.
What[x_0] is “the time traveled **to work**?"	What[x_0] is “the time Juan rowe spends?"
What[x_1] is “the time **returning from work**?"	
Equation: $22x_0 = 32x_1$ $2.25 = x_0 + x_1$	**Equation:** $22x_0 = 32x_0$

Case 3. Encoder fails to identify numbers required to solve a problem (32 of 118 problems)

Q. There are 48 erasers in the drawer and 30 erasers on the desk. Alyssa placed 39 erasers and 45 rulers on the desk. How many erasers are now there in total?

Gold-standard	**EPT-X**
“The number of erasers in the drawer" is 48.	“The number of erasers in the drawer" is 48.
“**The number of erasers on the desk**" is 30.	
“The number of erasers added on the desk" is 39.	“The number of erasers placed on the desk" is 39.
What[x_0] is “the total number of erasers?"	What[x_0] is “the total number of erasers?"
Equation: $x_0 = 48 + 30 + 39$	**Equation:** $x_0 = 48 + 39$

Table 13: Three representative erroneous cases of EPT-X

the ALG514 and DRAW subsets, EPT-X showed slightly lower but comparable scores: at most 1% lower on BLEU, 2-5% lower on ROUGE, about 30-50 less on CIDEr, and 7-9% less on BLEURT. Meanwhile, on the MAWPS subset, EPT-X showed much higher plausibility scores than humans: about 20% more on BLEU, 8-10% more on ROUGE, about 110 more on CIDEr, and 11% more on BLEURT. These results imply that EPT-X could quickly learn how to generate explanations as the MAWPS dataset has more examples with simpler explanations than the other two subsets.

Faithfulness: Table 12 implies that the generated explanation is insufficient to produce a correct equation. EPT-X model passed both tests only on MAWPS subset, which has simpler explanations than the other two subsets. On the other hand, the model only passed the comprehensiveness test on DRAW and ALG514 subsets. This result implies that though EPT-X can generate a simple explanation appropriately, EPT-X may forget to explain some essential information when the target explanation is complicated.

E Example error cases

Table 13 shows the three error cases of EPT-X. First, Case 1 shows that the encoder is often confused with an entity to others. In this example, the model mistakenly equated ‘Sears tower’ and ‘John Hancock center.’ So, the EPT-X cannot utilize the concept of reduced scale, which is a key concept to solve the given problem. Second, Case 2 shows that the encoder often forgets to explain detailed situations of a word problem. In this example, the model unified two different situations: (1) a situation that Juan drives to work and (2) a situation that Juan returns home. So, the EPT-X cannot utilize the concept of round trip, which is a key concept to write the second equation, $2.25 = x_0 + x_1$. Lastly, Case 3 shows that the encoder sometimes fails to identify whether a number is significant to solve a word problem or not. In this example, the model did not describe the second number, 30. Without explaining the number, it is not possible to count the number of erasers correctly.

Identifying the Human Values behind Arguments

Abstract

This paper studies the (often implicit) human values behind natural language arguments, such as to *have freedom of thought* or to *be broad-minded*. Values are commonly accepted answers to why some option is desirable in the ethical sense and are thus essential both in real-world argumentation and theoretical argumentation frameworks. However, their large variety has been a major obstacle to modeling them in argument mining. To overcome this obstacle, we contribute an operationalization of human values, namely a multi-level taxonomy with 54 values that is in line with psychological research. Moreover, we provide a dataset of 5270 arguments from four geographical cultures, manually annotated for human values. First experiments with the automatic classification of human values are promising, with F_1-scores up to 0.81 and 0.25 on average.

1 Introduction

How come people disagree on the best course forward in controversial issues, even if they use the same information to form their opinion? A way to get to the bottom of such disagreement is to repeatedly ask them why they see something as desirable. We observe that people have different beliefs and priorities of what is generally worth striving for (e.g., personal achievements vs. humility) and how to do so (e.g., being self-directed vs. respecting traditions), often referred to as *(human) values* (Searle, 2003). Some values tend to conflict and others to align (see Figure 1), which can cause disagreement on the best course forward, but also the support, if not formation, of political parties that promote the respective highly revered values. Moreover, one can observe different value priorities between cultures and disagreement thereon.

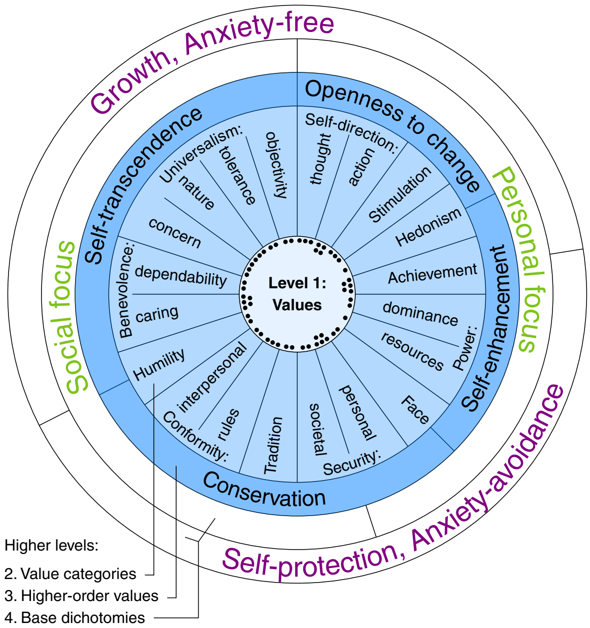

Figure 1: The levels of this paper's consolidated taxonomy of 54 values (shown as black dots) that are categorized on the more abstract levels 2–4 (cf. Section 3). Categories that tend to conflict are placed on opposite sites. Illustration adapted from (Schwartz et al., 2012).

Due to their outlined importance, human values are studied both in the social sciences (Schwartz, 1994) and in formal argumentation (Bench-Capon, 2003) for decades. According to the social sciences, a "value is a (1) belief (2) pertaining to desirable end states or modes of conduct, that (3) transcends specific situations, (4) guides selection or evaluation of behavior, people, and events, and (5) is ordered by importance relative to other values to form a system of value priorities." As Schwartz continues, these features "make it possible to conclude that security and independence are values,

Volume 1: Long Papers, pages 4459 - 4471
May 22-27, 2022 ©2022 Association for Computational Linguistics

whereas thirst and a preference for blue ties are not." Consider the following example:

"*Social media is good for us. Though it might make people less polite, it makes our lives much easier.*"

To understand the pragmatics of this argument, a reader has to acknowledge the belief (Point 1 in the definition above) that the "end state" (2) of *having a comfortable life* is desirable in general (3). To concur with the statement (4), the reader further has to prefer *having a comfortable life* over *being polite* (5)—ignoring other arguments on the topic for the sake of the example. Within computational linguistics, human values thus provide the context to categorize, compare, and evaluate argumentative statements, creating several possibilities: to inform social science research on values through large-scale datasets; to assess argumentation with respect to scope and strength; to generate or select arguments based on the value system of a target audience; and to identify opposing and shared values on both sides of a controversial topic.

However, the task to identify values in arguments seems daunting due to their large number, often implicit use in arguments, and vague definitions. On the other hand, the creation of larger argumentation datasets, advancements in natural language understanding, and the decade-long rigorous taxonomization of values by social scientists has put such an automatic identification within reach.

As a first endeavor on the automatic identification of values in written arguments, this paper makes three contributions: (1) a consolidated multi-level taxonomy of 54 human values taken from four authoritative cross-cultural social science studies (Section 3); (2) a dataset of 5270 arguments from the US (most arguments), Africa, China, and India, each of which manually annotated for all values by three annotators, corresponding to about 850k human judgments (Section 4); and (3) first classification results per taxonomy level, establishing a baseline and revealing promising results both within and across cultures (Section 5).

2 Background

Human values are of concern to most if not to all social sciences (Rokeach, 1973) and have also been integrated into computational frameworks of argumentation (Bench-Capon, 2003). In NLP, values have been analyzed for personality profiling (Maheshwari et al., 2017), but not yet for argument mining, as considered here.

2.1 Values in Social Science

Rokeach (1973) already described the two concepts of (1) a value as a belief pertaining to desirable end states or modes of conduct and (2) a value system as prioritization of values based on cultural, social, and personal factors. These definitions attribute values to persons rather than to objects, facilitating a systematic analysis (Rokeach, 1973). The paper at hand follows these definitions and targets the personal values behind arguments, that is, the values that the arguments, mostly implicitly, resort to.

Several proposed value schemes are domain-independent and hence suited to analyze generic argumentation. Our consolidated value taxonomy (Section 3) is thus based on these schemes. Combining research from anthropology, sociology, philosophy, and psychology, Rokeach (1973) estimates the total number of human values to be fewer than hundreds, and develops a practical survey of 36 values that distinguishes between values pertaining to desirable end states and desirable behavior.

Specifically for cross-cultural analysis, Schwartz et al. (2012) derived 48 value questions from the universal needs of individuals and societies, including *obeying all the laws* and *to be humble*. Moreover, Schwartz (1994) proposes a relatedness of values by their tendency to be compatible in their pursuit (see Figure 1). This relatedness reflects two "higher order" conflicts: (1) openness to change/own thoughts vs. conservation/submission, and (2) self-transcension (directed towards others/the environment) vs. self-enhancing (directed towards one's self), allowing to analyse values at several levels. Cheng and Fleischmann (2010) consolidates 12 schemes into a "meta-inventory" with 16 values, such as *honesty* and *justice*, revealing a large overlap in schemes across fields of research. However, as the meta-inventory is strictly more coarse-grained than Schwartz et al.'s theory we do not investigate it further in this paper.

Other schemes, however, pertain to specific purposes, making them less suited for our study. We give an overview for completeness. England (1967) suggested 66 values related to management decisions, such as *high productivity* and *prestige*, and categorized them by relevant entity, for example *business organizations* and *individuals*. Brown and Crace (2002) looked at 14 values for counseling and therapy, such as *responsibility* and *spirituality*, and Kahle et al. (1988) at nine for consumer research, such as *warm relationships* and *excitement*.

2.2 Values in Argumentation Research

Formal argumentation employs value systems to model audience-specific preferences, that is, an argument's strength depends on the degree to which the audience reveres the values the argument resorts to. Examples include value-based argumentation schemes (van der Weide et al., 2009), defeasible logic programming (Teze et al., 2019), and the value-based argumentation framework of Bench-Capon (2003). The latter is an extension of the abstract argumentation framework of Dung (1995) that has already been applied manually to analyze interactions with reasoning and persuasion subject to a specific value system (Atkinson and Bench-Capon, 2021). This paper presents a first step towards the large-scale automatic application of these works as it takes values to argument mining.

Feldman (2021) recently showed the strong connection between values and the moral foundation theory (Haidt, 2012). Like personal values, this theory analyzes ethical reasoning behind human choices, but considers five rather abstract "foundations:" care, fairness, loyalty, authority, and purity. Alshomary and Wachsmuth (2021) hypothesized that the foundations could be used for audience-specific argument generation. Kobbe et al. (2020) tried to classify arguments by foundations, but noted a low human agreement due to the vagueness of the foundations. We assume values can here contribute to the classification by foundations.

Values overlap with idea of *framing* in communication, that is, the selection and emphasis of specific aspects of (perceived) reality to promote a particular problem, causal interpretation, ethical evaluation, and/or recommendation (Entman, 1993). In frames, values can define the costs and benefits of options (Entman, 1993), while common value systems are used for evaluation. Framing has often been studied computationally for news (Naderi and Hirst, 2015; Chen et al., 2021), but also for political speech (De Vreese, 2005), and argumentation (Ajjour et al., 2019). In the latter, some values are so prevalent that they constitute frames of their own, indicating a potential use of values in frame identification. For example, 14 out of 54 values we use are also frames in the dataset of Ajjour et al.[1]

Values may be considered as aspects under which to group arguments. Some researchers have mined aspects from text (Trautmann, 2020) or used them to control argument generation (Schiller et al., 2021). Others have studied the task of opinion summarization in arguments (Egan et al., 2016; Misra et al., 2016; Chen et al., 2019), aiming at the most important aspects discussed in a debate. Related, the task of key point analysis (Bar-Haim et al., 2020; Friedman et al., 2021) is to generate a small set of concise statements that each represent a different aspect. We argue that analyzing the values found in a collection of arguments provides a new perspective to aspects in argumentation, focusing on the "why" behind an argument's reasoning.

3 Taking Values to Argument Mining

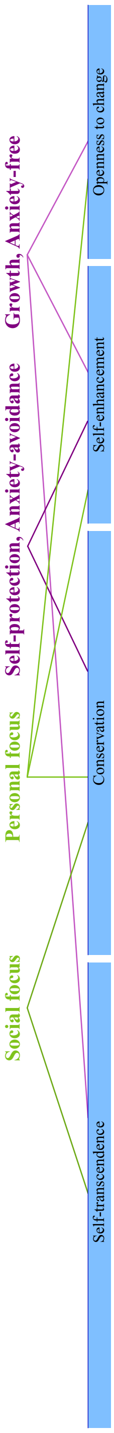
Human values have been considered in formal argumentation since about 20 years (Bench-Capon, 2003). However, to the best of our knowledge, our paper is the first that aims at identifying the values behind arguments computationally. The term "behind" reflects the fact that many arguments do not explicate values; for example, in the argument "no matter they felt forced to commit it: anyone who commits a crime should be prosecuted" no value is mentioned literally. The argument gains its persuasive strength when being connected to values, which can be both desirable behavior (*behaving properly*) or end states (*a safe country*). By putting forward an argument, its proponent wants the audience to connect the argument with its values. Formally, values are connected specifically with the argument's premise. However, automatic models might still improve when incorporating the textual conclusion as context for the textual premise. The task studied in this paper is to draw this connection between arguments and values automatically.

The heart of a value-based argumentation framework is a value taxonomy (or a set of values) that is both accepted and relevant. The research presented in this paper is largely based on the refined theory of Schwartz et al. (2012),[2] which, however, has been extended by us: Comparing Schwartz et al.'s refined theory with three other widespread value lists against a sample of our dataset, we decided to add and integrate nine values (see Table 1). We also asked the annotators to comment on supposedly missing values (see Section 4). For most of the additional 48 value descriptions that we received (*be humane*, *be fair*, *be modern*, etc.), we identified existing values or value combinations in the taxonomy that subsume them, suggesting to extend the value descriptions rather than adding new values.

---

[1] Per Jaccard similarity of value and frame names ≥ 0.5.

[2] Using the noun-phrase value names of Schwartz (1994).



Level			Source				Dataset frequency (size; cf. Section 4)

Table 1: The 54 values of the taxonomy with sources and dataset frequency. Level 4a contains two labels, *personal focus* and *social focus* while 4b refers to motivation regarding anxiety. Following Schwartz et al. (2012), each value has one label per level, except *have pleasure* (both *self-enhancement* and *openness to change* for Level 3) and the achievement values (both Level 4b labels). The main source taxonomy (●) is the Schwartz Value Survey (SVS, Schwartz et al., 2012). Additional values are taken from (○) the Rokeach Value Survey (RVS, Rokeach, 1973), the Life Values Inventory (LVI, Brown and Crace, 2002), and the World Values Survey (WVS, Haerpfer et al., 2020).

Only two of the added values are not directly related to the universal needs that Schwartz (1994) based the value categories on. The proposed category *universalism: objectivity* integrates well between the outward thinking of *universalism: tolerance* and the free thinking of *self-direction: thought* (see Figure 1). We adopt a uniform naming scheme where the value names reflect the distinction of Rokeach (1973) into instrumental (*be* . . .) and terminal (*have* . . .) values, and are easy to embed in sentences, for example, "it is good to *be creative*."

The taxonomy levels are chosen based on usefulness in social science research. The values at Level 1 are intended to be the items in surveys (Schwartz, 1994), which is why we also suggest to use them for dataset annotation. Moreover, Level 1 values can still be classified into being either instrumental or terminal. One could, however, create arbitrarily coarse- and fine-grained levels.[3]

The close connection of our taxonomy to social science research enables studies of value systems across disciplines that are beyond the scope of this paper. The grouping of values at higher levels allows for classifications at coarser levels of granularity, enabling investigations such as, whether a specific set of arguments focus on persons or society mainly, or whether they imply a rather anxiety-free or a rather anxiety-avoiding background (cf. Figure 1). Also, the circular organization of the taxonomy enables the analysis of major "directions" in a collection of arguments, which can, for example, be used to study value differences in argumentation datasets of different cultures. In addition, for the 41 values with a link to the World Values Survey (the WVS column in Table 1, Haerpfer et al., 2020), the corresponding dataset contains information on people's value priorities (i.e., value systems) collected rigorously for 51 territories, with the earliest survey from 1981 and the latest from 2020. These links allow comparing value distributions identified in regional datasets with survey data.

4 A Dataset of Values behind Arguments

This section presents the first dataset for studying human values behind arguments. Each of the 5270 arguments included was annotated by three crowdworkers for all 54 values from Section 3. The dataset, taxonomy description, and annotation interface are available online as Webis-ArgValues-22.[4]

4.1 Argument Sources of Different Cultures

Following the aspiration of a cross-cultural value taxonomy and using territories as a proxy for cultures, the dataset is composed of four parts: *Africa*, *China*, *India*, and *USA*. Each argument consists of one premise, one conclusion, and a stance attribute indicating whether the premise is in favor of (pro) or against (con) the conclusion. As existing argument datasets are almost exclusively from a Western background, we had to collect new suitable arguments for the non-US parts, drastically limiting their size. The respective non-US sources were recommended to us for their authenticity by students from the respective territory that work with our groups. Note that this data is not intended to represent the respective culture, but to train and benchmark classifiers across sources.

Africa We manually extracted 50 arguments from recent editorials of the debating ideas section of a pan-African news platform, *African Arguments*.[5] Premises could often be extracted literally, but conclusions were mostly implicit and had to be compiled from several source sentences.

China We extracted 100 arguments from the recommendation and hotlist section of a Chinese question-answering website, *Zhihu*.[6] We manually identified key points (premises and conclusions) in the answers and manually translated them to English using automated translation for a first draft.

India We extracted 100 arguments from the controversial debate topics 2021 section of *Group Discussion Ideas*.[7] This blog collects pros and cons on various topics from Indian news to support discussions. Premises and conclusions were used as-is.

USA We took 5020 arguments with a manual argument quality rating of at least 0.5 from the 30,497 arguments of the IBM-ArgQ-Rank-30kArgs dataset (Gretz et al., 2020). For the dataset, crowdworkers wrote one pro and one con argument for one of 71 common controversial topics. We rephrased the topics to represent conclusions.

Due to the difficulty of collecting datasets from various cultures, the number of respective arguments (250) is small compared to the US part. However, we will mainly use them for testing the robustness of identifying values in arguments.

---

[3] For example, with values such as "have no broken legs".

Argument	Values	Dataset part
∘ Pro “South Africa’s COVID-19 lockdown was too strict”: The economic ramifications of the lockdown have been huge, and have been felt hardest by those who were already most vulnerable.	Have a comfortable life, Have a stable society, Have equality	Africa
∘ Pro “We should protect our privacy in the Internet age.”: The leaked personal information will be defrauded by fraud gangs to gain trust and carry out fraudulent activities.	Have privacy, Have a stable society, Be compliant	China
∘ Con “Rapists should be tortured”: Throughout India, many false rape cases are being registered these days. Torturing all of the accused persons causes torture to innocent persons too.	Have a safe country, Have a stable society, Be just	India
∘ Pro “We should adopt an austerity regime”: An austerity regime will help to reduce the deficit of the country.	Have no debts, Have a stable society, Be responsible	USA

Table 2: Four example arguments (stance, conclusion, and premise) and their annotated values. We selected these to showcase different ways for resorting to *have a stable society*, the most frequent value, from each dataset part.

Part	Conclusions		Premises		Stances	
	#	Tokens	#	Tokens	# Pros	# Cons
Africa	23	10.6	50	28.1	37	13
China	12	7.3	100	24.5	59	41
India	40	6.6	100	30.3	60	40
USA	71	5.6	5020	18.5	2619	2401
Total	146	5.6	5270	18.9	2775	2495

Table 3: Numbers of unique conclusions and premises for each part of the contributed dataset, their mean number of space-separated tokens, and stance distribution.

Table 2 shows one example from each part. Note that we do not see any part as representative for the respective culture, but rather as a necessary approximation (see Section 7 for a discussion). Table 3 provides an overview of the dataset. Premises are longer than conclusions, with USA having the lowest average for both. The Africa part has the fewest premises per conclusion (2.2) and the US part the most (70.7). The skew between pros and cons is highest for Africa with a ratio of about 3:1. All these observations are results of the collection process and are natural variations for arguments.

4.2 Crowdsourcing of Value Annotations

We employed a custom three-part annotation interface, optimized for speed and task expertise acquisition through keyboard shortcuts and a clear template-like structure (see Appendix A for screenshots). Besides instructions and example arguments, a brief explanation of specific terms was given if needed (e.g., for the “996 overtime system” mentioned in several arguments from China). Below this introductory material, the main part of the interface consists of three panels. The first panel places the argument to be annotated in a scenario:

> *Imagine someone is arguing [in favor of/against] “[conclusion]” by saying: “[premise].”*

The second panel formulated the annotation task for a value as a yes/no question.[8] The question follows the operationalization of Section 3:

> *If asked “Why is that good?”, might this be their justification? “Because it is good to [value]”.*

For illustration, example implications of matching arguments were provided. Instructions stated that one to five values are typical for an argument, and more than 10 should be avoided. A third panel shows the annotation progress. Annotators could write feedback on both arguments and values.

The crowdsourcing ran on the MTurk platform, with annotators taking 2:40 minutes per argument on average, and totaling 90 days of 8-hour work. We required them to have an approval rate of at least 98%, at least 100 approved work tasks, and—for language proficiency—being located in the US. No further personal information was gathered. The annotators were first restricted to three annotation tasks. Manual quality checks at this stage resulted in 154 work rejections (5% rejection rate) due to ignored instructions. We then selected 27 annotators for annotating the bulk of arguments, ensuring at least 3 annotations per argument. As mandatory for MTurk, annotators were paid on a task basis, which led to an average hourly wage of $8.12 (current US federal minimum wage: $7.25). Additionally, we paid bonuses of total $65.65, especially to annotators who wrote extensive comments.

---

[8] To prevent order effects, the value order was randomized for each annotator, but then fixed to allow for learning.

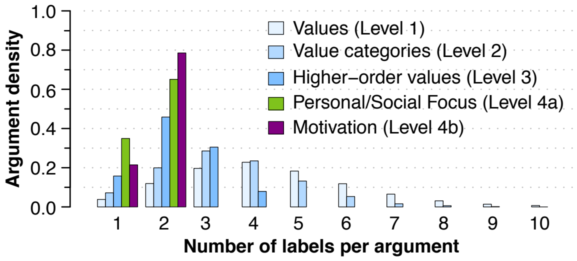

Figure 2: Fraction of arguments having a specific number of assigned labels for each level. The total number of labels for levels 1–4b are 54, 20, 4, 2, and 2.

We employed MACE (Hovy et al., 2013) to fuse the annotations into a single ground truth, applying it value-wise as suggested by the author for multi-label annotations. Despite the difficulty of the annotation task, the crowdworker annotators reached an average value-wise agreement α of 0.49 (Krippendorff, 2004). We found most disagreement arose from the complexity of annotating 54 values at once, with annotators sometimes confusing values despite the descriptions. For follow-up datasets, one could likely reduce such problems by training annotators on the arguments of our dataset with highest disagreement. One step we implemented for quality assurance is that we manually checked the 48 arguments (<1%) to which MACE assigned more than 10 values, reducing their values to the most prevalent 5–7 ones. The right side of Table 1 shows the frequency of each value in each dataset part, revealing that each value occurs at least once.

A value in the ground truth also automatically led to an assignment of all parent labels in the taxonomy (see Figure 1). Figure 2 shows the resulting level-wise distribution of labels per argument. As the majority of arguments are assigned both labels for Levels 4a and b, these base dichotomies for values are hence mostly not dichotomous for arguments. So, like the value systems of people, many arguments seem to resort to a broad spectrum of values from the value continuum at once. For example, the first argument in Table 2 resorts to both *having a comfortable life* (personal focus, self-protection) and *having equality* (social focus, growth). Similar to observations of Rokeach (1973, p. 50f) on value systems, this example showcases an interaction between values that change their psychological significance, where *having equality* gives *having a comfortable life* a social focus. We believe that our dataset enables scholars to study such interactions for arguments in the future.

5 Identifying Values behind Arguments

This section presents a first attempt at automatically identifying human values using standard approaches. The first experiment focuses on the USA dataset part alone, the second on a cross-cultural setting. We compare three approaches, for which we provide our implementation online:[9]

BERT. Fine-tuned multi-label bert-base-uncased with batch size 8 and learning rate 2^{-5} (20 epochs).

SVM. A linear kernel scikit-learn support vector machine trained label-wise with $C = 18$.

1-Baseline. Classifies each argument as resorting to all values. Thus always achieves a recall of 1.

Our evaluation focuses on the label-wise F_1-score and its mean over all labels (macro-average), as well as its constituents precision and recall. We report accuracy for completeness, though the heavily skewed label distribution makes it less suited. The evaluation employs macro-averages for all metrics to give the same weight to all values. Note that the 1-Baseline is especially strong for the F_1-score since it always achieves a recall of 1. By definition this baseline achieves at least as high—and in most cases higher—F_1-scores than label-wise random guessing according to the label frequency. For calculating the p-values when comparing approaches we employ the Wilcoxon signed rank significance test (Wilcox, 1996). As detailed in Section 4, most arguments actually have both labels of the base dichotomies (Levels 4a and b) assigned to them, so we do not discuss these levels deeper here.

5.1 Results on the USA Part

We first report results on the main part of our dataset (USA) as an experiment with matching training and test set. The approaches are trained on the arguments from 60 unique conclusions (4240 arguments, ~85%), validated on 4 (277, ~5%), and tested on 7 (503, ~10%). The conclusions were selected so that the different sets contain roughly the specified percentage of arguments. Unfortunately, this process led to different value distributions in the different sets. However, we deemed the conclusion-wise split more important for our experiments, as we want to test whether classifiers generalize to unseen conclusions. Only one very rare value, *be neat and tidy* (0.2% of arguments in USA part), does not occur in the test set. We thus exclude this value from evaluation.

1-Baseline	0.08	**1.00**	0.16	0.08	0.18	**1.00**	0.28	0.18	0.60	**1.00**	**0.75**	0.60	0.85	**1.00**	**0.92**	0.85	0.92	**1.00**	**0.96**	**0.92**

Table 4: Macro precision (P), recall (R), F_1-score (F_1), and accuracy (Acc) on the USA test set over all labels by level. Best scores per metric and level marked bold.

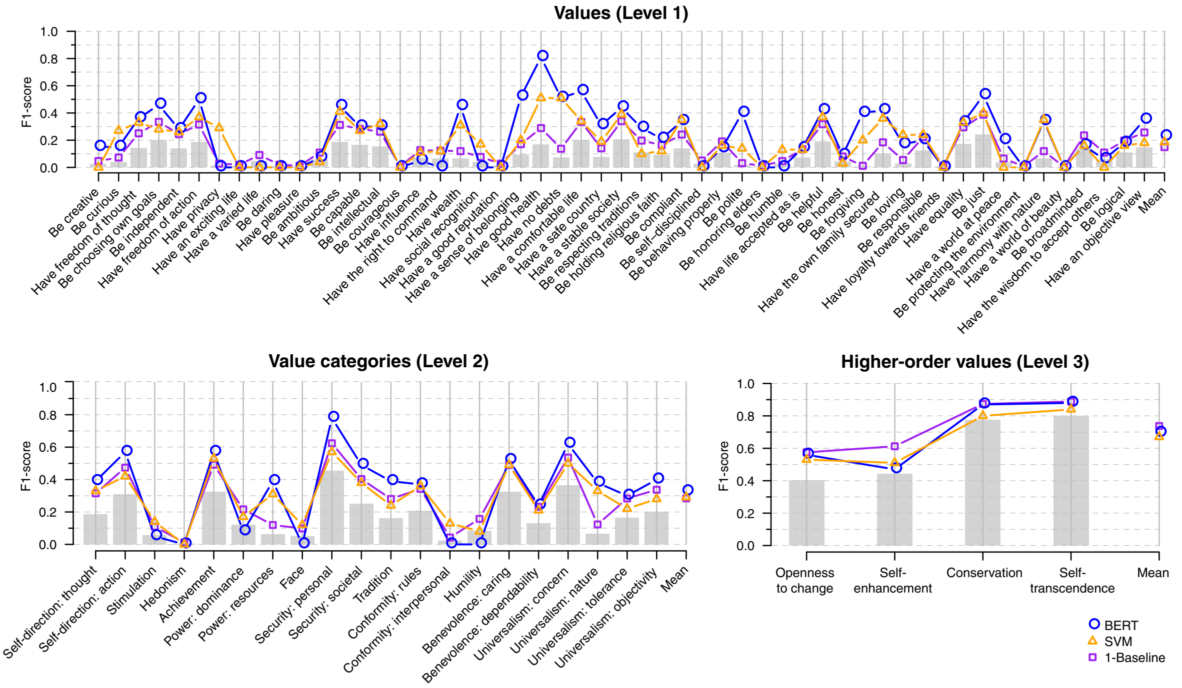

Figure 3: Parallel coordinates plot of F_1-scores on the USA test set over the labels by level. The grey bars show the label distribution, which is equal to the F_1-score of random guessing as per this distribution.

Table 4 shows the results averaged over all labels. BERT performs best according to F_1-score for Level 1 ($p = 0.007$ vs. SVM and $p = 0.001$ vs. 1-Baseline; $n = 53$) and for Level 2 ($p = 0.153$ and $p = 0.117$; $n = 20$), but is worse than or at the baseline for higher levels (n too small for test). The comparably bad performance at higher levels is somewhat surprising, as it indicates that the categories at these higher levels are harder to separate by state-of-the-art language-based approaches. Maybe hierarchical classification approaches (e.g., Babbar et al., 2013) can address this comparably weak performance by utilizing signals at each level of the hierarchy simultaneously. Moreover, while a F_1-score of 0.25 at Level 1 is encouraging for largely out-of-the-box approaches, clearly more work is needed. Though a recall of 0.19 may be acceptable for applications that not rely on completeness, a precision of 0.40 is clearly too low for practical uses.

As Figure 3 shows, however, considerably higher F_1-scores are reached by BERT for several values and value categories. Specifically, the identification works exceptionally well for the value *have good health* (F_1: 0.81) and the value-category *security: personal* (F_1: 0.78) that contains it. Other value categories with $F_1 \geq 0.5$ are *universalism: concern*, *self-direction: action*, *achievement*, and *benevolence: caring*. The out-of-the-box models thus perform reasonably well for a few selected values and categories within the USA part. Moreover, Figure 3 indicates some correlation of value frequency (grey bars) with classifier performance (colored lines). One reason for this correlation could be that the dataset is too small for training reliable classifiers on the infrequent values. Another reason might be that there is a more developed vocabulary concerning frequent values, making it easier for classifiers to identify these values. The results are distributed alongside the dataset for follow-up analyses.

Table 5: Macro F_1-score on each test set over all labels by level. Best scores per part and level marked bold. The scores for USA are the same as in Table 4.

5.2 Results Across Culture

For testing classification robustness, we here apply the same approaches without re-training to all test sets. The non-US parts are considerably smaller and as a result ~28% of the values are lacking arguments (cf. Table 1). However, the 1-Baseline is equally affected by this lack, thus providing for a comparison with the previous setting.

Table 5 shows the F_1-scores for each test set averaged over all labels. Once more, BERT performed best by the F_1-score for Level 1 ($p = 0.006$ vs. SVM and $p < 0.001$ vs. 1-Baseline; $n = 169$) and Level 2 (both $p < 0.001$; $n = 74$), whereas no significant difference was found for Level 3 ($p = 0.179$ and $p = 0.856$; $n = 16$). BERT and SVM perform on Level 1 and 2 similar across parts. Maybe due to the clarity of its editored arguments, BERT performs best for India, despite the 1-Baseline performing best for USA.

These findings constitute first evidence that using a cross-cultural value taxonomy could result in robust methods for identifying the values behind arguments, even though more data and research seem necessary to get there.

6 Conclusion

A computational identification of human values behind arguments is a challenging but also necessary task. With our research we contribute (1) a multi-level taxonomy with 54 values based on social science research, (2) a labeled dataset comprised of 5270 arguments from four sources, and (3) empirical analyses that cover multiple value granularity levels and compare different cultures.

Based on this work a logical next step are analyses that fully exploit relationships between labels. Hierarchical classification approaches appear promising here (e.g., Babbar et al., 2013); learning rules for multi-label classification (e.g., Loza Mencía and Jannsen, 2016) can provide insights into value-relationships.

Moreover, the dataset should be extended to include data from more cultures or territories, genres (e.g., blog posts), modalities (offline and spoken argumentation), and languages. Probably an automated translation with manual assurance, as we did for the dataset's China part, may not be sufficient. Though we optimized the annotation process, the argument acquisition requires a community effort to ensure the widest variety of data. Employing annotators from different cultures is a requirement to analyze and mitigate potential sources of bias. A subsequent step of ranking the annotated values by importance can be beneficial for certain use cases, especially when using the higher taxonomy levels.

Values are a major contributor to argument strength (Bench-Capon, 2021), and the large-scale mining from web data could improve all of argument categorization, assessment, and generation. For example, matching values between arguments could be effective for both supporting and countering arguments. Clearly expressing values behind arguments could avoid misunderstandings between humans and automated argumentation systems (Kiesel et al., 2021). Similarly, an "objective" highlighting of common values behind arguments across political camps could be a step towards resolving seemingly fundamental disagreements.

Finally, the analysis of values in large-scale text corpora can also be of interest of social science scholars. How are values expressed online? Combined with Internet archive data, one could even analyse references to values over time. We thus hope that this work can serve as a first step towards a better understanding of how the public sees and saw human values in everyday (digital) life.

7 Ethics Statement

Identifying values in argumentative texts could be used in various applications like argument faceted search, value-based argument generation, and value-based personality profiling. In all these applications, an analysis of values has the opportunity to broaden the discussion (e.g., by presenting a diverse set of arguments covering a wide spectrum of personal values in search or inviting people with underrepresented value-systems to discussions). At the same time, a value-based analysis could risk to exclude people or arguments based on their values. However, in other cases, for example hate speech, such an exclusion might be desirable.

While we tried to include texts from different cultures in our dataset, it is important to note that these samples are not representative of their respective culture, but intended as a benchmark for measuring classification robustness across sources. A more significant community effort is needed to collect more solid datasets from a wider variety of sources. To facilitate the inclusivity of different cultures, we adopted a personal value taxonomy that has been developed targeting universalism and tested across cultures. However, in our study, the annotations have all been carried out by annotators from a western background. Even though the value taxonomy strives for universalism, a potential risk is that an annotator from a specific culture might fail to correctly interpret the implied values in a text written by people from a different culture.

Finally, as mentioned in Section 4, we did not gather any personal information in our annotation studies, and we ensured that all our annotators get paid more than the minimum wage in the U.S.

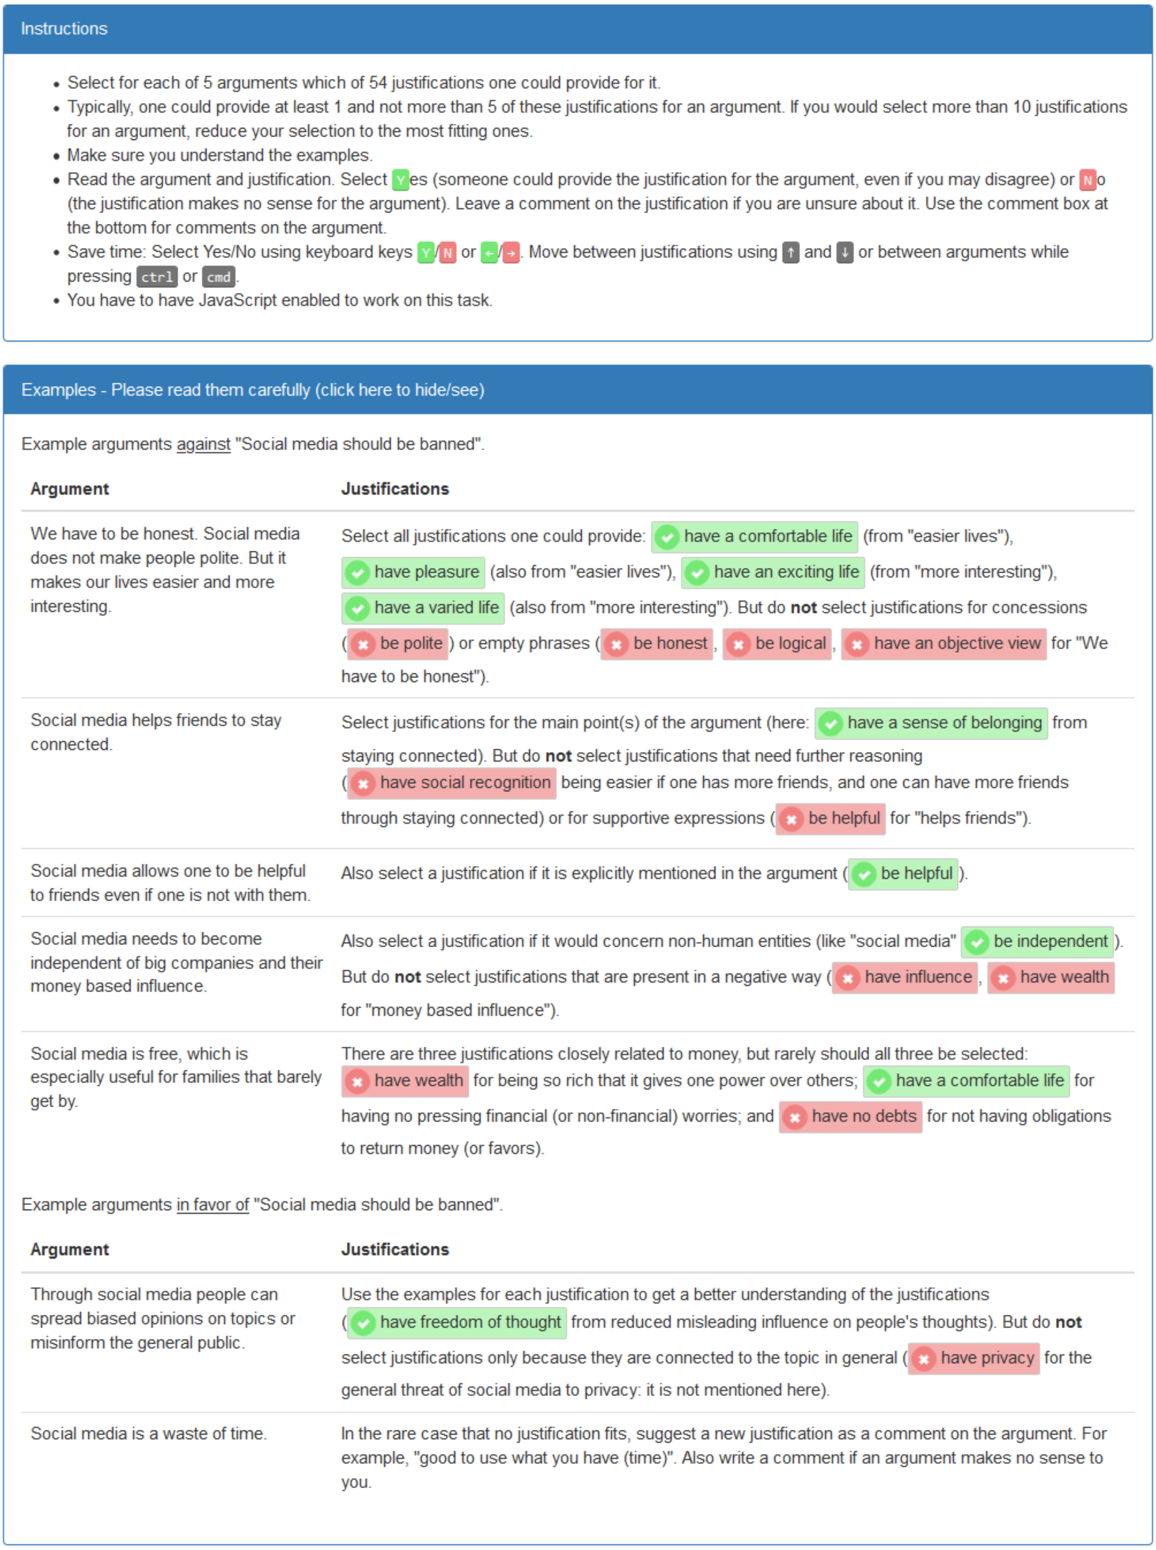
A Annotation Interface

Figure 4 and 5 show screenshots of the custom annotation interface. Its source code is distributed as part of the dataset at `https://github.com/webis-de/ACL-22`.



Instructions

- Select for each of 5 arguments which of 54 justifications one could provide for it.
- Typically, one could provide at least 1 and not more than 5 of these justifications for an argument. If you would select more than 10 justifications for an argument, reduce your selection to the most fitting ones.
- Make sure you understand the examples.
- Read the argument and justification. Select Yes (someone could provide the justification for the argument, even if you may disagree) or No (the justification makes no sense for the argument). Leave a comment on the justification if you are unsure about it. Use the comment box at the bottom for comments on the argument.
- Save time: Select Yes/No using keyboard keys Y/N or ←/→. Move between justifications using ↑ and ↓ or between arguments while pressing `ctrl` or `cmd`.
- You have to have JavaScript enabled to work on this task.

Examples - Please read them carefully (click here to hide/see)

Example arguments against "Social media should be banned".

Argument	**Justifications**
We have to be honest. Social media does not make people polite. But it makes our lives easier and more interesting.	Select all justifications one could provide: ✓ have a comfortable life (from "easier lives"), ✓ have pleasure (also from "easier lives"), ✓ have an exciting life (from "more interesting"), ✓ have a varied life (also from "more interesting"). But do **not** select justifications for concessions (✗ be polite) or empty phrases (✗ be honest, ✗ be logical, ✗ have an objective view for "We have to be honest").
Social media helps friends to stay connected.	Select justifications for the main point(s) of the argument (here: ✓ have a sense of belonging from staying connected). But do **not** select justifications that need further reasoning (✗ have social recognition being easier if one has more friends, and one can have more friends through staying connected) or for supportive expressions (✗ be helpful for "helps friends").
Social media allows one to be helpful to friends even if one is not with them.	Also select a justification if it is explicitly mentioned in the argument (✓ be helpful).
Social media needs to become independent of big companies and their money based influence.	Also select a justification if it would concern non-human entities (like "social media" ✓ be independent). But do **not** select justifications that are present in a negative way (✗ have influence, ✗ have wealth for "money based influence").
Social media is free, which is especially useful for families that barely get by.	There are three justifications closely related to money, but rarely should all three be selected: ✗ have wealth for being so rich that it gives one power over others; ✓ have a comfortable life for having no pressing financial (or non-financial) worries; and ✗ have no debts for not having obligations to return money (or favors).

Example arguments in favor of "Social media should be banned".

Argument	**Justifications**
Through social media people can spread biased opinions on topics or misinform the general public.	Use the examples for each justification to get a better understanding of the justifications (✓ have freedom of thought from reduced misleading influence on people's thoughts). But do **not** select justifications only because they are connected to the topic in general (✗ have privacy for the general threat of social media to privacy: it is not mentioned here).
Social media is a waste of time.	In the rare case that no justification fits, suggest a new justification as a comment on the argument. For example, "good to use what you have (time)". Also write a comment if an argument makes no sense to you.

Figure 4: Screenshot ot the first part of the annotation interface, containing instructions and examples.

Argument 3 of 5

Imagine someone is arguing in favor of "We should end the use of economic sanctions" by saying:

"we should end all economic sanctions because they cause harm to both countries by preventing free trade which in turn will cause an economic downturn."

Justification 47 of 54

If asked "Why is that good?", might this be their justification? "Because it is good to have wealth."

Select Yes or No below.

This justification does **not** refer to lacking the money for a decent living or some non-luxury item being too expensive. In this case select *have a comfortable life*.

For example, they might give this justification if the argument implies their chosen side is better with regard to:

- allowing people to gain wealth and material possession
- allowing to show one's wealth
- allowing to use money for power
- providing people with resources to control events
- resulting in financial prosperity

Comments on this justification (optional):

Might they give this justification? Yes or No. "Because it is good to..."

✖ be forgiving Y N
✖ have privacy Y N
✖ have the own family secured Y N
✓ have a stable society Y N
✖ have an exciting life Y N
✖ have the right to command Y N
✖ be protecting the environment Y N
✖ be behaving properly Y N
✖ have social recognition Y N
✖ have good health Y N

✖ have loyalty towards friends Y N
✖ have the wisdom to accept others Y N
✖ be broadminded Y N
✖ be courageous Y N
✖ be neat and tidy Y N
✖ be respecting traditions Y N
✖ have a comfortable life Y N
✖ be humble Y N
✖ have harmony with nature Y N
✖ have pleasure Y N

✖ be daring Y N
✖ have a world of beauty Y N
✖ be choosing own goals Y N
✖ be independent Y N
✖ be holding religious faith Y N
✓ be responsible Y N
✖ be helpful Y N
✖ have equality Y N
✖ have success Y N
✖ have an objective view Y N
✖ have influence Y N
✓ have a world at peace Y N

✖ be logical Y N
✖ be just Y N
✖ have a good reputation Y N
✖ be loving Y N
✖ be polite Y N
✖ have life accepted as is Y N
✖ have a safe country Y N
✖ be self-disciplined Y N
✖ be capable Y N
✖ be curious Y N
✖ be creative Y N
✖ have no debts Y N

✖ have freedom of thought Y N
✖ have a sense of belonging Y N
✓ have wealth Y N
be honoring elders Y N
be intellectual Y N
have a varied life Y N
be ambitious Y N
have freedom of action Y N
be compliant Y N
be honest Y N

Comments on this argument (optional):

Figure 5: Screenshot ot the second part of the annotation interface, which consists of three panels: (1) the top left panel places the argument in a scenario ("Imagine"); (2) the top right panel formulates the annotation task for a value (here: *have wealth*) as a yes/no question, describing the value with examples; and (3) the bottom panel shows the annotation progress for the argument and allows for a quick review of selected annotations.

BenchIE: A Framework for Multi-Faceted Fact-Based Open Information Extraction Evaluation

Abstract

Intrinsic evaluations of OIE systems are carried out either manually—with human evaluators judging the correctness of extractions—or automatically, on standardized benchmarks. The latter, while much more cost-effective, is less reliable, primarily because of the *incompleteness* of the existing OIE benchmarks: the ground truth extractions do not include all acceptable variants of the same fact, leading to unreliable assessment of the models' performance. Moreover, the existing OIE benchmarks are available for English only. In this work, we introduce BenchIE: a benchmark and evaluation framework for comprehensive evaluation of OIE systems for English, Chinese, and German. In contrast to existing OIE benchmarks, BenchIE is *fact-based*, i.e., it takes into account informational equivalence of extractions: our gold standard consists of *fact synsets*, clusters in which we exhaustively list all acceptable surface forms of the same fact. Moreover, having in mind common downstream applications for OIE, we make BenchIE *multi-faceted*; i.e., we create benchmark variants that focus on different facets of OIE evaluation, e.g., compactness or minimality of extractions. We benchmark several state-of-the-art OIE systems using BenchIE and demonstrate that these systems are significantly less effective than indicated by existing OIE benchmarks. We make BenchIE (data and evaluation code) publicly available.[1]

1 Introduction

Open Information Extraction (OIE) is the task of extracting relations and their arguments from natural language text in a schema-free manner (Banko et al., 2007). Consider the sentence *"Sen. Mitchell, who is from Maine, is a lawyer."*; an OIE system is expected to extract the triples *("Sen. Mitchell"; "is from"; "Maine")* and *("Sen. Mitchell"; "is"; "a lawyer")* from the sentence. OIE systems are used in many downstream tasks, including knowledge graph (KG) population (Gashteovski et al., 2020), open link prediction (Broscheit et al., 2020), and question answering (Yan et al., 2018). These downstream tasks lend themselves as natural setups for extrinsic OIE evaluation (Mausam, 2016). While valuable in concrete applications, such extrinsic evaluations do not measure the *intrinsic correctness* of the extracted facts: for that purpose, several benchmarks for intrinsic OIE evaluation have been proposed (Stanovsky and Dagan, 2016; Lechelle et al., 2019; Bhardwaj et al., 2019).

Automated benchmark evaluations are more feasible (i.e., faster and cheaper) than manual OIE evaluations (Hohenecker et al., 2020). The current benchmarks, however, use scoring functions that are based on approximate (token-level) matching of system extractions against ground truth facts, which seems to be substantially less reliable than human judgments of extraction correctness (Zhan and Zhao, 2020). This primarily stems from the *incompleteness* of existing OIE benchmarks: the gold standard extractions do not include *all* acceptable surface realizations of the *same fact*. Consider, for example, a sentence from the recent evaluation framework CaRB (Bhardwaj et al., 2019): *"Sen. Mitchell is confident he has sufficient votes to block such a measure with procedural actions"*; with the gold triple extraction (*"Sen. Mitchell"*; *"is confident he has"*; *"sufficient votes to . . . procedural actions"*). Intuitively, a system extraction with a more concise object—(*"Sen. Mitchell"*; *"is confident he has"*; *"sufficient votes"*)—could also be accepted, as it still captures the same core piece of knowledge, and would arguably be valuable in most downstream tasks.

To account for this, existing benchmarks credit system extractions for per-slot lexical overlap with gold extractions. Such scoring is overly lenient and overestimates the systems' ability to extract correct *knowledge facts*. Consider, e.g., a system

---

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 4472 - 4490

extraction (*"Sen. Mitchell"*; *"is confident he has"*; *"procedural actions"*) for the above-mentioned sentence. From the *factual* perspective, this extraction is clearly incorrect (*Sen. Mitchell* has *votes*, not *actions*). However, the popular CaRB benchmark with its token-level metrics would judge the extraction as having (1) perfect precision, since all extracted tokens can be found in corresponding slots of a gold extraction and (2) high recall, as all of the gold subject and predicate tokens as well as two gold object tokens (*"procedural"* and *"actions"*) are found within corresponding slots of the system extraction (Table 1). Moreover, by providing a single ground truth extraction per fact, existing OIE benchmarks fail to acknowledge that different downstream applications focus on different facets (i.e., aspects) of OIE extractions: e.g., for text summarization, one may prefer *minimal* extractions (Ponza et al., 2018), whereas knowledge base population benefits from strict correctness of entities in subject and object slots (Lin et al., 2020).

In this work, we depart from lenient OIE evaluations based on per-slot token overlaps and propose BenchIE, a novel *fact-centric* and *multi-faceted* OIE evaluation framework and benchmark at the core of which is the following question:

Does the system extraction express the same fact (i.e., the same unit of knowledge) as any of the ground truth extractions (and vice versa) w.r.t. the specific aspect of the OIE extraction that is of interest for one or more downstream applications?

Contributions. BenchIE advances the state of the art in OIE evaluation in the following: **(1)** it is the first **fact-centered** approach to OIE evaluation: to reliably answer the above question, we exhaustively list all correct extractions of the same fact. In contrast to existing benchmarks, BenchIE specifies *complete* sets of fact-equivalent extractions (dubbed *fact synsets*), allowing us to avoid error-prone evaluation based on token overlap measures; **(2)** BenchIE is the first **multi-faceted** OIE benchmark, allowing to test systems for different aspects of OIE extractions that may be relevant in concrete downstream applications; **(3)** BenchIE is a **multilingual** benchmark, covering English, Chinese, and German, and to the best of our knowledge the first with manually annotated (i.e., gold standard) extractions in all languages;[2] **(4)** finally, as a fact-based and multi-faceted benchmark, BenchIE allows us to perform what we believe to be the most comprehensive **profiling and comparative evaluation** of OIE systems. BenchIE portrays fact extraction abilities of six state-of-the-art OIE models much less favorably and points to their limitations that cannot be detected with existing benchmarks.

2 Matching Facts, Not Tokens

Most OIE systems extract *(subject, predicate, object)* triples, with concepts as subjects and objects and verb phrases (VPs) as predicates (Banko et al., 2007; Stanovsky et al., 2018; Lauscher et al., 2019; Gashteovski et al., 2017, 2019), though systems producing n-ary (Akbik and Löser, 2012), nested (Bhutani et al., 2016), and noun-mediated extractions (Yahya et al., 2014) also exist. Here we follow the most common practice and focus on VP-mediated facts. Our novel fact-based benchmark and evaluation paradigm can, however, equally be applied to other types of extractions (e.g., Friedrich et al. (2022) used this fact-based concept for OIE to create gold annotations for *NE-Centric OIE triples*; i.e., triples where each argument is a named entity and the relations could be either verb phrases or noun phrases).

2.1 Fact Synsets

We introduce the general concept of a *fact synset*: a set of *all* possible extractions (i.e., different surface forms) for a given fact type (e.g., VP-mediated facts) that are instances of the same fact. E.g., given the input sentence from Table 2, the extractions (*"Sen. Mitchell"*; *"has sufficient votes to block"*; *"such a measure"*) and (*"Sen. Mitchell"*; *"has sufficient votes to block"*; *"measure"*) capture the same fact and thus belong to the same fact synset.

Existing benchmarks fail to exhaustively list all acceptable extractions for the same fact. This is precisely why, in order to avoid penalizing systems for correct extractions that are not exactly the same as the gold triples, they resort to lenient token-based performance measures prone to two types of errors: (1) they punish correct fact extractions that have limited lexical overlap with the gold extraction of the same fact, e.g., (*"Sen. Mitchell"*; *"is confident he has"*; *"sufficient votes"*) vs. (*"Sen. Mitchell"*; *"is confident he has"*; *"sufficient votes to . . . procedural actions"*)

---

[2] Ro et al. (2020) introduce a multilingual version of the CaRB dataset by machine translating both sentences and extractions. However, automated translation seems to be highly unreliable for OIE – as shown by Kotnis et al. (2022), up to 70% of sentence or extraction translations obtained this way were incorrect.

Input sentence: *"Sen. Mitchell is confident he has sufficient votes to block such a measure with procedural actions."*
CaRB golden extraction: *("Sen. Mitchell"; "is confident he has"; "sufficient votes to block ...procedural actions")*

	OIE extraction		CaRB (P / R)		BenchIE
t_1	*("Sen. Mitchell"; "is confident he has";*	*"sufficient")*	1.00	0.44	0
t_2	*("Sen. Mitchell"; "is confident he has";*	*"sufficient actions")*	1.00	0.50	0
t_3	*("Sen. Mitchell"; "is confident he has";*	*"sufficient procedural actions")*	1.00	0.56	0
t_4	*("Sen. Mitchell"; "is confident he has";*	*"sufficient votes")*	1.00	0.50	1

Table 1: Difference in scores between CaRB and BenchIE. For the input sentence, CaRB provides only one extraction which covers all the words in the sentence. Then, for each input OIE extraction (from t_1 to t_4) it calculates token-wise precision and recall scores w.r.t. the golden annotation. In contrast, BenchIE provides 46 gold extractions for the same sentence and recognizes OIE extractions as valid if they exactly match any of them.

Input sentence: *"Sen. Mitchell is confident he has sufficient votes to block such a measure with procedural actions."*

f_1	*("Sen. Mitchell" | "he";*	*"is";*	*"confident [he has sufficient ... actions]")*
f_2	*("Sen. Mitchell" | "he";* *("Sen. Mitchell" | "he";*	*"is confident he has";* *"is confident he has";*	*"sufficient votes")* *"suff. votes to block [such] [a] measure")*
f_3	*("Sen. Mitchell" | "he";* *("Sen. Mitchell" | "he";* *("Sen. Mitchell" | "he";*	*"is confident he has sufficient votes to block"* *"is confident he has ... to block [such]";* *"is confident he has ... to block [such] [a]";*	*"[such] [a] measure")* *"[a] measure")* *"measure")*
f_4	*("Sen. Mitchell" | "he";* *("Sen. Mitchell" | "he";*	*"is confident he has ... [such] [a] measure with";* *"is confident he has ... [such] [a] measure";*	*"procedural actions")* *"with procedural actions")*

Table 2: An example sentence with four BenchIE fact synsets (f_1–f_4). BenchIE accounts for entity coreference and accepts triples with both *"Sen. Mitchell"* and *"he"* as subjects: the delimiter "|" is just a shorthand notation for different extractions. Similarly, the square brackets ([]) represent a shorthand notation for multiple extractions: triples both with and without the expression(s) in the brackets are considered correct.

and (2) they reward incorrect extractions that have high lexical overlap with a gold extraction, e.g., (*"Sen. Mitchell"*; *"is confident he has"; "procedural actions"*) vs. *("Sen. Mitchell"; "is confident he has"; "sufficient votes to block... with procedural actions").*

To prevent this, BenchIE relies on *exact matching* of system extractions against the gold fact synsets. Further, some OIE systems (over)generate extractions of the same fact; e.g., *("Sen. Mitchell"; "has sufficient votes to block"; "such a measure")* and *("Sen. Mitchell"; "has sufficient votes to block"; "measure").* Existing evaluation procedures do not acknowledge the *fact equivalence* of extractions and consequently reward OIE systems for multiply extracting the same fact. Our evaluation based on fact synsets directly remedies these shortcomings of existing OIE benchmarks.

2.2 Annotation Process

English Benchmark. To make BenchIE comparable to previous benchmarks, we annotate fact synsets on a subset of sentences from CaRB (Bhardwaj et al., 2019). Because exhaustive annotation of fact synsets is time consuming, we carried it on 300 (out of 1,200) randomly sampled CaRB sentences. To collect truly exhaustive fact synsets, two expert annotators independently labeled the selected 300 sentences in three rounds. **(1)** Each annotator first (independently) manually denoted every extraction in which a VP-predicate connects two concepts. The annotator then grouped the fact-equivalent triples into fact synsets.[3] To speed the annotation process up, we developed a dedicated web-based annotation tool AnnIE that facilitates the extraction of VP-mediated triples (e.g., we color-code verbs to indicate possible predicate heads) and their clustering into fact synsets;[4] **(2)** The annotators then carefully examined all gold extractions from the original CaRB dataset and added those judged to be correct, yet missing from the manually labeled fact synsets from the previous step; **(3)** Finally, each annotator compared the extractions of all OIE systems in evaluation (see §4) against the BenchIE's fact synsets (i.e., the result of the first two steps). Any system extraction not found in BenchIE was carefully examined and—if judged to be correct—added to the appropriate fact synset.[5] Finally, the

---

[3] We provide the annotation guidelines in Appendix A.1.

[4] We show AnnIE's interface in Appendix B. For further details about the tool, see Friedrich et al. (2022).

[5] Very few extractions were actually added in steps (2) and (3); i.e., there were very few correct extractions (from CaRB gold standard and output of OIE systems) that the annotators missed during manual annotation of fact synsets.

two annotators merged their independently created annotations by discussing and jointly resolving the disagreements. The overall annotation effort for the English dataset amounted to 80 hours per annotator. English BenchIE contains 136,357 unique gold extractions, grouped into 1,350 fact synsets. For comparison, CaRB (Bhardwaj et al., 2019) lists mere 783 gold triples for the same 300 sentences. Table 2 shows fact synsets for an example sentence.

Inter-Annotator Agreement (IAA). To validate BenchIE's annotations, we measure the inter-annotator agreement (IAA) between our two expert annotators. To this end, we quantify the agreement via *recall at the fact level* (see §2.3 for further details): for each annotator, we compute their fact-level recall as the percentage of fact synsets of the other annotator they *cover* with their extractions.[6] We average the fact-level recalls of the two annotators as the IAA score. We observed a high IAA score of 0.79. Upon manual inspection, we found that the annotators mostly agree on fact-synset level; most of the the disagreements are on extractions level (particularly, from marking the optional tokens within an extraction; see Appendix A.1.3 for details about the optional tokens).

Chinese and German Benchmarks. Two bilingual expert annotators – native in the target language and fluent in English (EN) – translated the original 300 English sentences to Chinese (ZH) and German (DE), respectively. Then, to collect exhaustive fact synsets in ZH and DE , they followed the same three annotation rounds described for §2.2. Due to substantial (primarily syntactic) differences compared to EN , we adjusted the annotation guidelines for these languages (see the Appendix A.2 and A.3 for more details). The statistics (number of fact synsets and extractions) of the ZH and DE benchmarks are given in Table 3. Compared to EN BenchIE, the ZH benchmark contains significantly fewer fact synsets (994 compared to 1,350) and more than two orders of magnitude fewer extractions. The drastically smaller number of extractions is primarily due to the lack of determiners and articles in Chinese. Their frequent occurrence in English combined with their neutrality w.r.t. extractions' correctness results in many mutually different yet fact-equivalent extractions. The numbers for German are, expectedly, much closer to those for English.

	#Extractions	#Synsets	#Extr. / Synset
CaRB	783	/	/
BenchIE EN	136,357	1,350	101.0
BenchIE DE	82,260	1,086	75.7
BenchIE ZH	5,318	994	5.4

Table 3: Multilingual BenchIE: Extraction statistics.

2.3 Evaluation Measure

We assume that BenchIE is (1) *complete*, i.e., that it contains (a) *all* VP-mediated facts expressed in input sentences and (b) for each fact, its every acceptable extraction as well; and (2) *sound*, i.e., that it does not contain any incorrect extraction that would capture a fact not stated in the sentence. Such a complete OIE gold standard enables not only a more reliable evaluation of OIE systems by means of exact matching, but also an evaluation at the more meaningful level of knowledge facts, rather than at the level of individual triples.

Concretely, we consider a system extraction to be correct if and only if it exactly matches some gold extraction from some fact synset. The number of *true positives (TPs)* is the number of fact synsets (i.e., different facts) *covered* by (at least one of the) system extractions. This way, a system that extracts N different triples of the same fact, will be rewarded only once for the correct extraction of the fact. BenchIE's false negatives (FNs) are then, intuitively, fact synsets not covered by any of the system extractions. Finally, each system extraction that does not exactly match any gold triple (from any synset) counts as a false positive (FP). We then compute *Precision*, *Recall*, and F_1 score (as the final score) from TP, FP, and FN in standard fashion.

3 Multi-Faceted OIE Benchmark

Different downstream applications care about different aspects of OIE extractions. For IE-based text summarization and simplification (Ponza et al., 2018; Štajner and Glavaš, 2017), e.g., triples should be minimal overall, across all slots (i.e., without unnecessary tokens), but the exact token placement across the slots (e.g., if a preposition is in the predicate or object) does not matter. For entity linking and knowledge base population (Lin et al., 2020), in contrast, the token placement between slots is critical: a token that is not part of an entity, should not be placed into subject or object. Acknowledging this, we create three additional variants of the English BenchIE, referred to as *facets*, each

---

[6] An extraction *covers* a fact synset if it exactly matches any of the synset's (fact-equivalent) gold triples.

<table>
<tr><td colspan="4">Input sentence: <i>"Sen. Mitchell is confident he has sufficient votes to block such a measure with procedural actions."</i></td></tr>
<tr><td>BenchIE-E</td><td><i>("Sen. Mitchell" | "he";</i></td><td><i>"is confident he has ... [such] [a] measure with";</i></td><td><i>"procedural actions")</i></td></tr>
<tr><td>BenchIE-C</td><td colspan="3"><i>"(Sen. Mitchell | he) is confident he has sufficient votes to block [such] [a] measure with procedural actions"</i></td></tr>

</table>

Table 4: Illustration of BenchIE's *facets* for one fact synset (f_4 from Table 2): all *acceptable* surface realizations under each facet are shown. "|" and square brackets have the same shorthand notation purpose as in Table 2.

corresponding to one aspect that is relevant in common OIE applications. This effort addresses recent calls for multi-dimensional analysis of NLP systems (Ethayarajh and Jurafsky, 2020; Narayan et al., 2021) and is well-aligned with recent efforts that create multi-faceted benchmarks for other NLP tasks (Liu et al., 2021; Väth et al., 2021) and datasets (Xiao et al., 2022).

3.1 BenchIE-E

The default, general-purpose BenchIE facet from the previous section was designed to be somewhat tolerant to token distribution accross slots (see Appendix A.1.2 for details): some tokens may be placed in either the predicate or object (e.g., the preposition *with* in the synset f_4 in Table 2). This enables a more flexible comparison of OIE systems that are designed for different purposes (i.e., systems that produce slightly different token placements are not punished) and is in line with prior work on intrinsic OIE evaluation, both automatic (Stanovsky and Dagan, 2016; Bhardwaj et al., 2019) and manual (Fader et al., 2011; Del Corro and Gemulla, 2013; Gashteovski et al., 2017). Such extraction flexibility, however, may not be desirable in tasks like automated KG construction (Wolfe et al., 2017; Jiang et al., 2019) or entity linking (Lin et al., 2020, 2021). Angeli et al. (2015) show empirically that extractions with wholesome entities and without additional tokens yield benefits in KG construction.

Since OIE is predominantly used for KG-related tasks (Weikum et al., 2020), it is paramount to have an evaluation facet that imposes strict(er) token boundaries on entity slots – subjects and objects. We thus create the *entity facet* of the benchmark (BenchIE-E) with this additional constraint of wholesomeness of subject and object concepts. BenchIE-E was constructed by one of our annotators (see §2.2) by removing from EN BenchIE's fact synsets the extractions in which subject and/or object was not a wholesome concept (see Table 4).

3.2 BenchIE-C

The default BenchIE facet (§2) compares OIE extractions against gold triples from fact synsets at the slot level: to be judged correct, an extraction must exactly match some gold triple in all slots. This criterion, however, is overly strict if extractions are to be used in applications like summarization or simplification (Ponza et al., 2018; Štajner and Glavaš, 2017), which commonly concatenate the content of the slots. In this case, it does not matter if a sequence of tokens occurs at the end of the subject or beginning of the predicate (analogously for predicate and object). To reflect this, we introduce the *concatenation facet*, BenchIE-C: for each gold BenchIE triple, we create the gold BenchIE-C utterance by simply concatenating the content of the triple's slots (see Table 4).

3.3 BenchIE-M

Our third additional evaluation facet addresses the aspect of *minimality* of OIE extractions (Gashteovski et al., 2017). More compact extractions can benefit both text generation (Ponza et al., 2018; Štajner and Glavaš, 2017) and KG-related tasks (Lin et al., 2020, 2021). If two triples t_1 and t_2 capture the same fact (i.e., are in the same fact synset), t_1 is considered *more compact* than t_2 if tokens of each t_1 slot make a (non-strict) subsequence of tokens in the corresponding t_2 slot (Gashteovski, 2020).[7] To allow for evaluation of minimality, BenchIE-M triples contain only the non-optional tokens (denoted in square brackets in Table 2) from the corresponding BenchIE triple. Consequently, BenchIE-M fact synsets on average contain many fewer extractions than the original BenchIE synsets.[8]

4 Fact-Level Evaluation

We first compare BenchIE's fact-level evaluation (i.e., default facet, §2) against CaRB's token-level

---

[7] At least one t_1 slot has to be a strict subsequence of the respective t_2 slot; t_1 and t_2 would be the same otherwise.

[8] This does not imply that each fact synset in BenchIE-M contains only one (i.e., minimal) triple (see Table 4).

		EN							ZH	DE
		Naive OIE	ClausIE	MinIE	Stanford	ROIE	OpenIE6	M^{2}OIE	M^{2}OIE	M^{2}OIE
P	CaRB	0.24	0.58	0.45	0.17	0.44	0.48	**0.60**	/	/
	BenchIE	0.03	**0.50**	0.43	0.11	0.20	0.31	0.39	0.18	0.09
	Δ	+0.21	+0.08	+0.02	+0.06	**+0.24**	+0.17	+0.21	/	/
R	CaRB	**0.70**	0.53	0.44	0.29	0.60	0.67	0.61	/	/
	BenchIE	0.02	0.26	**0.28**	0.16	0.09	0.21	0.16	0.10	0.03
	Δ	**+0.68**	+0.27	+0.16	+0.13	+0.51	+0.46	+0.45	/	/
F_1	CaRB	0.36	0.56	0.44	0.22	0.51	0.56	**0.61**	/	/
	BenchIE	0.03	**0.34**	**0.34**	0.13	0.13	0.25	0.23	0.13	0.04
	Δ	+0.33	+0.22	+0.10	+0.09	**+0.38**	+0.31	**+0.38**	/	/

Table 5: Comparison of performance of OIE systems on BenchIE and CaRB benchmarks for precision (P), recall (R) and F_1 score (F_1). The row Δ indicates the difference between CaRB score and BenchIE score (i.e., $\Delta = CaRB - BenchIE$). **Bold numbers** indicate highest score per row (i.e., highest score for P / R / F_1 per benchmark) or highest score difference per row (i.e., highest Δ for P / R / F_1).

scoring (Bhardwaj et al., 2019).[9] Our quantitative results confirm our intuitions and observations (see Table 1): CaRB systematically and substantially overestimates OIE systems' performance. BenchIE, we argue, portrays the fact extraction abilities of OIE systems more realistically.

4.1 Experimental Setup

OIE Systems. We tested six widely used OIE systems that extract VP-mediated facts for EN, namely: ClausIE (Del Corro and Gemulla, 2013), Stanford OIE (Angeli et al., 2015), MinIE (Gashteovski et al., 2017), ROIE (Stanovsky et al., 2018), OpenIE 6 (Kolluru et al., 2020) and M^{2}OIE (Ro et al., 2020). We additionally implemented the following naive baseline (Naive OIE): each verb (detected using spaCy's POS-tagger (Honnibal and Montani, 2017)) becomes the predicate, its entire preceding sentence context becomes the subject and succeeding context the object. For ZH and DE, we evaluated a supervised M^{2}OIE (Ro et al., 2020) model based on the multilingual BERT (Devlin et al., 2019), trained on a large EN dataset (Zhan and Zhao, 2020) and transferred (zero-shot) to target languages by means of its multilingual encoder.

Implicit and N-ary Extractions. Some OIE systems produce implicit extractions containing tokens that do not occur in the sentence.[10] As BenchIE does not contain implicit annotations, we remove such extractions from the OIE systems' output, to avoid penalizing OIE systems for extracting fact types not covered by the benchmark. To make CaRB directly comparable, we automatically remove all its implicit extractions too. ROIE and M^{2}OIE produce N-ary extractions (i.e., more than three slots), whereas BenchIE contains only triples. We follow standard practice (Del Corro and Gemulla, 2013) and convert those extractions into triples by concatenating the third and subsequent slots into a single object.

4.2 Results and Discussion

Table 5 summarizes results of OIE systems on BenchIE and CaRB. Across the board, BenchIE's fact-level precision and recall are significantly lower than CaRB's respective precision and recall computed on token level. On average, CaRB scores the OIE systems higher than BenchIE by 14 percentage points for precision, 38 percentage points for recall and 26 percentage points for the F_1 score.

Precision. System's precision on BenchIE is lower (albeit not so drastically lower as recall) than on CaRB because BenchIE, as a complete benchmark, punishes *incorrect facts*, i.e., extractions that cannot be found in BenchIE's fact synsets. CaRB, on the other hand, rewards any token overlap that the incorrectly extracted fact has against its gold triple(s) – in many cases such overlap is substantial and CaRB consequently rewards the incorrect fact with high precision. Consider, for example, the sentence from Table 1 and an incorrect fact extraction (*"Sen. Mitchell"*; *"is confident he has"*; *"sufficient actions"*); on BenchIE, this extraction is a false positive because it does not exist in any of the four fact synsets it lists for the sentence. CaRB, in contrast, rewards the extraction with perfect precision because all its tokens are accounted for in the corresponding slots of its gold triple (*"Sen. Mitchell"*; *"is confident he has"*; *"sufficient votes to ... actions"*).

---

[9] CaRB is an improved version of the widely-adopted OIE2016 benchmark (Stanovsky and Dagan, 2016); our findings for CaRB are thus likely to hold for OIE2016 as well.

[10] E.g., the triple *("Biden"; "be"; "President")* extracted from the phrase *"President Biden ..."*

In an attempt to quantify how much CaRB overestimates fact-level precision with its token overlap metric, we evaluated our Naive OIE baseline on both CaRB and BenchIE. While BenchIE reflects the poor quality of naive extractions with the near-zero performance, CaRB estimates its precision to be non-negligible (0.24) and even higher than that of the Stanford's OIE system (0.17). In contrast, BenchIE assigns much lower score to this baseline: precision of 0.03—8 times less than CaRB's score.

Recall. While CaRB somewhat overestimates fact-level precision of OIE systems, its overestimation of their recall is much more drastic: all tokens of its gold extractions that can be found in respective slots of a factually incorrect extraction of an OIE system contribute to the system's recall. The overestimation of CaRB's recall scores is best illustrated by the fact that our naive baseline (Naive OIE) obtains a score of 0.7, better than any of the six OIE systems under evaluation. In terms of recall, CaRB obviously rewards long extractions – the longer the system extraction is, the more likely it is to cover more tokens from gold standard extractions. Neural extractors OpenIE6, ROIE, and M^{2}OIE on average produce much longer extractions than rule-based systems like MinIE or Stanford (e.g., on average, a ROIE extraction has 16 tokens, whereas Stanford extraction has 7.7 tokens): accordingly, CaRB rewards the neural systems with much higher recall scores. BenchIE, on the other hand, credits only the OIE extractions that cover its fact synsets (and only once per fact synset). Our Naive OIE is, intuitively, highly unlikely to match gold extractions from fact synsets and BenchIE reflects this with a fact-level recall of only 2%. Similarly, BenchIE's recall scores reveal that the long extractions of neural OIE systems very rarely correspond to any acceptable variant of an expressed fact (e.g., ROIE's fact-level recall is only 9%).

Multilingual OIE. We evaluated M^{2}OIE (as the only multilingual model in our evaluation) on the Chinese and German versions of BenchIE. Quite expectedly, the performance for Chinese and German in target languages is below the source English performance. However, the drop due to the zero-shot language transfer is, at first glance – surprisingly, much larger for German than for Chinese: this goes against findings from other tasks, where transfer performance correlates with linguistic proximity between the source and target language (Lauscher et al., 2020). M^{2}OIE's Chinese performance is encouraging, as it surpasses the English performance of some of the other OIE models (e.g., its recall score is better than ROIE, and its precision score is better than Stanford's). We believe this is because (a) OIE is a highly syntactic task; and (b) Chinese language is syntactically simple and has the same word order as English (SVO). German language, on the other hand, despite overall linguistic proximity to English, has a different word order (SOV; from generative perspective), with the main verb often appearing at the very end of the sentence – this, we believe, is the main cause of poor OIE transfer between English and German. We believe BenchIE is a good starting point for multilingual OIE evaluation: we subsequently created additional data for Arabic, Galician, and Japanese: see Kotnis et al. (2022) and Friedrich et al. (2022) for details and further analyses.

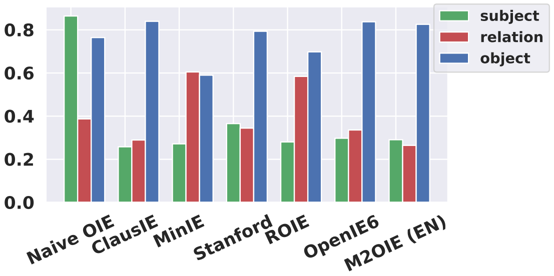

Figure 1: Relative proportion of errors per slot for OIE systems. Note that (1) fractions do not add up to 1 as extraction can be erroneous in more than one slot; and (2) the figure does not indicate systems' absolute error rates (for performance comparison, see Table 5).

5 Profiling OIE Systems with BenchIE

Token-based evaluation of existing OIE benchmarks (with real per-extraction scores in the range $[0, 1]$) makes pinpointing of extraction error source difficult. This limits their usability in automatic error analysis and system profiling. The fact that previous work performed OIE error analyses manually (Fader et al., 2011; Schneider et al., 2017) confirms this. BenchIE, in contrast, lists all acceptable extractions and thus naturally lends itself to reliable automatic error analysis and profiling.

5.1 Slot Errors

We carry out the analysis of errors per slots on the default BenchIE facet (§2), because it is application-agnostic, unlike the additional facets from §3. We observed that most of the errors in all OIE systems stem from extracting the objects (see Figure 1). For an SVO language like English,

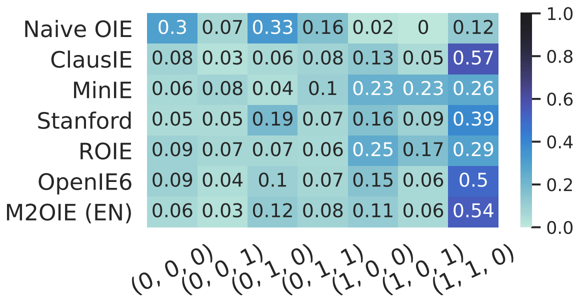

Figure 2: Distribution of incorrect extractions of OIE systems across different slot-error combinations.

correctly extracting subjects and predicates seems substantially easier than correctly extracting objects. MinIE (rule-based) and ROIE (neural) have higher shares of predicate mis-extractions. MinIE post-processes ClausIE's triples by moving words from objects to predicates. Since ClausIE most frequently makes object errors, this effectively redistributes those errors between predicates and objects of MinIE's extractions.

Figure 1, however, does not tell the whole story, as many extractions are erroneous in multiple slots. For more detailed insights, we assign each incorrect extraction to one of seven error buckets: each error bucket indicates one combination of extraction errors across the three slots. For example, the bucket $(1, 1, 0)$ contains extractions that match their *closest* gold triple in the subject and predicate, but not object. The closest gold triple is the one that matches the extraction in most slots.[11] The error-bucket analysis, summarized in Figure 2, reveals that, across all systems, most extractions with object errors actually have correct subjects and predicates (bucket $(1, 1, 0)$). MinIE deviates from this pattern and produces also many extractions with both incorrect object and predicate (bucket $(1, 0, 0)$) or only bad predicate (bucket $(1, 0, 1)$). Expectedly, most extractions of our naive baseline most often get only the predicate right (bucket $(0, 1, 0)$) or all three slots wrong (bucket $(0, 0, 0)$). This further emphasizes how misleading current token-based benchmarks can be – CaRB rewards this baseline with very high recall (see §4).

5.2 Bucketized Error Analysis

To understand where OIE systems fail systematically, we split the input sentences into buckets and measured the performance of OIE systems per bucket. Based on preliminary qualitative error analysis, we chose bucketization according to some linguistic properties of the sentences that produced erroneous triples. In particular, we examine the performance of OIE systems for sentence length, presence of conjunctions and case markers, since these appeared to be the most common reasons for failure. Note that BenchIE instances can be "bucketized" according to an arbitrary dimension interest, lending itself to diverse future fine-grained evaluations and analyses of OIE systems' behaviour. In general, we found that OIE systems exhibit weakest performance on long sentences (with more than 30 tokens) as well as those that contain conjunctions or have more than two case markers (Figure 3). For a more detailed discussion, see Appendix C.

5.3 Multi-Faceted Evaluation

Finally, we profile the OIE systems on our three special benchmark facets (§3): BenchIE-E, -C and -M. Figure 4 summarizes the performance of OIE systems on these three facets.

BenchIE-C. Ignoring slot boundaries, this facet is more lenient to OIE systems than the default facet – BenchIE-C yields higher scores than the regular BenchIE facet for *all* systems. The gap between the system's performance on BenchIE-C and BenchIE effectively quantifies how often the system misplaces tokens between adjacent slots. This gap is very small for Stanford OIE and MinIE – this means that, for extractions with correct overall token span, they also distribute the tokens between the slots correctly. For downstream tasks like text summarization, BenchIE-C results point to ClausIE as the best choice. Interestingly, we observed that CaRB's Precision for some systems (ClausIE and MinIE) effectively matches their Precision on BenchIE-C (see Figure 4), which is another indication that CaRB scores, in effect, neglect precise token distributions across slots.

BenchIE-E. This facet is stricter than the default BenchIE facet – it allows fewer token placement variants in subject and object. For all OIE systems the F_1 BenchIE-E score is thus lower than the corresponding BenchIE score. MinIE and Stanford OIE obtain very similar performance on BenchIE-C, BenchIE (default), and BenchIE-E: this means that their extraction (when correct in overall token span) most often have clean concepts in subject and object. All neural systems and ClausIE exhibit huge performance drops on BenchIE-E – this

---

[11] An incorrect extraction may have several "closest" gold triples that correspond to different error buckets. In this case, we increase the count for all competing buckets.

	(a) Sentence length				(b) Number of conjuncts			(c) Number of case markers				
	<=20	21-30	>30	all	0	>=1	all	<=1	2	3	>=4	all
Naive OIE	0.07	0.01	0.01	0.03	0.07	0	0.03	0.05	0.04	0.02	0.01	0.03
ClausIE	0.43	0.37	0.24	0.34	0.37	0.32	0.34	0.54	0.37	0.31	0.24	0.34
MinIE	0.47	0.36	0.21	0.34	0.38	0.31	0.34	0.42	0.39	0.29	0.3	0.34
Stanford	0.16	0.12	0.12	0.13	0.13	0.13	0.13	0.19	0.17	0.12	0.11	0.13
ROIE	0.18	0.13	0.09	0.13	0.19	0.09	0.13	0.22	0.14	0.11	0.09	0.13

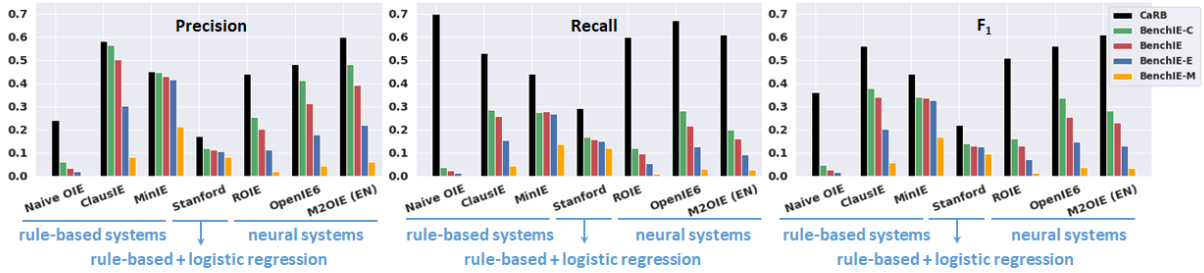

Figure 4: Multi-faceted evaluation of OIE systems.

means that their subject and object concept extractions are not clean, which makes these systems less suitable for tasks like KG population and entity linking. Out of the systems we evaluate, MinIE is the best fit for such downstream tasks.

BenchIE-M. This facet yields the lowest performance for all systems, as it punishes extractions with any unnecessary tokens. Expectedly, MinIE – a system tailored to produce minimal extractions – yields the best performance on this facet. But even MinIE "loses" half of its performance when minimality is enforced (BenchIE vs. BenchIE-M). This calls for more work on minimizing OIE extractions. Stanford OIE outperforms all systems except MinIE, which renders it a good pick when extraction minimality is beneficial for a downstream task.

Neural vs. Rule-Based Systems. Neural systems underperform their rule-based counterparts on most facets. This gap is most pronounced on BenchIE-E, whereas it is much smaller on BenchIE-C: these observations strongly indicate that neural systems struggle the most with correct distribution of tokens across the (adjacent) extraction slots. They also do not attempt to remove the optional (i.e., unnecessary) tokens, as indicated by extremely low performance on BenchIE-M. On CaRB, however, these same neural systems yield the best performance. Being trained and validated on datasets with extractions similar to CaRB's, neural extractors seem to overfit to CaRB evaluation. Our fact-based multi-faceted evaluation, however, reveals that their extractions are far less likely to be useful down the stream.

6 Conclusion

We introduced BenchIE: a benchmark for more reliable fact-level evaluation of OIE systems for English, Chinese and German. Unlike existing benchmarks, BenchIE takes into account fact-level equivalence of extractions: it consists of *fact synsets* that contain *all* acceptable surface forms of the same fact. Further, EN BenchIE is multi-faceted – it allows to evaluate OIE extractions w.r.t. several aspects relevant in common downstream tasks. Our experiments show that current benchmarks, with incomplete gold standard and approximate token-level matching, drastically overestimate fact extraction abilities of OIE systems. Currently, the limits of BenchIE are its relatively small size (300 sentences v.s. CaRB's 1,200) and its time-consuming annotation process. A promising research direction is the investigation of trade-off between the manual effort and completeness of different OIE annotation strategies. In this scenario, BenchIE is an ideal point of reference: it can precisely quantify the completeness of some larger (non-exhaustive) OIE dataset created with limited or no manual effort.

A Appendix: Annotation Guidelines

A.1 Annotation Guidelines for English

A.1.1 General Principle

The annotator should manually extract verb-mediated triples from a natural language sentence. Each triple should represent two entities or concepts, and the verb-mediated relation between them. For example, from the input sentence *"Michael Jordan, who is a former basketball player, was born in Brooklyn."*, there are three entities and concepts—*Michael Jordan, former basketball player* and *Brooklyn*—which are related as follows: *("Michael Jordan"; "is"; "former basketball player")* and *("Michael Jordan"; "was born in"; "Brooklyn")*.

Once the triple is manually extracted, it should be placed into the correct fact synset (see Section A.1.2).

A.1.2 Fact Synsets

Once a triple is manually extracted, the annotator should place the triple into its corresponding fact synset (for more details about the concept of fact synsets, refer to Section 2). In case there is no existing fact synset for the manually extracted triple, the annotator should create one and place the triple in that synset.

Coreference. The annotator should place extractions that refer to the same entity or concept under the same fact synset. Consider the following input sentence: *"His son , John Crozie, was an aviation pioneer."*; the following triples should be placed in the same fact synset:

- *("His son"; "was"; "[an]*[12] *aviation pioneer")*
- *("J. Crozie"; "was"; "[an] aviation pioneer")*

because *"His son"* and *"John Crozie"* refer to the same entity.

Token placements within the slots. The annotator should consider placing certain tokens in different slots, without damaging the meaning of the fact. Consider the input sentence *"Michael Jordan was born in Brooklyn."*. There is one fact synset (f_1) and its corresponding triples (t_1, t_2 and t_3):

f_1 t_1 : *("M. J."; "was born in"; "Brooklyn")*
t_2 : *("M. J."; "was born"; "in Brooklyn")*
t_3 : *("M. J."; "was"; "born in Brooklyn")*

In t_1, the preposition *"in"* is in the relation, while in t_2 it is in the object. Likewise, the annotator should allow for some flexibility w.r.t. the verbs. While the verbs and prepositions naturally belong to the relation, some OIE systems were designed with different goal in mind; e.g., to detect head verbs as relations for detecting clauses within the extractions (Del Corro and Gemulla, 2013) or to fit SRL frames for predicates (Stanovsky et al., 2018). We do not want to penalize the OIE systems for such design choices.

For BenchIE-E[13], however, this flexibility of token placements is not allowed. In particular, for f_1 the annotator is allowed to only extract t_1, while t_2 and t_3 should not be listed. Note that this is the only difference in the annotation guidelines between BenchIE-E and the standard BenchIE facet.

Passive voice. When possible, if an extraction is in passive voice, the annotator should place its active voice equivalent into the appropriate fact synset. For instance, consider the sentence *"The ball was kicked by John."*; then, the fact synset should contain the following triples:

- *("[The] ball"; "was kicked by"; "John")*
- *("John"; "kicked"; "[The] ball")*

Note that the opposite direction is not allowed. If the sentence was *"John kicked the ball."*, then the annotator is not allowed to manually extract the triple *("[The] ball"; "was kicked by"; "John")* because such extraction contains words that are not originally found in the input sentence (*"was"* and *"by"*). These are so-called implicit extractions and we do not consider them (for details, see Section A.1.8 of the appendix).

A.1.3 Optional Tokens

If possible, the annotator should label as *optional* all tokens that can be omitted in an extraction without damaging its semantics. Such tokens include determiners (e.g., *a, the, an*), honorifics (e.g., *[Prof.] Michael Jordan*) or certain quantities (e.g., *[some] major projects*. The optional tokens are marked with square brackets [ ]. In what follows, we show examples of considered optional token(s).

Determiners. Unless a determiner is a part of a named entity (e.g., *"The Times"*), it is considered as optional. For instance, the following triples are considered to be semantically equivalent:

---

[12] words in square brackets indicate optional tokens (see Section A.1.3)

[13] For details on BenchIE-E, see Section 3.1.

- *("Michael Jordan"; "took"; "the ball")*
- *("Michael Jordan"; "took"; "ball")*

The annotator, therefore, should annotate *("Michael Jordan"; "took"; "[the] ball")*, where the optional token is in square brackets.

Titles. Titles of people are considered optional; e.g., *("[Prof.] Michael Jordan"; "lives in"; "USA").*

Adjectives. The annotator should label adjectives as optional if possible. For example, in the following triple, the adjective *"smart"* can be considered optional: *("Albert Einstein"; "was"; "[a] [smart] scientist").* Note that the annotator should be careful not to label adjectives as optional if they are essential to the meaning of the triple. For instance, the adjective *"cold"* should not be labeled as optional in the triple *("Berlin Wall"; "is [infamous] symbol of"; "[the] cold war").*

Quantities. Certain quantities that modify a noun phrase can be considered as optional; e.g., *("Mitsubishi"; "has control of"; "[some] major projects").*

Words indicating some tenses. The annotator can treat certain verbs that indicate tense as optional. For instance, the word *"has"* in *("FDA"; "[has] approved"; "Proleukin")* can be considered as optional, since both VPs *"have approved"* and *"approved"* contain the same core meaning.

Verb phrases. It is allowed for the annotator to mark verb phrases as optional if possible; e.g. *("John"; "[continues to] reside in"; "Berlin").*

A.1.4 Attribution Clauses

Extractions that indicate attribution of another core piece of information should be placed in separate fact synset, because they indicate a separate piece of information with separate predicate. For example, the core information of the sentence *"Conspiracy theorists say that Barack Obama was born in Kenya."* is that Barack Obama was born in Kenya. As indicated by Mausam et al. (2012), it is important for OIE systems to extract the context about the attribution of such information. Therefore, the annotator should extract the core information—the triple *("Barack Obama"; "[was] born in"; "Kenya")*—in one fact synset, and the triples indicating attribution—*("Conspiracy theorists"; "say that"; "Barack Obama was born in Kenya")*—in another.

A.1.5 Incomplete Clauses

The annotator should not extract incomplete clauses, i.e., triples that lack crucial piece of information. Suppose there is the input sentence *"He was honored by the river being named after him".* The following triple should not be manually extracted: *("He"; "was honored by"; "[the] river")*, but the following triples should be: *("He"; "was honored by [the] river being named after"; "him")* and *("[the] river"; "being named after"; "him").*

A.1.6 Overly Complex Extractions

The annotators should not manually extract overly specific triples, such that their arguments are complex clauses. For instance, for the input sentence *"Vaccinations against other viral diseases followed, including the successful rabies vaccination by Louis Pasteur in 1886."*, the following triple should not be extracted: *("Vaccinations against other viral diseases"; "followed"; "including the successful rabies vaccination by Louis Pasteur in 1886")* because the object is a complex clause which does not describe a single concept precisely, but rather it is composed of several concepts.

A.1.7 Conjunctions

The annotator should not allow for conjunctive phrases to form an argument (i.e., subject or object). Such arguments should be placed into separate extractions (and in separate fact synsets). Consider the sentence *"Michael Jordan and Scottie Pippen played for Chicago Bulls.".* The annotator should manually extract the following triples:

- *("M. Jordan"; "played for"; "Chicago Bulls")*
- *("S. Pippen"; "played for"; "Chicago Bulls")*

The annotator should not, however, extract *("M. J. and S. P."; "played for"; "Chicago Bulls").*

A.1.8 Implicit Extractions

We focus on explicit extractions, which means that every word in the extracted triple must be present in the original input sentence. Therefore, implicit extractions—i.e., extractions that contain inferred information with words not found in the sentence—are not considered. One example implicit extraction is *("Michael Jordan"; "be"; "Prof.")* from the input sentence *"Prof. Michael Jordan lives in USA."*, where the triple infers that Michael Jordan is professor without being explicitly indicated in the sentence (i.e., the word *"be"* is not present in the input sentence, it is inferred).

A.2 Annotation Guidelines (Chinese)

The annotator should follow the same general principles as with the English annotation guidelines (Section A.1). Due to the language difference, we slightly adapted the annotation guidelines for the Chinese language. In what follows, we list those differences.

A.2.1 Articles

Chinese language does not contain articles (i.e., *"a", "an", "the")*. Therefore, in the manual translation of the sentences, there are no articles in the Chinese counterparts.

A.2.2 Prepositional Phrases within a Noun Phrase

Certain noun phrases with nested prepositional phrase cannot be translated directly into Chinese the same way as in English. For example, suppose we have the phrase *"Prime Minister of Australia"*. In Chinese, the literal translation of this phrase would be *"Australia's Prime Minister"*. For instance, in the English annotations the sentence *"He was the Prime Minister of Australia"* would have two fact synsets:

f_1 *("He"; "was [the] Pr. Min. of"; "Australia")*

f_2 *("He"; "was"; "[the] Pr. Min. [of Australia]")*

This is because the fact synset f_1 relates the concepts *"he"* and *"Australia"* with the relation *"was [the] Prime Minister of"*, while the second fact synset relates the concepts *"he"* and *"Prime Minister [of Australia]"* with the relation *"was"*.

In Chinese language, however, the construction of f_1 would not be possible, because the phrase *"Prime Minister of Australia"* cannot be separated into *"Prime Minister"* and *"Australia"*. Therefore, the golden annotation for this particular example in Chinese would be only one fact synset: *("He"; "was"; "[Australia's] Prime Minister")*, which is equivalent with f_2.

A.3 Annotation Guidelines (German)

In general, the annotators for German should follow the same guidelines described in Section A.1 for English. In what follows, we describe the differences which are specific for the German annotations.

A.3.1 Separable Verbs

Separable verbs (e.g., *"aufstehen"*) in German consist of a lexical core (a verb; *"stehen"*) and a separable particle (e.g., a preposition; *"auf"*). When used in a sentence, separable verbs in German are split in such manner that the separable particle goes to the end of the sentence. Consider the following sentence that contains the separable verb *"aufstehen"*: *"Ich stehe um 7 Uhr auf"*. To accommodate the verb-mediated relations, the annotator should extract the separable particle right after the separable core within the predicate: *("Ich"; "stehe auf um"; "7 Uhr")*

A.3.2 Modal Verbs

The modal verbs follow similar pattern as the separable verbs. Namely, the modal verb has the main predicate position within the sentence (directly followed by the subject), and the main verb that is modified by the modal verb is at the end of the sentence; e.g. sentence *"I must go to work"* and its German counterpart *"Ich muss zur Arbeit gehen"*. Following the same guidelines for verb-mediated predicates, the annotator should extract the modal verb together with the main verb: *("Ich"; "muss gehen zur"; "Arbeit")*.

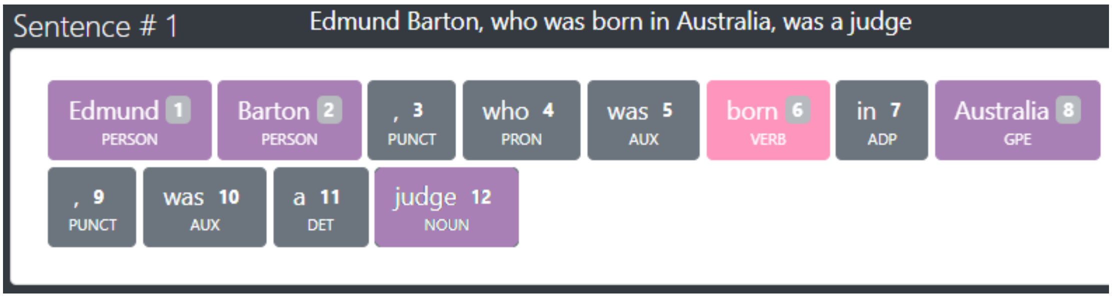
A.3.3 Passive Voice

Consider the following English sentence written in passive voice *"The letters were sent through the messenger"* and its German counterpart *"Die Briefe wurden durch den Boten geschickt"*. Following the spirit of extractions with verb-mediated relations, the annotator should extract the following triple: *("[Die] Briefe"; "wurden geschickt durch"; "[den] Boten")*.

B Annotation Tool

To facilitate the annotation process, we developed a web-based annotation tool: AnnIE (Friedrich et al., 2022). First, the annotator is given the input sentence as a string along with its tokenized form (Figure 5). Then, the tool highlights the tokens of interest that are candidates for the slots. In particular, we highlight the verbs in one color (candidate predicates) and the nouns in another (candidate arguments).

Then, the annotator can select the tokens with a UI and place them into slots. This forms one annotated triple. Note that the annotator can also annotate for optional tokens and phrases with the



Sentence # 1 Edmund Barton, who was born in Australia, was a judge

Figure 5: Highlighting tokens of interest: verbs (potential relations) and nouns (potential arguments).

Sentence # 1 Edmund Barton, who was born in Australia, was a judge

Figure 6: Manual labeling of OIE triples. The user selects tokens from the tokenized input sentence and places them into the correct slot: subject (green), predicate (yellow) or object (blue). Then, the user adds the extracted triple either to an active fact cluster (i.e., fact synset) or to a new one. The user can also select which tokens are optional by clicking the "Optional" button on an active token selection.

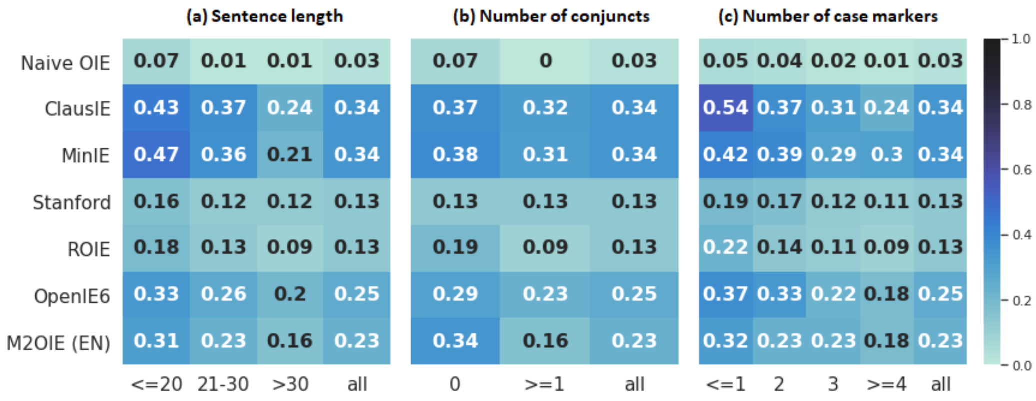


Figure 7: Bucketized experiments: F1 score according to different bucketizations of the input sentences: sentence length (a); number of conjunctions (b); number of case markers (c).

use of the mouse double click. Then, the annotator can place the newly annotated triple in either a new fact synset (cluster) or in an existing one (Figure 6). For more details on the annotation tool, see (Friedrich et al., 2022).

C Further Error Analysis

Based on preliminary qualitative error analysis, we chose bucketization according to some linguistic properties of the sentences that produced erroneous triples. In particular, we examine the performance of OIE systems for sentence length, presence of conjunctions and case markers, since these appeared to be the most common reasons for failure. Note that BenchIE allows for any type of bucketization, which can be used for diverse set of fine-grained evaluation for future research on OIE.

C.1 Sentence Length

Sentence length is a feature that can affect the performance of NLP systems for different tasks, including relation extraction (Alt et al., 2020) and named entity recognition (Arora et al., 2021). To evaluate how sentence length afffects performance of OIE systems as well, we split the sentences into three buckets: sentences shorter or equal than 20 tokens, between 21 and 30 tokens, and more than 30 tokens. The distribution of these buckets are 120, 113 and 67 sentences respectively.

We observed that shorter sentences usually yield the best performance for all OIE systems w.r.t. the F_1 score (Figure 7a). An extreme example is MinIE, which loses 26 percentage points from sentences shorter than 20 tokens to sentences longer than 30 tokens. Part of the reason why such sentences are harder to handle is because they contain more complex linguistic structures, such as conjunctions and case markers. Such sentences tend to to produce overly complex extractions that contain very complex structures in their arguments (see example extraction t_3 in Table 6).

C.2 Conjunctions

To examine the effect of the conjunctions on the performance of OIE systems, we bucketized the input sentences according to the dependency type `conj`, which relates two conjunct words in a sentence. In particular, we place the sentences with no conjuncts in one bucket, and the sentences with one or more conjuncts in another bucket. With such bucketization, half of the sentences are in the first bucket, and half in the other. We observed that the F1 score suffers when a sentence contains at least one pair of conjuncts (Figure 7b). This observation partially explains the observation from Section 5.1 that OIE systems have troubles identifying the objects correctly. In subsequent experiments, we observed that sentences with more than one conjuncts worsen the scores further compared to the sentences with one or no conjuncts. The triple t_5 in Table 6 is an example of such erroneous extraction.

Neural models seem to suffer the most due to the conjuncts. For instance, M^{2}OIE loses more than half of the F1 score points (from 0.34 down to 0.16) when at least one conjunct is found in the sentence. The exception for the neural systems is OpenIE 6, which is more stable (goes down from 0.29 to 0.23). The reason is because OpenIE 6 was specifically trained to handle conjunctions. Interestingly, ClausIE and MinIE—rule-based systems—lose approximately the same amount of F1 score points as the neural OpenIE 6. This indicates that neu-

Extraction ID	Extractions			BenchIE
Sentence s_1**:** *"A large gravestone was erected in 1866 , over 100 years after his death."*

ral models can be trained to handle conjunctions similarly as rule-based systems, though there is still room for improvement. We observed similar behaviors for coordinated conjunctions.

C.3 Case Markers

In preliminary qualitative experiments, we found that the objects are often overly specific because they include phrases that should in principle not be part of the expressed concept. Such excessively specific phrases are usually prepositional phrases or case markers. Consider, for example, the triple t_1 in Table 6. The object in this triple is overly specific and, thus, incorrect.

To quantify the effect of such case markers, we bucketized the data according to the number of the typed dependencies `case` that are found in the input sentences. We observed that, as the number of `case` dependencies increases, the performance of OIE systems decreases (Figure 7c). We observed similar behavior for the number of prepositions in a sentence. The rule-based system ClausIE is very sensitive w.r.t. this property, while MinIE is more stable. MinIE was built on top of ClausIE and also focused on restructuring the output of ClausIE, which is the likely reason why MinIE is more robust w.r.t. the case markers. Neural systems (ROIE, OpenIE 6 and M^{2}OIE) are very sensitive to this property, since their performance is much lower when we compare the buckets of 0 or 1 case dependency and the buckets with more than 4 case dependencies.

D More Detailed Discussion on Related Work

D.1 OIE Benchmarks

The currently existing benchmarks are based on token-based scoring. The first attempt to create an OIE benchmark was OIE2016 (Stanovsky and Dagan, 2016). The authors used a dataset from another task—QA-SRL (He et al., 2015)—and automatically ported it to OIE. For scoring an OIE triple, they follow the original task's guidelines (He et al., 2015) and match only the grammatical heads of each slot from the OIE triple with the ones from the golden datasets. Such approach has many drawbacks (Zhan and Zhao, 2020), because (1) every error in the automatic porting transfers over to the evaluation dataset; (2) triples are incorrectly (and over-optimistically) scored because it only considers token-overlaps on grammatical heads, not the whole slots. Being crowdsourced, CaRB (Bhardwaj et al., 2019) improves over OIE2016 by aggregating per-slot token-level precision and recall scores between system and gold extractions across the three slots (subject, predicate, and object). However, such approach is overly-lenient, as it allows for incorrect extractions to be scored positively (see examples in Table 1). Subsequent work followed similar evaluation procedures. For instance, Dong et al. (2021) propose a dataset that evaluates document-level OIE which uses the same scoring procedures as CaRB.

D.2 Multi-faceted Evaluation

While having a reliable single-metric benchmark is crucial for the progress of NLP, recent research indicated that focusing on single metrics is somewhat limited, because it does not provide further insights that go beyond the averaged scores (Ethayarajh and Jurafsky, 2020; Narayan et al., 2021). In particular, Ethayarajh and Jurafsky (2020) argue that single-metric scores ignore certain properties of the evaluated NLP models. Such properties, however, could be relevant for practitioners or for certain downstream tasks. As a consequence, the final evaluation score is computed at the expense of other properties of the model. To allow such multi-faceted evaluations, Liu et al. (2021) proposed ExplainaBoard, which scores NLP systems from several tasks across different facets, and Väth et al. (2021) propose a multi-faceted benchmark for visual question answering.

Due to the incompleteness of current OIE benchmarks—and because of the peculiarity of the task—no such multi-faceted evaluation for OIE has been proposed. For each tested extraction, the state-of-the-art benchmarks provide scores that are in the interval of $[0, 1]$. Such design is employed because the benchmarks are incomplete, which, in turn, makes it difficult to do proper multi-faceted evaluation. To tackle this issue, we propose a multi-faceted evaluation that scores OIE systems across several facets that are important for downstream tasks (see details in Section 3).

D.3 Automatic Error Analysis

Producing automatic error analysis with current benchmarks is not trivial because they are not exhaustive and do not provide crisp scores. For instance, when there are scores within the interval of $[0, 1]$ for each slot—as in CaRB—, it is hard to say where exactly the error occurred. Previous work on OIE performed error analysis manually (Fader et al., 2011; Schneider et al., 2017), which is very time-consuming and inefficient. In contrast to prior work, BenchIE is exhaustive benchmark that provides crisp scores, which allows for automatic per-slot error analysis. We discuss BenchIE's automatic error analysis approach in Section 5.

Leveraging Unimodal Self-Supervised Learning for Multimodal Audio-Visual Speech Recognition

Abstract

Training Transformer-based models demands a large amount of data, while obtaining aligned and labelled data in multimodality is rather cost-demanding, especially for audio-visual speech recognition (AVSR). Thus it makes a lot of sense to make use of unlabelled unimodal data. On the other side, although the effectiveness of large-scale self-supervised learning is well established in both audio and visual modalities, how to integrate those pre-trained models into a multimodal scenario remains underexplored. In this work, we successfully leverage unimodal self-supervised learning to promote the multimodal AVSR. In particular, audio and visual front-ends are trained on large-scale unimodal datasets, then we integrate components of both front-ends into a larger multimodal framework which learns to recognize parallel audio-visual data into characters through a combination of CTC and seq2seq decoding. We show that both components inherited from unimodal self-supervised learning cooperate well, resulting in that the multimodal framework yields competitive results through fine-tuning. Our model is experimentally validated on both word-level and sentence-level tasks. Especially, even without an external language model, our proposed model raises the state-of-the-art performances on the widely accepted Lip Reading Sentences 2 (LRS2) dataset by a large margin, with a relative improvement of 30%. [*]

1 Introduction

Audio-Visual Speech Recognition (AVSR) is a speech recognition task that leverages both an audio input of human voice and an aligned visual input of lip motions. It has been one of the successful application fields that involve multiple modalities in recent years. Due to the limited amount of labeled, multimodal aligned data and the difficulty of recognition from the visual inputs (i.e., lip reading), it is a challenging task to tackle.

Existing AVSR models tend to use extra data to increase the performance of the system, in a form of inserting an extra supervised learning stage in the training process. For example, many existing methods rely on an extra sequence level classification to bootstrap its learning on visual features. Petridis et al. (2018); Zhang et al. (2019) train their visual front-end on LRW (Chung and Zisserman, 2016) before learning on the AVSR task. Afouras et al. (2018a,b) chunks the MV-LRS data (Chung and Zisserman, 2017) into pieces of words and pre-train the model through classification. VoxCeleb (Chung et al., 2018) are also used in Afouras et al. (2020) for the same purpose. Learning an effective visual front-end could still be notoriously hard, even with these extra supervised learning tasks. Sometimes curriculum learning is required to adapt the learned visual front-end into AVSR task (Afouras et al., 2018a). End-to-end learning of large-scale AVSR data hasn't been successful until recently (Ma et al., 2021).

Although self-supervised learning could enable leveraging unlabelled or even unaligned data, it hasn't been adequately explored on this task. Shukla et al. (2020) is among the few attempts in this facet, in which it predicts lip motions from audio inputs. Their proposed learning schemes yield strong emotion recognition results but are relatively weak in speech recognition. Moreover, since in AVSR it is the lip shape and motions between frames rather than the objects in a single image that matters for recognizing speech contents, if pre-trained visual models tailored for tasks targeting at single frame images could work for AVSR remains unknown. In another scenario, self-supervised learning in unimodality has been well established as a paradigm to learn general repre-

sentations from unlabelled examples, such as in natural language processing (Brown et al., 2020; Devlin et al., 2019), speech recognition (Baevski et al., 2020), and computer vision (He et al., 2019; Chen et al., 2020a; Grill et al., 2020).

In this work, we rely on a simple but effective approach, which is to utilize unlabelled unimodal data by using pre-trained models that are trained in single-modality through self-supervised learning. Specifically, we use Baevski et al. (2020) pre-trained on the large LibriLight (Kahn et al., 2020) dataset as our audio front-end. For visual front-end, we found that it is not as straight-forward for it to leverage pre-trained models, as we have to substitute the first convolutional layer in MoCo v2 (Chen et al., 2020b) by a 3-D convolutional layer and fine-tune it through LRW. In total, our approach doesn't require a curriculum learning stage, and the overall training time has been decreased.

Experimental results show that our new front-ends significantly outperform previous ones by a big margin in both audio-only and visual-only settings, and a new state-of-the-art has been achieved in the final AVSR setting. To our best knowledge, this is the first work that successfully applies unimodal pre-trained models in the multimodal setting of AVSR.

2 Related Work

2.1 Audio-Visual Speech Recognition

The earliest work on AVSR could be dated back to around two decades ago, when Dupont and Luettin (2000) showed hand-crafted visual feature improves HMM-based ASR systems. The first modern AVSR system is proposed in Afouras et al. (2018a) where deep neural networks are used. The field has been rapidly developing since then. Most of the works are devoted into the architectural improvements, for example, Zhang et al. (2019) proposed temporal focal block and spatio-temporal fusion, and Lee et al. (2020) explored to use cross-modality attentions with Transformer.

The other line of research focuses on a more diversified learning scheme to improve AVSR performance. Li et al. (2019) uses a cross-modal student-teacher training scheme. Paraskevopoulos et al. (2020) proposes a multi-task learning scheme by making the model to predict on both character and subword level. Self-supervised learning has also been explored in Shukla et al. (2020), where the cross-modality setting is utilized by predicting frames of videos from audio inputs.

The end-to-end learning of AVSR systems are first seen in Tao and Busso (2020), albeit in a much simpler dataset than LRS2. More recent work (Ma et al., 2021) has made end-to-end learning on LRS2 possible by using a Conformer acoustic model and a hybrid CTC/attention decoder.

2.2 Self-Supervised Learning

Self-supervised learning has been chased in recent years since its ability to learn general representations of data through simple tasks that don't require labeling. Contrastive learning (Hadsell et al., 2006) has become the most impactful learning scheme in this field. In natural language processing, uni-or bi-directional language modelling (Brown et al., 2020; Devlin et al., 2019) have been used to significantly increase performances on various tasks. In audio speech processing, contrastive predictive coding (Baevski et al., 2020) has been proven to be powerful in speech recognition. In the visual domain, Earlier works create self-supervised tasks through image processing based methods, such as distortion (Gidaris et al., 2018),colorization (Zhang et al., 2016) and context prediction (Doersch et al., 2015). More recently, contrastive learning emerged as a paradigm of self-supervised learning, which results in a group of more expressive general visual representations, such as MoCo (He et al., 2019; Chen et al., 2020b), SimCLR (Chen et al., 2020a), BYOL (Grill et al., 2020), etc.

3 Architecture

The overall architecture of our model is shown in Fig. 1. The audio-visual model is comprised of four components, the front-ends and back-ends for both modalities, the fusion module, and the decoders.

3.1 Front-ends

Visual Front-end: Visual front-end serves as a component to capture the lip motion and reflect the lip position differences in its output representations. A naive way to apply pre-trained models in the visual front-end is to directly feed the RGB channels of each frame as input. However, since frames within a same clip in AVSR are largely similar in their contents while most pre-trained models in vision target at learning general representations reflecting the content of the whole image, this approach will result in similar outputs for all the frames, collapsing the informative lip position

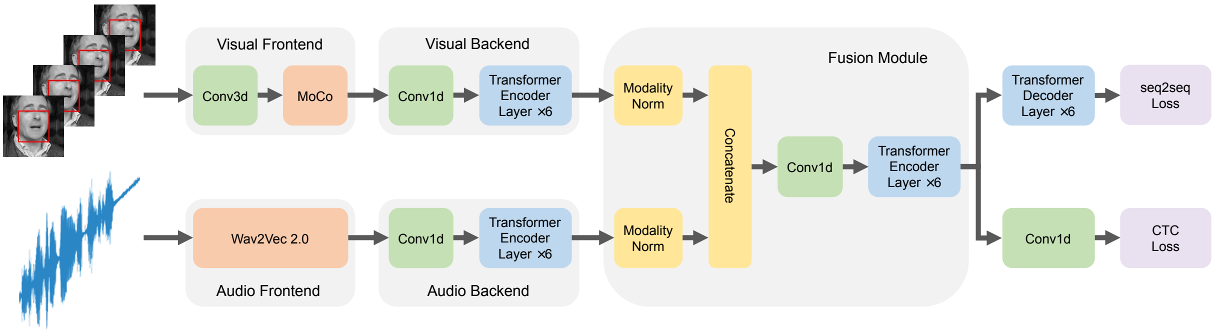

Figure 1: Overall architecture of our AVSR model.

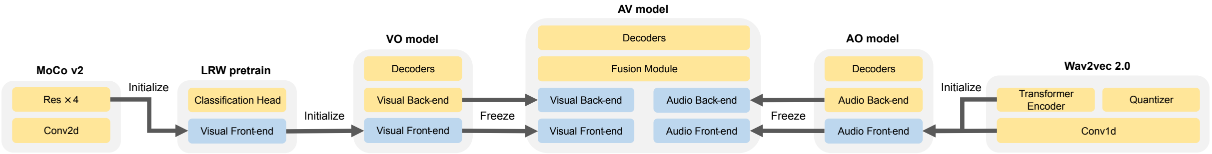

Figure 2: Training pipeline of the model. Yellow blocks represent new parameters that are randomly initialized, while Blue blocks represent parameters that are inherited from last training stage.

differences between frames.

To overcome the aforementioned problem while still being able to utilize the pre-trained model, we truncate the first convolutional layer in MoCo v2 (Chen et al., 2020b), which is pre-trained on ImageNet (Deng et al., 2009), and replace it with a layer of 3-D convolution. The outputs of 3-D convolutional layer are intentionally made identical to the input of the first ResBlock in MoCo v2 (see Table 1), thus providing a compatible interface to transfer higher layers of MoCo v2 into this task. On the other hand, we also adopt the common practice to convert the RGB input image to gray-scale before feeding it into the model, as it prevents the model from learning chromatic aberration information.

Audio Front-end: The audio front-end is rather straight-forward. We use wav2vec 2.0 (Schneider et al., 2019) pre-trained on Libri-Light (Kahn et al., 2020), like it is normally used for ASR tasks, both the 1-D convolutional layers and the stacked Transformer encoder layers are transferred into our audio front-end. The audio front-end takes as input raw audio wave of 16kHz, and produces one vector representation every 20ms. The audio feature dimensions are shown in Table 2.

3.2 Back-ends

Since the visual frames are in 25 FPS and the wav2vec 2.0 outputs are around 49 Hz, one should note that there is 2x difference in the frequency of frame-wise visual and audio representations at the output of their front-ends.[†] In the back-end, we use 1-D convolutional layers on the time dimension combined with Transformer encoder layers to provide single modality temporal modeling, as well as adjusting the features to have the same frequency.

Visual Back-end: The incoming MoCo v2 output to the visual back-end has a feature dimension of 2048, at a frequency of 25 vectors per second. In the visual backend, we keep this frequency while reducing the feature size to 512. See Table 1. For positional encodings of the Transformer, we use fixed positional encoding in the form of sinusoidal functions.

Audio Back-end: In the audio back-end, the incoming wav2vec 2.0 outputs have a feature size of 1024, at a frequency of 50 vectors per second. We downscale the frequency by setting the stride of 1-D convolutional layer to 2. The Transformer encoder layers have the identical size to that of the visual back-end, while using a separate set of parameters. Table 2 shows a clearer picture of audio front- and back-end dimensions.

[†] The odds are due to the larger receptive fields of wav2vec 2.0 1-D convolutional layers, which we circumvent by properly prefixing and suffixing the audio sequence and truncate the trailing audio vector. Thus a perfect 1:2 ratio of visual frames and audio front-end outputs are ensured.

Stage	Modules	Image sequence $(T_f \times 112^2 \times 1)$
Front-end	3-D convolution	$(T_f \times 28^2 \times 64)$
	MoCo v2	$(T_f \times 2048)$
Back-end	1-D convolution	$(T_f \times 512)$
	Transformer encoder	$(T_f \times 512)$

Table 1: The feature dimension of visual stream. The dimensions of features are denoted by $\{$temporal size $\times$ (spatial size^2) $\times$ channels$\}$. T_f denotes the number of visual frames.

Stage	Modules	Audio waveform $(T_s \times 1)$
Front-end	wav2vec 2.0	$(T_f \times 1024)$
Back-end	1-D convolution	$(\frac{T_f}{2} \times 512)$
	Transformer encoder	$(\frac{T_f}{2} \times 512)$

Table 2: The feature dimension of audio stream. The dimensions of features are denoted by $\{$temporal size $\times$ channels$\}$. T_s and T_f denote the number of sampled audio input and audio frames, respectively.

3.3 Fusion Module

Features from both the audio and visual modalities are fused together in this section, forming vector representation of 1024 dimensions at a relatively low rate of 25 Hz. We use LayerNorm (Ba et al., 2016) separately on each of the modalities before concatenating them on the feature dimension. The LayerNorm is required since it avoids one modality overtaking the whole representation with larger variance. Similar 1-D convolutional layers and a subsequent Transformer encoder block of 6 layers take the fused representations as input, and encode them for the decoders.

3.4 Decoders

Following the setting of Petridis et al. (2018), there are two decoders trained simultaneously based on the same output in the fusion module.

The first is a Transformer seq2seq decoder, a Transformer decoder with 6 layers is used, and we perform teacher forcing at character level by using ground truth characters as input during training.

The second one is arguably a decoder since it yields character probabilities for each timestep and relies on the CTC loss in training. 4 extra 1-D convolutional layers with ReLU activation are used on top of the last Transformer encoder layer output. We also include LayerNorm between each of the layers.

3.5 Loss Functions

In this work, we use a so called hybrid CTC/attention loss (Watanabe et al., 2017) for our training process. Let $\mathbf{x} = [x_1, \cdots, x_T]$ be the input frame sequence at the input of Transformer encoder in the fusion module and $\mathbf{y} = [y_1, \cdots, y_L]$ being the targets, where T and L denote the input and target lengths, respectively.

The CTC loss assumes conditional independence between each output prediction and has a form of

$$p_{\text{CTC}}(\mathbf{y}|\mathbf{x}) \approx \prod_{t=1}^{T} p(y_t|\mathbf{x}) \tag{1}$$

On the other hand, an autoregressive decoder gets rid of this assumption by directly estimating the posterior on the basis of the chain rule, which has a form of

$$p_{\text{CE}}(\mathbf{y}|\mathbf{x}) = \prod_{l=1}^{L} p(y_l|y_{<l}, \mathbf{x}) \tag{2}$$

The overall objective function is computed as follows:

$$\mathcal{L} = \lambda \log p_{\text{CTC}}(\mathbf{y}|\mathbf{x}) + (1-\lambda) \log p_{\text{CE}}(\mathbf{y}|\mathbf{x}) \tag{3}$$

where λ controls the relative weight between CTC loss and seq2seq loss in the hybrid CTC/attention mechanisms. The weight is needed not only when integrating the two losses into one training loss, but also fusing the two predictions during decoding, which we will revisit in the following subsections.

3.6 Training Pipeline

The final AVSR model is achieved through a pipeline of training stages.

For audio modality, the audio front-end is first pre-trained through self-supervised learning, which is done by wav2vec 2.0. Then the audio front- and back-end are trained through the audio-only (AO) setting, together with dedicated decoders.

For the visual modality, the visual front-end is first pre-trained through self-supervised learning, then modified and trained through sequence classification at word level video clips in LRW data. After that, the visual front-end is inherited by the visual-only (VO) model, where visual back-end and dedicated decoders are used.

The final AVSR model can be trained after the audio-only and visual-only models have converged.

Due to computational constraints, we pre-compute the audio and visual back-end outputs, and only learn the parameters in the fusion module and decoders part in this final stage. A detailed visualization of our training pipeline is depicted in Figure 2.

3.7 Decoding

Decoding is performed using joint CTC/attention one-pass decoding (Watanabe et al., 2017) with beam search. We apply shallow fusion to incorporate CTC and seq2seq predictions:

$$\begin{aligned}\hat{\mathbf{y}} = \arg\max_{\mathbf{y}\in\hat{\mathcal{Y}}} \{ &\alpha \log p_{\text{CTC}}(\mathbf{y}|\mathbf{x}) \\ &+ (1-\alpha)\log p_{\text{CE}}(\mathbf{y}|\mathbf{x})\}\end{aligned} \tag{4}$$

where $\hat{\mathcal{Y}}$ denotes predictions set of target symbols, while α is the relative weight that tuned on validation set.

4 Experiments

In this section, we will first introduce the datasets and various settings we used in each component of our model. Then we will present results of audio-only, visual-only and audio-visual settings. We also present a breakdown of the relative contribution of every component through ablation study.

4.1 Dataset

We use the large-scale publicly AVSR dataset, the Lip Reading Sentences 2 (LRS2) (Chung et al., 2017) as our main testbed. During training, we also use the Lip Reading in the Wild (LRW) (Chung and Zisserman, 2016) as a word-level video classification task to pre-train our visual front-end.

LRS2 consists of 224 hours of aligned audio and videos, with a total of 144K clips from BBC videos, the clips are at a length of sentence level. The training data contains over 2M word instances and a vocabulary of over 40K. The dataset is very challenging as there are large variations in head pose, lighting conditions, genres and the number of speakers.

LRW is a word-level dataset, consisting of 157 hours of aligned audio and videos, totalling 489K video clips from BBC videos, each containing the utterance of a single word out of a vocabulary of 500. The videos have a fixed length of 29 frames, the target word occurring in the middle of the clip and surrounded by co-articulation. All of the videos are either frontal or near-frontal. In our experiment, we only use the visual modality from this dataset to train our visual front-end.

4.2 Experimental Settings

We use character level prediction with an output size of 40, consisting of the 26 characters in the alphabet, the 10 digits, the apostrophe, and special tokens for `[space]`, `[blank]` and `[EOS/SOS]`. Since the transcriptions of the datasets do not contain other punctuations, we do not include them in the vocabulary.

Our implementation is based on the Pytorch library (Paszke et al., 2019) and trained on four NVIDIA A100 GPUs with a total of 160GB memory for 1 week. The network is trained using the Adam optimizer (Kingma and Ba, 2015) with $\beta_1 = 0.9$, $\beta_2 = 0.999$ and $\epsilon = 10^{-8}$ and an initial learning rate of 10^{-4}. We use label smoothing with a weight set to 0.01, learning rate warm up and reduce on plateau scheduler. The relative weight in CTC loss and seq2seq loss λ is set to 0.2. When decoding, we set α to 0.1. The samples in the pre-train set are cropped by randomly sampling a continuous range of $1/3$ words of the whole utterances, in order to match the length of clips in the train set. Over-length samples are further truncated at 160 frames to reduce memory occupation.

Preprocessing: We detected and tracked 68 facial landmarks using dlib (King, 2009) for each video. To remove differences related to face rotation and scale, the faces are aligned to a neural reference frame using a similarity transformation following Martínez et al. (2020). Interpolation and frame smoothing with a window width of 12 frames are used to deal with the frames that dlib fails to detect. Then a bounding box of 120×120 is used to crop the mouth ROIs. The cropped frames are further converted to gray-scale and normalized with respect to the overall mean and variance of the train set. Each raw audio waveform is normalized to zero mean and unit variance following Baevski et al. (2020).

Data Augmentation: Following Ma et al. (2021), random cropping with a size of 112×112 and horizontal flipping with a probability of 0.5 are performed consistently across all frames of a given image sequence when training visual-only and audio-visual models. For each audio waveform, additive noise is performed in the time domain following Afouras et al. (2018a) during training audio-only

Methods	WER

Table 3: Audio-only, visual-only and audio-visual results of word error rate (WER) tested on LRS2. Models with an * denote that results are using an external language model, which indicates an advantage over our model during evaluation. Models denoted with ** means that it uses a more powerful Transformer language model.

and audio-visual models. Babble noise are added to the audio stream with 5dB SNR and probability of $p_n = 0.25$. The babble noise is synthesized by mixing 20 different audio samples from LRS2.

Evaluation: For all experiments, word error rate (WER) are reported which is defined as WER $= (S + D + I)/N$. The S, D and I in the formula denotes the number of substitutions, deletions and insertions respectively from the reference to the hypothesis, and N is the number of words in the inference. The babble noise added to the audio waveform during evaluation is generated using the same manner as training, while we set a different seed to avoid model fit to a specific generated noise. Decoding is performed using joint CTC/attention one-pass decoding (Watanabe et al., 2017) with beam width 5 (the values were determined on the held-out validation set of LRS2). We don't use an external language model in our experiments.

4.3 Results

We present results for all experiments in Table 3, reporting WERs on visual-only, audio-only and audio-visual models. Note that many of the models listed here are also using extra training data in different stages of training pipeline, such as MV-LRS (Chung and Zisserman, 2017), LRS3 (Afouras et al., 2018b), LibriSpeech (Panayotov et al., 2015) and LRW.

We present the parameters of our model, TM-CTC model (Afouras et al., 2018a) and the current state-of-the-art model (Ma et al., 2021) in Table 4. Our model back-ends and fusion module configurations follow TM-CTC model, the hyper-parameters settings in the seq2seq decoder are the same as in the back-ends. The most significant difference is that we utilize pre-trained front-ends, resulting in a larger model size.

Audio-visual Setting: In the main audio-visual setting, the pre-train and train sets in LRS2 are used as train set in the final training stage. Our proposed audio-visual model achieves a WER of 2.6% without the help of an external language model, which improves by 1.1% over the current state-of-the-art (Ma et al., 2021). This is rather a big improvement, with a relative improvement of around 30%.

Audio-only Setting: The training data used for training audio-only model consists of 224 hours labelled data from LRS2, as well as the 60K hours unlabelled data from LibriLight (Kahn et al., 2020) that are indirectly used through inheriting wav2vec 2.0 parameters. Our model also achieves a WER of 2.7%, which reduces the WER of the current state-of-the-art (Ma et al., 2021) by 1.2%, indicating a relative improvement of 31%.

Visual-only Setting: The visual-only model uses labelled LRS2 data in its pre-train and train sets, the LRW for supervised pre-training, and indirectly using the 1.28M unlabelled images from ImageNet through MoCo v2. The visual-only model achieves a WER of 43.2%, lagging behind the current state-of-the-art E2E Conformer model (Ma et al., 2021) with 5.3%. Compared to E2E Conformer, the main difference is that a large Transformer language model is used during decoding, which itself brings a 4.5% difference compared with a normal RNN language model in their ablation studies (Ma et al., 2021). The gap between our visual-only model and the E2E Conformer model with a RNN language model is 0.8%, which resides in a quite reasonable range. Additionally, we use a 6-layers Transformer encoder for temporal modelling instead of a 12-layers conformer encoder, which resulted in a smaller back-end size.

If we consider a fairer comparison by only looking at benchmarks without using an external language model, the best-reported benchmark is Ren et al. (2021), which achieved a WER of 49.2%, lagging behind our model by 6.0%.

4.4 Ablation Studies

In this section, we investigate the impact of every individual building block by testing them in LRW, audio-only and visual-only settings.

MoCo v2 Contribution in Visual Word Classification: Results of visual word classification on LRW are shown in Table 5. We first train a model by replacing the ResNet-18 front-end in Stafylakis and Tzimiropoulos (2017) with a ResNet-50 front-end, matching the size of MoCo v2 but with fresh weights. This results in an absolute improvement of 2.1%. Then we initialize the ResNet-50 front-end with MoCo v2 weights and a further absolute improvement of 2.3% is observed, which implies that self-supervised learning is actually functioning in better represent the lip movement. Additionally, When Using 6 layers of Transformer encoder instead of TCN as back-end, we can observe another absolute improvement of 6.0%. We also noticed that using MoCo v2 front-end could significantly reduce the training time.

Performance Breakdown in Audio-only Setting: Results of audio-only model on LRS2 are shown in Table 6. Starting from Afouras et al. (2018a), we first train a model by replacing the STFT audio feature with a wav2vec 2.0 front-end pre-trained on LibriSpeech, resulting in an absolute improvement of 11.1%. Then we use another pre-trained model learned on an even larger unlabelled single modality dataset Libri-Light, and a further absolute improvement of 0.6% is observed. We further train the model with a hybrid CTC/attention decoder during the training stage, which results in another absolute improvement of 0.9%.

Method	Acc
Baseline(Stafylakis and Tzimiropoulos, 2017)	74.6%
+ ResNet-50 front-end	76.7%
+ MoCo v2 front-end	79.0%
+ Transformer encoder back-end	**85.0%**

Table 5: Ablation study on visual word classification performance on LRW.

Method	WER
Baseline(Afouras et al., 2018a)	15.3%
+ wav2vec 2.0 (LibriSpeech) encoder	4.2%
+ wav2vec 2.0 (LibriLight) encoder	3.6%
+ Hybrid CTC/attention	**2.7%**

Table 6: Ablation study on audio-only model performance on LRS2.

Performance Breakdown in Visual-only Setting: Results of the visual-only model on LRS2 are shown in Table 7. Starting from Afouras et al. (2018a), we first introduce end-to-end training by using a hybrid CTC/attention decoder (the front-end is still pre-trained through LRW), resulting in an absolute improvement of 16.0%. Then we initialize the front-end with pre-trained MoCo v2 weights, a same end-to-end training manner results in a further absolute improvement of 5.8%.

Method	WER
Baseline(Afouras et al., 2018a)	65.0%
+ Hybrid CTC/attention	49.0%
+ MoCo v2 front-end	**43.2%**

Table 7: Ablation study on visual-only model performance on LRS2.

Robustness under Noisy Inputs: To evaluate the model's tolerance to audio noise, we tested the performance of our model under babble noise with different SNR levels. Our audio-only and audio-visual models reach WERs of 32.5% and 24.5% when the SNR level is 0dB, respectively, which

Modality	Model	0dB	5dB	clean
AO	Afouras et al. (2018a)	58.0%	-	10.5%
	Our model	**32.5%**	6.8%	**2.7%**
AV	Afouras et al. (2018a)	33.5%	-	9.4%
	Our model	**24.5%**	6.3%	**2.6%**

Table 8: Word error rate (WER) under different SNR levels. The noises are synthesized babble noises.

reduce the reported result in Afouras et al. (2018a) by 25.5% and 9%[‡]. When the SNR level rises to 5dB, our audio-only and audio-visual model obtain WERs of 6.8% and 6.3%.

Besides achieving significant improvement over the baseline model under babble noise environment, we further investigate the model performance under human noise environment. The human noise is extremely challenging because the noise itself contains some words, while the model cannot easily distinguish which audio signal is the one to be recognized. We synthesize the human noise by randomly crop many 1 second signals from different audio samples in the LRS2 dataset. As shown in Fig. 3, we conduct experiments varying different levels of human noise, the models are trained using babble noise augmented audio. The WER increases greatly after the SNR level drops down under 0db. It is because the model may not be able to distinguish the two overlapped spoken words at a low SNR level.

And the overall performance under each SNR level is worse than babble noise, indicating that noise with specific information is harder than disorganized babble noise.

Recognition under Low Resource: A significant benefit of using self-supervised pre-trained models is that only a small amount of labelled data is needed for training a model. To further investigate the models' performance in low resource environment, we use the 28 hours train set of LRS2 to train an audio-only and a visual-only model. The results are shown in Table 9. The audio-only model trained with 28 hours data achieves a WER of 3.4%, which is a little bit worse than the one trained with 224 hours data. The result indicates that for the audio-only model, the self-supervised model pre-trained on a large-scale single modality dataset can significantly reduce the demands of data. While the visual-only model trained with 28 hours data has a great gap with the one trained with 224 hours data, the reason can be that the visual-only model is harder to train and demands a larger amount of data.

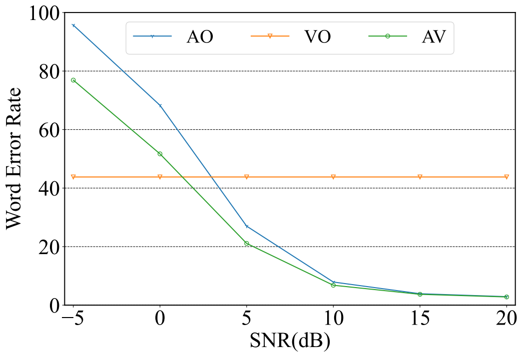

Figure 3: Word error rate (WER) under different SNR levels. The noises are human speech sampled from LRS2. AO: Audio-Only model, VO: Visual-Only model, AV:Audio-Visual model

Model	Training data (Hours)	WER (%)
audio-only	LRS2 (224)	2.7
	LRS2 train set (28)	3.4 (+0.7)
visual-only	LRS2 (224)	43.2
	LRS2 train set (28)	68.9 (+25.7)

Table 9: Performance of audio-only and visual-only models using different training data.

4.5 Discussion and Conclusion

In this work, we propose to utilize self-supervised learning for AVSR by simply incorporating the pre-trained model trained in massive unlabelled single modality data. Although the visual pre-trained models are not straight-forward to be transplanted into visual front-end, we still manage to integrate pre-trained models in both modalities for the AVSR task. Experimental results are impressive, resulting in a 30% relative improvement.

It's interesting to observe that self-supervised model in audio modality has an even larger improvement than that of the visual counterpart. We believe the reasons can be listed as follows:

- The training data scale of audio modality is significantly larger than that of visual modality, with the Libri-Light dataset used for pre-training wav2vec 2.0 consists of 60K hours audio signals, the ImageNet dataset, on the con-

---

[‡] Ma et al. (2021) also provides a performance under noisy inputs, however, we are not able to compare with them due to a lack of necessary details to generate the same noise.

trary, has only 1.28M images, roughly equivalent to 14 hours silent video under 25 FPS.

- The MoCo v2 model is pre-trained on images to better represent frame-level contents, while there are no pre-training steps to model the temporal correlation between frames. In contrast, the wav2vec 2.0 model is pre-trained on consistent audios, thus having a better temporal modelling ability.

As there has not emerged a dominating cross-modality self-supervised learning approach in the field of AVSR, in future work, we are going to explore two more directions in the self-supervised learning scenario based on this work. The first is utilizing the temporal correlations within the visual domain, while the other is the cross-modal correlations between the audio and visual modality. We hope this work could pave the way towards multimodality self-supervised learning, especially for various aspects in AVSR.

Ethical Statement

This work will not pose ethical problems, the data resources we use are all from published works and do not involve privacy issues related to data collection. The data is collected from BBC and contains thousands of diverse speakers, allowing the speech recognition models to generalize to all speakers. In terms of computational experiments, we used publicly available pre-trained models, which makes the training more environmentally friendly and lowers the computational requirements to reproduce our work.

A Decoding Algorithm

Algorithm 1 Hybrid CTC/attention one-pass decoding adapted from Watanabe et al. (2017). Notation: X is the speech input; L_{max} is the maximum length of the hypotheses to be searched, we set it to T; C is the decoded symbol sequence; `[b]` denotes `[blank]`.

```
Input: $X, L_{max}$
Output: $C$
$\Omega_0 = \{$[SOS]$\}$
$\hat{\Omega} = \emptyset$
$\gamma_0^{(b)}($[SOS]$) = 1$
for $t = 1, \cdots, T$ do
    $\gamma_t^{(n)}($[SOS]$) = 0$
    $\gamma_t^{(b)}($[SOS]$) = \prod_{\tau=1}^{t} \gamma_{\tau-1}^{(b)}($[SOS]$) \cdot p(z_\tau =$ [b]$|X)$
end for
for $l = 1 \cdots L_{max}$ do
    $\Omega_l = \emptyset$
    while $\Omega_{l-1} \neq \emptyset$ do
        $g = \text{HEAD}(\Omega_{l-1})$
        $\text{DEQUEUE}(\Omega_{l-1})$
        for each $c \in \mathcal{U}$ do
            $h = g \cdot c$
            if $c =$ [EOS] then
                $\log p_{\text{ctc}}(h|X) = \log\{\gamma_T^{(n)}(g) + \gamma_T^{(b)}(g)\}$
            else
                if $g =$ [SOS] then
                    $\gamma_1^{(n)}(h) = p(z_1 = c|X)$
                else
                    $\gamma_1^{(n)}(h) = 0$
                end if
                $\gamma_1^{(b)}(h) = 0$
                $\Psi = \gamma_1^{(n)}(h)$
                for $t = 2 \cdots T$ do
                    if $last(g) = c$ then
                        $\Phi = \gamma_{t-1}^{(b)}(g)$
                    else
                        $\Phi = \gamma_{t-1}^{(b)}(g) + \gamma_{t-1}^{(n)}(g)$
                    end if
                    $\gamma_t^{(n)}(h) = (\gamma_{t-1}^{(n)}(h) + \Phi)p(z_t = c|X)$
                    $\gamma_t^{(b)}(h) = (\gamma_{t-1}^{(b)}(h) + \gamma_{t-1}^{(n)}(h))p(z_t =$ [b]$|X)$
                    $\Psi = \Psi + \Phi \cdot p(z_t = c|X)$
                end for
                $\log p_{\text{ctc}}(h|X) = \log(\Psi)$
            end if
            $\log p(h|X) = \alpha \log p_{\text{ctc}}(h|X)$
                $+(1-\alpha) \log p_{\text{att}}(h|X)$
            if $c =$ [EOS] then
                $\text{ENQUEUE}(\hat{\Omega}, h)$
            else
                $\text{ENQUEUE}(\Omega_l, h)$
            end if
        end for
    end while
    $\Omega_l = \text{TOPK}(\Omega_l, W)$
end for
return $\arg\max_{C \in \hat{\Omega}} \log p(C|X)$
```

Algorithm 1 describes the hybrid CTC/attention decoding procedure. The CTC prefix probability is defined as the cumulative probability of all label sequences that have h as their prefix:

$$p_{\text{ctc}}(h|X) = \sum_{v \in (\mathcal{U})^+} p_{\text{ctc}}(h \cdot v|X) \tag{5}$$

where v denotes all possible symbol sequences except the empty. The CTC probability can be computed by keeping the forward hypothesis probabilities $\gamma_t^{(n)}$ and $\gamma_t^{(b)}$, where the superscripts (n) and (b) represents all CTC paths end with a non-`[blank]` or `[blank]` symbol, respectively.

The decoding algorithm is also a beam search with width W and hyperparameter α control the relative weight given to CTC and attention decoding. $\mathcal{U}$ is a set of symbols excluding `[blank]`, and a same token is used to represent `[SOS]` and `[EOS]` in our implementation.

Abstract

Sequence-to-sequence neural networks have recently achieved great success in abstractive summarization, especially through fine-tuning large pre-trained language models on the downstream dataset. These models are typically decoded with beam search to generate a unique summary. However, the search space is very large, and with the exposure bias, such decoding is not optimal. In this paper, we show that it is possible to directly train a second-stage model performing *re-ranking* on a set of summary candidates. Our mixture-of-experts SummaReranker learns to select a better candidate and consistently improves the performance of the base model. With a base PEGASUS, we push ROUGE scores by 5.44% on CNN-DailyMail (47.16 ROUGE-1), 1.31% on XSum (48.12 ROUGE-1) and 9.34% on Reddit TIFU (29.83 ROUGE-1), reaching a new state-of-the-art. Our code and checkpoints will be available at `https://github.com/ntunlp/SummaReranker`.

1 Introduction

In recent years, sequence-to-sequence neural models have enabled great progress in abstractive summarization (See et al., 2017; Lin et al., 2021). In the news domain, they have surpassed the strong LEAD-3 extractive baseline. With the rise of transfer learning since BERT (Devlin et al., 2019), leading approaches typically fine-tune a base pre-trained model that either follows a general text generation training objective like T5 (Raffel et al., 2019), BART (Lewis et al., 2020), ERNIE (Zhang et al., 2019b) and ProphetNet (Qi et al., 2021), or an objective specifically tailored for summarization like in PEGASUS (Zhang et al., 2020).

Most of these sequence-to-sequence models are history-based, where an output sequence is represented as a sequence of decisions and the probability of the sequence is computed as a product of decision probabilities. This is also known as the auto-regressive factorization. To transform the sequence of probabilities into summaries, beam search is commonly used. While auto-regressive decoding with beam search is simple and has many advantages, it can be difficult to encode global constraints such as grammaticality, coherence and factual consistency within this framework, properties that are believed to be useful in discriminating among candidate outputs. If the model starts decoding in a bad direction, mistakes might propagate, carry over the mistake of previous tokens to the generation of new ones, and the model has no way to know that it should adjust the decoding. Furthermore, these models are typically trained with teacher forcing (Williams and Zipser, 1989), which leads to an inherent discrepancy between training time and inference time known as the exposure bias problem (Bengio et al., 2015; Sun and Li, 2021).

Decoding methods such as beam search maintain a list of top-k best candidates, and output a single best one. In the case of beam search, candidates are sorted by decreasing log-probability, and the last $(k-1)$ hypotheses are discarded. However, these $(k-1)$ other hypotheses often contain considerably better sequences in terms of different evaluation measures. This observation holds over other decoding methods: diverse beam search (Vi-

jayakumar et al., 2016), top-k sampling (Fan et al., 2018) and top-p sampling (Holtzman et al., 2019). In Table 1, we illustrate this phenomenon with the *oracle* scores (maximum scores over the pool of candidates) for four popular decoding methods and five metrics on the CNN-DailyMail (Hermann et al., 2015) dataset with a PEGASUS model. The oracle ROUGE-1 scores are up to 10 points higher (+22.8%) than the top beam baseline. Moreover, oracle gains significantly increase when mixing several generation methods together, reaching an improvement of more than 13 ROUGE-1 points (+30.5%). Such a gap is larger than the progress made by research in the whole field of neural abstractive summarization in the last five years (Nallapati et al., 2016; Dou et al., 2021). This suggests that current abstractive models are not exploited to their full capacity, calling for better methods to identify the best summary candidate.

Given this assessment, we investigate whether it is possible to train a *second-stage* summarization model which learns to select the best summary among a set of candidates obtained from a base model and with a decoding process, which itself can potentially involve a set of decoding methods (e.g., beam search variants). This way, the model would recover the gap that separates it with the oracle. This raises the question of what makes a summary candidate the *optimal* one? Admittedly, summarization has been an underconstrained task and its evaluation is complex and remains an active research area (Kryscinski et al., 2019; Fabbri et al., 2021; Koto et al., 2021). To build a flexible approach, we use a multi-task learning framework based on a mixture-of-experts architecture in order to optimize *jointly* over several measures.

To design a robust re-ranker, we systematically explore the dimensions of summary re-ranking: base model, decoding process, and evaluation measure. Our system, named *SummaReranker*, is flexible and multi-task: it can be trained with any set of evaluation metrics. It is considerably less computationnally expensive to train than the single-stage summarization models that it is plugged on. We apply our system across three different datasets {CNN-DailyMail, XSum, Reddit TIFU} and two base models {PEGASUS, BART}. Optimizing ROUGE metrics leads to relative performance improvements from 1.31% to 9.34% depending on the dataset. It outperforms recently proposed second-stage summarization approaches RefSum (Liu et al., 2021) and SimCLS (Liu and Liu, 2021) and sets a new state-of-the-art on CNN-DailyMail and XSum (Narayan et al., 2018). We present extensive quantitative results coupled with a qualitative human evaluation.

2 Related Work

Re-ranking has been adopted in several branches of NLP for long. In syntactic parsing, Collins and Koo (2005) were the first to employ a re-ranker on the outputs of a base parser, followed by Charniak and Johnson (2005), who used a Maximum Entropy re-ranker. Passage re-ranking is used as the first stage of question-answering systems, to retrieve relevant passages where the answer might lay (Kratzwald and Feuerriegel, 2018; Nogueira and Cho, 2019). Some recent question-answering models also propose to perform answer re-ranking, to refine the answer selection (Kratzwald et al., 2019; Iyer et al., 2021). Re-ranking has also been used in neural machine translation. Checkpoint reranking (Pandramish and Sharma, 2020) generates several translation candidates with multiple model checkpoints, based on the observation (similar to the one we made in §1) that the oracle across checkpoints is of higher quality than just the last checkpoint. Bhattacharyya et al. (2021) use an energy-based model on top of BERT to select translation candidates with higher BLEU score.

In abstractive summarization, second-stage approaches such as re-ranking remain underexplored. Recently, RefSum (Liu et al., 2021) defined a second-stage summarization framework which helps address the problem of the train-test distribution mismatch in second-stage models. With a base GSum model (Dou et al., 2021), the authors reach a 46.18 state-of-the-art ROUGE-1 on CNN-DailyMail. In SimCLS (Liu and Liu, 2021), the authors train a second-stage model with contrastive learning, using a ranking loss to select the best summary candidate from a pool of 16 diverse beam search candidates, reaching 46.67 ROUGE-1 on CNN-DailyMail. Our approach differs from RefSum and SimCLS in terms of model architecture and loss function, as well as summary candidate generation process. In contrast with RefSum, we use a single base model, but mix several decoding methods, as our goal is single-model improvement. Unlike SimCLS, we do not use a ranking loss, but directly model the probability that a summary candidate is the best one. To the best of our knowledge, we are the first ones to propose a *multi-task* re-ranking system for abstractive summarization. This enables practitioners to leverage the recent rich literature in automatic abstractive summarization evaluation (Lin, 2004; Zhang et al., 2019a; Zhao et al., 2019a; Yuan et al., 2021).

3 Model

3.1 Re-ranking Framework

Our approach follows the paradigm of second-stage models. Specifically, given a source document S, a base model B, and a set of decoding methods $\mathbb{D}$, we get a pool of m summary candidates $\mathbb{C} = \{C_1, \ldots, C_m\}$. Given an evaluation metric μ in a set of metrics $\mathbb{M}$, we get associated scores for each candidates $\mathbb{S}_\mu = \{\mu(C_1), \ldots, \mu(C_m)\}$. Our goal is to train a model f_θ parameterized by θ to explicitly identify the best summary candidate C^*_μ according to the metric, which is given by:

$$C^*_\mu = \underset{C_i \in \mathbb{C}}{\arg\max}\ \{\mu(C_1), \ldots, \mu(C_m)\} \qquad (1)$$

We frame this problem as a binary classification. C^*_μ is the positive candidate, while other candidates are treated as negative. For a metric μ, the re-ranker f_θ is trained with a binary cross-entropy loss:

$$\mathcal{L}_\mu = -y_i \log p^\mu_\theta(C_i) - (1 - y_i) \log(1 - p^\mu_\theta(C_i)) \qquad (2)$$

where $y_i = 1$ if $C_i = C^*_\mu$, otherwise $y_i = 0$.

Binary classification has been successfully employed for re-ranking in prior work (Nallapati, 2004; Nogueira and Cho, 2019). While multi-way classification could be an alternative, we noticed that for each generation method, a significant fraction of candidates share the same score for one or several metrics, while it is rare that *all* candidates share the same score (Appendix C-D). Thus, there is not enough signal to distinguish m candidates into m different classes, but enough for two classes.

To optimize for N different metrics $\mathbb{M} = \{\mu_1, \ldots, \mu_N\}$ simultaneously, we use a separate prediction head (tower) for each and we minimize the average over metric losses defined as:

$$\mathcal{L} = \frac{1}{N} \sum_{\mu \in \mathbb{M}} \mathcal{L}_\mu \qquad (3)$$

3.2 Model Architecture

We first need to get a good representation of the summary candidate. To use contextual information, we concatenate the source with the candidate, separating the two with a special token: `[CLS] Source [SEP] Candidate`, and feed it to a pre-trained language model. In all experiments, we use RoBERTa-large (Liu et al., 2019) as encoder. Concatenating the source with the candidate enables RoBERTa to perform cross-attention between the two, which finds parts of the source relevant to the summary candidate. We take the `[CLS]` representation from RoBERTa's last layer, and feed it to a multi-layer perceptron (MLP).

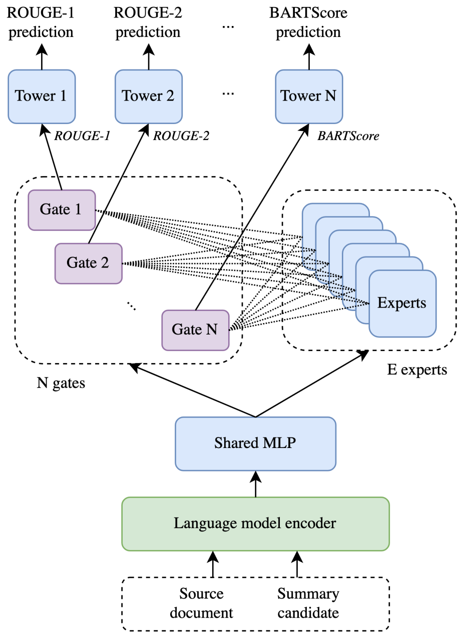

Figure 1: **SummaReranker model architecture**, optimizing N metrics. The summarization metrics here (*ROUGE-1*, *ROUGE-2*, ..., *BARTScore*) are displayed as examples.

Once we have a joint representation of the source with the candidate (noted $\boldsymbol{x}$), we perform multi-task learning in order to optimize for the desired metrics. Since metrics are different, yet may be strongly correlated (e.g., ROUGE variants), we adopt a mixture-of-experts (MoE) architecture. In particular, we follow the sparse MoE approach (Shazeer et al., 2017), which introduces experts dropout. To adapt it to multi-task training, we use the multi-gate approach proposed in Zhao et al. (2019b). Given E experts $\mathcal{E}_1, \ldots, \mathcal{E}_E$ and N prediction towers $\mathcal{T}_1, \ldots, \mathcal{T}_N$, the prediction for an input summary representation $\boldsymbol{x}$ for a metric μ indexed by $k \in \{1, \ldots, N\}$ is:

$$f^k_\theta(\boldsymbol{x}) = \mathcal{T}_k\Big(\sum_{i=1}^{E} \mathrm{softmax}(\boldsymbol{W}_k \boldsymbol{x})_{(i)} \mathcal{E}_i(\boldsymbol{x})\Big) \qquad (4)$$

where $\boldsymbol{W}_k$ is the weight matrix associated with gate

k. The corresponding prediction probability is:

$$p_{\theta}^{\mu} = \text{sigmoid}(f_{\theta}^{k}(\boldsymbol{x})) \tag{5}$$

Experts are shared across all tasks, and through the softmax gates the model learns how much weight to assign to each expert for each task.

Our SummaReranker model architecture is shown in Fig. 1. In practice, the shared bottom MLP consists in two fully-connected layers with ReLU activation (Glorot et al., 2011). Each expert $\mathcal{E}_i$ is also a two-layer MLP with ReLU, and each prediction tower $\mathcal{T}_k$ is a single-layer MLP. We set the number E of experts to be equal to twice the number of tasks (N), and the experts dropout to 50%, so that the effective number of experts being used during training matches N. Our model has 370.09 million trainable parameters, representing a slight 4.14% increase due to the mixture-of-experts compared to the off-the-shelf RoBERTa-large.

3.3 Tackling Training and Inference Gap

Second-stage learning approaches may suffer from an inherent distribution bias. Indeed, the base model has a different output distribution on the training set than on the validation and test sets. Thus, it is ineffective to train a second-stage model on the training set outputs of the base model.

To resolve this distribution shift, we shuffle the training set and randomly split it into equal parts, then fine-tune a pre-trained model on each half. Then, to build a training set for the re-ranker, we infer with each model on the half that it was not trained on. At testing time, we face two options:

- **Base setup**: in this setup, we infer on the test set with *one of the two base models trained on half the training set*, then apply the re-ranker. Since the base models are trained on less data, their performance on the test set worsens. However, we will show that SummaReranker brings improvements which more than compensate this performance drop.

- **Transfer setup**: this setup consists in applying SummaReranker on top of a base model *trained on the whole training set*. Note that SummaReranker is still trained in the same fashion as before. There could be a distribution mismatch in this setting too, since SummaReranker needs to rank summary candidates of a potentially higher quality (generated by a model trained on the full data) than the summaries that it was trained on (generated by a model trained on half the data). Nevertheless, SummaReranker still transfers well and considerably improves the performance of the base model in this transfer setup.

	R-1	**R-2**	**R-L**	**BS**	**BaS**
R-1	1.000	0.884	0.977	0.858	0.662
R-2	0.884	1.000	0.910	0.833	0.665
R-L	0.977	0.910	1.000	0.855	0.669
BS	0.858	0.833	0.855	1.000	0.682
BaS	0.662	0.665	0.669	0.682	1.000

Table 2: **Pearson correlation coefficient** between the five evaluation metrics {R-1, R-2, R-L, BS, BaS} for a base PEGASUS with beam search on **CNN/DM**. **R-1/2/L** denotes ROUGE-1/2/L, **BS** and **BaS** denote BERTScore and BARTScore.

If $\mathbb{D}$ is made of multiple decoding methods $\{\delta_1, ..., \delta_j\}$, each producing several candidates, the overall candidate set may be large, slowing down inference. Thus, to explore lower-resource inference setups, we separate the sets of decoding methods $\mathbb{D}_{\text{train}}$ and $\mathbb{D}_{\text{test}}$ used for training and inference, respectively, and enforce that $\mathbb{D}_{\text{test}} \subset \mathbb{D}_{\text{train}}$.

4 Experiments

4.1 Scope & Datasets

Throughout our experiments, we vary all the three dimensions of our re-ranking framework: the base model B, the set of decoding methods $\mathbb{D}$ and the set of scoring metrics $\mathbb{M}$.

As base models, we use PEGASUS (Zhang et al., 2020) and BART (Lewis et al., 2020), each one in their large version, as they are leading summarization models with publicly available checkpoints. We obtain pre-trained and fine-tuned checkpoints from the HuggingFace transformers library (Wolf et al., 2020).

For decoding methods ($\mathbb{D}$), we experiment with beam search (referred to as 1), diverse beam search (2), top-k sampling (3) and top-p sampling (4). For each decoding method, we set the number of candidates to 15, as it is close to the maximum which could fit in a standard 11GB RAM GPU when doing generation with PEGASUS-large.

As set of metrics, we first use ROUGE (Lin and Hovy, 2003), in its commonly used three flavours of ROUGE-1 (noted *R-1*), ROUGE-2 (noted *R-2*)

Dataset	Domain	# Data points			# Words	
		Train	Val	Test	Doc.	Summ.
CNN/DM	News	287,113	13,368	11,490	766.56	54.78
XSum	News	204,045	11,332	11,334	414.51	22.96
Reddit TIFU	Social media	33,704	4,213	4,222	385.59	20.59

Table 3: **Statistics** of the three datasets.

and ROUGE-L (noted *R-L*) for summarization evaluation. We also leverage recently introduced model based evaluation methods BERTScore (noted *BS*) (Zhang et al., 2019a) and BARTScore (noted *BaS*) (Yuan et al., 2021), which both rely on contextual word embeddings from pre-trained language models. Thus, our total set of metrics is $\mathbb{M}$ = {R-1, R-2, R-L, BS, BaS}. As seen in Table 2, R-1 and R-L are strongly correlated (Pearson correlation score of 0.977). BARTScore is the least correlated to other metrics, suggesting that it captures aspects complementary to the other four.

We train SummaReranker on the following datasets, covering multiple domains:

- **CNN-DailyMail** (Hermann et al., 2015) contains 93k and 220k articles from the CNN and Daily-Mail newspapers, respectively. We use the non anonymized version from (See et al., 2017).
- **XSum** (Narayan et al., 2018) contains 227k articles from the BBC for years 2010 - 2017. While also in the news domain, XSum is by design significantly more abstractive than CNN/DM and is made of single-sentence summaries.
- **Reddit TIFU** (Kim et al., 2019) contains 120k posts from the popular online Reddit forum. As in other summarization works (Zhang et al., 2020), we use the TIFU-long subset, containing 37k posts. As there is no official split, we build a random 80:10:10 split for training:validation:test.

We refer to Table 3 for statistics on each dataset.

4.2 Training & Inference Details

To help the model better discriminate between candidates, we found that sampling was useful. Specifically, during training, we rank candidates by decreasing sum of normalized scores for the evaluation metrics and keep the top m_{top} and bottom m_{bottom} candidates. Thus, training time varies in $\mathcal{O}(m_{\text{top}} + m_{\text{bottom}})$, while inference is in $\mathcal{O}(m)$ as we need to score each candidate. In practice, we found that taking $m_{\text{top}} = 1$ and $m_{\text{bottom}} = 1$ performed well, on top of decreasing the training time.

Model	Model stage	Decoding methods ($\mathbb{D}$)	R-1	R-2	R-L	Gain (%)
PEGASUS - 1st half	1	{1}	42.23	19.62	38.90	_

Table 4: **Base setup results** for SummaReranker applied to PEGASUS and BART on the **CNN/DM** dataset. **SR** refers to SummaReranker. **Decoding method {1}** is beam search, **{2}** is diverse beam search. Best scores for each type of model are in bold. **Gain** represents the mean relative gain over {R-1, R-2, R-L} compared to the best decoding method.

This means that at training time, the model only sees two candidates per data point. We scale the pool of candidates that these two are sampled from to *four* decoding methods, totalling 60 summary candidates per source document.

We train SummaReranker for five epochs. We use the Adafactor optimizer (Shazeer and Stern, 2018), with maximum learning rate 1e-5, warming up the learning rate linearly over the first 5% training steps. Training on CNN/DM takes four days on a single RTX 2080 Ti GPU.

For inference, we need to output a single candidate. After getting predicted probabilities across each metric $\mu \in \mathbb{M}$, we output the candidate maximizing the sum of predicted probabilities. Note that relaxing inference to allow for a different best candidate for each metric would improve performance, but is not practical. We perform inference with the model checkpoint maximizing the sum of the scores for the metrics on the validation set.

4.3 Base Setup Results

First, we investigate how our model performs in the base setup described in §3. We apply SummaReranker on top of PEGASUS and BART models fine-tuned on each half. For each model, we decode using beam search (1) and diverse beam search (2). The latter performs better for PEGASUS, while the former is better for BART. We then apply SummaReranker optimized jointly for R-1, R-2, and R-L on

Table 5: **Transfer setup results on CNN/DM**. **SR** refers to SummaReranker, m refers to the number of summary candidates, **BS** and **BaS** to BERTScore and BARTScore, respectively. Best scores for each type of model (single stage, second-stage) are in bold. † marks are results significantly better than the base model counterpart among metrics that SummaReranker was optimized for. Results for optimized metrics are shaded. **Gain** represents the mean relative gain over optimized metrics.

top of each of the two base models, for each decoding method, and finally when using both decoding methods. Results are shown in Table 4.

SummaReranker improves a base PEGASUS by 4.57% to 7.21% with 15 candidates, and 8.70% to 9.36% with 30 candidates. With BART, SummaReranker improves by 3.94% to 11.65% with 15 candidates, and 7.98% with 30 candidates. When using several decoding methods, we compare the reranker performance with the best baseline among decoding methods. Notably, with SummaReranker, PEGASUS and BART models trained on 50% of the training set now surpass their counterparts trained on *the whole* training set, achieving 46.19 R-1 with PEGASUS and 45.96 R-1 with BART. This is better than GSum (Dou et al., 2021), the best reported summarization model on CNN/DM.

4.4 Transfer Setup Results

Next, we look at how SummaReranker performs in the transfer setup. That means, we apply it on top of PEGASUS and BART models fine-tuned on the entire dataset, using public checkpoints. We also include R3F (Aghajanyan et al., 2020) and GSum (Dou et al., 2021) in our single-stage model comparison. In terms of second-stage approaches, we compare SummaReranker with RefSum (Liu et al., 2021) and SimCLS (Liu and Liu, 2021). Note that SummaReranker is trained as usual, on the outputs of two base models each trained on 50%.

We first optimize for ROUGE metric {R-1, R-2, R-L} with multi-task training on CNN/DM (Table 5). With two decoding methods, PEGASUS + SummaReranker sets a new state of the art on CNN/DM with 47.16 R-1, 22.55 R-2 and 43.87 R-L, corresponding to gains of 2.60/1.65/2.29 R-1/2/L or +5.44% from our diverse beam search baseline. As expected, the relative gains in transfer setup are lower than in base setup. Next, we optimize model-based metrics, and note the difficulty in improving BERTScore, compared to BARTScore. Optimizing jointly ROUGE and model-based metrics improves all metrics, but does not match the results when training only ROUGE. Interestingly, performance gains saturate when adding two extra decoding methods (top-k and top-p sampling), despite gains in the oracle scores observed in Table 1.

To assert statistical significance of performance gains, we perform a t-test between SummaReranker scores and scores from the base model with *each* of the decoding methods being used, and mark with † results where the p-value is smaller than 0.05 for *all* these decoding methods.

We also show experts utilization (obtained with

Table 6: **Transfer setup results on XSum and Reddit TIFU**. **SR** refers to SummaReranker, m refers to the number of summary candidates, **BS** and **BaS** to BERTScore and BARTScore, respectively. Best scores for each type of model (single stage, second-stage) are in bold. † marks are results significantly better than the base model counterpart among metrics that SummaReranker was optimized for. Results for optimized metrics are shaded. **Gain** represents the mean relative gain over optimized metrics. Reddit TIFU results in italic are not directly comparable due to a different data split.

softmax weights from the gates) for the model optimized on all five metrics in Fig. 2. Notably, some experts specialize in certain metrics (for instance, expert 0 on R-2 and expert 4 on R-L).

Then, we apply SummaReranker on XSum and Reddit TIFU, as shown in Table 6. We train SummaReranker using the three ROUGE metrics {R-1, R-2, R-L} as objective, and decoding methods {beam search, diverse beam search} to generate the candidates. On XSum, SummaReranker improves a base PEGASUS with beam search candidates by 1.31%, setting a new state-of-the-art of 48.12/24.95/40.00 R-1/2/L. On Reddit TIFU, we improve a base PEGASUS with beam search and diverse beam search (30 candidates) by 9.34%, reaching 29.83/9.50/23.47 R-1/2/L, and a base BART with beam search by 4.22%, reaching 28.99/9.82/22.96 R-1/2/L. Across datasets, training on a combination of beam search and diverse beam search candidates is consistently effective.

4.5 Ranking Evaluation

Beyond summary properties, we investigate the performance of re-ranking itself with rank-based evaluation measures. A perfect re-ranker should always single out the best summary from the rest, yielding oracle results. To evaluate how SummaReranker ranks the best summary, we compute the best summary candidate recall at different thresholds. Since several candidates might get the same metric scores (Appendix C), the best candidate recall at threshold k for the random uniform ranking baseline is not the standard $R@k = \frac{k}{m}$ anymore

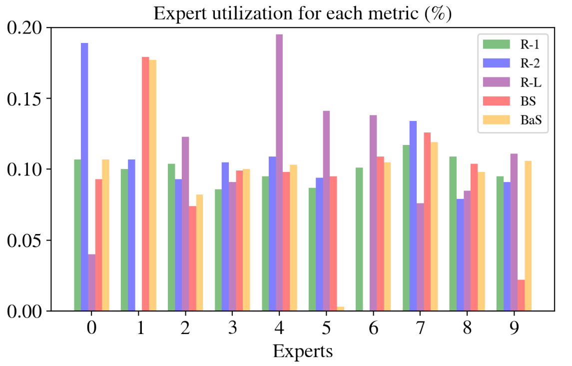

Figure 2: **Expert utilization** for a base PEGASUS with SummaReranker optimized with {R-1, R-2, R-L, BS, BaS} on **CNN/DM**, with 10 experts.

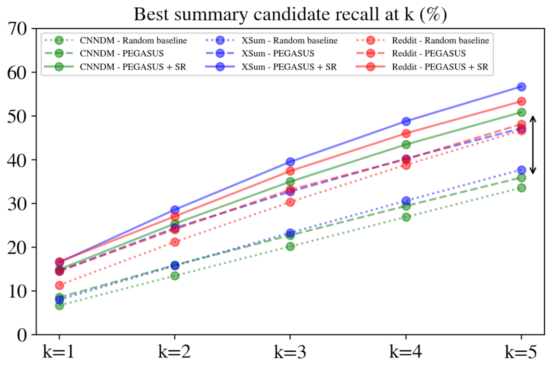

Figure 3: **Best summary candidate recall** with 15 diverse beam search candidates for PEGASUS on all three datasets. SR denotes SummaReranker. Dotted lines are random baselines, and dashed lines correspond to the base PEGASUS.

Source document: CPRE president Sir Andrew Motion, who is demanding a national clean-up. Council chiefs were condemned last night after claiming it was too dangerous to collect the roadside litter blighting Britain. Winchester Council in Hampshire said its annual clean-up of roads around the city had been hit by new Health and Safety Executive rules designed to protect litter-pickers from traffic. But the HSE denied tightening rules – and said councils were 'over-interpreting' legislation. Last night, former Poet Laureate Sir Andrew Motion, now president of the Campaign to Protect Rural England, accused town hall bosses and the Highways Agency of ruining the countryside by failing to remove rubbish. He said: 'Every day, people tell us that they are disgusted, angry and ashamed of the state of England's roads. 'Nobody wants to drive through our beautiful countryside or approach a vibrant city, heralded only by discarded rubbish.' Although laws to fine people who throw litter from vehicles were now in place, their implementation had been delayed by 'shameful time-wasting', Sir Andrew said. 'Without funding to tackle the problem, I fear our roads will become corridors of waste,' he added. Highways England – the Government-owned company launched last week to replace the Highways Agency – is required to keep the motorway network clean, but responsibility for clearing A-roads and trunk routes is divided between the agency and councils [...]

Reference: Winchester Council in Hampshire claimed annual clean-up hit by new rules. But the Health and Safety Executive denied tightening rules and added that councils were 'over-interpreting' legislation. Poet Laureate Sir Andrew Motion accused town hall bosses and Highways Agency of ruining the countryside by failing to remove rubbish.

Base PEGASUS summary: Council chiefs condemned for claiming it was too dangerous to collect litter. Winchester Council said its annual clean-up had been hit by new rules. Health and Safety Executive denied tightening rules and said councils were 'over-interpreting' legislation.

SummaReranker summary: Winchester Council said its annual clean-up had been hit by new rules. Health and Safety Executive said councils were 'over-interpreting' legislation. Sir Andrew Motion accused town hall bosses and Highways Agency of ruining countryside by failing to remove rubbish.

Figure 4: **Example of a summary** generated by SummaReranker trained for {R-1, R-2, R-L} on **CNN/DM**. The sentence in green is included in the SummaReranker summary, while the one in red is discarded.

but becomes instead:

$$R@k = \frac{\binom{m}{m_{\text{best}}} - \binom{m-k}{m_{\text{best}}}}{\binom{m}{m_{\text{best}}}} \tag{6}$$

where m_{best} is the number of best candidates.

Following Fig. 3, a PEGASUS with diverse beam search ranking of summary candidates (dashed lines) is not significantly better than the corresponding random baseline from eq. (6) (dotted lines) on CNN/DM and Reddit TIFU. However, it improves on it on XSum, confirming the observation made in Table 6 that it is harder to train a re-ranker on this dataset. On all three datasets, SummaReranker (solid lines) significantly pushes the recall at all thresholds. We note +14.90 absolute recall@5 improvement on CNN/DM (50.84 versus 35.94, indicated by the black arrow), +9.54 on XSum and +5.23 on Reddit TIFU.

4.6 Qualitative Evaluation

Lastly, we demonstrate that re-ranking improvements in quantitative metrics also translate to qualitatively better summaries. Fig. 4 shows an example of summary selected by SummaReranker, alongside its source document, ground-truth (reference) summary and output from the base model. SummaReranker is able to include a whole sentence which was missed by the base summary. We refer to Appendix K for full re-ranking demonstrations on each of the three datasets.

We also conduct a human evaluation. We asked three different humans to evaluate 50 randomly sampled test summaries for each dataset. Human raters were graduate students with professional English proficiency (TOEFL scores above 100 out of 120). Humans were shown the source document alongside the top beam search summary from PEGASUS, and the corresponding summary candidate selected by SummaReranker. They were asked to choose which one they believe is more faithful. They could choose a tie, because in some cases the base summary and the re-ranked one are very similar, or even identical (Appendix I). In Fig. 5, we see that on average, humans are more likely to pick the SummaReranker candidate.

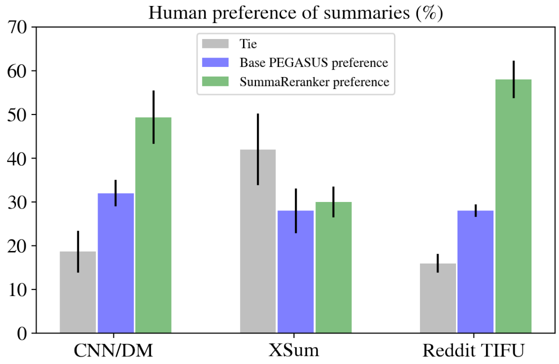

Figure 5: **Human evaluation** results on all three datasets. Black vertical bars are standard deviation across human raters.

5 Discussion

Abstractiveness Given that we are not modifying the base model nor its training procedure, we analyze whether our re-ranking system favors more abstractive candidates. In Fig. 6, we display the percentage of novel n-grams for n in {1,2,3,4}, for a base PEGASUS with beam search (blue) and diverse beam search (purple) decoding, and when adding SummaReranker in both cases (green and red, respectively). As first raised in (See et al., 2017), summary candidates are much less abstractive than ground truth summaries on CNN/DM. Yet, our re-ranker selects more abstractive candidates

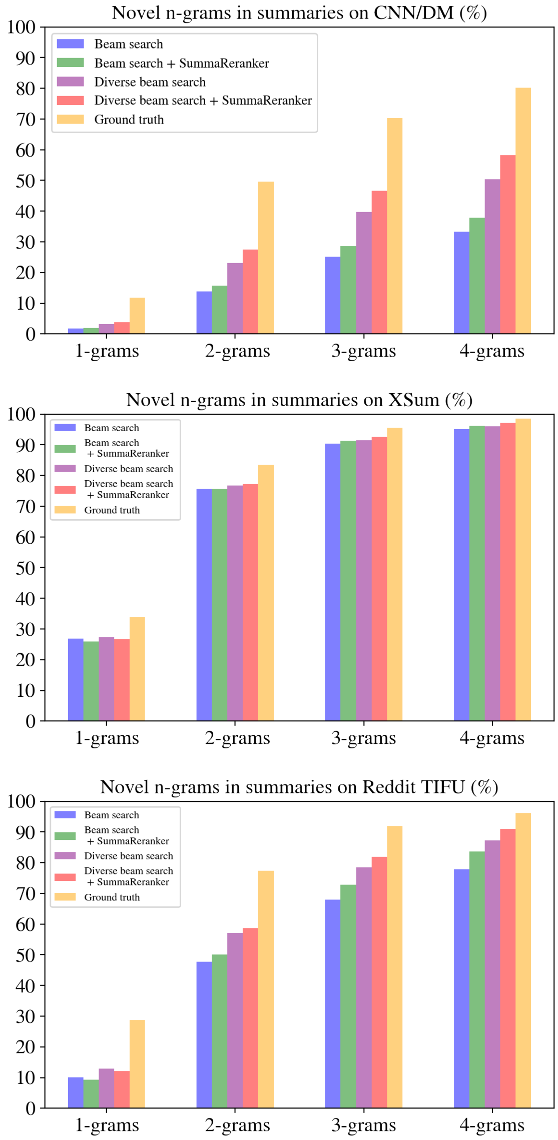

Figure 6: **Novel n-grams** with PEGASUS, across all datasets and with beam search and diverse beam search.

according to all n-grams metrics, even more so with diverse beam search, which is already more abstractive than beam search. This observation also holds on Reddit TIFU and XSum (other than 1-grams). XSum summary candidates are already almost as abstractive as the ground truth and it is harder to obtain significant abstractiveness gains through our re-ranking.

Speed/Performance trade-off On top of base model training and candidate generation, SummaReranker inference cost is linear in the number of candidates. A single candidate takes on average 38ms to be scored. As seen in Table 5 and Table 6, the performance gains from mixing several decoding methods to generate summary candidates are not scaling consistently (all four decoding methods are not better than just beam search and diverse beam search). To provide more insights on the speed/performance trade-off, we show in Appendix J SummaReranker performance when randomly sub-sampling $k \in \{1, \dots, 15\}$ candidates. On CNN/DM, re-ranking as few as two candidates is sufficient to improve on the baseline PEGASUS. On XSum, it needs three to eight, and on Reddit TIFU three to four. As a rule of thumb, it is better to score all candidates when possible, but six to eight candidates provide a good trade-off between speed and performance across datasets.

Further Work To encode the source jointly with the summary candidate, we need to truncate the source to a fixed number of tokens. Thus, we are limited by the maximum context window of the language model encoder (512 in the case of RoBERTa-large). Applying SummaReranker to long-document summarization, such as scientific articles summarization (Cohan et al., 2018) would need better long-range modeling. In §3, we weighted metric-dependent losses uniformly. We leave to further work the exploration of more complex weight balancing or multi-task learning objectives (Lin et al., 2019).

6 Conclusion

We introduced SummaReranker, the first multi-task re-ranking framework for abstractive summarization. Encoding the source with the candidate, our model predicts whether the summary candidate maximizes each of the metrics optimized for. SummaReranker works well across diverse datasets, models, decoding methods and summarization evaluation metrics. Summaries selected by SummaReranker improve the ROUGE state-of-the-art on CNN/DM and XSum. In addition, we also show that they are more abstractive and more likely to be preferred by human evaluators over base model outputs.

A Hyper Parameters & Packages

For evaluation metrics, we used the following packages:

- For ROUGE metrics (Lin and Hovy, 2003), we used the public *rouge-score* package from Google Research: `https://github.com/google-research/google-research/tree/master/rouge`
- For BERTScore (Zhang et al., 2019a), we used the public *bert-score* package shared by the authors: `https://github.com/Tiiiger/bert_score`
- For BARTScore (Yuan et al., 2021), we used the public code shared by the authors: `https://github.com/neulab/BARTScore`

Dataset	Model	LR	Epochs	Opt.	BS	LS	MP	Source tokens	Summary tokens
CNN/DM	PEGASUS	5e-5	10	Adafactor	256	0.1	No	1024	128
	BART	3e-5	10	Adam	80	0.1	Yes	1024	128
XSum	PEGASUS	5e-5	10	Adafactor	256	0.1	No	512	64
	BART	3e-5	10	Adam	80	0.1	Yes	512	64
Reddit TIFU	PEGASUS	1e-4	15	Adafactor	256	0.1	No	512	128
	BART	3e-5	15	Adam	80	0.1	Yes	512	128

Table 7: **Hyper-parameters** for **fine-tuning** the base models. **LR** designates the *learning rate*, **Epochs** is the number of epochs, **Opt.** is the *optimizer*, **BS** is the *batch size*, **LS** means *label smoothing*, and **MP** means *mixed precision*. **Source tokens** is the maximum size of the input document, **Summary tokens** the maximum size of the output summary.

Dataset	Model	Source tokens	Summary tokens	Length penalty	Repetition penalty	Trigram blocking
CNN/DM	PEGASUS	1024	128	0.8	1.0	No
	BART	1024	128	0.8	1.0	No
XSum	PEGASUS	512	64	0.8	1.0	Yes
	BART	512	64	0.8	1.0	Yes
Reddit TIFU	PEGASUS	512	128	0.6	1.0	Yes
	BART	512	128	1.0	1.0	Yes

Table 8: **Hyper-parameters** for the summary candidates **generation** with the base models.

B Oracle Scores

Decoding methods	# Summary candidates	R-1	R-2	R-L	BS	BaS
Beam search (top beam)	1	47.33	24.75	39.43	92.01	-1.92
Beam search	15	56.07	33.80	48.33	93.19	-1.82
Diverse beam search	15	**57.82**	**35.28**	**50.95**	**93.65**	**-1.63**
Top-k sampling	15	55.57	32.54	48.35	93.18	-1.86
Top-p sampling	15	56.74	33.94	49.60	93.40	-1.77
All four above	60	**62.30**	**40.84**	**55.92**	**94.24**	**-1.48**

Table 9: **Oracle scores** for four popular decoding methods and five summarization evaluation measures for a base PEGASUS model on **XSum**.

Decoding methods	# Summary candidates	R-1	R-2	R-L	BS	BaS
Beam search (top beam)	1	26.28	9.01	21.52	87.34	-3.46
Beam search	15	36.08	14.93	29.70	88.64	-2.89
Diverse beam search	15	36.70	15.22	**30.88**	**89.08**	**-2.81**
Top-k sampling	15	36.76	14.37	29.49	88.53	-3.14
Top-p sampling	15	**37.54**	**15.24**	30.50	88.69	-3.03
All four above	60	**43.25**	**20.70**	**36.41**	**89.71**	**-2.58**

Table 10: **Oracle scores** for four popular decoding methods and five summarization evaluation measures for a base PEGASUS model on **Reddit TIFU**.

Observations from Table 9 and Table 10 are consistent with the ones made in Table 1: oracle scores are widely above the top beam baseline, and keep increasing when mixing several decoding methods.

C Unique Candidates Scores

Dataset	Model	Generation method	Scoring metric R-1	R-2	R-L	BS	BaS
CNN/DM	PEGASUS	{1}	11.51	10.87	11.54	14.96	14.96
		{2}	14.34	14.09	14.34	14.99	14.99
		{3}	14.65	14.40	14.65	14.99	14.99
		{4}	14.68	14.41	14.69	15.00	15.00
	BART	{1}	11.51	10.90	11.54	14.93	14.95
		{2}	13.89	13.71	13.89	14.80	14.79
XSum	PEGASUS	{1}	8.90	7.91	8.56	14.99	14.99
		{2}	12.05	10.92	12.11	14.97	14.98
	BART	{1}	8.70	7.57	8.33	14.99	15.00
		{2}	7.37	6.63	7.37	14.59	14.99
Reddit TIFU	PEGASUS	{1}	9.19	6.31	8.85	14.99	14.99
		{2}	7.84	5.06	7.77	14.89	14.97
	BART	{1}	7.73	5.15	7.56	14.99	14.99
		{2}	7.42	3.92	7.38	14.89	14.97

Table 11: **Number of unique scores** among pools of 15 candidates generated on different datasets (CNN/DM, XSum, Reddit TIFU) with different base models (PEGASUS, BART) and different decoding methods ({1} stands for beam search, {2} is diverse beam search, {3} is top-p sampling and {4} top-k sampling). The lowest possible score of 1 indicates that all 15 candidates are assigned the same score under the metric being considered, while the highest of 15 means that all candidates are assigned a different score.

In Table 11, BERTScore (BS) and BARTScore (BaS) have results closer to 15, indicating that it is unlikely that two summary candidates share the exact metric score. This is understandable given that both these metrics are based on embeddings from pre-trained language models (BERT and BART, respectively), and embeddings values will vary whenever the input text is different, making it unlikely to have two candidates collude on the same score. In contrast, ROUGE measures n-gram overlaps, and two different summary candidates might get the same ROUGE score with the target summary (for instance if they only differ by n-grams not present in the target).

D Identical Candidates Scores

Dataset	Model	Generation method	Scoring metric R-1	R-2	R-L	BS	BaS
CNN/DM	PEGASUS	{1}	0.00	0.50	0.00	0.00	0.00
		{2}	0.00	0.03	0.00	0.00	0.00
		{3}	0.03	0.06	0.03	0.03	0.00
		{4}	0.00	0.03	0.00	0.00	0.00
	BART	{1}	0.00	0.47	0.00	0.00	0.00
		{2}	0.00	0.05	0.00	0.00	0.00
XSum	PEGASUS	{1}	0.06	3.34	0.10	0.00	0.00
		{2}	0.04	1.11	0.04	0.00	0.00
	BART	{1}	0.17	4.31	0.19	0.00	0.00
		{2}	0.04	2.59	0.04	0.00	0.00
Reddit TIFU	PEGASUS	{1}	2.04	21.15	2.04	0.00	0.00
		{2}	1.52	17.03	1.52	0.00	0.00
	BART	{1}	2.32	24.14	2.32	0.00	0.00
		{2}	1.73	21.60	1.73	0.00	0.00

Table 12: **Fraction of sets of candidates with all identical scores (%)** for pools of 15 candidates generated on different datasets (CNN/DM, XSum, Reddit TIFU) with different base models (PEGASUS, BART) and different decoding methods ({1} stands for beam search, {2} is diverse beam search, {3} is top-p sampling and {4} top-k sampling.

We note that cases where all scores are identical are a small minority. ROUGE-2 is more likely than other metrics to lead to such a scenario of all identical scores.

E Metrics Correlation

	R-1	R-2	R-L	BS	BaS
R-1	1.000	0.888	0.905	0.850	0.657
R-2	0.888	1.000	0.911	0.790	0.628
R-L	0.905	0.911	1.000	0.847	0.620
BS	0.850	0.790	0.847	1.000	0.690
BaS	0.657	0.628	0.620	0.690	1.000

Table 13: **Pearson correlation coefficient** between the five evaluation metrics {R-1, R-2, R-L, BS, BaS} for a base PEGASUS decoded with beam search on **XSum**.

	R-1	R-2	R-L	BS	BaS
R-1	1.000	0.806	0.927	0.766	0.600
R-2	0.806	1.000	0.856	0.679	0.524
R-L	0.927	0.856	1.000	0.768	0.564
BS	0.766	0.679	0.768	1.000	0.646
BaS	0.600	0.524	0.564	0.656	1.000

Table 14: **Pearson correlation coefficient** between the five evaluation metrics {R-1, R-2, R-L, BS, BaS} for a base PEGASUS decoded with beam search on **Reddit TIFU**.

Metrics correlation from Table 13 and Table 14 follow the same pattern as in Table 2.

F Base Setup Results

Model	Model stage	Decoding methods ($\mathbb{D}$)	R-1	R-2	R-L	Gain (%)
PEGASUS - 1st half	1	{1}	46.02	23.38	38.10	_
PEGASUS - 1st half	1	{2}	45.41	22.37	37.22	_

BART - 2nd half	1	{2}	25.83	8.38	20.97	_
PEGASUS - 1st half + SR	2	{1}	28.78	9.20	22.74	12.83
PEGASUS - 1st half + SR	2	{2}	28.63	8.71	22.71	18.53
PEGASUS - 2nd half + SR	2	{1}	28.87	9.24	22.73	11.70
PEGASUS - 2nd half + SR	2	{2}	28.41	8.46	22.44	14.63
BART - 1st half + SR	2	{1}	28.98	**9.62**	**22.96**	1.53
BART - 1st half + SR	2	{2}	**28.89**	8.70	22.40	-0.77
BART - 2nd half + SR	2	{1}	27.93	9.48	22.45	3.73
BART - 2nd half + SR	2	{2}	28.24	8.77	22.43	6.98
PEGASUS - 1st half + SR	2	{1, 2}	**29.93**	**9.40**	**23.50**	16.37
PEGASUS - 2nd half + SR	2	{1, 2}	29.65	9.24	23.22	13.53
BART - 1st half + SR	2	{1, 2}	29.00	8.78	22.32	-2.63
BART - 2nd half + SR	2	{1, 2}	29.15	9.11	22.96	4.70

Table 16: **Base setup results** for SummaReranker applied to PEGASUS and BART on the **Reddit TIFU** dataset.

Tables Table 15 and Table 16 complement the base setup results exposed in Table 4.

G Recall Curves

Threshold k	**k=1**	**k=2**	**k=3**	**k=4**	**k=5**
CNN-DailyMail - Random baseline	6.75	13.49	20.20	26.91	33.60
CNN-DailyMail - PEGASUS	8.57	15.93	22.76	29.43	35.94
CNN-DailyMail - PEGASUS + SR	14.97	25.40	35.00	43.46	50.84
XSum - Random baseline	8.05	15.81	23.33	30.62	37.72
XSum - PEGASUS	14.60	24.40	32.70	40.23	47.17
XSum - PEGASUS + SR	16.57	28.60	39.53	48.78	56.71
Reddit TIFU - Random baseline	11.39	21.22	30.35	38.83	46.70
Reddit TIFU - PEGASUS	14.54	24.11	33.16	40.10	48.11
Reddit TIFU - PEGASUS + SR	16.70	27.07	37.42	46.02	53.34

Table 17: Values of **recall** curves plotted in Fig. 3.

H Human Evaluation

	Tie		**Base model**		**SummaReranker**	
	Mean	Std	Mean	Std	Mean	Std
CNN/DM	18.67	9.50	32.00	6.00	49.33	12.20
XSum	42.00	16.33	28.00	10.20	30.00	7.12
Reddit TIFU	16.00	4.32	28.00	2.82	58.00	4.32

Table 18: Numbers of the **human evaluation** in Fig. 5.

I Candidate Selection

Dataset	**Model**	**Generation method**	**SR pick** the base candidate (%)	**SR pick** the best candidate (%)
CNN/DM	PEGASUS	{1}	3.57	14.81
		{2}	11.11	15.00
	BART	{1}	**2.75**	**15.51**
		{2}	6.67	13.54
XSum	PEGASUS	{1}	**4.86**	9.97
		{2}	20.73	16.57
	BART	{1}	8.01	18.19
		{2}	22.23	**23.80**
Reddit TIFU	PEGASUS	{1}	6.16	18.21
		{2}	16.82	23.09
	BART	{1}	**3.22**	24.04
		{2}	3.32	**32.88**

Table 19: **Re-ranking overlap with base and best candidates.** Fraction of time that the re-ranked summary coincides with the base model one (left), and one of the best ones (oracle scores) among generated candidates (right). **SR** is SummaReranker.

In Table 19, we observe that SummaReranker is more likely to stick to the base model candidate with diverse beam search. Results in bold represent the most ideal scenario: SummaReranker differs the most from the base setup (lowest scores of the left column), and matches the most one of the best candidates (highest scores of the right column).

J Speed/Performance Trade-off

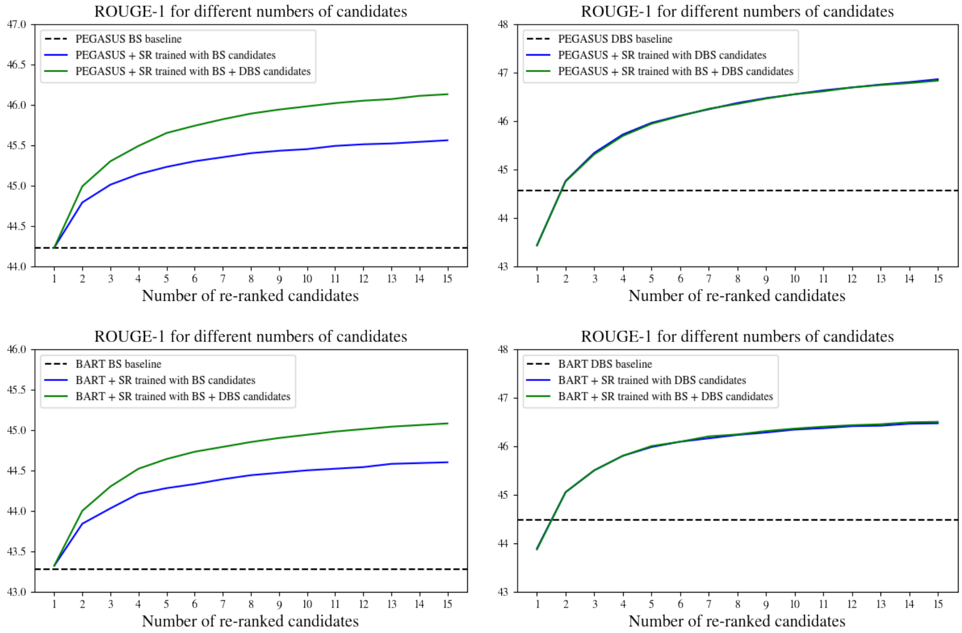

Figure 7: **ROUGE-1 on CNN/DM** for k sampled candidates at inference time, with $k \in \{1, \ldots, 15\}$. **SR** stands for SummaReranker, **BS** and **DBS** refer to beam search and diverse beam search, respectively.

In Fig. 8, we observe a failure mode of SummaReranker: on XSum and with PEGASUS when training the re-ranking with beam search candidates, performance decreases. However, the problem vanishes when SummaReranker is trained on a mixture of beam search and diverse beam search candidates.

Fig. 9 top left (PEGASUS with beam search) represents a curious case: re-ranking a *single* candidate is better than the top beam baseline. Since re-ranking a single candidate is equivalent to randomly sampling one candidate, this means that the top beam baseline is on average *lower* than sampling a random candidate. We observed that such cases are rare and usually the top beam baseline is better than the random baseline. When the top beam baseline is lower, it is of utmost importance to keep all candidate and use a second-stage method to identify a better one.

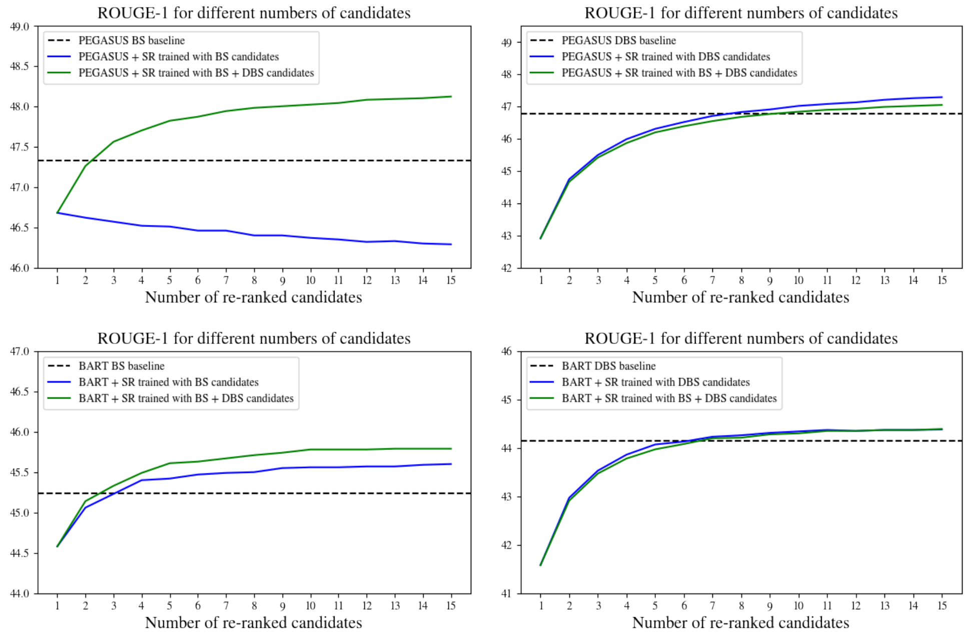

Figure 8: **ROUGE-1 on XSum** for k sampled candidates at inference time, with $k \in \{1, \ldots, 15\}$. **SR** stands for SummaReranker, **BS** and **DBS** refer to beam search and diverse beam search, respectively.

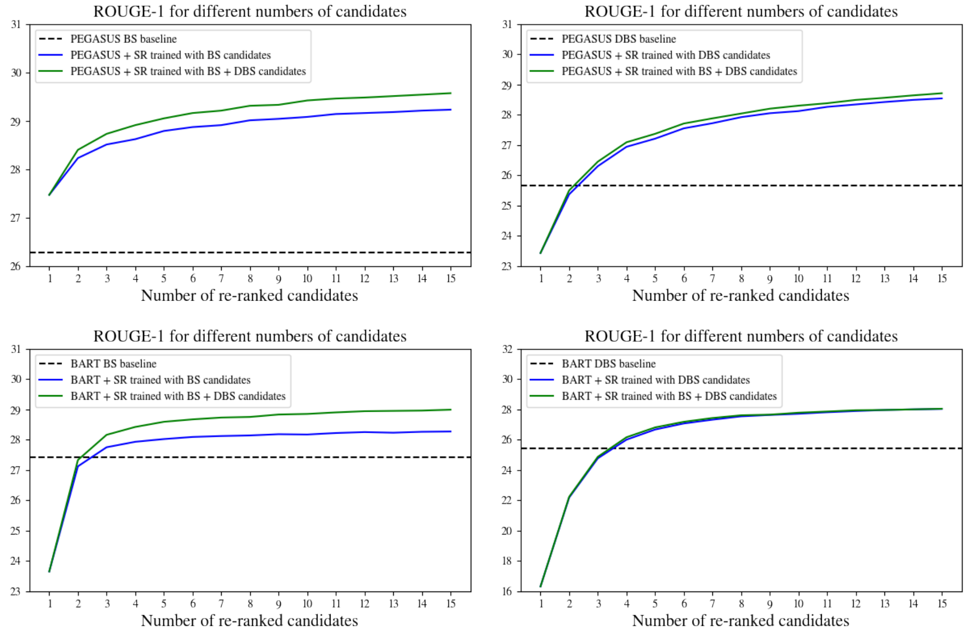

Figure 9: **ROUGE-1 on Reddit TIFU** for k sampled candidates at inference time, with $k \in \{1, \ldots, 15\}$. **SR** stands for SummaReranker, **BS** and **DBS** refer to beam search and diverse beam search, respectively.

K Re-ranking Examples

		CNN/DM
Source		Is this confirmation that Angel Di Maria is happy as a Manchester United player? The 27-year-old has endured a mixed start to his United career on-and-off the pitch since joining the club last summer - which has included an attempted burglary at his family home in Cheshire back in February. The midfielder has been linked with a move away from Old Trafford as a result, but speculation about his future could be squashed following his latest tattoo. Angel Di Maria (left) has a new No 7 tattoo which stands out among others on his left arm . Di Maria wears the No 7 shirt at Manchester United following his £60million from Real Madrid last summer. A new picture has been revealed on Twitter of Di Maria's latest piece of body art - the number seven which stands out strongly among others on his left arm. United's club record £60million signing of course adorns the No 7 shirt at the Red Devils - so could his latest tattoo suggest he's committed to Louis van Gaal's side for the long haul? However, before United fans get too carried away it must be noted that the former Real Madrid star does also wear the No 7 jersey for Argentina too. As well as adorning the No 7 shirt at United, 27-year-old (right) also wears that number for Argentina too.
Beam #1	Summary	Angel Di Maria has revealed his latest tattoo on Twitter. The 27-year-old has the No 7 shirt at Manchester United on his left arm. The Argentine has endured a mixed start to his United career. He has been linked with a move away from Old Trafford as a result.
	Reference scores	R-1: 38.6364, R-2: 18.6047, R-L: 34.0909 // Rank: 15
	Re-ranking	SummaReranker score: 0.1577 // SummaReranker score rank: 15
Beam #2	Summary	Angel Di Maria has a new tattoo of the No 7 shirt at Manchester United. The 27-year-old has endured a mixed start to his United career. The midfielder has been linked with a move away from Old Trafford. Di Maria also wears the No 7shirt for Argentina too.
	Reference scores	R-1: 59.0909, R-2: 34.8837, R-L: 56.8182 // Rank: 5
	Re-ranking	SummaReranker score: 0.3905 // SummaReranker rank: 6
Beam #3	Summary	Angel Di Maria has had a new No 7 tattoo on his left arm. The number stands out strongly among others on his arm. The 27-year-old joined Manchester United for a club record £60million last summer. Di Maria also wears the No 7 shirt for Argentina.
	Reference scores	R-1: 61.1765, R-2: 33.7349, R-L: 58.8235 // Rank: 4
	Re-ranking	SummaReranker score: 0.4447 // SummaReranker rank: 5
Beam #4	Summary	Manchester United's record signing has a new No 7 tattoo on his left arm. Angel Di Maria wears the number seven shirt at Old Trafford. The 27-year-old has endured a mixed start to his United career. He has been linked with a move away from Old Trafford as a result.
	Reference scores	R-1: 37.7778, R-2: 15.9091, R-L: 37.7778 // Rank: 14
	Re-ranking	SummaReranker score: 0.2528 // SummaReranker score: 10
Beam #5	Summary	Angel di Maria's latest tattoo shows him with the No 7 shirt at Manchester United. The 27-year-old has endured a mixed start to his United career. The midfielder has been linked with a move away from Old Trafford. Di Maria joined United for a club record £60million from Real Madrid.
	Reference scores	R-1: 53.3333, R-2: 27.2727, R-L: 48.8889 // Rank: 10

Source		Female officers will be able to wear a headscarf under their caps or berets, provided it is plain and is the same colour as the uniform. Headscarf bans on university campuses and state institutions - except for the judiciary, military and police - have also been lifted in recent years. The garment has been controversial in Turkey for years. Secularists regard it as a symbol of religious conservatism. Since the 1920s, Turkey has had a secular constitution with no state religion. The opposition have accused President Recep Tayyip Erdogan and his Islamist-rooted Justice and Development Party (AKP) of trying to reinterpret secularism. However, public debate has also evolved to accept the hijab as an expression of individual liberties, correspondents say. No strong opposition has been voiced against this latest move. President Erdogan has long embraced Turks' right to express their religious beliefs openly, but he says he is committed to secularism. In 2010, the country's universities abandoned an official ban on Muslim headscarves. Three years later, women were allowed to wear headscarves in state institutions - with the exception of the judiciary, military and police. That year, four MPs wore headscarves in parliament. Most people in Turkey are Sunni Muslims.

Reddit TIFU		
Source		here's my reconstruction of the fuck-up: during the visa application, i'm sifting through pages and pages of documentation with 15 tabs open on my browser and i arrive at a page with the title english requirement. it says something like "here's a list of approved test providers and you have to score a minimum cefr level of b1 to meet the english requirement." as someone who has taken many english exams such as toefl, ielts and pearson, i wonder what the hell a cefr level is, how come i've never heard of this and start popping new pages. turns out you have to score that much from ielts or this much from pearson or that much from other exams. cool. i'm thinking, currently i have 2 valid ielts exams that meet the criteria and a pearson's from which i've scored 90/90, sweet! i'll just submit pearson's and done. so i pay 2000aud and get an appointment, submit my documents and come back home. "hey wifey, it was really easy, let's do the same for you and get it done quickly." pay another 2000aud and my wife submits her application. 3 days after my submission, i get an e-mail saying a decision has been made, yay? more like nay, refused because we don't accept pearson's. 2 days later, wife gets refuses as well because we refused your husband. 2000 down the drain, luckily they are refunding the healthcare extras. turns out i failed to go back to that webpage and click on the link to get access to the most ridiculous list of approved english tests. there's not a mention of pearson, what's more, it doesn't have idp melbourne so my ielts exams are useless as well. on the plus side, i learn there are other ways to meet the requirement. if you have a diploma from an australian uni, just submit your diploma and you're good to go? why didn't you give me a call or send me an email and say "hey, you made a mistake silly" and i'd be like here's my diploma or something, wtf is refusing? this will stick to our international travel cv like a fucking bug. plus, i had to ask my future employer for another certificate, which takes another two weeks and makes me look like an idiot. then i'll have to submit another application, pay another 4000 and yada yada. A bit of background: we are turkish citizens living in australia as permanent residents obtained by using the same pearson's test. i'm working as a post-doctoral researcher and hopefully starting another post-doctoral position in scotland, not giving up!

Abstract

The ability to sequence unordered events is evidence of comprehension and reasoning about real world tasks/procedures. It is essential for applications such as task planning and multi-source instruction summarization. It often requires thorough understanding of temporal common sense and multimodal information, since these procedures are often conveyed by a combination of texts and images. While humans are capable of reasoning about and sequencing unordered procedural instructions, the extent to which the current machine learning methods possess such capability is still an open question. In this work, we benchmark models' capability of reasoning over and sequencing *unordered multimodal* instructions by curating datasets from online instructional manuals and collecting comprehensive human annotations. We find current state-of-the-art models not only perform significantly worse than humans but also seem incapable of efficiently utilizing multimodal information. To improve machines' performance on multimodal event sequencing, we propose sequence-aware pretraining techniques exploiting the sequential alignment properties of both texts and images, resulting in >5% improvements on perfect match ratio.

1 Introduction

Instructions are essential sources for agents to learn how to complete complex tasks composed of multiple steps (e.g., "making a wood sign from scratch"). However, instructions do not always come in a proper sequential order, for example, when instructions must be combined across sources (e.g., to accomplish a complex task there might be *multiple* useful resources for certain task-steps come out from a single Google search). Therefore, *sequencing **unordered** task-steps* is crucial for comprehending and inferring task procedures, which requires thorough understanding of event causal and temporal common sense. It is essential for applications such as multi-source instruction summarization and robot task planning (Garattoni and Birattari, 2018).

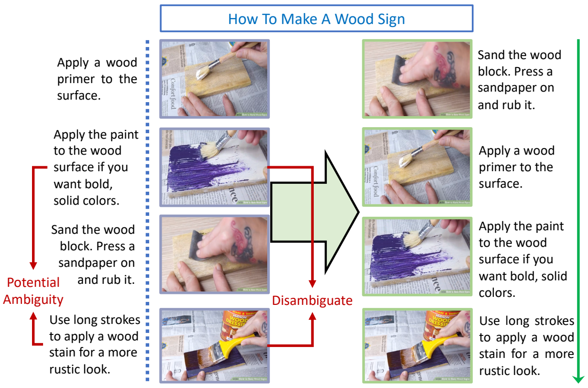

Figure 1: **Multimodal task procedure sequencing:** The left column shows unordered instruction steps from the manual *How To Make Wood Signs*. Each step is a text description and its associated image. Without the complementary information from the visuals, a novice may have difficulty inferring the proper task order. Considering multimodal information, the proper order can be correctly inferred (right column).

Existing work has studied sequencing unordered *texts* from paper abstracts or short stories (Chen et al., 2016; Cui et al., 2018). However, real-life tasks are often complex, and multimodal information is usually provided to supplement textual descriptions to avoid ambiguity or illustrate details that are hard to narrate, as illustrated in Figure 1.

To investigate whether current AI techniques can efficiently leverage multimodal information to sequence unordered task instructions, we curate two datasets from *online instructional manuals* (Hadley et al.; Yagcioglu et al., 2018). We consider two representative instruction domains: cooking recipes and "How-To" instructions (WikiHow). We establish human performance for the sequencing task on a subset of each data resource. As certain steps to perform a task can potentially be interchangeable,[1] we collect annotations of possible **orders**

---

[1] For example, without special requirements, preparing certain ingredients of a dish, such as slicing carrots or cucumbers, does not necessarily need to follow a specific order.

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 4525 - 4542
May 22-27, 2022 ©2022 Association for Computational Linguistics

alternative to the originally authored ones to create *multiple references*. Such additional annotation provides not only better measurement of human and model performance by alleviating unintended biases from content creators, but also a useful resource for future research of models that are aware of task-step dependencies and interchangeability.

To measure the ability of state-of-the-art AI techniques to sequence instruction steps, we construct models consisting of: (1) an **input encoder** which encodes image, text, or multimodal inputs, and (2) an **order decoder** which predicts step order using the encoded representations. They are jointly trained with the order supervisions.

Our preliminary studies show that multimodal information is consistently helpful for the sequencing task. However, compared to humans, current models are less efficient in utilizing multimodal information. We hypothesize that it is because the models do not effectively capture the sequential information in the vision modality nor the sequential alignment between multimodal contents. To address this, we propose to equip models with capabilities of performing **sequential aware multimodal grounding**. Specifically, we propose several self-supervised objectives, including sequence-based masked language modeling, image region modeling, and content swapped prediction, to pretrain the models before finetuning them on the downstream sequencing task.

The proposed pretraining techniques are shown to be effective in improving multimodal performance, enjoying a >5% improvement on the perfect match ratio metric. However, it is still significantly behind human performance ($\sim$ 15% in perfect match ratio metric). The same trend is observed when alternative orders are considered.

Our key contributions are two-fold: (1) We propose a multimodal sequencing task with two curated instructional manuals, and comprehensive human annotations. (2) We investigate model performance on sequencing unordered manuals, and propose sequence-aware pretraining techniques to more effectively use the multimodal information. Our experiments and extensive analysis provide insights on which task categories are most challenging for the state-of-the-art models. They also shed the light that more sophisticated sequential multimodal grounding are required to further improve the performance for the proposed multimodal sequencing task.

2 Problem Definition

Given a task procedure S consisting of N steps, where each step $S_i \in S$ can consist of two types of contents: a textual description T_i of tokens $\{T_{i,k}\}_{k=1}^{n_T}$ and/or image(s) $I_i = \{I_{i,k}\}_{k=1}^{n_I}$.[2] A model is required to take as inputs a random permutation of S, *i.e.* $S_p = \{S_{p_1}, ..., S_{p_N}\}$, where p is a permutation (S_{p_j} can take one of the following three modalities: T_{p_j}, I_{p_j}, and $\{T_{p_j}, I_{p_j}\}$), and predict the correct order of S_p, *i.e.* argsort(S_p).

3 Datasets and Human Annotation

We are interested in understanding the current state-of-the-art models' performance on this multimodal instruction sequencing task. To this end, we curate instruction datasets to support our study.

3.1 Instruction Manual Datasets

There are three major features we require for the target datasets: (1) It is multimodal. (2) It consists of task procedures as sequences of steps. (3) Different modalities are used intentionally to complement each other. In light of these, we consider the following two datasets:

RecipeQA. We start from a popular as well as intuitive choice of instruction manuals, recipes, which fully fulfill the aforementioned criteria. RecipeQA is a multimodal question answering dataset consisting of recipes scraped from *Instructables.com* (Yagcioglu et al., 2018). We utilize the recipes collected in RecipeQA and convert each unique recipe into sequential multimodal steps for our task.

WikiHow. To expand the types of instruction manuals for our task beyond recipes, we also consider a popular “How To ..." type of instructions, WikiHow, which is an online knowledge base that consists of human-created articles describing procedures to accomplish a desired task. Each article contains a high level goal of a task, a short summary of the task procedures, and several *multimodal* steps where each step consists of a description paired with one or a few corresponding images.

We scrape the entire WikiHow knowledge resource, containing more than 100k unique articles (mostly) with multimodal contents , as well as the hierarchically structured category for each article. Table 1 presents the essential statistics of the two datasets (more details are in Append. Sec. A).

---

[2] For computational concerns, we set $n_I = 1$ in this work.

Type	Counts

(b) RecipeQA

Table 1: **General statistics of the two datasets**: We provide the detailed component counts of the datasets used in this work, including the statistics of tokens and sentences from the instruction steps (lower half of the two tables).

3.2 Human Performance Benchmark

To ensure the validity of our proposed multimodal sequencing task, we establish the human performance via Amazon Mechanical Turk. Since our dataset is constructed from resources that are not directly designed for the sequencing task, the quality of random samples is unverified. Specifically, some articles in WikiHow may not have a notion of proper order among the steps.[3] As a result, to construct a high quality test set particularly for WikiHow for establishing human performance, we first identify a set of categories which are more likely to feature proper order, *e.g. Home and Garden* and *Hobbies and Crafts*.[4] A random proportion is then sampled and the co-authors further downsample the subset to 300 samples with the aforementioned criteria via majority vote. For RecipeQA, we randomly sample 100 recipes from the dataset. And hence, the resulting two subsets serve as our **golden-test-set** for performance benchmarking.

Human Performance. Prompted with a task goal and a randomly scrambled sequence of the task-steps (can be one of the following modalities: multimodal or text/image-only), workers are asked to examine the contents and decide the proper performing order. Human performance are then computed against the original authored orders as the ground truths, averaged across the whole set.[5]

Alternative Orders. When performing a task, some steps can be interchangeable. To take the interchangeability into consideration in our benchmark task, we also collect possible alternative orders to the original ones to create multiple references. For each instance in our golden-test-set, given the instruction steps sequenced in their original order, we ask workers to annotate alternative orders if the presented task-steps can be performed following a different order.[6]

Although in this work we are mainly focusing on sequential instructions and hence the interchangeability is also gauged in a sequential manner, we want to point out that the nature of task-step interchangeability is also highly related to parallel (branching) steps of tasks (Sakaguchi et al., 2021). We argue that the actions that can be performed interchangeably imply no direct dependencies are among these actions and thus can potentially be parallelized, and hence our alternative order formulation can help inferring these parallel actions.

More details of the two human annotation tasks can be found in Append. Sec. B.

4 Models

To benchmark the proposed task, we construct models comprising: (1) an **encoder** which encodes multimodal or text/image-only inputs, and (2) an **order decoder** which utilizes the encoded representations to predict the orders. To help models capture **sequentiality in task-steps** better as well as adapt to our target task domains, we pretrain the encoders with several self-supervised objectives on the instructions before integrating them with the decoder.

4.1 Input Encoders

Text-Only Encoders. We use *RoBERTa* (Liu et al., 2019) for text-only inputs. Although the next-sentence prediction in BERT (Devlin et al., 2019)

---

[3] No temporal or other dependencies among the task-steps, *e.g.* "How to be a good person", where each step depicts a different aspect and tips of being a good person.

[4] Although the data used for training is not cleansed and thus can be noisy, we believe models can still learn to sequence from many of the articles designed to have proper order.

[5] We design an algorithm to compute the inter-annotator agreements (IAAs), see Append. Sec. B.3 for details. The IAAs for (*multimodal*, *text-only*, *image-only*) versions in WikiHow is: (0.84, 0.82, 0.69), and (0.92, 0.87, 0.81) in RecipeQA.

[6] The alternative order annotation IAAs for (*multimodal*, *text-only*, *image-only*) versions in WikiHow is: (0.73, 0.71, 0.78), and (0.79, 0.76, 0.79) in RecipeQA.

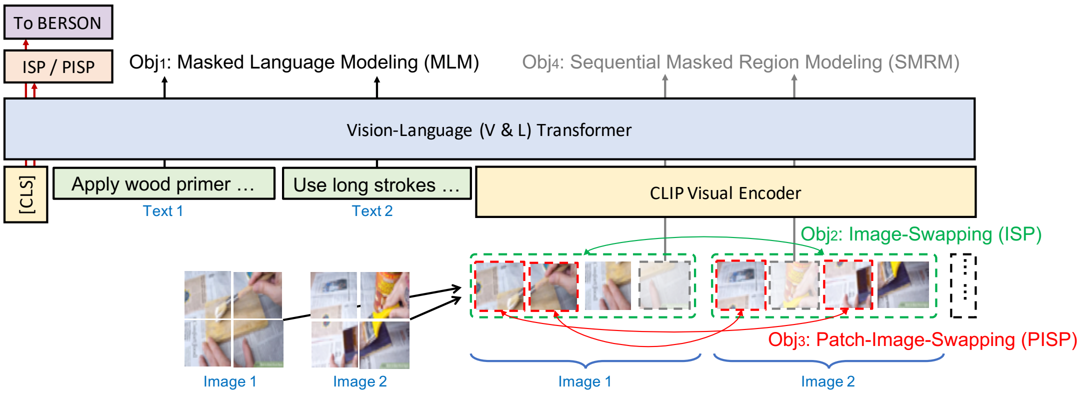

Figure 2: **Sequence-aware pretraining** includes: (1) masked language modeling (MLM), (2) image-swapping prediction (ISP/PISP) which requires the model to predict if some images (image-patches) are swapped, and (3) sequential masked region modeling (SMRM) where models are asked to reconstruct masked regions in each image within the input sequence.

can potentially be exploited for sequencing, we empirically find that RoBERTa performs better.

Multimodal Encoders. We consider the following two V&L models mainly due to their easy adaptation to our proposed sequencing task:

VisualBERT (Li et al., 2019) grounds object detected image regions (*e.g.* by Faster-RCNN (Ren et al., 2016)) to language with a single transformer model (Vaswani et al., 2017). VisualBERT is pretrained with: (1) multimodal masked language modeling (MLM)[7], and (2) image-text matching prediction (ITM), where the image in an image-caption pair is randomly replaced with another one to create misalignment, and the model is required to predict whether the current pair is aligned.

CLIP-ViL (Shen et al., 2021) is also a single-stream V&L model similar to VisualBERT, while the visual encoder is replaced by a patch-based model inspired by the ViT (Dosovitskiy et al., 2021) in CLIP (Radford et al., 2021), where the image features are taken as *gridded-image-patches* as shown in Figure 2. The pretraining objectives remain the same as VisualBERT. Empirically, both Shen et al. (2021) and this work find such patch-based model tends to yield better downstream performance.

Image-Only Encoders. We attempt to provide an image-only baseline on our sequencing task with two visual encoders: (1) *ResNet*-based (He et al., 2016) Faster-RCNN model (also the visual encoder in VisualBERT) where both the detected regional features and the whole-image-feature are used, and (2) the aforementioned patch-based *CLIP* model.[8]

4.2 Sequence-Aware Pretraining

The standard multimodal grounding techniques (Li et al., 2019; Lu et al., 2019; Su et al., 2020; Chen et al., 2020a) do not explicitly concern the sequentiality of text and associated image sequences, and hence may fall short of effectively utilizing the sequential properties in multimodal inputs. To encourage models to have better awareness of the sequential alignments in multimodal instruction steps, we propose to pretrain the encoders with the following self-supervised objectives: (1) masked language modeling (**MLM**), (2) (patch-based) image-swapping predictions (**ISP/PISP**), and (3) sequential masked region modeling (**SMRM**). Figure 2 illustrates an overview of the pretraining paradigm.

For the proposed objectives, the inputs to the models are generally *ordered* instruction step sequences, which can be further sub-sampled to produce length-varying subsequences. Although we do not find this necessarily benefit the downstream performance, it is observed that the sub-sampling helps the model converge faster. While all of our proposed objectives can be applied to sequence with arbitrary length ($\geq$ 2), without loss of generality and for simplicity, the following sections assume the sub-sampled sequence is of length 2.

4.2.1 Masked Language Modeling

The standard MLM (Devlin et al., 2019) is employed by the text-only models to adapt a pretrained language model to the target domain (task instructions). Following prior V&L works, we apply MLM to multimodal models. Specifically, we ensure that the textual description of each step T_i gets similar amount of tokens being masked-out such that the models can potentially exploit the

---

[7] RoBERTa is used to initialize VisualBERT and CLIP-ViL.

[8] Without confusion, throughout the paper we term the ViT- and CLIP-inspired visual encoder simply as CLIP.

image sequences more.[9]

4.2.2 Swapping-Based Prediction

This objective concerns, with certain probability, randomly swapping a pair of items in a sequence and asking the model to judge whether the resulting sequence is properly ordered or not (*i.e.* binary classification). We mainly perform the swapping in the image modality and hence it can be viewed as a sequence-aware version of ITM objective in most V&L models. As in ITM, the output representation at the `[CLS]` token is used to make the prediction.

Standard. For an ordered sequence S, we can randomly swap two[10] items of S, $\{S_i, S_j\}$, where $i < j$, to $\{S_j, S_i\}$, with a certain probability δ. Our preliminary studies find that swapping the textual contents does not necessarily help the downstream performance for either text-only or multimodal models, so we only perform the swapping on the images $\{I_i, I_j\}$ in both multimodal and image-only models. For patch-based image inputs (or regional features), the whole patches of an image are swapped with those of another one within the same sequence, as illustrated in **Obj**$_2$ in Figure 2.

Patch-Based. We can perform the aforementioned swapping prediction with a finer granularity, directly on the image patches. Assuming each image I_i is cropped into w patches (or w detected regions), *i.e.* $\{\mathbf{i}_{i,k}\}_{k=1}^{w} = \{\mathbf{i}_{i,1}, ..., \mathbf{i}_{i,w}\}$, we randomly select M (ranging from 1 to w) number of patches each from the two images I_i, I_j (*i.e.* $\{\mathbf{i}_{i,p}\}, \{\mathbf{i}_{i,q}\}, p, q \in M$-sized sampled indices) to be swapped with probability δ. Specifically, for each image patch $\mathbf{i}_{i,m} \in I_i$, a randomly selected image patch $\mathbf{i}_{j,n} \in I_j$ is sampled to be swapped with. The sampled M-sized indices do not need to be the same set of integers for each image. The **Obj**$_3$ in Figure 2 illustrates the patch-based swapping prediction with $w = 4$ and $M = 2$.

4.2.3 Sequential Masked Region Modeling

Prior works extend the masked learning to the visual modality, where the masked target is either a predefined discrete visual vocabulary (Sun et al., 2019; Bao et al., 2021) or (soft) object class labels (Lu et al., 2019; Su et al., 2020; Chen et al., 2020a). In this work, we construct a feature-based target vocabulary dynamically in each training batch. We first randomly select the same amount of $X\%$ ($X = 15$) patches for **each image** to be masked out (replaced with 0-tensor), and then construct a target vocabulary from the original output representations (before masking) of these patches.

Concretely, denote the output representation of an input image-patch $\mathbf{i}_{i,m}$ as $h(\mathbf{i})_{i,m}$ and the masked positions of I_i as D_i, we can construct a candidate list from all the output representations of the patches at the masked positions of each image, *i.e.* $C = \{h(\mathbf{i})_{i,m}\} \cup \{h(\mathbf{i})_{j,n}\}, m, n \in D_i, D_j$. Denote the masked image patches (the gray-colored image patches in Figure 2) as $\mathbf{mask(i)}_{i,m}$, for each output masked representation $h(\mathbf{mask(i)})_{i,m}$, we concatenate it with all the candidates, *i.e.* $h(\mathbf{mask(i)})_{i,m} || h(\mathbf{i'}), \forall \mathbf{i'} \in C$, which results in $|C|$ concatenated representations for each masked position. A $|C|$-way multi-class classification can then be performed by maximizing the probability of $p(\mathbf{i}_{i,m} | h(\mathbf{mask(i)})_{i,m}; C)$. For robust training, we additionally: (1) shuffle the candidate set C for each masked position to prevent overfitting, and (2) ensure the overlapping of masked positions in each pair of images, $D_i \cap D_j$, is < 50%, allowing the models to utilize information of similar regions from other images in the sequence.

4.2.4 Overall Training Objective

As the mechanism in some objectives cannot guarantee mutually exclusive impacts (*e.g.* performing ISP and PISP simultaneously may create confusing swapped patches), we employ a turn-taking fashion, with uniform probability, one of the objectives (**Obj**) is sampled for each training mini-batch. The overall pretraining objective is defined as below:

$$L = L_{\text{MLM}} + L_{\textbf{Obj}}, \textbf{Obj} \sim \{\text{ISP}, \text{PISP}, \text{SMRM}\} \quad (1)$$

4.3 Order Decoder – BERSON

BERSON is a recently proposed state-of-the-art neural sentence ordering framework (Cui et al., 2020), where a pointer network (Vinyals et al., 2016) exploits both the local (relative pairwise order) and global (self-attentions on top of the entire input sequence) information of the inputs to decode the predicted order. BERSON mainly exploits the `[CLS]` output representations for relational understanding, which aligns well with how our encoders are pretrained (Figure 2). We integrate our encoders (with or without sequence-aware pretraining) into BERSON, replacing its original BERT encoder. The BERSON-module-specific components are freshly initialized and then the entire integrated module is finetuned on our sequencing task.

---

[9] As higher chances that the complementary textual information is also masked out from different steps.

[10] Two is our minimum number for a valid subsequence.

5 Experiments and Analysis

Our experiments seek to answer these questions: (1) How valid is the proposed task for humans to complete? (2) Is multimodality helpful? (3) Can the proposed sequence-aware pretraining utilize multimodality more effectively? (4) How would results differ when alternative orders are considered?

5.1 Evaluation Metrics

We adopt metrics from sentence ordering works:

Position-Based metrics concern the correctness of the absolute position of each item in a sequence, including: (1) **Accuracy (Acc)** which computes the ratio of absolute positions in the ground truth order that are correctly predicted; (2) **Perfect Match Ratio (PMR)** which measures the percentage of predicted orders exactly matching the ground truth orders; and (3) **Distance (Dist.)** which measures the average distance[11] between the predicted and ground truth positions for each item.

Longest Common Subsequence computes the average longest subsequences in common (Gong et al., 2016) between the predicted and ground truth orders ($\mathbf{L}_q$). We also consider a stricter version, longest common substring, which requires the consecutiveness for the comparisons ($\mathbf{L}_r$).

Kendall's Tau (**τ**) (Lapata, 2003) is defined as $1 - 2 \times (\#\ inversions)/(\#\ pairs)$, where the inversion denotes that the predicted relative order of a pair of items is inverted compared to the corresponding ground truth relative order, and $\#\ pairs = \binom{N}{2}$ for N-length sequence.

Each metric focuses on different perspectives of the predictions, *i.e.* position metrics concern the absolute correctness, while common subsequence and τ metrics measure if general sequential tendency is preserved despite incorrect absolute positions.

5.2 Implementation Details

We use the original data splits for RecipeQA. For WikiHow, to prevent models' exploiting knowledge from similar articles, we split the data so that certain (sub)categories do not overlap in each split. We use only the train splits in each dataset to perform their respective pretraining. More details of the data splits are in Append. Sec. A. Preliminary studies show that joint training with both RecipeQA and WikiHow data does not necessarily improve the downstream performance, thus the models evaluated in the two datasets are trained simply using their respective training sets for faster convergence.

We cap the overall sequence length at 5 and each step description with maximally 5 sentences for both models and humans. The maximum input length per step is 60 tokens (overall maximum length $= 300$) for training and GPU memory efficiency. $\delta = 0.5$ for both ISP and PISP. All images are resized to 224×224, and 32×32 patch is used for CLIP-based models, resulting in $7 \times 7 = 49$ patches per image. Aside from standard positional embedding, we only supplement a modality token type embedding (text:=0, image:=1) to the multimodal models. Pretrained weights for each encoder is obtained either from their corresponding code bases or by running their codes on our setup.[12]

5.3 Standard Benchmark Results

Table 2 summarizes both the human and model performance for each input modality evaluated using the original ground truth orders on the golden-test-set, whereas Table 3 summarizes a more detailed breakdown of the model performance when incrementing combinations of pretraining objectives.

As is shown, multimodal information is verified consistently helpful for humans. Compared under same scenario with or without the sequence-aware pretraining, the two multimodal models consistently outperform their text-only counterparts, where the proposed pretraining technique is shown particularly effective for the patch-based multimodal model (CLIP-ViL). However, our top-performing models still exhibit significant gaps below human performance, especially in PMR.

Additionally, we observe a different trend in the two datasets where the multimodality benefits more in RecipeQA than WikiHow. The gap between the multimodal human and model performance is larger than the text-only counterparts in WikiHow, while a reversed trend is shown in RecipeQA. We hypothesize that recipes may contain more domain-specific language usages and/or less words for the pretrained language models and hence benefits more from the our in-domain sequence-aware pretraining. Humans, on the other hand, benefit more from the images in WikiHow as its texts are hypothesized to contain more ambiguities.

WikiHow Category Analysis. We are interested in knowing on which categories of WikiHow our

Table 3: **Model ablation studies:** We provide a performance breakdown for incremental combinations of the pretraining objectives, ablated on the best performing models (CLIP and CLIP-ViL) from Table 2 for each dataset and modality.

models perform closer to humans, and on which the multimodal information is most efficiently utilized. In Figure 3 we select categories with the top and least performance gaps (with PMR metric, top=3, least=2) between the human and our best performing models. We observe that the categories on which multimodal models outperform the text-only ones the most are also the categories the models perform closest to humans, *e.g. Home and Garden*. We hypothesize that the images in these categories are well complementary to the texts and that our sequence-aware grounding performs effectively. In contrast, in categories such as *Arts and Entertainment* and *Hobbies and Crafts* where humans still enjoy benefits from multimodal information, our models have difficulty utilizing the multimodal information. We hypothesize that better visual understanding may alleviate the potentially suboptimal grounding as images of these categories can contain many non-common objects.

5.4 Evaluating with Alternative Orders

For each instance where alternative ground truth orders exist, the performance is computed by the best each predicted order can obtain against all the ground truth orders[13], denoted by **multi-reference performance**, and the subset containing these instances is denoted as the **multi-reference subset**.[14]

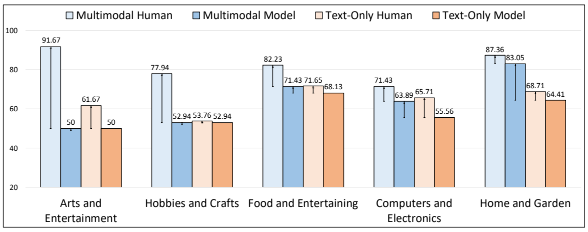

Figure 3: **Top-3 and least-2 categories of human-model performance difference (in PMR):** The selected categories have >10 samples. The difference bars on the multimodal model series are compared against the text-only model series.

Statistics. Table 5 lists the essential statistics of the multi-reference subsets, including the counts of the multi-reference instance for each dataset and modality, as well as the per-instance statistics.

Multi-Reference Performance. The noticeable main competitors in Table 2 are multimodal and text-only models, and hence for conciseness, in Table 4 we mainly report the multi-reference version

---

[13] Jointly considered from all the evaluation metrics.

[14] The overall average number of ground truth references becomes 1.19, 1.23, 1.09 for multimodal, text-only, and image-only versions in WikiHow; and 1.10, 1.17, 1.14 in RecipeQA.

$*$ The size of the **Multi.** subsets in (*text-only*, *multimodal*) are: (49, 51)/300 in WikiHow and (12, 3)/100 in RecipeQA.

Table 4: **Multi-reference performance:** († denotes human performance) Our golden-test-set can be decomposed into two subsets: **Single** where each instance in this subset only has one single originally authored ground truth, and **Multi.** where each instance features multiple ground truths from alternative orders. For the **Multi.** subset, two types of performance can be computed: **single** considers only the originally authored ground truth and **multi** computes the multi-reference performance. **All** denotes the entire test-set combining the results from **Single** and **Multi.** subsets. Results are reported on the two main competitors: multimodal and text-only using the best performing models from Table 2 in each modality. **% of instances benefit w. multi-reference** indicates that of what percentage of instances *in each multi-reference subset* humans and the models benefit (for each instance if its performance improves *in any of the metrics*) from alternative ground truth orders.

of their best performing variants with the selected metrics. Several trends still hold: (1) Multimodal models still outperform the text-only counterparts. (2) Human performance is still well above models' even under multi-reference setups. Additionally, both humans and models perform significantly worse in the multi-reference subset when single (original) ground truth is enforced, implying the validity of our alternative order annotations.

We originally hypothesize that enforcing the original authored order to be the only ground truth would be unfair to the text-only models, as images can often better represent the detailed scene changes omitted by the texts, while in reality certain steps may not need to strictly follow the authored order. Judging from the number of instances that improve after evaluating with alternative orders, the text-only model indeed benefits more from the multi-reference setup. Examining the general trends in Table 4, one can conclude that the textual contents indeed posses certain levels of ambiguities where images can help to alleviate. However, as the performance gaps between multimodal and text-only models are still significant under the multi-reference settings, advantages of multimodality. Note that humans achieve perfect performance on the multi-reference subset in RecipeQA, though unlikely it may seem, it is mainly due to recipes tend to have rarer possible alternative orders.

Modality	WikiHow (300)			RecipeQA (100)		
	Cnt	Min/Max	Avg/Std	Cnt	Min/Max	Avg/Std
Image-Only	24	2/4	2.1/1.4	13	2/3	2.1/0.3
Text-Only	49	2/6	2.4/0.9	12	2/6	2.4/1.1
Multimodal	51	2/4	2.1/0.5	3	2/6	4/1.6

Table 5: **Multi-reference subset statistics:** We report the count (cnt) of multi-reference instances in each dataset across the three modalities, and their basic statistics.

Categories	Mean Per-Instance Refs. (Cnt)		
	Multimodal	Text	Image
Home and Garden	2.00 (7)	2.14 (7)	2.00 (3)
Hobbies and Crafts	2.00 (5)	2.73 (11)	2.00 (2)
Food and Entertaining	2.20 (15)	2.22 (14)	2.17 (12)
Others	2.28 (7)	2.67 (5)	2.00 (4)
Personal Care and Style	2.33 (3)	2.00 (1)	2.00 (1)

Table 6: **Top-5 mean alternative orders by categories:** We list top-5 categories in WikiHow according to the number of average ground truth references in their multi-reference subset. We again only list the categories with total instance count >10.

WikiHow Categories. Table 6 lists the WikiHow categories with the most (top-5) annotated multi-reference ground truths. Note that the categories with more annotated alternative ground truths are also among the worse performance from both humans and models (Figure 3). We provide sample qualitative inspections in Append. Sec. C.1.

6 Related Work

Sequence Ordering. Story sequencing test is a popular way of examining children's abilities on sequential reasoning which is shown evident for procedural understanding (Tomkins, 1952; Baron-Cohen et al., 1986; Loucks et al., 2017). In NLP, existing works attempt the sequencing task as sorting a series of unordered sentences (Chen et al., 2016; Cui et al., 2018; Logeswaran et al., 2018; Oh et al., 2019; Lee et al., 2020; Calizzano et al., 2021) from paper abstracts or short paragraphs. While certain prior work also attempts to extend it to incorporate multimodality (Agrawal et al., 2016), the dataset used, Visual StoryTelling (Huang et al., 2016), features album images that were not intended to be procedural nor supply unstated details to complement the texts. In computer vision, existing work leverages shuffle frame prediction for learning video representations (Lee et al., 2017; Xu et al., 2019; Wang et al., 2020; Li et al., 2020) as well as cycle consistency constraints for learning temporal dynamics (Epstein et al., 2021). Zellers et al. (2021) also features a pairwise relative frame re-ordering objective to learn temporal common sense from scripted videos, however, as their downstream tasks mainly concern visual reasoning and ordering by frame-text-matching (also on Visual StoryTelling), the re-ordering objective is more focused on the visual modality. Our work takes a different perspective to tackle a comprehensive multimodal sequencing task with a focus on the procedural task-solving knowledge and gauging the helpfulness of complementary information in different modalities.

Task/Procedure Understanding. Other works have utilized WikiHow for learning task knowledge. In NLP, textual descriptions of WikiHow have been used for abstractive summarization (Koupaee and Wang, 2018), procedural understanding (Zhou et al., 2019; Tandon et al., 2020), and intent estimation (Zhang et al., 2020a). Prior work (Zhang et al., 2020b) considers WikiHow for learning event temporal ordering, but limited to only pairwise relations. A concurrent work uses WikiHow to infer visual goals (Yang et al., 2021). We hope our curation can help advancing the goal of comprehensive multimodal procedural understanding.

Another popular form of comprehending given procedures is through a *multiple choice* machine comprehension task. Prior work has utilized text book figures (Kembhavi et al., 2017) as a *holistic* "reading reference" for models to select the correct order of certain (textually described) events from *given multiple choices*. Another work attempts the original visual ordering task of RecipeQA (Liu et al., 2020) (also an multiple choice task). However, we argue that our task tackles a more complex task as the desired orders need to be directly derived and the event-wise complementary multimodal understanding is not an essential component in these existing works.

Multimodality. Beside models used in this work, there are several recent advanced multimodal grounding techniques (Tan and Bansal, 2019; Li et al., 2019; Lu et al., 2019; Su et al., 2020; Chen et al., 2020b; Huang et al., 2020; Wen et al., 2021). We utilize VisualBERT and CLIP-ViL for their simplicity to be adapted to our task and easier integration to our proposed pretraining techniques, however, our framework is able to incorporate any of the aforementioned multimodal models.

7 Conclusions

In this work we present studies of language and multimodal models on procedure sequencing, leveraging popular online instructional manuals. Our experiments show that both multimodality and our proposed sequence-aware pretraining are helpful for multimodal sequencing, however, the results also highlight significant gaps below human performance ($\sim$ 15% on PMR).

We provide insights as well as resources, such as the multi-reference annotations of the sequencing task, to spur future relevant research. We also anticipate that the alternative orders defined and annotated in our work can benefit more comprehensive task-procedure understanding. Future work such as predicting task steps which can be parallel or interchangeable, and understanding step dependencies can be explored.

Acknowledgments

Many thanks to Liunian Harold Li for his original CLIP-ViL implementation; to I-Hung Hsu and Zi-Yi Dou for their helpful discussion and feedback; and to the anonymous reviewers for their constructive suggestions. This material is based on research supported by the Machine Common Sense (MCS) program under Cooperative Agreement N66001-19-2-4032 with the US Defense Advanced Research Projects Agency (DARPA) and a CISCO research contract. The views and conclusions contained herein are those of the authors and should not be interpreted as necessarily representing DARPA, CISCO, or the U.S. Government.

Ethics and Broader Impacts

We hereby acknowledge that all of the co-authors of this work are aware of the provided *ACM Code of Ethics* and honor the code of conduct. This work is mainly about sequencing a given series of multimodal task procedures, represented by text descriptions along with their images. The followings give the aspects of both our ethical considerations and our potential impacts to the community.

Dataset. We collect the human performance on our sequencing task (both the standard human performance and the alternative order annotations) via Amazon Mechanical Turk (MTurk) and ensure that all the personal information of the workers involved (e.g., usernames, emails, urls, demographic information, etc.) is discarded in our dataset. While the sequence orders either from the original author intended ones or those annotated by the workers for the standard performance may possess unintended biases against certain population group of people (*e.g.* due to cultural differences or educational differences, some tasks may be performed differently from the original intended orders), we anticipate the additional multi-reference annotation can alleviate such an issue as well as provide a broader view to approach procedural understanding, *i.e.* certain task-steps can be interchanged.

This research has been reviewed by the **IRB board** and granted the status of an **IRB exempt**. The detailed annotation process (pay per amount of work, guidelines) is included in the appendix; and overall, we ensure our pay per task is above the the annotator's local minimum wage (approximately $12 USD / Hour). We primarily consider English speaking regions for our annotations as the task requires certain level of English proficiency.

Techniques. We benchmark the proposed sequencing task with the state-of-the-art large-scale pretrained language and multimodal models with our novel sequence-aware pretraining techniques. As commonsense and task procedure understanding are of our main focus, we do not anticipate production of harmful outputs, especially towards vulnerable populations, after training models on our proposed task.

A Details of Datasets

A.1 Image Contents

For simplicity and computational concerns, in this work we only pair one image to each of its associated task-step textual descriptions. However, in both WikiHow and RecipeQA, each task-step can have more than one associated images or visual contents represented by short clips or GIFs. We simply select the first image, which is supposed to be the most representative, for those step featuring multiple images; and sample the frame in the middle of time interval for clips or GIFs. Nevertheless, our framework does not assume any limitation on how many images per step to be processed.

A.2 WikiHow Categories

The category in WikiHow generally forms a hierarchical directed acyclic graph. Each category can have its relevant subcategory, which usually spans finer-granularity of category types. For example, a possible category traversal path is: *Cars and Vehicles →Public Transport →Air Travel*, which can lead to the article *How to Overcome the Fear of Flying*. We attach these full category traversal paths as an additional feature to each of the article in our dataset, and we also will provide a complete list of the taxonomy composed by all the categories and subcategories in WikiHow. We include the category-data counts in Table 7 for a reference, where we only show the top-level category here. The more in-depth categories can be referred to in the full released version of the dataset.

A.3 Train-Dev Splits

For RecipeQA we use the original data splits which ensure no identical recipe appears in more than one set (each recipe has its unique recipe-id), as this dataset only has one category and the data quality is much more uniform than that of WikiHow, *i.e.* most recipes fulfill our target dataset criteria.

For WikiHow, we split the data according to the third level category to prevent models from exploiting too similar task knowledge in the same category, where the level (three) is empirically decided. Specifically, we ensure that the third-level categories where the articles in our golden-test-set belong to, do not appear in the train set. We first split the WikiHow dataset into train, development, and test set following this strategy, and then construct our golden-test-set by sub-sampling a subset of this (larger) test set followed by manual inspections, to ensure its quality. And then, we simply join the remaining test set samples to the development set. Refer to Table 1 in the main paper for detailed statistics.

Categories	**Counts**
Arts and Entertainment	4675
Cars and Other Vehicles	2044
Computers and Electronics	15023
Education and Communications	7406
Family Life	1747
Finance and Business	6228
Food and Entertaining	7670
Health	8800
Hobbies and Crafts	9217
Holidays and Traditions	736
Home and Garden	9460
Personal Care and Style	6523
Pets and Animals	5281
Philosophy and Religion	828
Relationships	2877
Sports and Fitness	3271
Travel	746
Work World	1579
Youth	2389
Others	21

Table 7: **Top-Level Categories of WikiHow:** Number of unique articles in each top-level category of the WikiHow dataset. The categories are sorted by alphabetical order. In total there are 19 top-level categories (same as what this page indicates: https://www.wikihow.com/Special:CategoryListing), and one "others" category for standalone leaf nodes without real linkages to these top-level categories.

B Details of Human Annotation

B.1 Golden-Test-Set Selections

In order to construct a high-quality test set for humans to evaluate, we manually select the samples which meet our general criteria: (1) the tasks are procedural in both texts and images (2) the task's images are designed to complement the textual descriptions or provide a more illustrative information for some unstated implicit knowledge. We ask three of our internal members (co-authors) to perform such manual selection, and preserve ones that have majority votes. In total, we select 300 samples for WikiHow and 100 samples for RecipeQA.

B.2 General Annotation Procedure

B.2.1 Standard Performance Benchmark

We collect the human performance via Amazon Mechanical Turk (MTurk). Each MTurk worker is required to read the provided instruction carefully, as shown in Figure 5a, and then perform the task, which is designed to be done in an intuitive *drag-n-drop* (illustrated in Figure 5b) fashion.

Each MTurk HIT is designed to have five sets of sequencing tasks followed by a few additional questions such as confidence level of the worker when inferring the order, and whether different modalities are helpful in a particular task. For each unique sample in the selected golden-test-set, we construct three annotation sets each for one modality version: multimodal, text-only, and image-only. We launch the HITs containing the same sample but with different modalities with a week gap to prevent potential memorization if the same worker happens to annotate the exactly identical data sample. We estimate the time required to complete each of our HITs to be 10-15 minutes, and adjust our pay rate accordingly to \$2 or \$3 USD depending on the length of the task. This roughly equates to a \$12 to \$15 USD per hour wage, which is above the local minimum wage for the workers. In total we receive annotated HITs from around 80 workers for WikiHow, and 14 workers for RecipeQA.

In order to ensure annotation quality and filter potential MTurk spammers, we design a few sets to be our *qualification rounds* for later on worker pool selection. The Pearson correlation between the performance of the qualification samples and the overall HIT performance is 0.6 with p-value < 0.05. Since it is positive correlated and significant, we censor assignments with substantially low overall performance (<20% on accuracy metric), and relaunch the HITs containing those samples for a few more rounds for higher quality annotations.

Finally, since the agreement is sufficiently high (see Section 3.2), we simply compute the human performance using all of the collected annotated orders from all the participated workers, which result in reasonably high human performance upper bound for our proposed sequencing task.

B.2.2 Annotating Alternative Orders

We deliberately ask a different set of MTurk workers than those participated in the standard performance benchmark round for annotating the alternative orders. In total we receive HITs from around 70 workers for WikiHow, and 40 workers for RecipeQA. The monetary rewards and other general settings follow the same procedure as in the standard performance collection. We compute pairwise IAAs for each worker against every other workers, using the method described in Append. Sec. B.3, and then we place a threshold to filter out workers that tend to have too low IAAs (which is a likely indicator that a worker is either a spammer or not understanding our task well). As the final IAAs among the selected pool of workers are sufficiently high (see Section 3.2), for each instance we perform a majority vote on the annotated alternative orders to serve as the final multi-references.

B.3 Inter-Annotator Agreements (IAA)

B.3.1 Standard Performance

As orders concern not only positioning of the items but also more complicated relative information among the items in a sequence, we propose to measure the agreements among orders centering around the concept of **pairwise relationship**. Specifically, we transform an integer sequence order to an one-hot encoded representation of the $\binom{N}{2}$ pairs of relative relations. Consider an example: suppose three items (`1, 2, 3`) are to be ordered, and all the pairwise relations are {`12, 13, 21, 23, 31, 32`}. The transformed one-hot representation is defined as: R_{123} = {`12`: 1, `13`: 1, `21`: 0, `23`: 1, `31`: 0, `32`: 0} = {110100}, *i.e.* , $R(ij) = 1$ iff ij is a valid relatively ordered pair. Similarly, R_{231} = {001110}.

Using the aforementioned definition of R, we can compute Cohen's Kappa inter-annotator agreement score for a pair of annotated order per each instance. The overall scores can be computed by firstly taking the average of pairwise Kappa scores of annotations for each instance, and then taking the average across the entire dataset.

B.3.2 Alternative Orders

To evaluate the agreements for the alternative orders, we focus on the *differences* between an order and the ground truth in their transformed representations. We first compute the *one-hot difference* between an alternative order to the ground truth order, *e.g.* suppose ground truth order is simply $o_g =$`123`, and an alternative order is $o_1 =$`132`, then $R^{diff}_{o_g,o_1}$ = $abs|${110100} - {110001}$|$ = {000101}. To focus on the agreements of *the differences to the original ground truth*, we apply the Kappa score on a pair of orders by retaining the union of the positions where each order differ from the ground truth in their one-hot representations. For example, if $o_2 =$`213`, then $R^{diff}_{o_g,o_2}$ = $abs|${110100} - {011100}$|$ = {101000}, and hence the differences to the ground truth are at positions $4, 6$ from o_1 and $1, 3$ from o_2, *i.e.* the union is $\{1, 3, 4, 6\}$. Computing the Kappa scores

Algorithm 1 Alternative Order IAA Per Instance

```
Require: ${A_n}_{n=1}^{N}$: A list of annotation series, where $A_n = \{a_{n,k}\}_{k=1}^{K_n}$ denotes $K_n$ orders annotated by $n$th worker for an instance.
Require: $f(x, y)$: IAA scoring function.
Initialize $S$: empty score list
for $i$ = 1 to N do
    for $j$ = $i + 1$ to N do
        One-hot encode $\{a_{i,k}\}$, and $\{a_{j,k}\}$
        Assume $K_i < K_j$    // otherwise swap
        while $\{a_{i,k}\}$ not empty do
            Find best match according to $R^{diff}$
            $\hat{m}, \hat{n} = \arg\max_{m,n} f(R^{diff}_{o_g,o_{i,m}}, R^{diff}_{o_g,o_{j,n}})$
            $\{a_{i,k}\}$.pop($\hat{m}$); $\{a_{j,k}\}$.pop($\hat{n}$)
            $S = S \cup$ score
        end while
        while $\{a_{j,k}\}$ not empty do
            $S = S \cup f(o_g, o_{j,m})$; $\{a_{j,k}\}$.pop($m$)
        end while
    end for
end for
return mean($S$)
```

on $R^{diff}_{o_g,o_1}$ and $R^{diff}_{o_g,o_2}$ at these positions leads to computing the scores on lists {0011} and {0110}.

To compute the agreements of two series of alternative orders from two annotators (the series can have different lengths), we first iteratively find all the best matching pair of orders from the two series (each order in a series can only be matched **once**). When one series contain more orders than the other, the remaining unmatched orders will be compared to the ground truth to serve as the penalty. For a particular instance, we take the mean of all the Kappa scores (the best-matching-pair and penalty scores) as the IAA for the two annotators, as detailed in Algorithm 1. The overall IAA is computed similarly to the standard case.

B.4 Additional Statistics

Apart from the main sequencing task, we also ask the annotators for their confidence of predictions and if multimodality is helpful for deciding the order in the standard benchmark round. We hereby provide two more statistics obtained from the workers: the percentages of confidence levels and which modality (modalities) helps for deciding the order.

Modality Helps. As which modality is potentially more helpful, we include the percentages of each answer category in Table 8. It can be noticed that majority of workers (> 60%) think that multimodal (both modalities) is helpful, and especially in the recipe data, there are > 90% of workers indicating the effectiveness of utilizing multimodal inputs.

Dataset	Both	Text-Only	Image-Only	Neither
RecipeQA	90.4	1.0	8.6	0.0
WikiHow	62.9	33.7	2.4	1.0

Table 8: **Which modality helps?** We compute the percentage of each answer category. In both datasets, majority of the annotations indicate that both modality are helpful for deciding the orders.

Confidence Level	**WikiHow**	**RecipeQA**
5 (Very)	54.61	64.75
4 (Fairly)	27.38	23.00
3 (Moderately)	12.24	7.00
2 (Somewhat)	5.21	4.75
1 (Not-At-All)	0.56	0.50

Table 9: **Confidence Level Statistics (%):** In both datasets, majority (> 80%) of the annotators indicate at least > 4 (fairly) confidence level, which can help justify the validity of the human performance.

Confidence Levels. As shown in Table 9, majority of workers feel at least fairly confident (score of 4) about their predictions, which can justify the validity of our selection of golden-test-set.

C Additional Results

C.1 Qualitative Inspections

Figure 4 shows a few qualitative examples in different categories. Figure 4a shows that while step 1 and 3 may seem confusing if only looking at the texts, the images can help deciding the proper order, whereas models may fail to grasp such multimodal information in Figure 4b. In Figure 4c we show an example where multi-reference benefits both humans and the models, although in reality it should be more commonsensical to *stir* before *refrigerating* the mixtures.

C.2 Image-Only Multi-References

We also provide the detailed multi-reference performance break down on the image-only modality using the best performing models in Table 2, CLIP, in Table 10 for references.

D More Model Details

Multimodal Model Considerations. Bugliarello et al. (2020) suggests that many V&L models can

achieve similar downstream performance if well trained, and thus we consider the models presented in this work, VisualBERT and CLIP-ViL, due to their simplicity of adapting to our sequencing task, as well as their main differences being how the visual inputs are encoded (via standard object detector networks or patch-based models like CLIP), which suits our proposed objectives well.

Swapping-Based Predictions. In Section 4.2.2 we mention that we do not observe necessary improvements when swapping the textual contents. Our hypothesis is that the pairwise loss function applied in the BERSON module already takes care of this especially for the textual contents. And that the stronger discourse-level hints inherent in the textual descriptions may make this operation unnecessary. On the other hand, both image and multimodal alignment does not share this similar property with the texts, and hence this reasons why swapping the visual modality suffices this particularly pretraining objective.

D.1 Training & Implementation Details

Training Details. All the models in this work are trained on a single Nvidia A100 GPU[15] on a Ubuntu 20.04.2 operating system. The hyperparameters for each model are manually tuned against different datasets, and the checkpoints used for testing are selected by the best performing ones on

Table 12: **Search bounds** for the hyperparameters of all the models.

the held-out development set, which is constructed using the method described in Append. Sec. A.3.

Implementation Details. The implementations of the transformer-based models are extended from the HuggingFace[16] code base (Wolf et al., 2020), and our entire code-base is implemented in PyTorch.[17] The computer vision detector model used in one of our image-only encoders, ResNet-based Faster-RCNN (Ren et al., 2016), adopts the detectron2 open sourced module, and their pretrained weights are obtained from the official implementation from Facebook AI Research.[18] Implementation of BERSON modules are adapted from the original author's implementation, where more details can be found in their paper. Implementation of the VisualBERT is obtained from the *MMF*[19] framework from Facebook AI Research, and CLIP-ViL model is obtained and adapted from the original author's released code repository.[20] We use this same repository for the image-only encoder CLIP.

D.2 Hyperparameters

For the sequencing task, we train all the models for 5 or 10 (for multimodal models) epochs for all the model variants, where the training time varies from 2-4 hours for the text-only models and 6-8 hours for the multimodal models. We list all the hyperparameters used in Table 11. We also include the search bounds and number of trials in Table 12, that all of our models adopt the same search bounds and ranges of trials.

D.3 WikiHow Images

Although the images in WikiHow can often be synthetic or "cartoon-ish", we observe that modern object detectors can still propose meaningful regions, regardless of whether the object class prediction is sensible or not. We include some predicted bounding boxes in Figure 6 for references. And hence, although there may be concerns on suboptimal visual understanding from these images, we do believe both of our ResNet and CLIP visual encoders can extract reasonably useful features.

E Releases & Codes

The scraped WikiHow dataset will be released upon acceptance, along with a clearly stated documentation for usages. We will also release the code for processing the RecipeQA dataset particularly for our procedure sequencing task, where the original dataset can be obtained from their project website.[21] If permitted by the authors of the BERSON model, we will also release the cleaned code repository which encompasses the majority of the implementations in this work upon acceptance. We hope that by sharing the datasets and their essential tools, more interest could be drawn into research on multimodal procedure understanding and its future research directions.

Sequence the Events:

(Please Read) The goal of this HIT: below are 5 sets of initially randomly ordered events, sampled from several steps of our collected visual instrunctional manuals (with its title/goal specified). **We request that you put them into the proper order** that you think they should occur (or need to be performed in). We ask you to do following two things:

1. **Order the blocks:** Drag each block **in the first row** into its appropriate slot **in the second row**. As long as the color of the block changes in the bin you choose, it is a proper action. No need to perfectly fit the blocks into some bins. (But of course it is more desired.)
2. **Answer the questions:** For each set, there are some followed-up questions to be answered, make sure to put your choices for each of them.

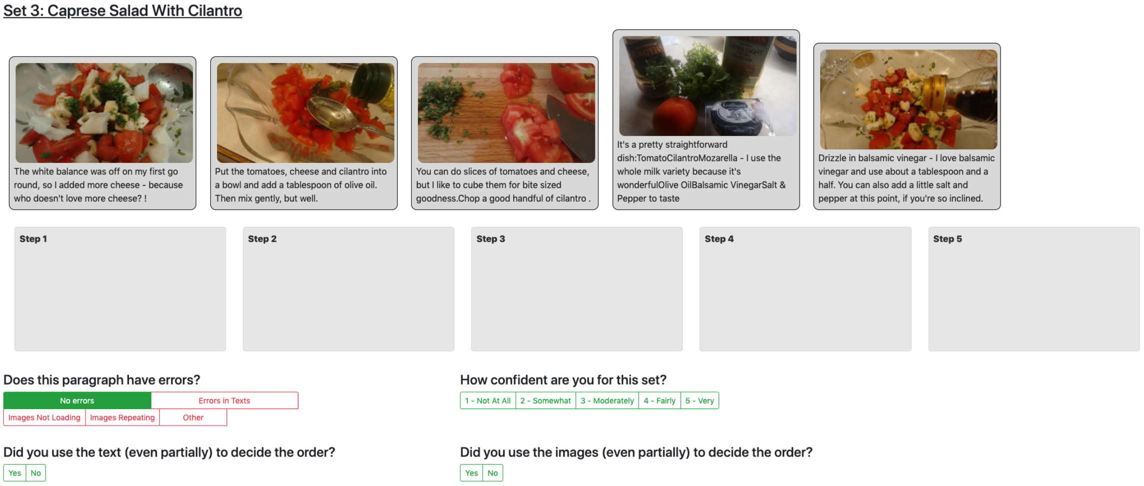
Some set may not come with images and it is intended, no need to be concerned!

NOTE[1]: If you happen to find some glitches, e.g. clickable questions overlapping, please try to stretch your browser to find the most suitable resolution.

NOTE[2]: You can try to refresh the page to resolve some glitches from the droppable boxes.

NOTE[3]: One of the (random) set is intended to be relatively simpler and used as a qualification sample to filter spamming inputs! Please try your best for each set as the rewards may be affected upon detecting spamming inputs.

(a) Human Annotation Instruction



Set 3: Caprese Salad With Cilantro

The white balance was off on my first go round, so I added more cheese - because who doesn't love more cheese? !

Put the tomatoes, cheese and cilantro into a bowl and add a tablespoon of olive oil. Then mix gently, but well.

You can do slices of tomatoes and cheese, but I like to cube them for bite sized goodness.Chop a good handful of cilantro .

It's a pretty straightforward dish:TomatoCilantroMozarella - I use the whole milk variety because it's wonderfulOlive OilBalsamic VinegarSalt & Pepper to taste

Drizzle in balsamic vinegar - I love balsamic vinegar and use about a tablespoon and a half. You can also add a little salt and pepper at this point, if you're so inclined.

Does this paragraph have errors?

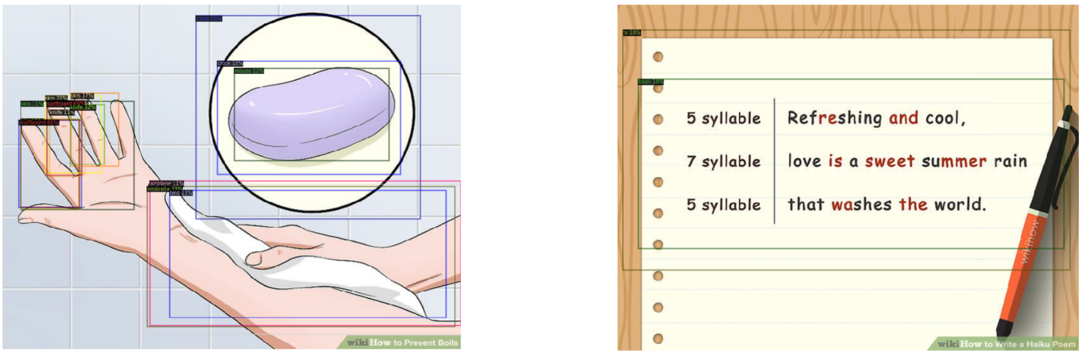
How confident are you for this set?

Did you use the text (even partially) to decide the order?

Did you use the images (even partially) to decide the order?

(b) Sample Annotation Interface

Figure 5: **MTurk Annotation User Interface: (a)** We ask the annotator to follow the indicated instruction, and perform the sequencing task. **(b)** The annotation task is designed for an intuitive *drag-and-drop* usage, followed by a few additional questions such as confidence level and whether each modality helps. (This example is obtained from RecipeQA dataset.)



(a) Detected Image Regions 1

(b) Detected Image Regions 2

Figure 6: **Proposed image regions by Detectron2:** We show some examples that even these synthetic and cartoon-ish images in the WikiHow dataset can provide meaningful representations which can be utilized by strong pretrained object detection modules. We show few top-detected objects with their bounding boxes and predicted classes. Note that while the classes may be wrongly predicted, the proposed regions are all meaningful.

Zoom Out and Observe: News Environment Perception for Fake News Detection

Qiang Sheng, Juan Cao*, Xueyao Zhang, Rundong Li, Danding Wang, Yongchun Zhu

Abstract

Fake news detection is crucial for preventing the dissemination of misinformation on social media. To differentiate fake news from real ones, existing methods observe the language patterns of the news post and "zoom in" to verify its content with knowledge sources or check its readers' replies. However, these methods neglect the information in the external *news environment* where a fake news post is created and disseminated. The news environment represents recent mainstream media opinion and public attention, which is an important inspiration of fake news fabrication because fake news is often designed to ride the wave of popular events and catch public attention with unexpected novel content for greater exposure and spread. To capture the environmental signals of news posts, we "zoom out" to observe the news environment and propose the News Environment Perception Framework (NEP). For each post, we construct its macro and micro news environment from recent mainstream news. Then we design a popularity-oriented and a novelty-oriented module to perceive useful signals and further assist final prediction. Experiments on our newly built datasets show that the NEP can efficiently improve the performance of basic fake news detectors.[1]

1 Introduction

The wide spread of fake news on online social media has influenced public trust (Knight Foundation, 2018) and poses real-world threats on politics (Fisher et al., 2016), finance (ElBoghdady, 2013), public health (Naeem and Bhatti, 2020), etc. Under such severe circumstances, automatically detecting fake news has been an important countermeasure in practice.

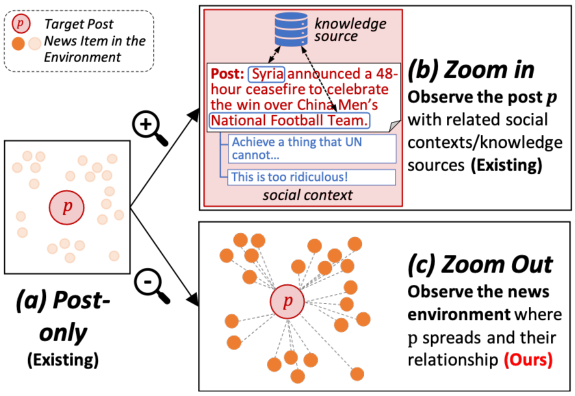

Figure 1: Existing methods for fake news detection rely on (a) the post content itself and (b) related post-level signals like social context and knowledge. Unlike (a) and (b), our method captures (c) signals from *news environments*.

Besides directly observing the post's content patterns (Volkova et al., 2017; Wang et al., 2018) (Figure 1(a)), most existing methods for fake news detection "zoom in" for finding richer post-level signal by checking user replies to the post (Shu et al., 2019a; Zhang et al., 2021) and verifying the claim with knowledge sources (Popat et al., 2018; Wang et al., 2020) (Figure 1(b)). However, these methods neglect a different line of "zooming out" to observe the external *news environment* where a fake news post is created and disseminated. Our starting point is that a news environment, which represents recent mainstream media opinion and public attention, is an important inspiration of the fabrication of contemporary fake news. Since any gains of fake news achieve only if it widely exposes and virally spreads, a fake news creator would carefully design how to improve the post's visibility and attract audiences' attention in the context (environment) of recently published news. Such intentional design connects fake news with its news environment and conversely, we might find useful signals from the news environment to better characterize and detect fake news.

Figure 2 shows an example, where we name the whole set of recent news items the *macro* news environment and the event-similar subset as the

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 4543 - 4556

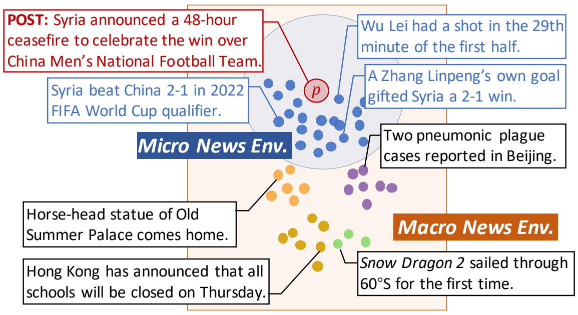

Figure 2: A fake news post p and its news environment containing recent news items in three days (2019/11/12 to 2019/11/14). Only the items in events that are reported multiple times (differentiated by dot colors) are displayed for brevity. We can see that p falls in a *popular* event on a Syria-China World Cup qualifier compared with other events and focuses on a *novel* aspect (unusual celebration in Syria).

micro news environment. For the fake news post p on Syria's ceasefire thanks to a win over China in a football match, we observe two important signals from its news environments:

1) Popularity. In the *macro* news environment that contains all recent news items, p is related to a relatively popular event (Syria-China football match) among the five events in different domains. This would bring p greater exposure and further greater impact.

2) Novelty. In the *micro* news environment, the items mostly focus on the game itself (e.g., "Wu Lei had a shot"), while p provides novel side information about Syria's unusual celebration. This would help catch audiences' attention and boost the spread of p (Vosoughi et al., 2018).

Unfortunately, these potentially useful signals could be hardly considered by post-only and "zoom-in" methods, as they focus on digging in the direction towards inherent properties of a single post (e.g., styles, emotions and factual correctness), rather than observing the surrounding environments of the post.

To enable fake news detection systems to exploit information from news environments, we propose the News Environment Perception Framework (NEP). As presented in Figure 3, for the post p, we construct two news environments, MacroEnv and MicroEnv, using recent mainstream news data to facilitate the perception from different views. We then design a popularity-oriented and a novelty-oriented perception module to depict the relationship between p and these recent news items. The environment-perceived vectors are fused into an existing fake news detector for prediction.

Our contributions are as follows:

- **Problem**: To the best of our knowledge, we are the first to incorporate news environment perception in fake news detection.
- **Method**: We propose the NEP framework which exploits the perceived signals from the macro and micro news environments of the given post for fake news detection.
- **Data & Experiments**: We construct the first dataset which includes contemporary mainstream news data for fake news detection. Experiments on offline and online data show the effectiveness of NEP.

2 Related Work

Fake news detection is mostly formulated as a binary classification task where models are expected to accurately judge the given post as real or fake. Existing works focus on discovering distinctive features *in* the post from various aspects as Figure 2 shows, which we roughly group them as:

Post-only methods aim at finding shared patterns in appearances across fake news posts (Figure 1(a)). Text-based studies focus on better constructing features based on sentiment (Ajao et al., 2019), writing style (Przybyla, 2020), language use (Volkova et al., 2017), discourse (Karimi and Tang, 2019), etc. Other works rely on deep neural models to encode contents and handle certain scenarios, such as visual-based (Qi et al., 2019; Cao et al., 2020), multi-modal (Wang et al., 2018; Qi et al., 2021) and multi-domain (Nan et al., 2021) detection. Our NEP provides additional news environmental information and can coordinate with post-only methods (will show in Section 4).

"Zoom-in" methods introduce related sources to understand the post delicately. One line is to use *social contexts* (bottom of Figure 1(b)). Some directly analyze the network information to find patterns shaped by user relationship and information diffusion (Shu et al., 2019b; Zhou and Zafarani, 2019; Nguyen et al., 2020; Silva et al., 2021), and others leverage collective wisdom reflected by user responses (Ma et al., 2018; Kochkina et al., 2018; Shu et al., 2019a; Zhang et al., 2021). For example, a refuting reply saying *"FYI, this is false"* would be an important reference to make a prediction. Another line refers to *knowledge sources* (top of Figure 1(b)) and aims at verifying the post with retrieved evidence for detection. The knowledge sources can be webpages (Popat et al., 2018; Ma

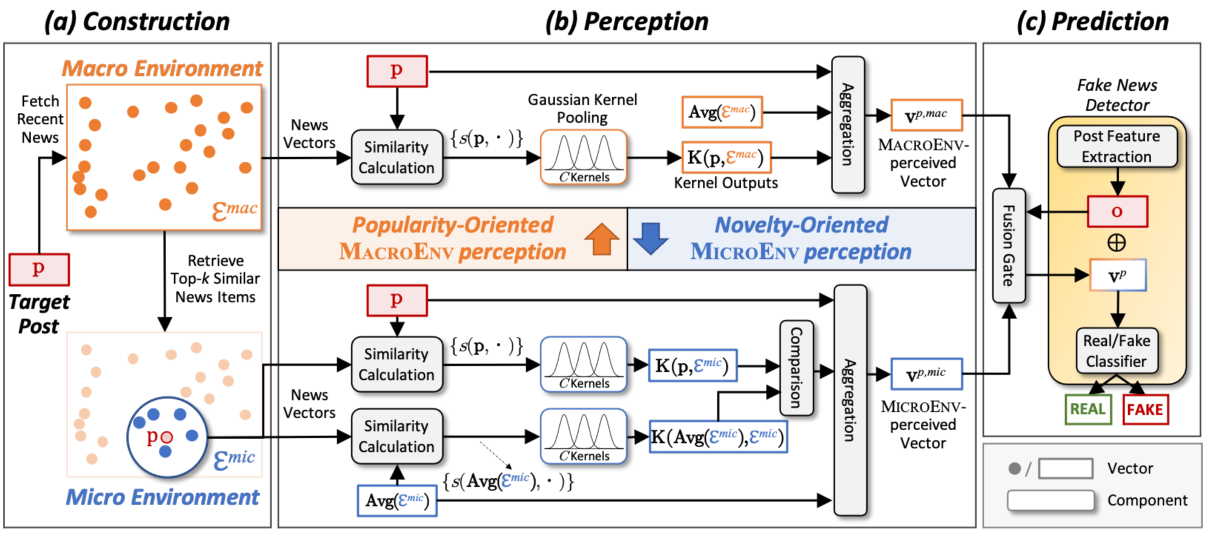

Figure 3: Architecture of the News Environment Perception Framework (NEP). **(a) Construction:** The macro and micro news environments (MACROENV and MICROENV) of the target post p (whose representation vector at the construction and perception stages is $\mathbf{p}$) are constructed using recent mainstream news items. **(b) Perception:** We perceive p's popularity in the MACROENV and novelty in the MICROENV based on the outputs of Gaussian Kernel Pooling ($\mathbf{K}$) which counts on similarities ($\{s(\cdot,\cdot)\}$) in a soft manner. This results in two environment-perceived vectors, $\mathbf{v}^{p,mac}$ and $\mathbf{v}^{p,mic}$. **(c) Prediction:** Environment-perceived Vectors are fused with a gate guided by the extracted post feature $\mathbf{o}$ (does not necessarily equal $\mathbf{p}$) from the fake news detector such as EANN (Wang et al., 2018), BERT (Devlin et al., 2019), and others. Fused $\mathbf{v}^p$ and $\mathbf{o}$ are fed into the final classifier (typically, an MLP) for prediction of p being fake or real.

et al., 2019; Vo and Lee, 2021; Wu et al., 2021; Sheng et al., 2021b), knowledge graphs (Cui et al., 2020), online encyclopedias (Thorne et al., 2018; Aly et al., 2021), fact-checking article bases (Augenstein et al., 2019; Shaar et al., 2020), etc. Our NEP starts from a different view, for it "zooms out" to observe the news environment where the post spreads. Note that our method is *not equivalent* to a knowledge-based method that uses news environments as evidence bases, as it does not pick evidential news items to prove or disprove the given post, but aims at reading the news "atmosphere" when the post is published. In that sense, "zoom-in" and "zoom-out" methods can actually be integrated for comprehensively detecting fake news (will also show in Section 4).

3 Proposed Method

Figure 3 overviews our proposed framework NEP, whose goal is to empower fake news detectors with the effective perception of news environments. Given a post p, we first construct its macro and micro environment (MACROENV and MICROENV) using recent news data. Then we model the post-environment relationships to generate environment-perceived vectors $\mathbf{v}^{p,mac}$ and $\mathbf{v}^{p,mic}$. Finally, the two vectors are fused with post representation $\mathbf{o}$ derived from the fake news detector to predict if p is real or fake.

3.1 News Environment Construction

The environment is the objects, circumstances, or conditions by which one is surrounded (Merriam-Webster, 2021). Accordingly, a news environment should contain news reports which can reflect the present distribution of mainstream focuses and audiences' attention. To this end, we collect news items published by *mainstream media outlets* as basic environmental elements, in that their news reports generally face a large, common audience.

Let $\mathcal{E}$ be the set of all collected news items published earlier than p. We construct a macro environment (MACROENV) and a micro environment (MICROENV), which are defined as follows:

- MACROENV is the set of news items in $\mathcal{E}$ released within T days before p is published:
  $$\mathcal{E}^{mac} = \{e : e \in \mathcal{E}, 0 < t_p - t_e \le T\}, \quad (1)$$
  where t_p and t_e respectively denote the publication date of p and the news item e.
- MICROENV is the set of news items in $\mathcal{E}^{mac}$ that are relevant to p. Here, we query $\mathcal{E}^{mac}$ using p and obtain the top k as the set:
  $$\mathcal{E}^{mic} = \{e : e \in \text{Topk}(p, \mathcal{E}^{mac})\}, \quad (2)$$

where $k = \lceil r|\mathcal{E}^{mac}|\rceil$ and $r \in (0, 1)$ determines the proportion.

Intuitively, the time-constrained environment MACROENV provides a macro perspective of what the mass audience read and focus on recently, while the further relevance-constrained one MICROENV describes the distribution of items about similar events. We use a pretrained language model $\mathcal{M}$ (e.g., BERT (Devlin et al., 2019)) to obtain the post/news representation. For p or each item in the macro/micro environment e, the initial representation is the output of $\mathcal{M}$ for the [CLS] token:

$$\mathbf{p} = \mathcal{M}(p), \quad \mathbf{e} = \mathcal{M}(e). \tag{3}$$

3.2 News Environment Perception

The perception of news environments of p is to capture useful signals from existing mainstream news items. The signals are expected to discover unique post-environment interactive patterns of fake news. Starting from the motivation of fake news creators to widely diffuse fabricated information to the whole online news ecosystem, we guide the model to perceive from two important diffusion-related perspectives, i.e., popularity and novelty, in the MACROENV and the MICROENV.

Popularity-Oriented MACROENV Perception. A fabricated post would be more likely to go viral and thus gain more influence when it is related to trending news. Thus, a fake news creator might consider how to chase clouts of hot events during writing a fake news post. Here we consider how popular the main event of p is in the MACROENV. We transform the perception of popularity into the similarity estimation between p and individual news items. That is, if many items in the MACROENV are similar to p, then p might be also popular in such an environment. Following (Reimers and Gurevych, 2019), we first calculate cosine similarity between $\mathbf{p}$ and each news item (say, i) in $\mathcal{E}^{mac}$:

$$s(\mathbf{p}, \mathbf{e}_i) = \frac{\mathbf{p} \cdot \mathbf{e}_i}{\|\mathbf{p}\| \|\mathbf{e}_i\|}. \tag{4}$$

The similarity list $\{cos(\mathbf{p}, \mathbf{e}_i)\}_{i=1}^{|\mathcal{E}^{mac}|}$ of variable length $|\mathcal{E}^{mac}|$ does not work well with networks mostly taking fixed-dimensional vectors as inputs. Thus, the list requires a further transformation, where we expect the transformed environment-perceived vector to reflect how similar p is to the environment without much information loss. Following (Xiong et al., 2017; Liu et al., 2020), we here choose to calculate a soft *counting* on the list to obtain a distribution that mimics a hard bin plot. Specifically, we employ a Gaussian Kernel Pooling proposed in (Xiong et al., 2017) across the range of cosine similarity to get soft counting values. Assuming that we use C kernels $\{\mathbf{K}_i\}_{i=1}^{C}$, the output of k-th kernel is:

$$\mathbf{K}_k^i = \exp\left(-\frac{(s(\mathbf{p}, \mathbf{e}_i) - \mu_k)^2}{2\sigma_k^2}\right), \tag{5}$$

$$\mathbf{K}_k(\mathbf{p}, \mathcal{E}^{mac}) = \sum_{i=1}^{|\mathcal{E}^{mac}|} \mathbf{K}_k^i, \tag{6}$$

where μ_k and σ_k is the mean and width of the k-th kernel. In Eq. (5), if the similarity between $\mathbf{p}$ and $\mathbf{e}$ is close to μ_k, the exponential term will be close to 1; otherwise to 0. We then sum the exponential terms with Eq. (6). This explains why a kernel is like a soft counting bin of similarities. We here scatter the means $\{\mu_k\}_{k=1}^{C}$ of the C kernels in $[-1, 1]$ to completely and evenly cover the range of cosine similarity. The widths are controlled by $\{\sigma_k\}_{k=1}^{C}$. Appendix B.1 provides the details. A C-dim similarity feature in the MACROENV is obtained by concatenating all kernels' outputs and normalizing with the summation of the outputs:

$$\mathbf{K}(\mathbf{p}, \mathcal{E}^{mac}) = \mathrm{Norm}\left(\bigoplus_{k=1}^{C} \mathbf{K}_k(\mathbf{p}, \mathcal{E}^{mac})\right), \tag{7}$$

where $\bigoplus$ is the concatenation operator and $\mathrm{Norm}(\cdot)$ denotes the normalization.

By calculating $\mathbf{K}(\mathbf{p}, \mathcal{E}^{mac})$, we obtain a soft distribution of similarities between p and the MACROENV as the perception of popularity. To enrich the perceived information, we generate the MACROENV-perceived vector for p by fusing the similarity and semantic information. Specifically, we aggregate the post vector, the center vector of the MACROENV $\mathbf{m}(\mathcal{E}^{mac})$ (by averaging all vectors), and the similarity feature using an MLP:

$$\mathbf{v}^{p,mac} = \mathrm{MLP}(\mathbf{p} \oplus \mathbf{m}(\mathcal{E}^{mac}) \oplus \mathbf{K}(\mathbf{p}, \mathcal{E}^{mac})). \tag{8}$$

Novelty-Oriented MICROENV Perception. Different from MACROENV, MICROENV contains mainstream news items close to $\mathbf{p}$, which indicates that they are likely to share similar events. However, even in a popular event, a post may still be not attended if it is *too* similar to others. Vosoughi et al. (2018) found that false news was more novel than true news on Twitter with the reference to the tweets that the users were exposed to (could be regarded as a user-level news environment). This might explain why fake news spread "better". We thus consider how novel p is in the event-similar MICROENV.[2]

If the content of a post is novel, it is expected to be an outlier in such an event. Here, we use the center vector $\mathbf{m}(\mathcal{E}^{mic})$ of MICROENV as a reference. Specifically, we again use Eqs. (5) to (7), but here, calculate *two* similarity features $\mathbf{K}(\mathbf{p}, \mathcal{E}^{mic})$ and $\mathbf{K}(\mathbf{m}(\mathcal{E}^{mic}), \mathcal{E}^{mic})$. The latter serves as a reference for the former and facilitates the model "calibrate" its perception. The generation of the MICROENV-perceived vector for p is as follows:

$$\mathbf{u}^{sem} = \mathrm{MLP}(\mathbf{p} \oplus \mathbf{m}(\mathcal{E}^{mic})), \tag{9}$$

$$\mathbf{u}^{sim} = \mathrm{MLP}(\mathrm{g}(\mathbf{K}(\mathbf{p}, \mathcal{E}^{mic}), \mathbf{K}(\mathbf{m}(\mathcal{E}^{mic}), \mathcal{E}^{mic}))), \tag{10}$$

$$\mathbf{v}^{p,mic} = \mathrm{MLP}(\mathbf{u}^{sem} \oplus \mathbf{u}^{sim}), \tag{11}$$

where the comparison function $\mathrm{g}(\mathbf{x}, \mathbf{y}) = (\mathbf{x} \odot \mathbf{y}) \oplus (\mathbf{x} - \mathbf{y})$ and $\odot$ is the Hadamard product operator. $\mathbf{u}^{sem}$ and $\mathbf{u}^{sim}$ respectively aggregate the semantic and similarity information. The MLPs are individually parameterized. We omit their index numbers in the above equations for brevity.

3.3 Prediction under Perceived Environments

As our environment perception does not necessarily depend on a certain detection model, we expect our NEP to have a good compatibility with various fake news detectors. In our NEP, we achieve this by gate fusion. Take a post-only detector as an example. We apply the gate mechanism for adaptively fusing $\mathbf{v}^{p,mac}$ and $\mathbf{v}^{p,mic}$ according to $\mathbf{o}$:

$$\mathbf{v}^{p} = \mathbf{g} \odot \mathbf{v}^{p,mac} + (\mathbf{1} - \mathbf{g}) \odot \mathbf{v}^{p,mic}, \tag{12}$$

where the gating vector $\mathbf{g} = \mathrm{sigmoid}(\mathrm{Linear}(\mathbf{o} \oplus \mathbf{v}^{p,mac}))$, sigmoid is to constrain the value of each element in $[0, 1]$, and $\mathbf{o}$ denotes the last-layer feature from a post-only detector.[3] $\mathbf{o}$ and $\mathbf{v}^{p}$ are further fed into an MLP and a softmax layer for final prediction:

$$\hat{\mathbf{y}} = \mathrm{softmax}(\mathrm{MLP}(\mathbf{o} \oplus \mathbf{v}^{p})). \tag{13}$$

When working with more complex detectors that rely on other sources besides the post, we can simply concatenate those feature vectors in Eq. (13). For example, we can concatenate $\mathbf{v}^{p}$ with the post-article joint representation if the fake news detector is knowledge-based. During training, we minimize the cross-entropy loss.

Table 1: Statistics of the datasets.

Dataset	Chinese			English		
	Train	Val	Test	Train	Val	Test
#Real	8,787	5,131	5,625	1,976	656	661
#Fake	8,992	4,923	5,608	1,924	638	628
Total	17,779	10,054	11,233	3,900	1,294	1,289
#News Items	583,208			1,003,646		
Min/Avg/Max of $\lvert\mathcal{E}^{mac}\rvert$ in 3 days	41 / 505 / 1,563			308 / 1,614 / 2,211		

4 Experiment

We conduct experiments to answer the following evaluation questions:

- **EQ1:** Can NEP improve the performance of fake news detection?
- **EQ2:** How effective does the NEP model the macro and micro news environments?
- **EQ3:** In what scenarios do news environments help with fake news detection?

4.1 Datasets

We integrated existing datasets in Chinese and English and then collected news items released in the corresponding time periods. The reasons why we do not use a single, existing dataset include 1) no existing dataset provides the contemporary news items of verified news posts to serve as the elements in news environments; 2) most datasets were collected in a short time period and some suffer from a high class imbalance across years.[4] The statistics are shown in Table 1 and the details are as follows:

Chinese Dataset

Post: We merged the non-overlapping parts of multiple Weibo datasets from (Ma et al., 2016) (excluding those unverified), (Song et al., 2019), (Zhang et al., 2021) and (Sheng et al., 2021a) to achieve a better coverage of years and avoid spurious correlation to specific news environments (e.g., one full of COVID-19 news). To balance the post amount of real/fake classes across the years, we added news posts verified by a news verification system NewsVerify[5] and resampled the merged

---

[2] We perceive the novelty in the MICROENV rather than the MACROENV to mitigate the effects of event shift.

[3] Empirically, we take the output of one of the last few dense layers whose dimensionality is moderate.

[4] For example, Weibo-20 (Zhang et al., 2021) is roughly balanced as a whole but has a ratio of 5.2:1 between real and fake news samples in 2018.

set. The final set contains 39,066 verified posts on Weibo ranging from 2010 to 2021.

News Environment: We collected the news items from the official accounts of six representative mainstream news outlets that have over 30M followers on Weibo (see sources in Appendix A). The further post-processing resulted in 583,208 news items from 2010 to 2021.

English Dataset

Post: Similarly, we merged the datasets from (Kochkina et al., 2018) (excluding unverified), (Augenstein et al., 2019) (excluding those without claim dates), and (Shaar et al., 2020). For posts or claims from fact-checking websites, we used the provided claim dates instead of the publication dates of the fact-checking articles, to avoid potential data contamination where the later news environment is more likely to contain corresponding fact-checking news and support direct fact verification. We obtained 6,483 posts from 2014 to 2018 after dropping the posts labeled as neutral and re-sampling.

News Environment: We use news headlines (plus short descriptions if any) from Huffington Post, NPR, and Daily Mail as the substitute of news tweets due to the Twitter's restriction (see sources in Appendix A). The bias rates of the three outlets are respectively left, center, and right according to AllSides Media Bias Chart[6], for enriching the diversity of news items. We preserved the news headlines from 2014 to 2018 and obtained a set of 1,003,646 news items.

4.2 Experimental Setup

Base Models Technically, our NEP could coordinate with any fake news detectors that produce post representation. Here we select four post-only methods and two "zoom-in" (knowledge-based) methods as our base models.[7]

Post-Only: 1) Bi-LSTM (Graves and Schmidhuber, 2005) which is widely used to encode posts in existing works (Shu et al., 2019a; Karimi and Tang, 2019); 2) EANN$_{\text{T}}$ (Wang et al., 2018) which uses adversarial training to remove event-specific features obtained from TextCNN (Kim, 2014); 3) BERT (Devlin et al., 2019); 4) BERT-Emo (Zhang et al., 2021) which fuses a series of emotional features with BERT encoded features for classification (publisher emotion version).[8]

"Zoom-in": 1) DeClarE (Popat et al., 2018) which considers both the post and retrieved documents as possible evidence; 2) MAC (Vo and Lee, 2021) which build a hierarchical multi-head attention network for evidence-aware detection.

Implementation Details We obtained the sentence representation from SimCSE (Gao et al., 2021) based on pretrained BERT models in the *Transformers* package (Wolf et al., 2020)[9] and were

---

[6] `https://www.allsides.com/media-bias/media-bias-ratings`

[7] We do not select social context-based methods because it would be impractical to integrate our NEP with them at the cost of timeliness, for the model has to wait for the accumulation of user responses/reposts. We suppose that an asynchronous integration at the *system* level (using post-only/knowledge-based methods with NEP to obtain instant predictions, and update the results later) would be an option, which is beyond our scope.

[8] As our work is based on the post text, we use the text-only variant of the original EANN that excludes the image modality and the publisher-emotion-only variant in (Zhang et al., 2021) that excludes the social emotion features.

post-trained on collected news items. We frozed SimCSE when training NEP. For DeClarE and MAC, we prepared at most five articles in advance as evidence for each post by retrieving against fact-checking databases.[10] In environment modeling, $T = 3$, $r = 0.1$, and $C = 22$. We limit $|\mathcal{E}^{mac}| \geq 10$. We implemented all methods using PyTorch (Paszke et al., 2019) with AdamW (Loshchilov and Hutter, 2019) as the optimizer. We reported test results w.r.t. the best validation epoch. Appendix B provides more implementation details.

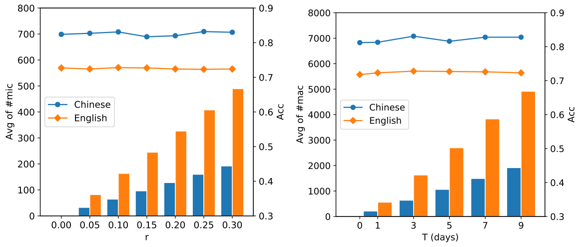
Evaluation Metrics. As the test sets are roughly balanced, we here report accuracy (Acc.), macro F1 score (macF1) and the F1 scores of fake and real class (F1_{fake} and F1_{real}). We will use a new metric for skewed test data (see Section 5).

4.3 Performance Comparison (EQ1)

Table 2 shows the performance of base models with and without the NEP on the two datasets. We have the following observations:

First, with the help of our NEP, all six base models see an performance improvement in terms of accuracy and macro F1. This validates the effectiveness and compatibility of NEP.

Second, for post-only methods, F1_{fake} generally benefits more than F1_{real} when using NEP, which indicates that news environments might be more helpful in highlighting the characteristics of fake news. This is a practical property of the NEP as we often focus more on the fake news class.



(a) Proportion Factor r (b) Day Difference T

Figure 4: Effects of (a) the proportion factor r and (b) the day difference T. Lines show the accuracies and bars show the average numbers of news items in the micro/macro environments.

Third, the "zoom-in" knowledge-based methods outperform their corresponding post-only base model (here, Bi-LSTM) with the help of relevant articles, but the improvement is small. This might be led by the difficulty of finding valuable evidence. Our NEP brings additional gains, indicating that the information perceived from news environments is different from verified knowledge, and they play complementary roles.

4.4 Evaluation on Variants of NEP (EQ2)

Ablation Study. We have two ablative groups as shown in Table 3:

w/o Fake News Detector: We directly use one of the two environment-perceived vectors or both to see whether they can work when not cooperating with the fake news detector's output $\mathbf{o}$. The macro F1 scores on both datasets indicate their moderate effectiveness as sole inputs, and that coordinating with a post-only detector is a more practical setting.

w/o Environment Perception Modules: By respectively removing MacroEnv and MicroEnv from the best-performing models BERT-Emo+NEP and DeClarE+NEP, we see a performance drop in macro F1 when removing either of them, indicating

---

[10] We attempted to collect webpages using our posts as queries as Popat et al. (2018) did but rare ones could serve as evidence except fact-checking articles. As an alternative, we directly used articles from (Sheng et al., 2021a) for Chinese and collected ~8k articles from a well-known fact-checking website `Snopes.com` for English.

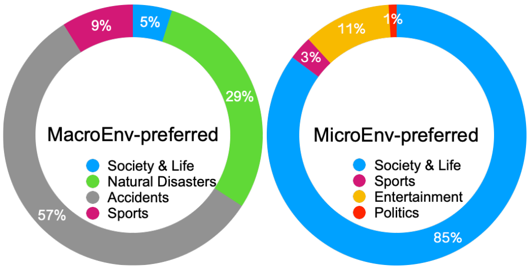


Figure 5: Categories of MACROENV- and MICROENV-preferred samples.

that the two environments are both necessary and play complementary roles in detection.

Effects of the proportion factor r for the MICROENV. We adjusted r from 0.05 to 0.30 with a step of 0.05 on BERT-Emo+NEP to see the impact of the scale of the MICROENV ($T = 3$). As Figure 4(a) shows, the change of r leads to an increase on the size of the MICROENV, but only fluctuations w.r.t. the accuracy. We do not see significant improvement after $r = 0.1$. We speculate that a too small r may hardly cover enough event-similar items while a large r may include much irrelevant information, bringing little gains (e.g., $r = 0.3$ in Chinese) or even lowering the performance (e.g., $r = 0.15$ for both datasets).

Effects of the day difference T for the MACROENV. We set $T = 1, 3, 5, 7, 9$ on BERT-Emo+NEP to see how many days of news items to be considered is proper ($T = 0$ exactly corresponds to the base model). Figure 4(b) shows a tendency similar to (a). We find the highest accuracy when $T = 3$ on both of the two datasets. This is reasonable as the popularity should be considered in a moderately short time interval to allow the events to develop but not to be forgotten.

4.5 Environment Analysis (EQ3)

Categorization of macro- and micro-preferred samples. We selected the top 1% of Chinese fake news samples which NEP relies more on MACROENV or MICROENV according to the gate vectors. Then we manually categorized these samples to probe what information the macro/micro environment might provide. From Figure 5, we see that MACROENV is more useful for samples about natural disasters and accidents (e.g., earthquakes and air crashes), while MICROENV works effectively in Society & Life (e.g., robbery and education). This is in line with our intuition: MACROENV-preferred fake news posts are often related to sensational events, so the popularity in MACROENV would help more; and MICROENV-preferred ones are often related to common events in daily news, and thus its novelty in MICROENV would be highlighted. This analysis would deepen our understanding on the applicability of different news environments.

Case study. Figure 6 shows three fake news cases in different scenarios. Case (a) relies more on MICROENV than MACROENV. We can see moderate popularity of its event about Huawei but the message about HarmonyOS is novel among the items on the 5G and cooperations. In contrast, the admit card in case (b) is moderately novel but Gaokao is the most popular event, so the NEP puts higher weight on MACROENV. Case (c) is a popular and novel fake news about Japan's great healthcare for citizens coming back from Wuhan which is posted during the first round of COVID-19 pandemic in China. The exploitation of both-side information makes a tie between the two environments. These cases intuitively show how NEP handles different scenarios. We incorporate further analysis on the case that the news environment might be ineffective in Appendix D.

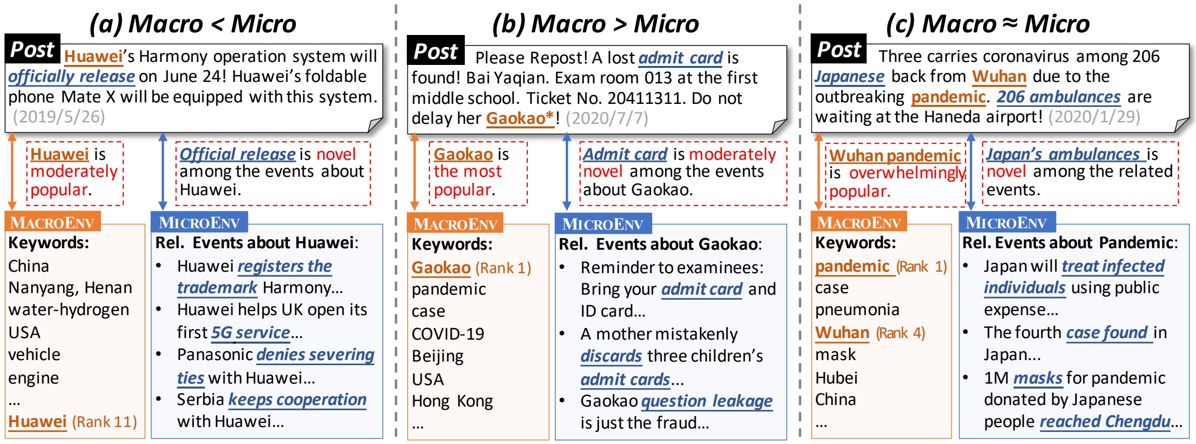
5 Discussion in Practical Systems

Evaluation on skewed online data. We tested BERT-Emo and BERT-Emo+NEP on a dump of seven-month data from a Chinese fake news detection system. Different from offline datasets, this real-world set is highly skewed (30,977 real vs. 309 fake, roughly 100:1).[11] Under such skewed circumstance, some metrics we used in Tables 2 and 3 could hardly show the differences of performances among models (e.g., a model predicting all samples as real will have an incredible accuracy of 0.990). Here, we report macro F1 and standardized partial AUC with false positive rate of at most 0.1 ($\text{spAUC}_{\text{FPR}\leq 0.1}$, McClish, 1989, see Appendix C for the calculation detail) under different real/fake ratios (from 10:1 to 100:1). As shown in Figure 7, NEP brings relative improvements of 16.89% and 5.20% in macF1 and $\text{spAUC}_{\text{FPR}\leq 0.1}$, showing its effectiveness in skewed, real scenarios.

Friendliness to Practical Systems. The NEP is not only a new direction for fake news detection but also inherently friendly to practical systems: **1) Timeliness.** Our NEP works *instantly* as it only requires the post and mainstream news published a few days before. In practice, a system would not

---

[11] The online test set and the offline sets do not intersect.



*Gaokao: National College Entrance Examination in China.

Figure 6: Three fake news cases with different preferences on environmental information. Underlined regular words hit the keywords in the MacroEnv and *underlined italic* words are related to the MicroEnv. Keywords are extracted using TextRank (Mihalcea and Tarau, 2004).

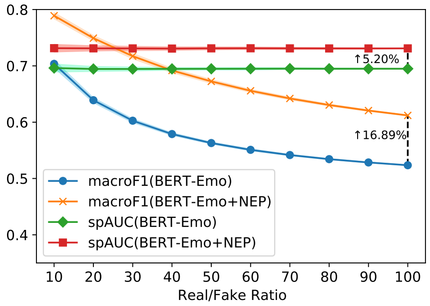


Figure 7: Macro F1s and spAUCs on the online data in different real/fake ratios. We sampled 100 times from the 100:1 set for each fo the first nine ratios. Shadows show the standard deviations. The percentages denote relative improvements using the NEP.

construct the required collection on demand but prepare it ahead by maintaining a queue of news items. **2) Compatibility.** Our perception module can be integrated with existing methods, which we validated on six representative ones (Table 2). **3) Data Accessibility.** The data to construct news environments is easy to access, especially compared with obtaining credible knowledge sources. The advantages may encourage the deployment of NEP into practical systems.

6 Conclusion and Future Work

We proposed the NEP to observe news environments for fake news detection on social media. We designed popularity- and novelty-oriented perception modules to assist fake news detectors. Experiments on offline and online data show the effectiveness of NEP in boosting the performance of existing models. We drew insights on how NEP help to interpret the contribution of macro and micro environment in fake news detection.

As this is the first work on the role of news environments for fake news detection, we believe further exploration is required for a deeper understanding of the effects of news environments and beyond. In the future, we plan to explore: 1) including historical news or background to handle posts weakly related to the present environment; 2) modeling post-environment relationships with diverse similarity metrics or even from other perspectives; 3) investigating the effects of different news environments (e.g., biased vs. neutral ones) to make the environment construction more principled; 4) extending this type of methodology from the text-only detection to multi-modal and social graph-based detection.

Acknowledgements

The authors thank Guang Yang, Peng Qi, Zihao He, and anonymous reviewers for their insightful comments. This work was supported by the Zhejiang Provincial Key Research and Development Program of China (No. 2021C01164).

Ethical Considerations

Application. Our framework does not present direct societal consequence and is expected to benefit the defense against the fake news issue. It can serve as a detection module for fake news detection systems, especially when the given post is closely related to the events that happened recently, with no need to wait for the accumulation of user responses or query to knowledge sources. Due to the requirement of real-time access to open news sources (source list can be determined as needed), it might be easier to deploy for service providers (e.g., news platforms) and media outlets.

Data. Our data is mostly based on existing datasets, except the news items for constructing news environments. All news items (or headlines) are open and accessible to readers and have no issues with user privacy. The media outlets in the English dataset might be considered "biased", so we carefully select a left, a center, and a right outlet (whose headlines are available) according to the AllSides Media Bias Chart. In China, a media outlet might be state-run (e.g., CCTV News), local-government-run (e.g., The Paper), or business-run (e.g., Toutiao News). With no widely recognized bias chart of Chinese media as a reference, we select media outlets based on their influence (e.g., number of followers) on Weibo from the three categories for the sake of representativeness.

A Sources of News Items as the Environmental Elements

Table 4 shows the selected news outlets that provides news items as the elements for news environment construction in Chinese and English.

B Supplementary Implementation Details

B.1 Kernel Settings

We use $C = 22$ kernels for softly counting the cosine similarities. Following (Xiong et al., 2017), we first determine 21 kernels whose μs scatter in $[-1, 1]$ with an interval of 0.1 and σ^2s are all 0.05. Then we add a kernel with a μ of 0.99 and a σ^2 of 0.01, specially for extremely similar situations. The final kernel list is [(-1.0, 0.1), (-0.9, 0.1),$\cdots$, (1.0,0.1), (0.99, 0.01)]

B.2 Post-Training SimCSE

We post-trained the BERT models for two epochs, with the temperature coefficient τ of 0.05, the dropout rate of 0.3 (Chinese, hereafter, C) and 0.1 (English, hereafter, E), and the maximum length of 256 (C) and 128 (E).

B.3 Implementation of Base Models

- **Bi-LSTM**: The hidden dims are 128 (C) and 256 (E). The maximum lengths are 256 (C) and 128 (E). The number of layers are 1 (C) and 2 (E). We use *sgns.weibo.bigram-char*[12] (Li et al., 2018) for Chinese and *glove.840B.300d*[13] (Pennington et al., 2014) for English to obtain the word embeddings. The Chinese texts are segmented using *jieba*[14] and the English texts are tokenized using *NLTK* (Bird, 2006).
- **EANN**$_{\mathrm{T}}$: The hidden dims, maximum lengths, and word embeddings are the same as Bi-LSTM. The kernel size for both datasets are $[1, 2, 3, 4]$. The numbers of filters are 20 (C) and 30 (E). We ran K-means (Hartigan and Wong, 1979) in the *scikit-learn* package to gather the training samples into 300 clusters (corresponding to 300 events).[15]
- **BERT** and **BERT-Emo**: We use *bert-base-chinese* and *bert-based-uncased* for Chinese and English, respectively. The maximum lengths are 256 (C) and 128 (E). The dimension of each token representation is 768.
- **DeClarE** and **MAC**: The Bi-LSTM component keeps the same settings as the post-only Bi-LSTM. The maximum lengths of articles are 100 (C) and 256 (E).

C Calculation of spAUC

Real-world fake news detection systems inevitably face a challenge of high imbalance of data (#real>>#fake), even if pre-screening procedures like check-worthiness estimation (Hassan et al., 2017; Atanasova et al., 2018) are equipped. In the online test, we use the standardized partial AUC (spAUC) (McClish, 1989) for evaluation. It is suitable to our scenario where we expect the method to find fake news posts as many as possible with an acceptable misclassification rate of real ones. The partial AUC over the false positive rate $[0, x]$ is:

$$\mathrm{pAUC}_{\mathrm{FPR}\leq x} = \int_0^x \mathrm{ROC}(x)\,\mathrm{d}x, \tag{14}$$

where ROC is the Receiver Operating Characteristic curve. The spAUC is calculated as

$$\mathrm{spAUC}_{\mathrm{FPR}\leq x} = \frac{1}{2}\left(1 + \frac{\mathrm{pAUC}_{\mathrm{FPR}\leq x} - \frac{1}{2}x^2}{x - \frac{1}{2}x^2}\right). \tag{15}$$

Figure 8: A case that is weakly related to its news environment.

In our experiment, we use the implementation in the *scikit-learn* package.[16]

D Analysis on the Case Weakly Related to News Environments

Figure 8 shows a case that is weakly related to its news environment. Its words have no intersection with the keywords in the macro environment and the top similar events seem not very related. In this case, our NEP has limited utility as its nature of recency. That might explain why the performances were mostly lower than the post-only methods when we evaluated the NEP alone. For this case, it actually has some novelty (a novel and simple test of personal stress) but is involved with a long-lasting discussed topic—mental health, instead of a hot event being discussed at the very moment. This inspires us to explore how to incorporate more historical and background references to build a comprehensive understanding of the connection between a fake news post and broader societal environments in the future.

Abstract

Multi-encoder models are a broad family of context-aware neural machine translation systems that aim to improve translation quality by encoding document-level contextual information alongside the current sentence. The context encoding is undertaken by *contextual parameters*, trained on document-level data. In this work, we discuss the difficulty of training these parameters effectively, due to the sparsity of the words in need of context (i.e., the training signal), and their relevant context. We propose to pre-train the contextual parameters over split sentence pairs, which makes an efficient use of the available data for two reasons. Firstly, it increases the contextual training signal by breaking intra-sentential syntactic relations, and thus pushing the model to search the context for disambiguating clues more frequently. Secondly, it eases the retrieval of relevant context, since context segments become shorter. We propose four different splitting methods, and evaluate our approach with BLEU and contrastive test sets. Results show that it consistently improves learning of contextual parameters, both in low and high resource settings.

1 Introduction

Neural machine translation (NMT) has seen substantial improvements in recent years, fostered by the advent of the Transformer model (Vaswani et al., 2017). A remaining challenge for modern machine translation (MT) is the ability to contextualize translation of the current sentence with other sentences in the document (Läubli et al., 2018). For this reason, contextual NMT has recently triggered a lot of attention and many approaches have been proposed in the literature. A common taxonomy (Kim et al., 2019; Li et al., 2020) divides them in two broad categories: single-encoder (concatenation) approaches (Tiedemann and Scherrer, 2017; Agrawal et al., 2018; Ma et al., 2020; Zhang et al., 2020) and multi-encoder approaches (Jean et al., 2017; Tu et al., 2017; Bawden et al., 2018; Miculicich et al., 2018; Voita et al., 2018; Maruf et al., 2019; Zheng et al., 2020). Multi-encoder models are more flexible and can be more efficient than concatenation approaches, but they have been criticized as being mere regularization methods (Kim et al., 2019; Li et al., 2020). In some cases, they have even been shown to perform worse than sentence-level systems on discourse-aware targeted test suites (Lopes et al., 2020).

In this work, we address this criticism by showing that training multi-encoder models is difficult because of two reasons: (i) the sparsity of *contextual training signal*, i.e. the signal that pushes systems to translate in a context-aware fashion, which comes from the words that need context to be correctly translated; (ii) the sparsity of relevant context words, the ones needed to disambiguate translation. A trivial way to improve context-aware learning is by increasing the amount of document-level training data. Large document-level parallel corpora are not always available, but some works have proposed data augmentation techniques to remedy scarcity (Sugiyama and Yoshinaga, 2019; Stojanovski et al., 2020; Huo et al., 2020). However, as we will show in our experimental section, this solution is not efficient and often sub-optimal. We therefore introduce a novel pre-training strategy, *divide and rule (d&r)*, that is based on a simple and yet powerful technique to augment the contextual training signal and to ease learning efficiently: splitting parallel sentences in segments (see Figure 1). Simply put, feeding a context-aware model with a sequence of incomplete, shorter, consecutive segments, forces it to look for context (i.e., surrounding segments) more frequently, and makes it easier to retrieve relevant context because segments are shorter. This results in faster and improved learning. We pre-train multi-encoder models on split datasets and evaluate them in two ways: BLEU score, and

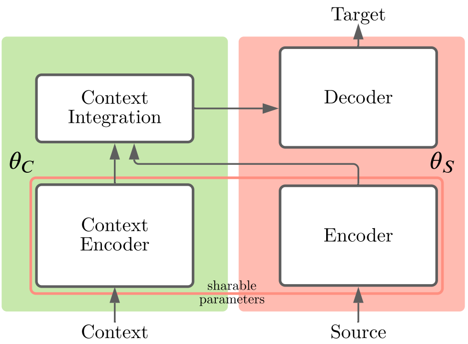

Figure 2: Multi-encoder approach integrating context outside the decoder.

contrastive test sets for discourse phenomena.

Our main contributions are the following: (i) we show that context-aware multi-encoder models need to be trained carefully, because the contextual training signal is sparse, as well as the context elements useful for contextualization; (ii) we propose the *d&r* pre-training strategy, which fosters training of contextual parameters by splitting sentences into segments, with four splitting variants; (iii) we support this strategy with an analysis of the impact of splitting on the distribution of discourse phenomena; (iv) we demonstrate that this strategy is both effective and efficient, as it allows multi-encoder models to learn better and faster than by simply increasing the training data.

2 Background

2.1 Single-encoder approaches

The most straightforward approach to context-aware NMT consists in concatenating the context to the current sentence before feeding it to the standard encoder-decoder architecture (Tiedemann and Scherrer, 2017; Agrawal et al., 2018; Junczys-Dowmunt, 2019; Ma et al., 2020; Zhang et al., 2020). A special token is introduced to mark the boundaries between sentences. Generation can then follow two strategies: the *many-to-many* strategy consists in translating all the source sentences, and then discarding contextual sentences; the *many-to-one* strategy consists in translating the current sentence only. The modeling capacity of concatenation methods is limited to few sentences because the complexity of attention scales quadratically with sentence length, although some recent works try to solve this constraint (Tay et al., 2020).

2.2 Multi-encoder approaches

Multi-encoder models couple a self-standing sentence-level NMT system, with parameters θ_S, with additional parameters for modeling the context either on source side, target side, or both. We refer to these parameters as the *contextual parameters* θ_C. The full context-aware architecture has parameters $\Theta = [\theta_S; \theta_C]$. Most of the multi-encoder models can be described as instances of two architectural families (Kim et al., 2019), that only differ in the way the encoded representations of the context and the current sentence are integrated.

Outside integration. In this approach, depicted in Figure 2, the encoded representations are merged outside the decoder (Maruf et al., 2018; Voita et al., 2018; Zhang et al., 2018; Miculicich et al., 2018; Maruf et al., 2019; Zheng et al., 2020). This can happen in different ways, such as by simple concatenation of the encodings, or with a gated sum.

Inside integration. Here the decoder attends to the context representations directly, using its internal representation of the decoded history as query (Tu et al., 2018; Kuang et al., 2018; Bawden et al., 2018; Voita et al., 2019b; Tan et al., 2019).

Many of these works found it useful to share parameters of current-sentence and context encoders (Voita et al., 2018; Li et al., 2020). In this way, the amount of contextual parameters to learn, $|\theta_C|$, and the computational cost are drastically reduced. Shared representation can also be cached to be re-used and further processed by contextual parameters without the need of re-encoding sentences from scratch, which represents an advantage with respect to single-encoder approaches. Most of the approaches proposed in the literature focus on a few previous sentences, where most of the relevant context is concentrated.

Two-step training. Multi-encoder models are commonly trained following a two-step strategy (Tu et al., 2018; Zhang et al., 2018; Miculicich et al., 2018; Maruf and Haffari, 2018; Li et al., 2020). The first step consists in training θ_S independently on a sentence-level parallel corpus $\mathcal{C}_S$. Secondarily, contextual parameters θ_C are trained on a document-level parallel corpus $\mathcal{C}_D$, while fine-tuning or freezing θ_S. Note that $\mathcal{C}_S$ can also include sentences from $\mathcal{C}_D$.

2.3 Evaluating context-aware MT

Novel MT systems are usually evaluated by computing BLEU (Papineni et al., 2002) on the test data. However, BLEU is ill-equipped to capture the improvements achieved by context-aware MT (Hardmeier, 2012), because contextualization can improve the translation of only a small fraction of the words in a document, while most of the words can be correctly translated without knowing the context. For instance, only a fraction of the anaphoric pronouns in a document has its nominal antecedent outside its own sentence. However, despite being sparse, these few cases strongly impact the quality of translation (Läubli et al., 2018; Popescu-Belis, 2019). Consequently, a number of discourse-targeted test sets and automatic metrics have been proposed to measure improvements in context-aware MT (Maruf et al., 2021), the most widely adopted ones being contrastive test sets.

Contrastive test sets (Bawden et al., 2018; Müller et al., 2018; Voita et al., 2019a) consist of a number of source sentences, each paired with a correct translation and some incorrect ones. Models are assessed on their ability to rank the correct translation first. In many cases, this can be identified only by looking at context, which is provided for both source and target sides. Therefore, the ranking accuracy reflects the context-modeling ability of the evaluated translation system.

3 The double challenge of sparsity

Some works criticized multi-encoder methods (Kim et al., 2019; Li et al., 2020), arguing that they do not improve sentence-level baselines in terms of BLEU when the baseline is well regularized. When there are improvements, it is argued that the context-encoder simply works as a noise-generator that makes training more robust, and the improvements are not due to better context-modeling. Along this path, Lopes et al. (2020) showed that multi-encoder architectures struggle to model contextual information, and even deteriorate the performance of a sentence-level baseline on contrastive test sets. In fact, many proponents of multi-encoder models only show BLEU improvements, without providing any kind of targeted evaluation. This doesn't allow a direct evaluation of their context-modeling capability. We posit that training the contextual parameters of multi-encoder models is non-trivial because of two challenges: (i) the sparsity of the training signal, which comes from the words that need context to be correctly translated (most of the words of a sentence can be translated without context); (ii) the sparsity of context words that are useful for contextualization (most of the context is useless). As such, missing the right experimental setting can lead to unsuccessful training and unconvincing results.

More data? A trivial way to offset sparsity is to increase the volume of training data. In fact, existing works that report strong results with targeted evaluation train their contextual parameters with millions of document-level sentence pairs (Bawden et al., 2018; Müller et al., 2018; Voita et al., 2019b; Zheng et al., 2020; Wong et al., 2020; Kang et al., 2020). In contrast, many works in the literature train models with the TED talks' subtitles released by the IWSLT shared tasks (Cettolo et al., 2012), which only consist of a couple of hundred thousand parallel sentences. In the experimental section, we will show that IWSLT's subtitles are not sufficient to effectively train multi-encoder models. It follows that one can not make fair comparisons between alternative architectures in such experimental settings. On the other hand, we will give an empirical confirmation to the intuition that increasing the volume of training data helps learning contextual parameters. However, increasing the amount of training data is an inefficient solution, and one that is not always feasible: large document-level training sets may not be available in many languages. In the following section, we propose a pre-training solution that makes an efficient use of the available data for learning contextual-parameters effectively.

4 Proposed Approach

One way to simulate document-level data is to split sentences in two or more segments (Luong et al., 2016). In this way intra-sentential syntactic relations are broken, and a word previously disam-

```
input: Parallel corpus $\mathcal{C}$, minimum source length $l_{min}$, function $\text{wheresplit}()$
for $i = 1, \ldots, |\mathcal{C}|$ do
    if $len(S^i) \geq l_{min}$ then
        $m_S, m_T = \text{wheresplit}(S^i, T^i, ...)$
        $S^{i,1} = S^i_{<m_S}$ and $S^{i,2} = S^i_{\geq m_S}$
        $T^{i,1} = T^i_{<m_T}$ and $T^{i,2} = T^i_{\geq m_T}$
    end if
end for
return Split corpus $\mathcal{C}_D$
```

biguated by looking at its neighbours in the sentence, now requires contextual information from the other segment in order to be correctly translated. Moreover, splitting sentences increases the concentration of relevant words within the context segment, as we will show in Section 4.2. Within the framework of MT, if we split the source sentence, its corresponding reference has to be split too. The proposed approach, *divide and rule* (*d&r*), consists in pre-training the model on a dataset $\mathcal{C}_D$ that results from splitting all the sentences of a parallel corpus $\mathcal{C}$ that have at least l_{min} tokens, as described by Algorithm 1. Each source-side sentence S^i, with index $i = 1, ..., |\mathcal{C}|$, is split into $S^{i,1}$ and $S^{i,2}$. Its corresponding reference T^i is split into $T^{i,1}$ and $T^{i,2}$. The resulting corpus is a document-level parallel corpus $\mathcal{C}_D$, such that, if the original corpus C was itself document-level, then $\mathcal{C}_D$ keeps the same document boundaries as C. Figure 1 illustrates two examples of parallel sentences that are split in the middle. In both examples, a context-aware system needs to look at $S^{i,1}$ for translating $S^{i,2}$ correctly, i.e. to look at past context. In the first one, the English neuter pronoun “it" could be translated into “il" or “elle", according to the gender of its antecedent (there is no singular neuter 3rd-person in French). The antecedent “a project", which is in the previous segment, allows to disambiguate it into “il". In the second example, the adjective “possible” can be correctly translated into its plural version “possibles” by looking back at the noun it refers to: “organisms”.

4.1 Splitting methods

In Algoritm 1, the wheresplit function returns the token indices m_S and m_T of S^i and T^i, where the sentence is split. In this work, we propose and experiment with four variants of this function.

Middle-split. The simplest strategy is to split both the source and the target in the middle. In this case, $\text{wheresplit} = \text{middlesplit}(S^i, T^i)$ returns $m_S = \lfloor len(S^i)/2 \rfloor$ and $m_T = \lfloor len(T^i)/2 \rfloor$. Following this method, it can happen that $S^{i,j}$ and $T^{i,j}$, with $j = 1, 2$, are not parallel, as illustrated in the second example of Figure 1. The verb “are” belongs to $S^{i,1}$, but its translation “sont” does not belong to its corresponding reference segment $T^{i,1}$. In other words, sometimes the splitting can separate a set of words from their reference, which end up in the other segment. Clearly, this method requires the two languages not to excessively diverge in terms of word order, to avoid too large mismatches between $S^{i,j}$ and $T^{i,j}$, with $j = 1, 2$.

Aligned-split. As a solution to the misalignment problem between source and target segments, we can calculate word alignments A^i, and use them to inform our splitting strategy by setting $\text{wheresplit} = \text{alignedsplit}(S^i, T^i, A^i)$, where alignedsplit splits each sentence close to the middle, while avoiding to separate aligned words in different segments.

Synt-split. The objective of splitting being to break intra-sentential syntactic and semantic relations in order to force the model to exploit the context more frequently, we can run an NLP toolkit over the training set to retrieve relations L (e.g. syntactic dependencies or coreferences), and then by defining $\text{wheresplit} = \text{syntsplit}(S^i, T^i, L^i)$ so that it splits sentences close to the middle, while ensuring that at least a relation is broken whenever possible. Since not all relations raise translation ambiguities when broken, one can choose which of them must be prioritized; in this work we chose pronominal coreferences.

Multi-split. The aforementioned methods can be extended to splitting sentences in more than two segments. The more we split sentences the more likely it is that context is needed for each segment, hence increasing training signal for contextual parameters.

In Section 6.3, we present an empirical comparison between the four splitting methods. We refer to Appendix A and to our implementation[1] for further details.

4.2 Impact on discourse phenomena

To give an explicit picture of how and why sentence splitting helps learning contextual parameters, we

---

[1] https://github.com/lorelupo/divide-and-rule

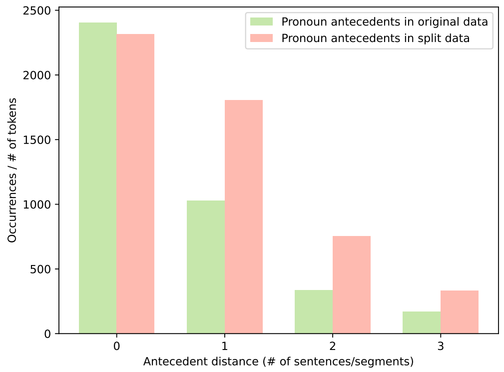

Figure 3: IWSLT's number of antecedents of anaphoric pronouns at a given distance in terms of sentences or segments (in split data), divided by the number of tokens that the model needs to attend for resolving the coreference.

processed the source training data of IWSLT17 with CoreNLP (Manning et al., 2014) and we computed some statistics on coreference chains and dependency parse trees, before and after applying the *middle-split* method. Statistics show how splitting the sentences of a document helps in two ways:

More cases. Splitting generates new cases that require context for disambiguation, making training signal more abundant. When syntactic dependencies are split in two segments, the model needs to access the context for reconstructing the syntactic structure of the source sentence and correctly translate it, as shown in Figure 1. In order to have an idea of the magnitude of this effect, we calculated the percentage of the sentences where the splitting method breaks at least one syntactic dependency between the main verb of the sentence (the root) and : (i) the subject or object (18.1% of the sentences); (ii) any complement (9.5%); (iii) any modifier (9.3%). If we consider all the dependencies with the root, except punctuations, we find that in 84.8% of the sentences at least a syntactic dependency is broken. Given such high proportion, the *middle-split* variant is in fact a good approximation of a syntactically supported splitting approach. These cases add up to the many other cases of broken relations, such as coreferences, which make the overall contextual training signal more abundant.

Denser cases. The splitting also has the effect of shortening the average length of text sequences, which eases the job of context-aware systems because they have to attend to fewer words while looking for context. In Figure 3, we show how many antecedents of an anaphoric pronoun are present in the data at a given distance d, expressed as number of sentences from the current one for original data, and number of segments for split data. $d = 0$ means that both the pronoun and its antecedent are in the same sentence (or segment); $d = 1$ means that the antecedent is in previous sentence (or segment), and so on. We show statistics up to $d = 3$, which is the maximum context distance that we experiment with. The absolute number of antecedents is divided by the average length of a sentence or segment. The resulting bar plot shows that splitting sentences into segments makes pronominal antecedents more dense in the set of context tokens that the model is attending, which fosters the learning of contextual parameters. The same effect applies to the other discourse phenomena that require contextual disambiguation.[2]

5 Experimental setup

5.1 Data

We conduct experiments for three language pairs: English→Russian/German/French, on different domains. Following Kim et al. (2019), we pre-train sentence-level baselines on large sentence-level parallel data to make them as robust as possible. In particular, we employ data released by Voita et al. (2019b) for En→Ru (6.0M sentences from OpenSubtitles2018 (Lison et al., 2018)), data from the WMT17[3] news translation shared task for En→De (∼5.2M sentences), and data from WMT14[4] for En→Fr (∼35.8M sentences). We train the contextual parameters of context-aware models in two settings, while freezing the rest of the parameters:

High resource data. For En→Ru, it consists of the document-level data released by Voita et al. (2019b). For the other two language pairs, we build the training set by assembling (i) News-Commentary-v12 for En→De and News-Commentary-v9 for En→Fr; (ii) Europarl-v7 for En→De/Fr; (iii) TED talks subtitles released by IWSLT17 (Cettolo et al., 2012) for En→De/Fr.

Low resource data. For En→Ru, it consists of a random subset of the high resource documents, amounting to 1/10th of its total. For En→De/Fr, we use IWSLT17's TED talks alone.

The resulting size of the two training settings after pre-processing is reported in Table 1. In the

High Res	1.50M (8.3)	2.29M (27.29)	2.31M (27.6)

Table 1: Millions of sentence pairs used for training context-aware models, and their average source length.

case of En→De/Fr, baselines and context-aware models that were trained on high resources are also fine-tuned on IWSLT17, so that both high and low resource settings can be bench-marked on the IWSLT17's test set 2015. Test-sets 2011-2014 are used as development set. For En→Ru, we use the dev and test sets provided by Voita et al. (2019b). [5]

5.2 Evaluation

Besides evaluating average translation quality with BLEU (Papineni et al., 2002),[6] we employ three contrastive test suites for the evaluation of the translation of discourse phenomena.[7]

En→Ru EllipsisVP (Voita et al., 2019b). Consisting of 500 examples from OpenSubtitles2018, each containing multiple contrastive hypotheses to evaluate the translation of verb phrase ellipses. Source sentences contain an auxiliary verb (e.g. "do") and an omitted main verb, which can be imputed thanks to one of the three context sentences. Voita et al. (2019b) proposed test sets for the evaluation of other discourse phenomena, but we do not use them because they are conceived for systems using target-side context too.

En→De ContraPro (Müller et al., 2018). A large-scale test set from OpenSubtitles2018 (Lison et al., 2018), that measures translation accuracy of the English anaphoric pronoun *it* into the corresponding German translations *er*, *sie* or *es*. Examples are balanced across the three pronoun classes (4,000 examples each). Each example requires identification of the pronominal antecedent, either in the source or target side, that can be found in the current sentence or any of the previous ones.

En→Fr ContraPro (Lopes et al., 2020). A large-scale test set from OpenSubtitles2018, completely analogous to the previous one but focused on the translation of two English pronouns: *it* and *they*. It consists of 3,500 examples for each target pronoun type: *il* or *elle* for *it*, *ils* or *elles* for *they*.

5.3 Models

We experiment with three models:

K0. A sentence-level baseline, following the *Transformer-base* by Vaswani et al. (2017).

K1. A context aware multi-encoder architecture with *outside integration* (see Section 2.2), that encodes a single past source sentence as context.

K3. A context aware multi-encoder architecture with *outside integration*, that encodes three past source sentences as context.[8]

For both *K1* and *K3*, sentence-level parameters θ_S follow the *Transformer-base* configuration (hidden size of 512, feed forward size of 2048, 6 layers, 8 attention heads, total of 60.7M parameters), while contextual parameters θ_C follow hierarchical architecture with source-side encoder proposed by Miculicich et al. (2018) (hidden size of 512, feed forward size of 2048, 8 attention heads, total of 4.7M parameters).[9] Context-aware models are trained following the *two-step strategy* described in Section 2.2. Sentence-level parameters θ_S of both *K1* and *K3* are initialized with *K0* and freezed. This has the advantage of saving time and computation, since only a small fraction of parameters (θ_C) is trained (4.7M over a total of 65.2M).

6 Results and Analysis

6.1 Training contextual parameters is hard

In this section we provide evidence about the difficulty of training contextual parameters on document-level data. In the first block of lines of Table 2, after the results of the sentence-level baseline *K0*, we report performance of context-aware models trained on original document-level data, comparing low and high resource settings.

When trained on low resources, models display good BLEU on the test set, generally without relevant degradation with respect to *K0*, or even with some improvements. However, such marginal fluctuations in BLEU are difficult to interpret, as they do not necessarily correspond to better or worse translation (Freitag et al., 2020). Accuracy on the contrastive test sets also increases marginally over baseline, if at all, for En→De/Fr.

---

[5] We report in Appendix C a re-cap of the datasets used and details about pre-processing.

[6] Moses' *multi-bleu-detok* (Koehn et al., 2007) for De/Fr, *multi-bleu* on lowercased Ru as Voita et al. (2019b).

[7] Whenever relevant, we calculate the statistical significance of the differences between models' accuracies with the paired McNemar test (McNemar, 1947).

[8] Although the splitting does not increase the number of inter-segment phenomena for $d > 1$, it strengthens the signal by making it more dense (see Section 4.2). Thus, *K3* and any wider-context model can profit from the proposed approach.

[9] Details can be found in Appendix C

		En→De		En→Fr		En→Ru		Avg.
Model	Setting	BLEU	**ContraPro**↑	BLEU	**ContraPro**↑	BLEU	**Ellipsis-VP**↑	Train Hours
K0	-	32.97	46.37	41.63	79.46	31.37	25.40	-

K1-d&r	High Res	32.82	**61.09***	41.81	84.17	31.09	59.40*	16.5 (5.7x)
K3-d&r	High Res	33.07	59.56*	41.91	**85.66***	31.27	**60.40***	22.3 (6.4x)

Table 2: BLEU score on testsets and accuracy (%) on contrastive sets. The last column reports the average context-aware training time (in hours), including the time for *d&r* pre-training. The symbol * denotes statistically significant ($p<0.01$) improvements w.r.t *K0* and non-*d&r* counterparts (first block of rows).

K1 even shows a slight degradation of performance over the sentence-level baseline for En→Fr. These results highlight the struggle of contextual parameters to learn an appropriate use of context, other than acting as mere regularizers, as it was suggested by Kim et al. (2019) and Li et al. (2020). On Russian instead, models display some improvements w.r.t. *K0*. This aligns with our expectations, since En→Ru Low Res has a volume of inter-sentential discourse phenomena (such as coreferences) that is comparable with En→De/Fr Low Res, but sentences are 2.5x shorter.[10] In other words, the *double challenge of sparsity* is mitigated on this corpus.

When trained on high resources, systems show substantial improvements in their context-modeling capabilities, on all language pairs. Instead, BLEU improves of a few decimal points only, showing its limits to measure improvements in context-aware translation. These results confirm the intuition discussed in Section 3: increasing the volume of data is a trivial solution to mitigate sparsity.

6.2 Divide and rule

In this section, we show that the proposed pre-training strategy is a more efficient answer to the double challenge of sparsity than simply adding more data, and one that allows improvements when resources are abundant too. The second block of Table 2 displays performance of models that have undergone *d&r* pre-training on the same document-level data as the models in the previous block, but where sentences were split in two segments following the *middle-split* method with $l_{min} = 7$ (see 4.1). During *d&r* pre-training, *K1* and *K3* encode one and three past segments (instead of sentences), respectively. After *d&r* pre-training, models have been tuned and evaluated on original, non-split data. The pre-training proves to be very effective, as all models show strong improvements in terms of accuracy on the test suites, with the sole exception of *K1-d&r* on En→Fr High Res. The average improvement is of **+10.79** accuracy points on Low Res, **+8.49** on High Res, showing that *d&r* brings strong improvements even when data are abundant. Interestingly, improvements are not uniformly distributed across language pairs and domains: **+17.20** on average for En→Ru, **+8.67** for En→De, **+3.09** for En→Fr. In terms of BLEU instead, we keep seeing minor fluctuations. This confirms that, while context-aware translation improves dramatically, the average translation quality measured with BLEU stays more or less constant.[11] It is now evident that a proper assessment of multi-encoder approaches can not be undergone without careful training of contextual parameters that targets the problem of sparsity.

Efficiency. A comparison between *-d&r* models trained on Low Res against models trained on High Res without *d&r* shows another quality of the *d&r* pre-training strategy: efficiency. The same context-aware models achieve superior performances with 1/10th of the document-level data and a much shorter training time (last column).

6.3 Impact of the splitting method

Following Section 4.1, we study the impact of using a different splitting method other than *middle-split*. All the variants are applied to the En→De/Fr

---

[10] See Table 1; more details can be found in Appendix B

[11] To verify that the improvements on test suites after *d&r* pre-training really come from a better use of context, we present in Appendix D an analysis of pronoun translation by antecedent distance, and an ablation study in which we test models on ContraPro with inconsistent context.

	Middle↑	Aligned↑	Synt↑	Multi↑
		En→De		
K1-d&r	60.21	+0.69*	-2.67*	-
K3-d&r	56.22	-1.38*	+1.33*	+1.13*
		En→Fr		
K1-d&r	84.06	+0.27	+0.15	-
K3-d&r	85.50	+0.20	+0.33**	-0.09

Table 3: Comparison of accuracy of context-aware pronoun translation (ContraPro) by *d&r* pre-trained models with the *middle-split* method (first column) and the other proposed methods (relative difference). *: $p < 0.01$, **: $p < 0.05$.

low resource setting (IWSLT), with $l_{min} = 7$, and the *d&r* pre-trained models are evaluated on ContraPro. The *aligned-split* method is based on alignments learned with *fast_align* (Dyer et al., 2013), while for the *synt-split* method we retrieve intra-sentential pronominal coreferences with CoreNLP (Manning et al., 2014), and we try to split them wherever present in a sentence-pair. We split sentences as close to the middle as possible, while attempting to break the maximum number of coreferences.[12] Finally, for the *multi-split* method, we split sentence-pairs in a half for $len(S^i) \geq 7$, and also in three segments of identical size for $len(S^i) \geq 15$. The performance differences between models pre-trained with *middle-split* and the other variants are reported in Table 3. As we can see, splitting variants allow small improvements in 7 cases out of 10, although variations are marginal: the simple *middle-split* method seems to be already close to optimal. This observation can be explained by multiple elements. Firstly, *middle-split* produces segment pairs that are already well aligned: most of the source and target segments are aligned with the exception of one or two words, and the fact of having only a few misplaced words might act as a regularization factor. Secondly, *middle-split* breaks a syntactic relation for the vast majority of sentences already, as explained in Section 4.2, which means that improvements achieved with syntactically driven splitting can only be marginal. Thirdly, splitting in more than one segment can be beneficial in some cases, because it allows to break more syntactic relations and increase density of signal, but it also increases the risk of misalignment between source and target, and might make the task too hard. Finally, tools like *fast_align* and CoreNLP are characterized by a non-negligible language-dependent error rate, which affects the performance of the methods. In conclusion, *d&r* pre-training with *middle-split* seems to be the most convenient alternative for most use-cases because of its efficacy, its simplicity and its language-independence.

6.3.1 On the scope of middle-split

Even though *middle-split* relies on word order similarity between source and target languages, we argue that the required degree of similarity is met by a large number of language pairs, in the order of millions. In fact, there are around 4,000 written languages in the world (Eberhard et al., 2021), and most of them can be grouped in a few types with similar word orders, as shown by the ample literature on word order typologies (Tomlin, 2014; Dryer and Haspelmath, 2013).

The primary order of interest is the *constituent order*, concerning the relative order of subject (S), object (O) and verb (V) in a clause. There are seven possible language types with respect to the constituent order (Dryer, 2013c): SOV, SVO, VSO, VOS, OVS, OSV, NDO (non-dominant order). Tomlin (2014) estimates that more than 40% of the world languages belong to the SOV type (languages adopting the SOV order), another 40% belong to the SVO type, while almost 10% of languages adopt VSO order. The other types are rarer. As we have shown above, the *middle-split* method is beneficial both in the case of language pairs of the same type, that deploy the same constituent order, like En-Fr/Ru, which all adopt SVO order, as well as for language pairs that belong to different types, as for En-De, where English is SVO and German is NDO, deploying both SOV and SVO according to the use cases (Dryer, 2013c).

Similar observations also apply when we look at other word order categories. For instance, when looking at the order of modifiers or adverbials, languages can be clustered in a few types too, where the wide majority of languages belong to the biggest or second biggest type (Dryer, 2013b,a). Therefore, we believe that our method can be beneficial for millions of language pairs, including many low resource languages belonging not only to same word order types, but also slightly different ones (as in the case of SOV and SVO).

---

[12] More sophisticated *synt-split* methods could be devised, targeting other discourse phenomena, or several of them at the same time, with different degrees of priority.

	En→De		En→Fr

Table 4: Comparison between various context-aware models trained on low resources (1st block) and our *d&r* pre-trained multi-encoder models trained on the same data. We report BLEU scores on the IWSLT test-set and accuracies (in %) on ContraPro. The models annotated with * have the advantage of accessing target-side context, while all the other context aware models access source-side context only.

6.3.2 Benchmarking

For a wider contextualization of our results, we report in the first block of Table 4 some experimental results by Lopes et al. (2020), who trained and evaluated various context-aware approaches on the same low-resource setting (IWSLT17), adopting the very same experimental setup as ours. Specifically, they trained and evaluated:

K0: a baseline like ours;

Zhang2018: a multi-encoder model that encodes three past source sentences, with both *inside integration* (see 2.2) and *outside integration* (Zhang et al., 2018);

Tu2018: a multi-encoder model that encodes all the past context (at any distance) with a caching system with *inside integration* in the decoder, both on the source and the target side (Tu et al., 2018);

Concat21: a *many-to-one* (2-to-1) single-encoder approach (see 2.1) that exploits contextual information from one past source sentence;

Concat22: a *many-to-many* (2-to-2) single-encoder approach that exploits contextual information from one past sentence, both on the source and the target side;

Multi-encoder models (*Zhang2018* and *Tu2018*) perform poorly or even lag behind *K0*, confirming the difficulty of multi-encoder models to learn contextualization on low resources and without any help against the problem of sparsity. Instead, concatenation approaches are stronger, likely because they do not have extra contextual parameters to train and simply finetune the same sentence-level Transformer architecture on the context-aware task. This makes them less affected by the problem of sparsity. Our splitting strategy proves to be very effective, since both *d&r* pre-trained models outperform *Concat21* using the same amount of training data. Moreover, *K1/3-d&r* beat the strong *Concat22* on En→Fr, which has the non-negligible advantage of using also the target-side context along the source-side. This benchmarking show that multi-encoder models are a viable solution for context-aware NMT, but that they need to be carefully (pre)-trained to harness their capabilities. We leave to future works a more detailed comparison between single-encoder and multi-encoder approaches, as well as between *d&r* and other recently proposed pre-training strategies for context-aware models (e.g., Fernandes et al. (2021)).

7 Conclusions

Multi-encoder models are a broad family of context-aware NMT models. In this work we have discussed the difficulty of training contextual parameters due to the sparsity of the words in need of context, and the sparsity of their relevant context. We have proposed a pre-training approach called *divide and rule*, based on splitting the training sentences, with four variants. After having analysed the implications of splitting on the distribution of discourse phenomena within the training data, we have shown that *d&r* allows to learn contextual parameters better and faster than by simply increasing training data. We have also shown that the simplest and language independent splitting variant, *middle-split*, is a strong baseline that can be easily applied for pre-training any multi-encoder NMT model.

Table 5: Number of coreference antecedents at a given distance d from the mention in the current sentence, for both original and split En→Fr IWSLT17. In brackets, the same figure divided by the average number of tokens that the model has to attend to resolve the coreference (#tokens). At the bottom, the number of sentences for which at least one syntactic dependency is split in two segments when using the split data. The percentage of examples that need context after splitting is 29.17% if we consider pronominal coreferences only, 39.8% if we consider all coreferences.

A Splitting methods

We provide here some extra details on the splitting methods that have been proposed and tested. For full details, we refer to our implementation.

Aligned-split. As already mentioned, we use $\mathrm{wheresplit} = \mathrm{alignedsplit}(S^i, T^i, A^i)$, which takes as input the word alignments A^i:

$$A^i = \{(j,k)|S^i_j \text{ and } T^i_k \text{ are aligned}\},$$

where $j = 1, ..., |S^i|$ and $k = 1, ..., |T^i|$ are the indices of the words belonging to S^i and T^i, respectively. $\mathrm{alignedsplit}$ initially takes $m_S = \lfloor len(S^i)/2 \rfloor$ and $m_T = \max\{k \colon (j,k) \in A^i, j \leq m_S\}$. Then, it checks whether this choice is not breaking apart two aligned words. Formally, it checks that:

$$S^i_j \in S^{i,1} \wedge T^i_k \in T^{i,1} \text{ or } S^i_j \in S^{i,2} \wedge T^i_k \in T^{i,2}. \quad (1)$$

Coreferences - original data			
d	#tokens	Occurrences	
		All	Pronouns
0	8.32	36,628 (4402)	27,179 (3267)

1	8.32	46,227 (5556)	34,104 (4099)
2	12.48	33,566 (2690)	22,676 (1817)
3	16.64	18,961 (1139)	12,248 (736)

Table 6: Same as in table 5 for the Low Res En→Ru.

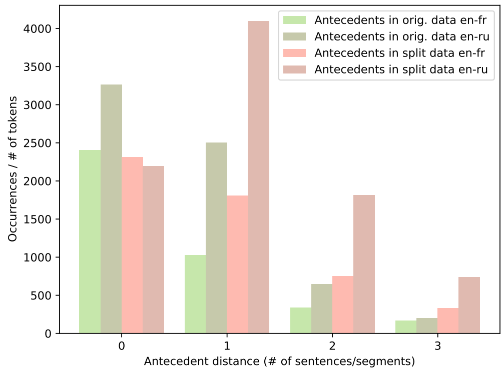

Figure 4: En-Fr IWSLT vs Low Res En-Ru OpenSubtitles2018: comparison of the number of antecedents of anaphoric pronouns at a given distance in terms of sentences/segments, divided by the number of tokens that the model needs to attend for resolving the coreference. Since sentences are much shorter in En-Ru data (8.32 vs. 21.02 tokens on average), the density of discourse phenomena within the sentence is much higher.

If this condition is not encountered, it tries to split the sentence pairs in the neighbouring distance, where condition (1) is met. If the condition can not be met (e.g., because one of the two segments would be too short (<3 tokens)), $\mathrm{alignedsplit}$ falls back on $\mathrm{middlesplit}$.

Synt-split. In our implementation, the function $\mathrm{wheresplit} = \mathrm{syntsplit}(S^i, T^i, L^i)$ takes as input the coreference relation L^i detected by CoreNLP on the source sentence i. If L^i is not empty, it means that a relevant intra-sentential relation is present (in our experiments, we look at pronominal coreferences). In this case, the algorithm checks whether splitting in the middle ($m_S = \lfloor len(S^i)/2 \rfloor$) allows to break L^i, i.e., to separate the two related tokens in different segments. If

	Total	$d = 0$	$d = 1$	$d = 2$	$d = 3$	$d > 3$
K0	46.37	**83.3**	32.4	44.8	48.9	71.9

Relative Size	100.0%	20.0%	59.0%	12.6%	4.8%	3.7%

Table 7: Accuracy(%) of Low Res models on ContraPro En→De by pronoun antecedent distance. The first column represents the weighted average, calculated on the basis of the sample size of each group.

middle-split does not achieve this goal, m_S is set to the closest index from the middle that breaks the relation, except for the case in which breaking the relation would mean generating a too short segment (<3 tokens). In this case, the algorithm falls back to *middle-split*.

B Impact of splitting

In Table 5, we provide details on the syntactic features and the impact of splitting (with *middle-split*) for En→Fr IWSLT17, while Table 6 shows the equivalent figures for the Low Resource subset of En→Ru OpenSubtitles2018. A visual comparison of the two datasets is presented in Figure 4. This complementary information confirms that the *middle-split* method is an effective way to strengthen the contextual training signal and to facilitate its exploitation by context-aware NMT systems, in different text domains.

C Experimental Setup

C.1 Data recap

We recap in Table 8 the datasets that we use at each stage of training and test. The sentence-level training concerns the baselines, whose parameters are also used to initialize the sentence-level encoder and decoder of the context-aware models (Θ_S). Concerning En→Ru, Voita et al. (2019b) released two datasets extracted from OpenSubtitles2018: a document-level dataset of 1.5M sentences with context (document boundaries are available), and a sentence-level dataset of 6M sentences, which includes the sentences of the document-level dataset.

C.2 Data preprocessing

The Opensubtitles2018 release by Voita et al. (2019b) has been already pre-processed. Therefore, we only apply byte pair encoding (Sennrich et al., 2016) using 32k merge operations jointly for source and target languages.

The other datasets are tokenized with the Moses toolkit (Koehn et al., 2007), further cleaned by removing long sentences, and byte pair encoded using 32k merge operations jointly for source and target languages. While IWSLT provides document boundaries for TED subtitles, the WMT releases of New-Commentary and Europarl do not provide them. Therefore, a small fraction of sentences in the High Resource setting will be paired with wrong context. However, we found the models to be robust against occasional random context (see also Voita et al. (2018) and Müller et al. (2018)). In order to make the models correctly learn how to translate headlines (the first line in a document), we need to have headlines in the training set. As such, we set artificial document boundaries in News-Commentary and Europarl, following the average document length of TED talks.

C.3 Training and evaluation

All models are implemented in *fairseq* (Ott et al., 2019). After having pre-trained the baseline on 4 Tesla V100 for 200k steps, we train all models on a single Quadro RTX 6000, with a fixed batch size of approximately 16k tokens,[13] as it has been shown that Transformers need a large batch size for achieving the best performance (Popel and Bojar, 2018). We stop training after 5 consecutive non-improving validation steps (in terms of loss on dev). Corresponding validation performance for each reported test result with *middle-split* are reported in Table 9. We train models with the optimizer configuration and learning rate (LR) schedule described in Vaswani et al. (2017). The maximum LR is 0.0007 for baselines on En→Ru/De, 0.001 for models on En→De/Fr low resource settings, and 0.0005 for all the others. In the En→De/Fr

Table 10: Performance (BLEU) of *K0* on the development set according to different values of length penalty.

High Resource setting, contextual-parameters are finetuned on IWSLT17 with an initial LR of 0.0002 that shrinks by a factor of 0.99 at every epoch. We use label smoothing with an epsilon value of 0.1 (Pereyra et al., 2017) for all settings. Since the sentence-level parameters are pre-trained on a large amount of parallel data (WMT), the models are pretty robust to generalization, and dropout can be set to 0.1, which gave the best results for the non-contextual baseline *K0*. At inference time, we use beam search with a beam of 4 for all models. We adopt a length penalty (P_{len}) of 0.6 for all models ($P_{len} < 1$ favors shorter sentences), with the exception of En→Fr models, to which we assign $P_{len} = 1$. The LR for training was searched in $\{0.001, 0.0007, 0.0005, 0.0002\}$). The LR achieving the best loss on the validation set after convergence was selected. P_{len} was searched in $\{0.6, 0.7, 0.8, 0.9, 1.0, 1.1, 1.2\}$ for *K0* only (see Table 10). The length penalty resulting in the best BLEU score on the validation set was then used for all models within the same language pair. The other hyperparameters were set according to the relevant literature (Vaswani et al., 2017; Popel and Bojar, 2018; Voita et al., 2019b; Lopes et al., 2020).

D Results Analysis

D.1 Accuracy by antecedent distance

Here, we want to investigate more in details the performance of the proposed approach on the accuracy of ambiguous pronoun translation. We report in Table 7 the accuracy on En→De ContraPro, detailed by varying antecedent distance. We notice that all the improvements achieved by *-d&r* models are related to those pronouns whose antecedent is in the context ($d \geq 1$), which is in line with the expectations of context-aware models exploiting context for disambiguation. *K1-d&r* is very strong in translating pronouns with antecedent distance $d = 1$, surpassing *K0* and *K1* baselines by 22+ points of accuracy. Similarly, *K3-d&r* surpasses baselines by a large margin on $0 \leq d \leq 3$, beating all the other models on $d = 2, 3$, as expected. We notice however that *K3-d&r* lacks behind *K1-d&r* on $d = 1$. On one side, this could be explained by the fact that *K1-d&r* is more specialized at modeling a single past sentence. On the other side, we also notice that the hierarchical context-encoding architecture by Miculicich et al. (2018), at the core of *K3*, is not aware of the distance of the context sentences that are encoded. Hence, we believe that *K3-d&r* might perform worse on $d = 1$ than *K1-d&r* because it gives the same importance to further

	En→De		En→Fr	
Model	**BLEU**	**ContraPro**	**BLEU**	**ContraPro**
K0	32.97 (+0.00)	46.37 (0.00)	41.44 (-0.00)	79.46 (0.00)
K1	33.06 (+0.06)	46.7 (-0.35)	41.75 (-0.12)	79.05 (-0.19)
K3	32.73 (-0.13)	46.21 (-0.27)	41.47 (+0.15)	79.24 (-1.29)
K1-d&r	33.1 (-0.34)	47.6 (-12.61)	41.64 (-0.14)	78.94 (-5.12)
K3-d&r	33.05 (-0.31)	47.96 (-8.26)	41.55 (-0.13)	79.05 (-6.45)

Table 11: BLEU and accuracy results on ContraPro (and their changes) when the context provided to the model is inconsistent. All models are trained on the Low Resource setting.

away context ($d = 2, 3$). Since pronouns with antecedent distance $d = 1$ are the most frequent in the test set, *K1-d&r* has the highest average result (reported in “Total"). It has to be noticed also that *K3* is more affected by the challenge of sparsity than *K1*, since it has to spot relevant context among 3x more tokens. This might be the reason why *K3* starts beating *K1* only when the training setting is the most favorable to context-aware learning: with *d&r* pre-training plus high resources.

D.2 Ablation: shuffling context

We want to verify that the proposed approach improves learning by making the context-aware model to rely on its modeling of the context. Table 11 shows the performance of models trained on Low Res, when the evaluation is undertaken by randomly shuffling the context of every sentence with other sentences from the same dataset (c.f. Scherrer et al. (2019)). In brackets, the delta w.r.t. the results with consistent context presented in the main table of the paper. A random context is inconsistent with the current sentence in many cases, and thus misleading for a context-aware system. Indeed, *-d&r* models display a significant drop in accuracy when they are evaluated with inconsistent context, which confirms that they rely on context information to achieve the improvement in pronoun translations. Nonetheless, the same models prove to be robust against being shown a random context as they obtain a similar performance to *K0*. In other words, the splitting method does not produce models that are over reliant on context. This robustness is confirmed by BLEU: the average translation quality is very slightly affected by the shuffling. The changes are so small that are probably negligible. This results also show once again that BLEU is ill-equipped to measuring improvements in document-level translation.

Saliency as Evidence: Event Detection with Trigger Saliency Attribution

Abstract

Event detection (ED) is a critical subtask of event extraction that seeks to identify event triggers of certain types in texts. Despite significant advances in ED, existing methods typically follow a "one model fits all types" approach, which sees no differences between event types and often results in a quite skewed performance. Finding the causes of skewed performance is crucial for the robustness of an ED model, but to date there has been little exploration of this problem. This research examines the issue in depth and presents a new concept termed trigger salience attribution, which can explicitly quantify the underlying patterns of events. On this foundation, we develop a new training mechanism for ED, which can distinguish between trigger-dependent and context-dependent types and achieve promising performance on two benchmarks. Finally, by highlighting many distinct characteristics of trigger-dependent and context-dependent types, our work may promote more research into this problem.

1 Introduction

Event detection (ED) is the first and a crucial step of event extraction, which aims to identify events of certain types in plain texts (Ahn, 2006; Nguyen and Grishman, 2015; Mitamura et al., 2017). Previous methods to ED typically adopt a "one model fits all types" approach, seeing no difference between event types and using a single model to address them all (Ji and Grishman, 2008; Li et al., 2013; Chen et al., 2015; Lin et al., 2020). However, such approaches produce quite skewed performance on different types. Tasking the ACE benchmark as an example, we note the state-of-the-art ED model (Wadden et al., 2019) can strike 90% in F1 for the type DIVORCE, yet only 50% for the type START-POSITION, and it is more surprising that the training set of DIVORCE is eight times smaller than that of START-POSITION. Finding the causes underlying the skewed performance is crucial to the robustness of an ED model; however, this problem is still understudied in current research.

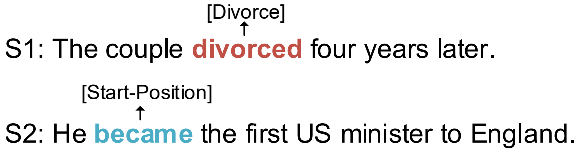

Figure 1: Two typical event instances of DIVORCE and START-POSITION (taken from the ACE 2005 benchmark), where the trigger words are colored.

In this study we take a fresh look at above problem and for the first time attribute the skewed performance to the *contextual patterns of events*. Let consider the two typical instances of DIVORCE and START-POSITION shown in Figure 1. Intuitively, they demonstrate distinct patterns: the DIVORCE event is more *trigger-dependent*, and the trigger word (i.e., "divorced") is very indicative of the event's occurrence; by contrast, the START-POSITION event is more *context-dependent* — the event semantic is primarily expressed by contexts rather than the trigger "become", which is a merely light verb. We hypothesize an ED model performs poorly on context-dependent types because capturing context semantics is challenging (Lu et al., 2019; Liu et al., 2020b). With the above intuitions, two questions rise: (i) Can we estimate an event's pattern quantitatively? (ii)) How to robustify an ED model by characterizing such patterns?

To address the first question, we introduce a brandy new concept called *trigger saliency attribution*, which can explicitly quantify an event's contextual pattern. Figure 2 illustrates the key idea: to determine how much an event is trigger-dependent or context-dependent, we measure the trigger's contribution to expressing overall the event semantic. Specifically, we first assign each sentence a global event label that represents the overall event semantic. Then, inspired by the feature attribution method

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 4573 - 4585
May 22-27, 2022 ©2022 Association for Computational Linguistics

(Simonyan et al., 2014; Sundararajan et al., 2017), we regard each word as a feature and compute its contribution (i.e., saliency value) for predicting the global event label. Finally, by examining the ground-truth trigger's saliency value, we can tell how much an event depends on triggers or contexts: a higher value, for example, indicates that the trigger contributes more to the event, implying the event is more trigger-dependent.

To answer the second question, we develop a new training mechanism based on trigger saliency attribution, which uses saliency as evidence to enhance learning. Our method is simple and straightforward — instead of using a single model to detect all event types, we group event types with similar patterns together (assessed by trigger saliency attribution) and develop separate models for each group. This strategy enables different models to capture distinct patterns — for example, the model for context-dependent type can focus on mining contextual information for learning. To further boost learning, we also propose two saliency-exploration strategy to augment the above framework, which can explicitly integrate saliency information into learning and produce improved performance particularly for context-dependent types (§ 6.2).

To verify the effectiveness of our approach, we have conducted extensive experiments on two ED benchmarks (i.e., ACE 2005 (LDC, 2005) and MAVEN (Wang et al., 2020)). According to the results: (i) Our trigger saliency attribution method can capture the underlying pattern and well explain the skewed performance, obtaining Spearman's correlation coefficients of 0.72 and 0.61 with per-type F1 on ACE 2005 and MAVEN respectively; (ii) Our new training regime based on saliency demonstrates improved results on the two benchmarks. On ACE 2005, for example, it produces a 2% absolute gain in F1 over methods training different event types jointly. Finally, in ablation studies, we compare and highlight many significant characteristics (e.g., linguistic and lexical patterns) of trigger-dependent and context-dependent event types; our work may inspire future research into their patterns.

To summarize, our contributions are three-fold:

- We analyze the origins of an ED model's skewed performance and propose a new notion termed trigger saliency attribution, which can assess the underlying pattern of events. Our findings, as a seminal study, raises the possibility that the traditional "one model fits all types" paradigm may need to be changed.

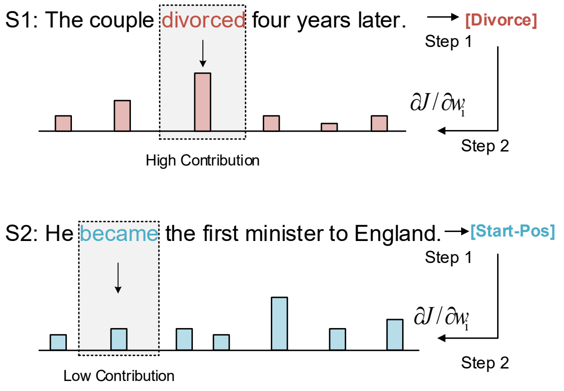

Figure 2: Illustration of trigger saliency attribution, where the saliency value of a trigger can quantify its contribution to the overall event semantic.

- We present a new ED training mechanism based on trigger saliency attribution that achieves promising results on two benchmarks, especially when dealing with context-dependent event types.

- We highlight several diverse patterns of trigger-dependent and context-dependent event types, and our findings may stimulate future research into their differences.

2 Background and Related Work

Event Detection. ED is a critical subtask of event extraction that seeks to locate event instances in text, which has received a lot of attention from researchers. Traditional methods for ED typically use fine-grained features (Ahn, 2006; Ji and Grishman, 2008; Liao and Grishman, 2010; Hong et al., 2011; Li et al., 2013), whereas newer methods rely on neural networks (Chen et al., 2015; Nguyen and Grishman, 2015; Feng et al., 2016; Nguyen and Nguyen, 2019; Liu et al., 2018a, 2019a,b), which have investigated the use of syntactic information (Liu et al., 2018b; Lai et al., 2020), document-level cues (Wadden et al., 2019; Lin et al., 2020; Du and Cardie, 2020; Liu et al., 2020b; Lai et al., 2021; Pouran Ben Veyseh et al., 2021; Li et al., 2021; Chen et al., 2021; Liu et al., 2021), and external supervision signals (Tong et al., 2020; Liu et al., 2020a) to boost learning. However, most methods recognize no distinction between event types and train a single model to identify all event types, resulting in rather skewed performance on different event types. Two seminal works (Lu et al., 2019;

Liu et al., 2020b) have observed the comparatively poor performance on context-dependent texts and offered a better context-exploration strategy to improve training. Nonetheless, they are in a position to improve performance rather than investigate the root causes. Our approach, on the other hand, takes a fresh look at the issue and aims to define the underlying patterns of events for learning.

Feature Attribution. The goal of feature attribution (FA) is to assess how important an input feature for model prediction, which has sparked a lot of interest in interpreting model decisions (Simonyan et al., 2014; Sundararajan et al., 2017). Formally, suppose we have an input vector $x = (x_1, x_2, ..., x_n) \in \mathbb{R}^n$ and a function $\mathcal{F}$: $\mathbb{R}^n \rightarrow [0, 1]$ representing a model. The attribution value of x, with respect to the output $\mathcal{F}(x)$, is defined as a vector $A_{\mathcal{F}}(x) = (a_1, a_2, ..., a_n) \in \mathbb{R}^n$, where a_i measures the contribution of x_i to $\mathcal{F}(x)$. The existing FA methods are classified as gradient-based methods, which consider the gradient of the output to the input as the attribution value (Simonyan et al., 2014; Springenberg et al., 2015), and reference-based methods, which consider the difference between the model's output and some "reference" output, in terms of the difference between the input and some "reference" input, as the attribution value (Ribeiro et al., 2016; Sundararajan et al., 2017). FA have been used to interpret model predictions in applications including image classification (Simonyan et al., 2014), machine translation (Ding et al., 2017), text classification (Chen et al., 2018), and others (Bastings and Filippova, 2020). To the best of our knowledge, this is the first work introducing FA to ED for quantifying the underlying event patterns.

Integrated Gradient. Integrated Gradient (Sundararajan et al., 2017) is a specific (reference-based) FA method that views the feature attribution value as the accumulated gradient along the line between the model's input x and a reference input x', which denotes the lack of a feature[1]. Particularly, the attribution value of x_i (i.e., the i^{th} dimension of x) with respect to an output $\mathcal{F}(x)$ is defined as:

$$a_i = (x_i - x'_i) \times \int_{\alpha=0}^{1} \frac{\partial \mathcal{F}(x' + \alpha \times (x - x'))}{\partial x_i} d\alpha \quad (1)$$

where $\frac{\partial \mathcal{F}(x)}{\partial x_i}$ indicates the gradient of $\mathcal{F}(x)$ to x_i. In our approach, we prefer Integrated Gradient to other FA methods due to its computing efficiency and effectiveness in addressing a wide range of text based tasks (Sundararajan et al., 2017; Liu and Avci, 2019; Bastings and Filippova, 2020).

```

3 Trigger Saliency Attribution

Algorithm 1 provides an overview of our trigger saliency attribution method, which consists of three major steps: (i) sentence-level event classification, (ii) word-level saliency estimation, and (iii) type-level saliency estimation. Let $s = [w_1, w_2, \cdots, w_N]$ be a sentence of N words, and the ED task corresponds to predicting an event label sequence $Y_s = [y_1, y_2, \cdots, y_N]$, where $y_i \in \mathcal{T} \cup \{\text{O}\}$ indicates the event label of w_i, $\mathcal{T}$ is a set containing all pre-defined event types, and O is a "null type" denoting no-trigger words.

Sentence-Level Event Classification. We start by giving s a sentence-level event label $\mathcal{G}_s$, which represents the overall event semantic. Let the label be $\mathcal{G}_s = [g_1, g_2, ..., g_{|\mathcal{T}|}] \in \mathbb{R}^{|\mathcal{T}|}$, where $g_i \in \{0, 1\}$ indicates whether a trigger of the i^{th} event type is contained by s (g_i=1) or not (g_i=0). Following that, we construct a sentence-level event classifier and aim to learn a mapping from s to $\mathcal{G}_s$. Particularly, we devise a BERT based sentence classifier (Devlin et al., 2019) and adopt a multi-label binary cross-entropy loss for optimization:

$$\mathcal{L}(\mathcal{G}_s; \boldsymbol{X}_s) = -\frac{1}{|\mathcal{T}|} \sum_{i=1}^{|\mathcal{T}|} g_i \cdot \log(\boldsymbol{o}_i^s) + (1 - g_i) \cdot \log(1 - \boldsymbol{o}_i^s) \quad (2)$$

where $\boldsymbol{X}_s$ is the input embedding of s in BERT, $\boldsymbol{o}^s \in \mathbb{R}^{|\mathcal{T}|}$ indicates the logits vector computed by the classier, and $\boldsymbol{o}_i^s$ denotes the i^{th} element of $\boldsymbol{o}^s$.

Word-Level Saliency Estimation. Based on the sentence-level classifier, we next use Integrated Gradient (Sundararajan et al., 2017) to calculate the contribution (i.e., saliency value) of each word

---

[1] In text related tasks, x' is usually set as a sequence of embedding vectors with all zero values (Wallace et al., 2019).

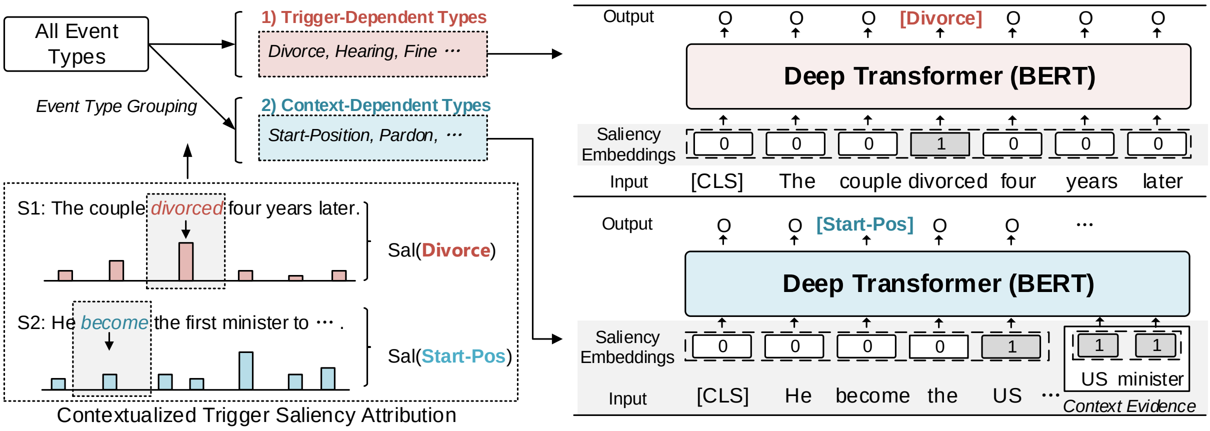

Figure 3: The overview of our saliency enhanced ED model; it first divides event types into different sets based on their patterns and then uses separate models, with different saliency-exploration strategies, to address each set.

to the prediction. We utilize the loss function as the desired model (Wallace et al., 2019), and calculate the saliency of w_i, more accurately, its BERT representation $\boldsymbol{x}_i \in \boldsymbol{X}_s$, regarding the loss by:

$$\boldsymbol{\alpha}_{w_i} = (\boldsymbol{x}_i - \boldsymbol{x}'_i)\times \int_{\alpha=0}^{1} \frac{\partial \mathcal{L}(\mathcal{G}_s; \boldsymbol{X}' + \alpha \times (\boldsymbol{X}_s - \boldsymbol{X}'))}{\partial \boldsymbol{x}_i} d\alpha \qquad (3)$$

where $\boldsymbol{X}'$ is a sequence of all-zero vectors (serving as a reference input), and $\boldsymbol{x}'_i$ denotes the i^{th} element in $\boldsymbol{X}'$. We then normalize $\boldsymbol{\alpha}_{w_i}$ as a scalar value α_{w_i} with a sentence-wise normalization:

$$\alpha_{w_i} = e^{\|\boldsymbol{\alpha}_{w_i}\|_2} / \sum\nolimits_{n=1}^{N} e^{\|\boldsymbol{\alpha}_{w_n}\|_2} \qquad (4)$$

where $\|\|$ denotes the L_2 norm. In actuality, we may not be concerned with a word's saliency to the general event semantic $\mathcal{G}_s$, but rather with a specific event type $T \in \mathcal{T}$. To this end, we replace $\mathcal{G}_s$ with the one-hot representation of T in Equation (3) for evaluation. Finally, we represent the word-level saliency of w_i with respect to the event type T by $\alpha_{w_i}^{(T)}$, and we suppose $\alpha_{w_i}^{(T)} = 0$ if the sentence does not describe any event of type T.

Type-Level Saliency Estimation. Based on the word-level saliency, we measure the type-level trigger saliency value (regarding an event type T) as:

$$\text{SL}(T) = \frac{\sum_{(s,Y_s)} \sum_{w \in \{w_i | y_i = T\}} \alpha_w^{(T)}}{\#\,\text{of training examples of type}\, T} \qquad (5)$$

where (s, Y_s) ranges over each training instance; $\{w_i | y_i = T\}$ is a set containing all of the triggers of type T in s. The type-level saliency vale $\text{SL}(T)$ indicates how trigger-dependent or context-dependent an event type T is, and it has been shown to correlate strongly with the per-type model performance (§ 6.1).

4 Saliency Enhanced ED

Based on trigger saliency attribution, we devise a new training paradigm for ED, which can distinguish event types with similar patterns for learning and achieves promising results. The overview is shown in Figure 3, and the technical details follow.

Event Type Division. Based on type-level saliency estimation, we divide all event types into a trigger-dependent set $\mathcal{T}_{\text{trigger}} = \{T | \text{SL}(T) \geq \lambda\}$ and a context-dependent set $\mathcal{T}_{\text{context}} = \{T | \text{SL}(T) < \lambda\}$. The threshold λ is empirically determined as the median of all per-type trigger saliency values, implying that the event types are evenly divided into two sets[2].

Saliency-Enriched Event Detector. Following that, we create separate ED models for $\mathcal{T}_{\text{trigger}}$ and $\mathcal{T}_{\text{context}}$. Each model is implemented using the BERT architecture (Devlin et al., 2019), and given a sentence s, it performs a word-by-word classification over BERT's output to generate a label sequence: $\tilde{Y}_s = (\tilde{y_1}, \tilde{y_2}, \cdots, \tilde{y_N})$, with $\tilde{y_i}$ being the predicted event label for w_i. Based on the different characteristics of trigger-dependent and context-dependent types, we devise different saliency-exploration methods to boost learning.

(i) Word Saliency Embeddings. Given that trigger-dependent types often have indicative trig-

---

[2] We have tried using more than two sets for division in our pilot experiments, but the results were negative.

gers, we build a mechanism called word saliency embeddings (WSEs) in the model for $\mathcal{T}_{\text{trigger}}$ to capture such regularities. Specifically, we first quantify each word's saliency value[3] as 0 or 1 based on λ, i.e., the threshold we used previously for distinguishing event types, and then use a separate embedding vector to distinguish 0 and 1, similar to word embeddings. Such embeddings are incorporated into the model[4] to capture a regularity that words with high saliency values are more likely to be triggers. Note WSEs are also incorporated in the model for the $\mathcal{T}_{\text{context}}$, which on the other hand seeks to learn the opposite regularity that words with high saliency values may not be triggers.

(ii) Saliency as Context Evidence. In the event detector for $\mathcal{T}_{\text{context}}$, we also devise a regime for interpreting salient information as context evidence for reasoning. Consider the previous example S2. Our method identifies the context words "US minister" as the most salient words (with saliency values larger than λ) expressing the overall event semantic. Here we regard salient contexts as supplementary evidence and concatenate them with the sentence for learning, as shown in the bottom of Figure 3. Compared with WSEs, this method can additional capture the lexical semantics of the salient words, which has been shown to considerably aid in the recognition of context-dependent event types (§ 7).

Model Ensemble. In the testing stage, we combine the results of two models to make a final prediction. If ambiguous cases occur, i.e., the two ED models predict different event types for the same word, we use the type with a higher probability as the result. We use cross-entropy loss for optimization. For example, the model for $\mathcal{T}_{\text{trigger}}$ is trained by minimizing the following loss:

$$\mathcal{L} = -\sum\nolimits_{(s,Y_s)} \sum\nolimits_{(w_i,y_i)\in(s,Y_s)} \log P(y_i|w_i) \tag{6}$$

where (s, Y_s) refers to each training instance; (w_i, y_i[5]) ranges over each pair of word and its ground-truth event label; $P(y_i|w_i)$ denotes the conditional probability that the model predicts y_i for w_i. We use Adam (Kingma and Ba, 2015) with default hyper-parameters for parameter update.

		Dev.	8,042	204,556	18,904

Table 1: Statistics of ACE 2005 and MAVEN, where # Sen., # Tok., and # Trig. indicate the number of event types, sentences, tokens, and triggers respectively.

5 Experimental Setups

Datasets. We conduct experiments on ACE 2005 (LDC, 2005) and MAVEN (Wang et al., 2020). ACE 2005 defines 33 event types and contains 599 documents. We adopt a common split for evaluation following previous works (Li et al., 2013; Wadden et al., 2019). MAVEN is a newly released corpus defining 168 more fine-grained event types (Wang et al., 2020). Because the MAVEN test set is not publicly available and our study is concerned with per-type performance, we instead use the MAVEN development set for assessment and divide the original MAVEN training set as 9:1 for training and validating. Table 1 displays the comprehensive data statistics for the two datasets.

Evaluation Metrics. We adopt the following metrics to evaluate our model: (i) Spearman's rank correlation coefficient, which can determine the statistical dependency between two ranked variable sequences. The metric is defined as $\rho = 1 - \frac{6\sum d_i^2}{n(n^2-1)}$, where d_i is the difference between the i^{th} pair of ranked variables, and n is the sequence length. We use it to measure how well our trigger saliency attribution results correlate with per-type model performance. (ii) Precision (P), Recall (R) and (Micro) F1, which are widely used to assess the *overall performance* of an ED model. (iii) Macro F1, the arithmetic mean of class-wise F1-scores, which will be low for models that only perform well on common types but badly on rare types.

Implementations. In our trigger saliency attribution method, the sentence-level classifier is built on the `BERT-base`. The batch size is set to 20, and the learning rate is set to 1e-5. After 5 epochs, it achieves 74.8% in F1 on the ACE 2005 development set, matching the state-of-the-art performance (Liu et al., 2019c). As for the two ED models, we consider `BERT-base` architectures. The batch size is set to 20, chosen from [1, 5, 10, 20, 30]. The

---

[3] To prevent label leaking, at the testing stage we use predicted labels rather than ground-truth labels for attribution.

[4] Because combining external embeddings with BERT remains difficult, we alter the segmentation embeddings in BERT to WSEs, motivated by (Wu et al., 2019).

[5] Note in the event detector for $\mathcal{T}_{\text{trigger}}$, we should consider y_i as O for $y_i \in \mathcal{T}_{\text{context}}$.

Setting	Method	Dataset ACE 05	Dataset MAVEN
Static	# of Training Instances	0.06	0.09
	Trigger Variance	0.26	0.25
Dynamic	Trigger Attention	0.12	0.14
	Trigger Saliency (Ours)	**0.72**	**0.61**

Table 2: The Spearman's ρ correlation ($\rho \in [-1, 1]$) between per-type F1 and different criteria (high correlation is considered when $\rho > 0.6$).

learning rate is set to 1e-5, chosen from a range from 1e-3 to 1e-6. The dimension of word saliency embeddings is empirically set to 100. To allow for further investigation, we have made our code publicly available at `https://github.com/jianliu-ml/SaliencyED`.

6 Experimental Results

6.1 Results of Correlation Measurement

Table 2 shows the Spearman's rank correlation between per-type F1 and four criteria: 1) the number of training instances (regarding an event type); 2) trigger variance, defined as the ratio of the number of unique event triggers to the total number of event triggers (regarding an event type); 3) trigger attention value, which corresponds to the ground-truth trigger's attention value in the BERT model; 4) trigger saliency attribution (our method). We use a state-of-the-art ED model (Wadden et al., 2019) and perform a 5-run average on the development set to obtain the per-type F1 score.

According to the results, our trigger saliency attribution approach correlates the best with model performance, yielding a score as high as 0.72 and 0.61 in Spearman's ρ correlation. This suggests that our method can well explain the skewed performance. Our other findings are interesting: (i) Surprisingly, the number of training examples shows a negligible correlation (ρ = 0.06 and 0.09) with per-type F1. This implies that simply collecting more training data may not be an effective way to improve an ED model. (ii) The trigger variance metric demonstrates a moderate association (ρ = 0.25 and 0,26), indicating that the diversity of event triggers is a factor influencing model performance. (iii) The trigger attention value also shows a poor association, which may be another proof that attention is not explainable (Jain and Wallace, 2019).

Lastly, Figure 4 visualizes correlations between per-type F1 and the number of training instances and our trigger saliency attribution method. In addition to noting that our method adequately explains the per-type F1-score, we find that $\lambda = 0.25$ may be a good threshold for distinguishing between trigger-dependent and context-dependent event types.

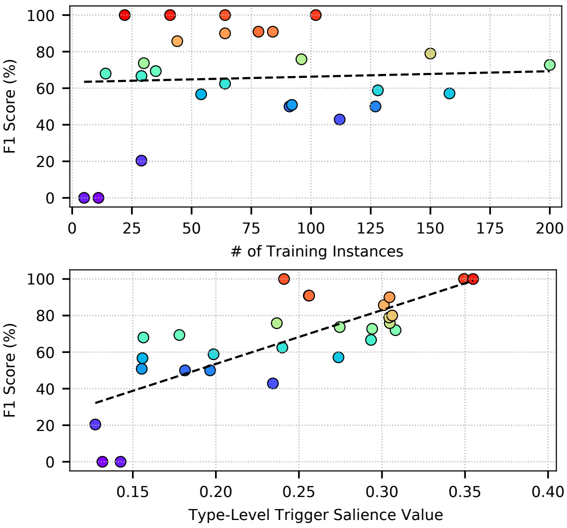

Figure 4: Correlation between per-type F1 and (i) the number of training instances (top), and (ii) type-level trigger salience value (bottom), based on ACE 2005. Each point indicates a specific event type.

6.2 Results of Saliency Enhanced ED

To test the efficacy of our saliency enhanced ED model: 1) For ACE 2005, we compare our model with (i) DYGIE++ (Wadden et al., 2019), which uses a graph view to learn context features; (ii) TriggerQA (Du and Cardie, 2020), which uses a question answering formulation for the task; (iii) OneIE (Lin et al., 2020), which adopts cross-sentence features for the task. Because pre-processing has a significant impact on the results (Orr et al., 2018), to ensure a fair comparison, we only consider models using the same pre-processing steps as in (Wadden et al., 2019). 2) For MAVEN, we use the BERT+CRF proposed in the original work (Wang et al., 2020) for comparison. As a baseline, we also construct a model called BERTEns, which ensembles two BERT models similar to ours but does not differentiate event types. We refer to our approach that merely separates event types for learning (without saliency-exploration strategies) as SaliencyED (SL), and our full approach as SaliencyED (Full). Table 3 displays performances of different models.

The results have confirmed our approach's effectiveness. Particularly: (i) our full model achieves the best Micro F1 score (75.8% and 67.1%) on

	Method	P ▲	R ▲	F1 ▲	F1 ▽
ACE	DYGIE++ (2019)	-	-	73.6	65.7
	TriggerQA (2020)	71.2	73.7	72.4	64.5
	OneIE (2020)	-	-	75.2	66.6

Table 4: Results on trigger-dependent (TD) and context-dependent (CD) event types, where F1 ▲ and F1 ▽ indicate Micro and Macro F1 respectively.

Method	F1 ▲	F1 ▽
SaliencyED (SL)	70.0	56.9
SaliencyED (SL) + WSE	70.2	57.3
SaliencyED (SL) + Evidence	**70.6**	**57.5**
SaliencyED (SL) + MaskAtt	70.4	57.1
SaliencyED (Full)	71.5	57.8
SaliencyED (Full) + Gold Arguments	**78.2**	**68.9**

Table 5: Ablations on context-dependent types. F1 ▲ and F1 ▽ indicate Micro and Macro F1 respectively.

ACE 2005 and MAVEN without the use of sophisticated architectures or external resources, as DYGIE++ and OneIE do. (ii) Impressively, with the identical architectures, our full model SaliencyED (Full) outperforms BERTEns by 2.8% and 1.7% in F1 on the two datasets, respectively; SaliencyED (SL), which only differentiates event types for training, outperforms BERTEns by 1.6% in F1. This emphasizes the significance of identifying event patterns for ED. (iii) Our method gives the best Macro F1 on two datasets, indicating that it performs well on both common and rare event types.

Table 4 shows the performance breakdown for trigger-dependent (TD) and context-dependent (CD) types. According to the results, different models consistently produce good performance on TD types but low performance on CD types, implying that the patterns found by our trigger saliency attribution method are reasonable. When comparing SaliencyED (SL) and SaliencyED (Full), we see that the saliency-exploring method is more effective on CD types (+2.3% in F1) than on TD types (+0.3% in F1). This makes sense because detecting context-dependent events relies significantly on context reasoning, and our method can just use important contexts as evidence to improve learning.

7 Discussion

Ablation Study. We undertake an ablation study in Table 5 to investigate different model components, using the more challenging context-dependent (CD) types as an example. In the variant models, +WSE and +Evidence denote supplementing SaliencyED (SL) with word saliency embeddings and context evidence, respectively. +MaskAtt is an approach for calculating attention that masks the word itself, which can drive the model to focus more on contexts for learning; +Gold Argument is an oracle method that uses gold event arguments as evidence for learning. Based on the results, +Evidence outperforms +WSE and +MaskAtt, indicating its efficacy. Interestingly, +MaskAtt also boosts performance, implying that the contexts of CD events do carry important information for asserting the event. Finally, the superior performance of +Gold Arguments implies that finding indicative evidence (e.g., event arguments) is the key factor boosting learning on CD types.

Impact of Event Type Division. We use our event type division method as a baseline and compare it to three other event type division strategies: 1) at random; 2) based on the amount of training instances; 3) based on development set performance. According to the results, the first two strategies decrease performance by 1.27% and 1.41% in Micro F1 on ACE, and 1.53% and 1.40% on MAVEN, which suggests that an inappropriate separation of event types impairs learning. The third strategy based on development performance improves learning (+0.8%/+1.1% on ACE/MAVEN), but it

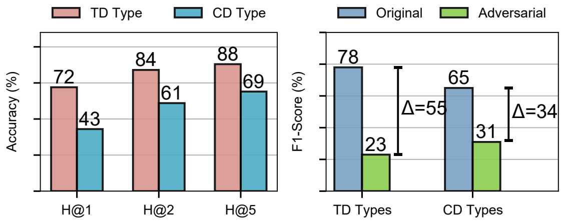

Figure 5: Left: Top k accuracy (hit@k) when the most salient word appears to be an event trigger. Right: Performance drop in an adversarial attack, where the event trigger is masked for sentence-level classification.

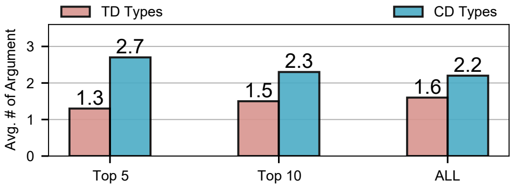

Figure 6: A comparison of the average amount of event arguments in TD and CD types.

is still inferior to our approach. An explanation is that the final model performance is the product of a combination of factors, and thus categorizing event types based on development set performance may not assure that event types with similar patterns are grouped together, resulting in inferior results.

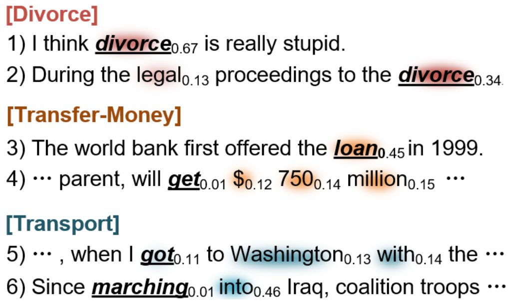
Distinctions in TD/CD Types. We use ACE 2005 as a case to highlight the distinct characteristics between TD and CD types. Figure 5 (Left) depicts the top k accuracy (hit@k) in the case where the most salient word in a sentence appears to be an event trigger; Figure 5 (Right) depicts the performance drop in an adversarial attack in which the gold event triggers are masked for sentence-level event type classification. The CD and TD types exhibit opposing behaviors: TD types display excellent H@k accuracy but a significant performance loss in adversarial attack, whereas CD types exhibit the opposite tendency. This implies that the CD and TD types respectively rely on triggers and contexts. Figure 6 shows a comparison of the number of event arguments for TD and CD types. Clearly, CD types have a larger number of event arguments than TD types. This is also another indication that CD types rely on contexts — they require more arguments to convey an event.

Linguistic/Lexical Insights. Table 6 give typical TD and CD types on ACE 2005 (Please refer to Appendixes for the full set). Intuitively, the TD types appear to be finer-grained and concrete, whereas the CD types appear to be coarser-grained and abstract. For example, we may further subdivide a CD type TRANSFER_MONEY into finer-grained ones like LOAN and PURCHASE. We provide linguistic/lexical insights by comparing the hierarchy levels of TD/CD types on WordNet (Miller, 1992). Accordingly, triggers of TD types are at the lower level of WordNet, with an average of 5.6 hypernyms; yet CD type triggers are at a higher level of WordNet, with 2.3 hypernyms. This finding supports our intuition that TD types are more concrete whereas CD types are more abstract.

8 Most Trigger-Dependent (TD) Types:
Divorce$_{(0.434)}$, Hearing$_{(0.355)}$, Fine$_{(0.349)}$, Injure$_{(0.308)}$, Be_Born$_{(0.306)}$, Elect$_{(0.305)}$, Sentence$_{(0.304)}$, Die$_{(0.304)}$

8 Most Context-Dependent (CD) Types:
Start_Org$_{(0.127)}$, Pardon$_{(0.129)}$, Nominate$_{(0.132)}$, Extradite$_{(0.134)}$, Acquit$_{(0.142)}$, Merge_Org$_{(0.151)}$, Transfer_Money$_{(0.155)}$, End_Org$_{(0.156)}$

Table 6: Typical TD and CD types on ACE 2005.



[Divorce]
1) I think ***divorce***$_{0.67}$ is really stupid.
2) During the legal$_{0.13}$ proceedings to the ***divorce***$_{0.34}$.
[Transfer-Money]
3) The world bank first offered the ***loan***$_{0.45}$ in 1999.
4) ··· parent, will ***get***$_{0.01}$ $\$_{0.12}$ 750$_{0.14}$ million$_{0.15}$ ···
[Transport]
5) ··· , when I ***got***$_{0.11}$ to Washington$_{0.13}$ with$_{0.14}$ the ···
6) Since ***marching***$_{0.01}$ into$_{0.46}$ Iraq, coalition troops ···

Figure 7: Case visualization, where the ground-truth event triggers are underlined. Color is used to represent words with large saliency values (≥ 0.1).

Case Visualization. Figure 7 depicts the saliency map of several cases. Accordingly, event triggers of TD types do usually have large saliency values. For example, case 2) is the instance of DIVORCE with the lowest trigger saliency value, which is still as high as 0.34. In contrast, event triggers of CD types typically have low saliency values. For example, case 4) and 6) show random instances of TRANSFER-MONEY and TRANSPORT, where the trigger saliency values are only 0.01.

8 Conclusion

In this study, we analyze the origins of an ED model's skewed performance and introduce a new notion called trigger saliency attribution to quantify the pattern of events. We devise a new training paradigm for ED that can distinguish between trigger-dependent and context-dependent types for learning, yielding promising results on two benchmarks. We also examine the differences between the two types extensively, and our work may promote future research on this problem. In the future, we would apply our method to other tasks (e.g., relation extraction) where contextual patterns matter.

Abstract

In the field of sentiment analysis, several studies have highlighted that a single sentence may express multiple, sometimes contrasting, sentiments and emotions, each with its own experiencer, target and/or cause. To this end, over the past few years researchers have started to collect and annotate data manually, in order to investigate the capabilities of automatic systems not only to distinguish between emotions, but also to capture their semantic constituents. However, currently available gold datasets are heterogeneous in size, domain, format, splits, emotion categories and role labels, making comparisons across different works difficult and hampering progress in the area. In this paper, we tackle this issue and present a unified evaluation framework focused on Semantic Role Labeling for Emotions (SRL4E), in which we unify several datasets tagged with emotions and semantic roles by using a common labeling scheme. We use SRL4E as a benchmark to evaluate how modern pretrained language models perform and analyze where we currently stand in this task, hoping to provide the tools to facilitate studies in this complex area.

1 Introduction

Emotion detection – a long-standing open problem in Natural Language Processing (NLP) – is the task of automatically associating one or more emotions with a text. Even though emotional states are highly subjective and often depend on several factors, such as one's past experiences, culture and education, the automatic identification, categorization and analysis of emotions in texts has been found to be beneficial in a wide array of downstream tasks, such as hate speech detection (Markov et al., 2021), sarcasm detection (Chauhan et al., 2020), and modeling political discourse (Huguet Cabot et al., 2021), *inter alia*.

In the past decade, Deep Learning techniques have become ubiquitous in the development of automatic systems for an increasing number of NLP tasks, including emotion detection (Chatterjee et al., 2019). However, most of the effective neural-based approaches still require significant amounts of training data in order to learn to perform at their best. For this reason, with a view to bootstrapping the development of neural systems for emotion detection, there have been several efforts to annotate corpora with emotions manually (Bostan and Klinger, 2018).

Nevertheless, over the past few years, numerous studies have indicated that a short text, even a single sentence, may contain multiple – at times concurring, at other times contrasting – sentiments and emotions. And not only this, two emotions in the same sentence may be experienced, targeted, and/or caused by different semantic constituents which, similarly to predicate-argument structures in Semantic Role Labeling (SRL), can be linked to form abstract semantic structures. The potential applications in social media analysis, abuse detection, and other actively studied areas in NLP (Rajamanickam et al., 2020) of such automatically-extracted emotion-focused semantic structures have prompted researchers to create datasets aimed at investigating the capabilities of modern systems to parse emotional events (Oberländer et al., 2020). Unfortunately, despite the increasing interest in this area, currently available gold datasets feature heterogeneous structures and characteristics, ranging from varying sizes to different domains, file format, splits and, most importantly, non-overlapping emotion categories. We argue that this heterogeneity obstructs, or at least hinders, further progress in this relatively new area of sentiment analysis.

In this paper, we take a step towards addressing the above-mentioned issues and introduce a unified framework for Semantic Role Labeling for Emotions (SRL4E). In SRL4E, we unify several gold but heterogeneous datasets that contain anno-

tations both for emotions and for their semantic constituents, so as to obtain a new homogeneous dataset that covers diverse domains and that can be used to train, validate and evaluate current and future work in this task. Our contributions can be summarized as follows:

- We propose a unified gold benchmark for training and evaluating a system on Semantic Role Labeling for Emotions (SRL4E);
- We take advantage of SRL4E to show the inadequacy of training a model on domain-specific data and the benefits of our unified framework;
- We show the advantages of bilingual transfer from English to Chinese, and vice versa, in SRL4E.

We release SRL4E at `https://github.com/SapienzaNLP/srl4e` in the hope that our unified framework will become a stepping stone for the development and evaluation of current and future approaches to Semantic Role Labeling for Emotions.

2 Related Work

Emotion classification datasets. Currently, there are a wide variety of datasets annotated with emotion classes, ranging across different domains and using different annotation schemes. Among others, we can find datasets on emotional experiences (Scherer and Wallbott, 1994), children's fairy tales (Alm et al., 2005), news headlines (Strapparava and Mihalcea, 2007), blog posts (Aman and Szpakowicz, 2007, 2008), news (Lei et al., 2014), social media posts and reviews (Buechel and Hahn, 2017), dialogs (Li et al., 2017; Chatterjee et al., 2019), Facebook posts (Preoţiuc-Pietro et al., 2016), with many focusing on tweets (Mohammad, 2012; Mohammad and Bravo-Marquez, 2017; CrowdFlower, 2016; Liu et al., 2017; Schuff et al., 2017) due to their tendency to have dense emotional content. To meet such a diversity of contents and formats, Bostan and Klinger (2018) created a unified resource for emotion classification comprising many of the aforementioned datasets, while Tafreshi and Diab (2018), instead, added an additional clause-level annotation layer to some existing resources. More recent efforts, such as GoEmotion (Demszky et al., 2020), XED (Öhman et al., 2020) and CancerEmo (Sosea and Caragea, 2020), provide, respectively, emotion annotations for Reddit comments, multilingual subtitles and blog posts about health problems.

Although the above-mentioned corpora have enabled systems to perform emotion detection across different domains, their annotations are sentence-level and, therefore, introduce an oversimplification: they indicate only the overall sentiment and/or emotion that appears in a given text, neglecting the cases in which a short text, even a single sentence, may express multiple emotions. Furthermore, the aforementioned datasets do not indicate which part of the text elicits an emotion and who experiences, is the target of, or causes that emotion. As a consequence, a system trained on these datasets may produce predictions that are hard to interpret and more difficult to use in real-world applications. To overcome these problems, we rely on resources that not only indicate emotions, but also identify their semantic constituents, namely, emotional CUES, EXPERIENCERS, TARGETS and STIMULI.

Emotion Taxonomy. Among the studies that aim to identify the fundamental emotions, Ekman (1992) proposed a set of six categories: *anger*, *disgust*, *fear*, *joy*, *sadness* and *surprise*; Plutchik (1980) shared the same set with two additions: *anticipation* and *trust*. Instead of relying on discrete categories, Russell (1980) proposed the circumplex model where every emotion can be described by three continuous values: *arousal*, *dominance* and *valence*. More recent studies in psychology use more fine-grained sets of emotions, ranging from 12 (Cowen et al., 2019b) to 28 categories (Cowen and Keltner, 2020), devised depending on the context of the study, e.g., speech prosody and facial expressions.

However, the analysis of Demszky et al. (2020) over a fine-grained set of 28 emotions suggests that a large number of categories results in more frequent disagreements on similar classes (such as *anger* and *annoyance*, or *excitement* and *joy*) which, in turn, can lead to low inter-annotator agreement and unbalanced distributions among some of these categories. Therefore, we adopt Plutchik's *Wheel of Emotions* (Plutchik, 2001), which provides clearly distinct and well-defined coarse-grained categories, whose composition can be used to virtually describe all other fine-grained sets. Moreover, some datasets in SRL4E (Mohammad et al., 2014; Kim and Klinger, 2018; Bostan et al., 2020) already use Plutchik's or Plutchik-based categories.

Emotions and SRL. Over the past few years, automatic systems for SRL have achieved impressive performance in identifying and labeling predicate-argument relations (Shi and Lin, 2019; Conia and Navigli, 2020; Blloshmi et al., 2021; Conia et al., 2021), and have long become useful tools in several downstream tasks, from Question Answering (He et al., 2015) to Machine Translation (Marcheggiani et al., 2018). Defined by Màrquez et al. (2008) as the task of answering the question "*Who did What to Whom, Where, When and How?*", SRL is almost a natural choice for the extraction of the semantic constituents of those events that elicit emotional states. Indeed, emotional CUES can be seen as particular types of predicates, and their semantic constituents as their arguments.

Among the currently available datasets for emotion detection, there are some that also provide this kind of more granular semantic information. In particular Aman and Szpakowicz (2007) and Liew et al. (2016) released corpora that indicate multiple emotions and their corresponding emotion CUES in each sentence; Ghazi et al. (2015) and Gao et al. (2017) indicate the cause of an emotion, with the latter providing such annotations both in English and in Chinese. Finally, Mohammad et al. (2014), Mohammad et al. (2015), Kim and Klinger (2018) and Bostan et al. (2020) provide annotations for emotion CUES, EXPERIENCERS, TARGETS and STIMULI, employing, however, different sets of emotions in different domains. This means that the results of a system trained on one of these datasets cannot be compared against the results of another system trained on a different dataset, emphasizing the need for a unified framework to train and evaluate future approaches to this task. This is also evidenced by the success of existing works, e.g. Bostan and Klinger (2018) for sentence-level Emotion Classification and Raganato et al. (2017) for Word Sense Disambiguation. In SRL4E, not only do we aggregate the resources under the same task formulation, but we also manually correct their inconsistencies and unify the different emotion schemes.

3 SRL4E

In this Section, we introduce SRL4E. We first describe the categories of emotions and the format of the semantic roles we adopt to unify the annotation scheme of the original datasets. Next, we provide a short overview of the datasets included in SRL4E. Finally, we give a formal definition of the task.

3.1 Cue, Experiencer, Target, Stimulus

The task of SRL (Gildea and Jurafsky, 2000) is aimed at identifying, given an input sentence, who or what the participants are in an action or event denoted by a predicate. As mentioned in Section 2, this is comparable to answering the question "*Who* did *What* to *Whom*, *Where*, *When* and *How*?" (Màrquez et al., 2008). When it comes to emotions, however, the task does not necessarily revolve around an action, but more precisely around an *emotional cue*, a word or an expression that acts as a trigger for an emotion. Therefore, it would be more appropriate to reformulate the question as: "*Who* feels *What*, *towards Whom* and *Why*?". To answer this question, we first need to define a set of semantic roles, i.e., semantic relations that can exist between an emotion CUE and its semantic constituents. Following previous work (Mohammad et al., 2014; Bostan et al., 2020), we take a subset of semantic roles, namely, EXPERIENCER, TARGET and STIMULUS, from those defined in the "Emotion" semantic frame of FrameNet (Baker et al., 1998). While the use of thematic roles allows for human-readable labels (Kipper Schuler, 2005; Di Fabio et al., 2019), we also provide their respective definitions in Table 1.

3.2 Choosing a common set of emotions

In psychology, the debate on which categories are best suited for describing emotions is still open (Barrett et al., 2018; Cowen and Keltner, 2018; Cowen et al., 2019a). There are numerous studies that try to tackle this problem, and some of the most authoritative were briefly described in Section 2, above. In this work, we adopt Plutchik's Wheel of Emotions (Plutchik, 1980, 2001) to standardize the heterogeneous emotion categories used in the various datasets. Plutchik's Wheel of Emotions is composed of a coarse-grained set of 8 basic emotions: *anger*, *fear*, *sadness*, *disgust*, *surprise*, *anticipation*, *trust*, and *joy*. These emotions can be compounded into "dyads" which express the much wider range of human feelings, with the advantage of maintaining a solid and unambiguous base set. For example, combining *anticipation* together with *joy* describes the emotion of *optimism*, whereas *anticipation* with *sadness* describes *pessimism*. Further compositions are described in Appendix A.

SRL4E includes 6 datasets:

Role	Definition
CUE	Trigger word or expression that describes (even implicitly) an emotion.
EXPERIENCER	Person or entity that feels or experiences the emotion identified by the CUE.
TARGET	Person or entity towards whom/which the emotion identified by the CUE is directed.
STIMULUS	Entity, action or event that causes the emotion identified by the CUE.
Emotions	*anger*, *anticipation*, *disgust*, *fear*, *joy*, *sadness*, *surprise*, *trust*, and *other*.

Table 1: Definitions of semantic roles (CUE, EXPERIENCER, TARGET, STIMULUS) and emotion categories we use in SRL4E.

- Kim and Klinger (2018) and Bostan et al. (2020) use Plutchik's or Plutchik-based emotions;
- Aman and Szpakowicz (2007) and Gao et al. (2017) use Ekman's or Ekman-based emotions, which are a subset of Plutchik's set and can be directly mapped to it;
- Mohammad et al. (2014) use 19 emotions, but provide a mapping to Plutchik's emotions;
- Liew et al. (2016) use 28 emotions for which we provide a mapping to Plutchik's emotions.

We provide a more detailed description of each dataset in Section 3.3.

As a further contribution, we produce an alignment of each set of emotions to a sentiment polarity – positive, negative, neutral, or other (used when polarity cannot be inferred based on the emotion category) – to allow SRL4E also to be used to train and evaluate a system on Semantic Role Labeling for Sentiments.

3.3 Sources

In the following, we describe the datasets that we included in SRL4E. For each dataset, we provide general information, including source, domain, format and tagging scheme. We also indicate where we intervened manually to identify and correct errors such as typos, format errors and inconsistencies. Table 2 reports the sizes of the original and converted datasets in SRL4E. Table 3 summarizes which annotations form part of the original corpora and, therefore, which ones are also part of SRL4E. We report the license, availability and link of each resource in Appendix B.

Blogs. This dataset, proposed by Aman and Szpakowicz (2007), consists of 5,202 sentences, extracted from 173 online blog posts. Each sentence is annotated using Ekman's six emotion categories and *no emotion*, along with intensities. The words or spans that indicate emotions are marked, allowing us to remap them to the CUE in our unified format. The dataset was annotated by two experts. For each sample, we decided to consider only the CUES that were annotated with the same emotion by both annotators. Where possible, we manually identified and corrected some annotations containing typos.

Table 3: Annotations for each of the datasets making up SRL4E.

Elections. This dataset, introduced by Mohammad et al. (2014, 2015), includes 1,385 unique tweets related to the 2012 US presidential election and collected using the Twitter API. The tweets were annotated via crowdsourcing using an informative tagging scheme which comprised not only

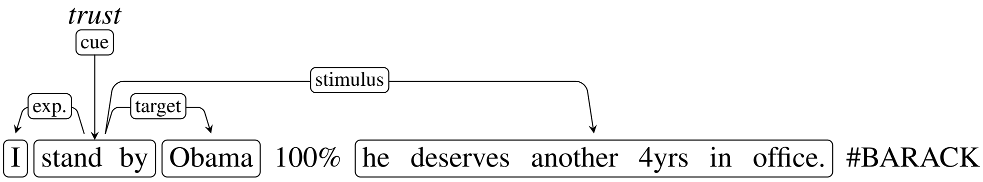

Figure 1: A sentence from the Elections dataset (Mohammad et al., 2014) using the SRL4E format. Here, the CUE expression is "stand by", and its associated emotion is Trust. The participants to the emotion are "I" (EXPERIENCER of Trust), "Obama" (TARGET of Trust), and "he deserves another 4yrs in office" (STIMULUS of Trust).

a set of 19 emotions, but also other features such as emotion intensity, valence, purpose, style, CUE, EXPERIENCER, TARGET and STIMULUS. Each sample was annotated by multiple people, i.e., each sample appears more than once with different annotations, one for each annotator. We adjudicated role spans by majority voting, discarding all the tweets with conflicting annotations.

EmoTweet. EmoTweet, presented by Liew et al. (2016), is the largest dataset that we include in our unified resource. It comprises 15,553 tweets, collected through the Twitter API using various sampling strategies (e.g., by user, by topic, random, etc.) and annotated via crowdsourcing. The original tagging scheme of this dataset features 28 emotion categories along with valence and arousal. For each emotion, the CUES are indicated and are easily mappable to our unified format. However, a mapping to Plutchik's emotions is not provided by the authors, so we formulated a conversion scheme based on the similarity of the emotion categories with those from other works that are instead mapped to Plutchik's emotions, such as Demszky et al. (2020). In addition, we also intervened to identify and manually correct some typos in the annotations.

GNE. GoodNewsEveryone, proposed by Bostan et al. (2020), is a dataset composed of 5,000 news headlines from 82 sources, annotated via crowdsourcing. It is labeled with writer and reader emotions using a set of emotions derived from Pluthick's classes and is, therefore, easily mappable to the standard Plutchik set. To keep the annotations consistent with those of the other datasets in our unified framework, we considered only the writer's emotions. GNE provides annotations for every semantic role we include in our framework, namely, CUE, EXPERIENCER, TARGET and STIMULUS, making this resource highly valuable for our purposes. Whenever possible, we identified and manually corrected the annotations that contained typos.

NTCIR 13 ECA. This dataset was proposed as a part of the NTCIR 13 Emotion Cause Analysis task. It consists of 1,826 unique sentences from English novels and 2,022 unique sentences from Chinese news, annotated using Ekman's classes. Moreover, emotion keywords and causes are annotated, making them suitable to be considered, respectively, as CUE and STIMULUS in our unified format.

REMAN. Relational EMotion ANnotation, introduced by Kim and Klinger (2018), is a corpus consisting of 1,720 fictional text excerpts from Project Gutenberg. These documents were annotated using an informative tagging scheme, which included emotion categories based on Plutchik's set, CUE, EXPERIENCER, TARGET, STIMULUS, named entities, events and coreferences, making it another desirable dataset for our unified framework. For some sentences, we automatically identified and manually corrected some typos in order to increase the overall quality of this dataset.

3.4 Task Definition

Here we provide a more formal definition of the SRL4E task. Unlike the majority of previous work on emotion detection, instead of assigning an emotion to a sentence, we associate each emotion with a CUE. In this way, in each sentence, more than one CUE can be identified and associated with its corresponding emotion category and semantic roles, allowing the coexistence of multiple emotions, EXPERIENCERS, TARGETS and STIMULI in the same sentence. A visual representation of the relationship between CUE, emotion category and roles is shown in Figure 1. To the best of our knowledge, other than SRL4E, Liew et al. (2016) and Kim and Klinger (2018) are the only approaches that leverage CUES to model the presence of multiple emotions in a sentence.

In general, the task of Semantic Role Labeling

Resource	text	cue	exp.	targ.	stim.
Blogs	13.95	2.09	–	–	–
Elections	16.66	8.29	0.02	2.19	7.92
EmoTweet	15.94	3.72	–	–	–
GNE	11.32	1.44	1.80	4.64	7.19
NTCIR (EN)	57.71	1.37	–	–	8.72
REMAN	59.15	1.84	1.53	3.81	7.36
All	19.87	2.86	1.46	4.18	7.55

Table 4: Average length (in words) of text and roles of the corpora in SRL4E (only English ones are reported). Note: EXPERIENCER average length is less than one because it is very often labeled as "author" and in this case it does not appear explicitly in the text.

for Emotions can be divided into three key steps: CUE identification, emotion classification and role identification. While there are no hard constraints on the order of these steps, we believe that CUE identification should be done first since its output will serve as the input of the other two steps, however, we also believe that our framework could be a step towards the development of joint approaches that solve the three steps at the same time.

Cue identification. As we described earlier, the CUE acts similarly to a predicate in SRL. Indeed, the main objective of CUE identification is to recognize where and how many emotions are present in a sentence, and what their trigger words or expressions are. The output of this step consists of a set of CUES, each corresponding to an emotion in the text, as illustrated in Figure 1.

Emotion classification. Traditional approaches in emotion classification take as input a sentence and output the emotion class corresponding to that sentence. In SRL4E, instead, given a pair (sentence, CUE) we want to classify the emotion expressed in the sentence by the indicated input CUE. Note that the result of this approach is not necessarily the same as a sentence-level approach.

Role identification. As previously stated, SRL aims at identifying the semantic constituents of an action expressed by a predicate. In SRL4E, instead, we are interested in identifying the actants of an emotional event which is hinted at by the CUE. Therefore a CUE can be considered in the same way as a predicate in SRL and role identification consists in identifying all those spans of text that have a semantic relationship – EXPERIENCER, TARGET, STIMULUS – with the CUE.

Figure 2: Distribution of categories in the corpora of SRL4E. Note: for each dataset the sum is not necessarily 100%, since there are samples where more than one CUE appears, and others where no CUES (and therefore no emotions) appear at all.

4 Data Analysis

Emotion classes distribution. Depending on the dataset, the distribution of emotion classes changes drastically, as illustrated in Figure 2. For example, in Elections, which contains random tweets related to an American election campaign, almost 45% of samples are tagged with *disgust*, as one might expect: this is because many of the tweets in question tend to discredit the opposing party; similarly, the second most used class is *trust* in the tweets in favor of candidates. Another interesting example is GNE, where the most frequent category is *surprise*, highlighting the sensationalistic tone typically found in newspaper headlines. It is worth noting that, in contrast to each individual dataset, our unified dataset includes a fairly balanced distribution between categories, where the only category that appears more often is *joy* (20%), while all the others are between 6% and 10%, approximately.

Other statistics. The statistics reported in Table 4 show the heterogeneity of the resources included in our framework, with very different text and role lengths. In fact, datasets containing sentences from similar domains share similar values. For example, REMAN and the English version of NTCIR both come from novels and they have comparable text lengths, from 58 to 59 words on average. Instead, Blogs (from online blog posts), Elections and EmoTweet (from tweets) have much shorter sentences, from 14 to 16 words, approximately.

Table 4 also shows that almost all CUES are very short, usually around 1-2 words; only those datasets involving tweets have a much higher value. In fact, in EmoTweet and Elections, CUES contain 4 and 8 words on average, respectively, due to their dense emotional content and, therefore, their larger number of trigger expressions. It is interesting to note that all datasets feature a similar average length for STIMULI, regardless of the domain.

Borderline examples. SRL4E's formulation is based on the presence of CUES within sentences, which are seen as the trigger of the emotion in that context. This formulation particularly suits those domains where emotions are expressed explicitly, such as GNE, NTCIR and REMAN. However, handling CUES becomes non-trivial in some situations, for example in social networks (Elections and EmoTweet) and blog posts (Blogs). In these contexts, language features numerous implicit references and ironic content, where the mere presence of an emoji or a particular punctuation mark completely changes the context. In our task formulation, the presence of a CUE is a fundamental requirement even if it may be difficult to identify, as we want to be able to model multiple, sometimes opposite, emotions in the same sentence. Here is an example:

- “@user Quieter. My sis, brother in law and habibti are going back to Ireland this afternoon [;/]$_{\text{CUE}}$ Tennis doubles [sounds fun]$_{\text{CUE}}$! [Enjoy]$_{\text{CUE}}$! #Juice!”

In this case, the *sadness* emotion is associated only with the first CUE, which is “;/”, while the *joy* emotion is associated with the other two. Even if a CUE is composed only of punctuation marks (or emojis), it may still be the only useful signal for disambiguating the emotion, or for separating the presence of multiple emotions in the same sentence.

5 Experiments

In this Section, we analyze the benefits that our unified framework can bring to a neural model, based on recent contextualized representations from a pretrained language model.

5.1 Emotion Classification

The main roadblock to the development of neural models for Semantic Role Labeling for Emotions is the heterogeneity of the emotion labels employed by each currently available dataset. Therefore, we first evaluate the benefits that a unified framework brings in emotion classification. Note that, differently from traditional sentence-level Emotion Detection, here we are interested in assigning an emotion to a given (sentence, CUE) pair, so as to allow a sentence to be assigned different emotions depending on the CUE considered.

Model description. We design a simple neural baseline composed mainly of a BERT-based word representation module and a stack of BiLSTM layers. Given an input sentence $\mathbf{w}$ and a pre-identified CUE $\mathbf{c}$, the two are concatenated as an input sequence $\mathbf{s} = \text{[CLS]}\ \mathbf{w}\ \text{[SEP]}\ \mathbf{c}\ \text{[SEP]}$ and fed into the BERT-based word representation module, obtaining a sequence of word encodings $\mathbf{e} = \text{BERT}(\mathbf{s})$. These word encodings are further processed by a stack of 2 BiLSTM layers with hidden size 512 to obtain a new sequence of output encodings $\mathbf{o} = \text{BiLSTM}(\mathbf{e})$. Finally, the output encoding $\mathbf{o}_{\text{[CLS]}}$ corresponding to the [CLS] token is fed into a linear classifier which outputs the emotions corresponding to the (sentence, CUE) pair.

Each model configuration is trained to minimize a binary cross-entropy loss for emotion classification (more than one emotion can be assigned to a given input), for a total of 20 epochs with Adam and a learning rate of 10^{-3}, leaving the weights of the underlying language model frozen.

Results. Table 5 shows the results of our system on emotion classification. First, our unified framework reveals that a system trained on a single dataset can achieve good results on the test set of the same dataset, i.e., on an in-domain evaluation, but is not able to perform as well on other datasets, i.e., on out-of-domain evaluations. Instead, the same system trained jointly on the datasets of SRL4E is able not only to perform consistently across all the test sets, but also to improve over the same system trained on in-domain data only, demonstrating empirically the effectiveness of employing a unified scheme for emotion classification. This is not a given, since each dataset differs – sometimes significantly – from the others in domain and linguistic register. On average, when using multilingual-BERT as the underlying language model, our unified framework provides an improvement of 11.2% in F1 score over EmoTweet, the second best dataset (64.3% against 53.1%). Moreover, Table 5 shows that our unified framework

allows our system to improve in bilingual emotion classification (77.8% against 22.8% in F1 score on ALL).

5.2 Cue Identification

We now turn to CUE identification, where we aim to find every CUE in an input sentence. We frame this subtask as a BIO-tagging problem and devise a neural model to highlight the benefits of our unified framework in this task.

Model description. For CUE identification, we use a similar system architecture to the one we used for emotion classification. However, this time the input of the BERT-based word representation module is just the input sentence, whereas the output is a sequence of BIO tags. Specifically, the output encodings $\mathbf{o} = \mathbf{o}_1, \dots, \mathbf{o}_n$ produced by the last BiLSTM layer are given to a classifier which learns to predict B-cue, I-cue or O.

Results. As one can see in Table 6, similarly to what we observed in emotion classification, our unified framework highlights how a model trained on a single dataset is not robust to out-of-domain evaluations. Instead, the same model trained on all the datasets in SRL4E shows consistent results across all the test sets, providing a significant improvement in F1 score over the second best dataset, EmoTweet (56.5% against 47.3% in F1 score on ALL, with an absolute improvement of 9.2%).

5.3 Role Identification

Model description. For role identification, we use an approach similar to that for CUE identification. Indeed, similarly to CUE identification, we model role identification as a BIO-tagging problem, with the only difference being that we provide the pre-identified CUE in input, i.e., the input sequence is $\mathbf{s}$ = [CLS] $\mathbf{w}$ [SEP] $\mathbf{c}$ [SEP], where $\mathbf{w}$ is the input sentence and $\mathbf{c}$ is the CUE span.

Results. We find that our results on the identification of each role are in line with the results from CUE identification, leading us to draw similar conclusions (see Tables 7, 8 and 9). In general, we see a familiar pattern in which training our baseline model on a single dataset results in good perfor-

mances on that specific dataset, but with significantly lower results on out-of-domain data.

5.4 Result Analysis

Results generally benefit from a unified resource. For instance, emotion classification and STIMULUS identification almost always struggle in out-of-domain evaluations, while they perform better when the model is trained on all the datasets at the same time.

The only exception is CUE identification: when our model is trained on all the data in SRL4E, the performance drops when measured on each dataset separately. This is to be expected: while STIMULI follow a similar syntactic pattern across domains, CUES appear in very different forms (e.g., Twitter usually contains highly informal language with explicit emotions, while news headlines tend to try to describe events objectively, making emotions more implicit). Instead, when the datasets share a similar domain, the model is able to generalize well, even in cross-lingual settings (such as the English and Chinese versions of NTCIR), highlighting once again the advantages of our unified framework.

6 Conclusion and Future Work

Recently, the study of emotions in NLP has been gaining interest, due to their potential not only for application to downstream tasks, but also for enhancing the interpretability of automatic outputs, especially when emotions are accompanied by information about their semantic constituents, i.e., their experiencers, targets and stimuli. However, recent efforts to provide manually annotated data for emotions and their semantic constituents have been heterogeneous in their annotation scheme, making it difficult to train, evaluate, and compare novel approaches.

In this paper, we aimed at addressing these issues and presented a unified framework for the Semantic Role Labeling of Emotions (SRL4E). Our framework collects, cleans, and unifies the annotation schemes of six datasets that provide information about emotions and their semantic roles, making it easy to train and evaluate existing and future systems. We conducted several experiments to demonstrate empirically that our unified scheme is beneficial in each subtask, namely, emotion classification and role (experiencer, target, stimulus) identification, especially in bilingual settings (English-Chinese). With SRL4E, we hope to stimulate future research in this complex area at the intersection of Emotion Detection and Semantic Role Labeling. We release the software to reproduce the benchmark and our experiments at `https://github.com/SapienzaNLP/srl4e`.

A Plutchik's Wheel of Emotions

Pluthick's basic emotions – *anger*, *anticipation*, *disgust*, *fear*, *joy*, *sadness*, *surprise* and *trust* – can be compounded into "dyads" to form even more complex feelings. The compositions are shown in Figure 3. These can be used to describe the emotional context in which basic emotions are not enough, but a more fine-grained set is needed.

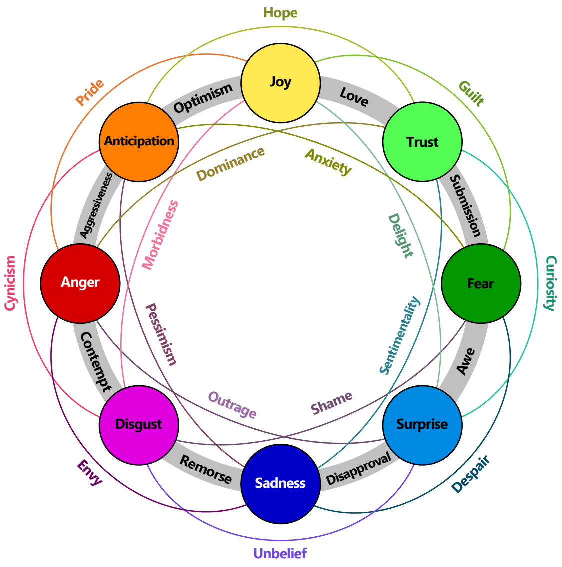

Figure 3: Pluthick's emotion dyads (Wikimedia, 2020)

- **REMAN.** This dataset is freely available online[4] under CC BY 4.0 license.

A summary of the above information is reported in table 10.

C Comparison

Oberländer et al. (2020) did, in fact, aggregate a similar set of corpora (which is now actually a subset of SRL4E) for addressing emotion classification, however, we stress that our task formulation is different: their goal is to study which semantic roles allow models to infer emotions.

Instead, SRL4E proposes a novel task formulation, together with a unified dataset for such a task. Moreover, as opposed to the above mentioned work, SRL4E assigns emotions to CUES, not to whole sentences. Finally, our dataset is larger, treats Emotion Classification as a multi-label classification task (i.e. multiple emotions can be assigned to the same CUE) and features a manual correction of annotations issues (e.g. typos, inconsistencies).

D Experiments: Additional Results

Additional experiments were conducted to compare the performance of the models in monolingual and multilingual settings. Results for emotion classification and sentiment classification are reported in Tables 11 and 12, respectively.

E SRL4E Format Example

SRL4E generates a set of JSON files. An example of how a sample is represented in SRL4E format is shown in Listing 1.

Abstract

In linguistics, there are two main perspectives on negation: a semantic and a pragmatic view. So far, research in NLP on negation has almost exclusively adhered to the semantic view. In this article, we adopt the pragmatic paradigm to conduct a study of negation understanding focusing on transformer-based PLMs. Our results differ from previous, semantics-based studies and therefore help to contribute a more comprehensive – and, given the results, much more optimistic – picture of the PLMs' negation understanding.

1 Introduction

Transformer-Based pre-trained language models (PLMs) have become the *de facto* standard in a variety of natural language processing tasks. Based on the original transformer architecture (Vaswani et al., 2017), researchers have proposed a number of extraordinarily successful architectures, such as BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), XLNet (Yang et al., 2019), and smaller versions such as DistilBERT (Sanh et al., 2019). Such transformer-based models perform impressively at standard natural language understanding (NLU) benchmarks, often outperforming the human benchmark, as evinced by the GLUE and SuperGLUE Leaderboards (Wang et al., 2018 and Wang et al., 2019).

While it is impossible to deny the performance of these models at such benchmarks, it is another, particularly challenging question whether this performance is driven by simple shallow heuristics or by any real understanding of the languages that they are processing.[1] This study contributes to answering this question with a focus on negation.

Answering the question is important for both theoretical and practical reasons. On the theoretical side, the study contributes to a more accurate understanding of the driving forces behind the predictions issued by PLMs. The phenomenon of negation, being both highly semantically relevant and having a small footprint on the syntactic surface of a sentence, is ideally suited for this purpose. For real-world applications, it is crucial to know whether the model predicts based on simple contextual clues or on a real understanding of negation. For instance, for NLU applications, it makes a substantial difference whether a certain microblog recommends that one should "(not) get vaccinated against covid-19".

The question is challenging for two main reasons. First, because the models' performance is typically strong. However, it is wrong, not correct predictions that potentially unveil underlying heuristics. Second, as we will show, it requires careful, linguistically conscientious construction of the datasets to be able to draw sound conclusions even from wrong predictions. For example, if a model predicts "fly" in example (1), this has been taken by most researchers as a clear indication that the model does not understand negation, especially if its confidence in this prediction is similar to the confidence with which it predicts "fly" in example (2).

(1) Birds cannot **fly**.

(2) Birds can **fly**.

In contrast, our hypothesis is that this behavior of the models is not due to lack of negation understanding, but to a failure to, as it were, resolve the context in samples such as (1) and (2). While human beings automatically read sentences such as (1) within a default context, perhaps something like a biology class in primary school, where it is clear that birds can fly, this does not mean that it is never sensible or appropriate to say that they

---

[1] Compare the appendix, section A, for a more elaborate sketch of the theoretical background of our concept of real understanding.

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 4602 - 4621
May 22-27, 2022

cannot.[2] Our hypothesis is grounded in the linguistic research tradition called "pragmatics", while virtually all research in NLP focusing on negation understanding is based on the competing tradition called "semantics" (for a case in point, see Kassner and Schütze, 2020, who use samples very similar to (1) and (2)). Semanticists tend to assume that truth values and appropriateness of propositions are unambiguous and context-independent. Pragmatics, in contrast, emphasizes the importance of context and of syntactic, prosodic and other details to judge the appropriateness of a sentence. See below, section 3, for more details and references.

To test our hypothesis, we construct datasets that, while being designed to be challenging to the models, provide a micro-context that allow us to rule out failure to resolve context as a cause of wrong predictions by the models.

In detail, we contribute to the investigation of transformer-based PLMs in three ways. **First**, following the pragmatic tradition in linguistics, we develop a novel testing approach for negation understanding. Rather than using isolated sentence-pairs such as (2) and (1), our approach builds on automatically creating pragmatically and stylistically sound micro-contexts. **Second**, by tailoring our datasets to the individual models to be tested, and by varying a number of possibly influencing factors, we are able to pin down precisely the true driving forces behind the models' predictions. **Finally**, by fine-tuning the most successful models, we gain a view towards the potential for improving the performance with such fine-tuning.

2 Previous NLP Research on Negation

We emphasize that our study is not directly connected to research on negation clue and scope detection (for an overview on that research, see Khandelwal and Sawant, 2019). Rather, our experiments test whether the models are able to process the information contained in a negated sentence to predict a semantically admissible token in a following sentence.

Hence, our research is connected to other work that examines various aspects of transformer-based PLMs (the field is often called "BERTology", testifying to the dominance of BERT-focused studies in this area). Rogers et al. (2020) provides an overview. There are studies examining the inner functional differentiation of the system's parts, such as Voita et al. (2019), whose findings suggest that many of the attention heads of the original transformer are superfluous; Kovaleva et al. (2019) examine the functions of BERT's attention heads and find none that are specifically dedicated to negations. Wiedemann et al. (2019) report state of the art performance in word-sense disambiguation using BERT's contextualized word embeddings. Forbes et al. (2019) study the models' abilities to learn so-called "physical commonsense". Zhang et al. (2021) find that large models fare better in particular regarding common-sense reasoning (and show little improvement over smaller models with regard to semantic or syntactic tasks).

As we are trying to get the models to commit mistakes that reveal underlying shallow heuristics, our research is connected to so-called adversarial attack or probing studies. These studies are trying to go beyond the NLU benchmarks such as GLUE and SuperGLUE to see whether the models achieve their impressive performance using shallow heuristics or real understanding. There are such studies in the field of argument reasoning (Niven and Kao, 2019) and natural language inference (McCoy et al., 2019). Geirhos et al. (2020) have proposed a general diagnosis of the problem of shallow heuristics, and Ribeiro et al. (2020) have urged a more comprehensive, multi-dimensional approach to testing the abilities of these models instead of simply submitting them to automated benchmarks.

Furthermore, as we are studying negation by testing whether the models are able to draw very simple inferences, research in natural language inference (NLI) is also relevant for our work. In this regard, Gururangan et al. (2018) show that, in the main datasets used in NLI, negated sentences are biased towards contradiction, Wallace et al. (2019) show that certain triggers can be inserted context-independently and lead to a stark decline in NLI accuracy, and Hossain et al. (2020) show that simply ignoring negation does not substantially decrease model performance in many NLI datasets. Notably, Jeretic et al. (2020) is among the rare NLP studies that presuppose a pragmatic background, studying the ability of PLMs to cope with implicatures.

Of particular importance for our study are contri-

---

[2] For instance, when observing an ostrich, somebody might use (1) as a shorthand for "These are some birds that cannot fly". Furthermore, one can imagine example (1) to pop up in multiple-choice examinations, many dialogues ("Birds cannot fly? – Of course they can!"; "Barcelona cannot win the Champions league!" – "Oh yes, and birds cannot fly."), fictional literature, etc.

butions by Warstadt et al. (2020), Ettinger (2020), and Kassner and Schütze (2020). All three studies develop minimal pairs to examine the ability of PLMs to correctly categorize a number of linguistic phenomena, including negation. Hence, all of these studies are squarely based on the semantic side of the ongoing debate in linguistics between semantics and pragmatics (see above, section 1, examples (1) and (2)), and all of them find that the models largely ignore negation, as for each minimal pair, the predictions differ little between positive and negated sentence; Ettinger (2020) finds slightly better performance for more natural examples, hinting at the relevance of pragmatics in this context.

3 Linguistics & Philosophy of Language: Understanding Negation Between Semantics and Pragmatics

Negation is a multi-faceted phenomenon that can be realized in a number of ways. In the study of negation, it is common to distinguish two very different approaches in linguistics and philosophy of language: semantics and pragmatics (for a recent discussion of the distinction, see Preyer (2018)). The tradition of semantics has been initiated in its modern, formal-logical form by Frege (1892). Arguably the most important analysis of negation in this semantic tradition is Russell (1905). For a recent contribution in this tradition with a focus on computability, see Moot and Retoré (2019). As mentioned above, (section 1), semanticists often try to context-independently assess the truth of a proposition.

Pragmatic studies of negation understanding have traditionally had a focus on the readings of ambiguous negated sentences, and on systematic ways in which conversational contexts and other non-semantic features systematically disambiguate such sentences (e.g., identifying types of contexts in which example (1) is read as containing a negated universal quantifier, as opposed to the types of contexts in which it is read as containing a negated existential quantifier). Noveck (2009) provides an overview on recent experimental-pragmatic research on negation understanding. For a study with a focus on the influence of context on human's understanding of negation, see Kaup (2009). In his seminal study of negation, Horn (2001, 368f.) also discusses contextual factors, Davis (2016) continues in Horn's footsteps.

Furthermore, according to the orthodox Gricean version of conversational implicatures (see Davis, 2019 for an introduction, for canonical texts by Grice see Grice, 1975, Grice and Strawson, 1956, and Grice, 1978), one can assume that participants follow conversational maxims, including the one of relation. This maxim urges the participants to a conversation to only contribute statements that are relevant. Accordingly, merely repeating the same assertion in a discourse would be seen as apparently violating this maxim, and hence as calling for a non-standard interpretation according to which the statement is, *pace* first appearances, in agreement with that maxim.

Based on this pragmatic perspective on meaning, and on its emphasis on the importance of context in particular, testing anybody's negation understanding abilities with minimal pairs such as examples (1) and (2) is questionable: There are many contexts in which it is appropriate to say that birds cannot fly, and these contexts might be more common than others where, say, it is appropriate to say that birds cannot breastfeed – even if the latter, but not the former would be considered true from a zoological point of view. This pragmatic perspective then grounds our hypothesis that it is context resolution, not negation understanding, that explains the models' performance on minimal-pairs such as (1) and (2), which is the main evaluation method in current research.

4 Dataset

Following our pragmatic outlook and our hypothesis, we construct our datasets always using micro-contexts to guide the models and to avoid confounding inability to determine context with inability to understand negation. Furthermore, we pay careful attention to grammatical details that might influence prediction, and we construct our positive examples (those not containing a negation) such that they respect the maxim of relation.

We here give the generic way how we create our datasets. In the following section 5, we discuss the experiment-specific details of the templates used in each of the experiments. As we are tailoring our datasets to each individual model, we actually create some 12 million of potentially different test sentences in total. We have discussed each of the templates (43 in total) with a native speaker and philosopher of language, Dr. David Dolby. We detail how his review has influenced the dataset in the appendix, section C.

4.1 Step 1: Hand-Craft Templates

For each experiment, the first step consists in hand-engineering suitable templates. A simple example for the kind of template that we want to test the models on is given by (3), together with possible replacements for the placeholders in curly brackets.

(3) FNAME{Petra} is PROF{an architect} who doesn't like to ACT{sail}. However, she does like to MASK.

In template (3), "FNAME" (its male counterpart being "MNAME") is a placeholder for entries in a list of female first names to be used in the following step, "PROF" is a placeholder for a profession, also to be used in the next step. The ACT-placeholder will be replaced with a verb specific to the respective name and profession as well as to the respective PLM under scrutiny. A model that understands negation is not going to predict "sail" (or, more generally speaking, any verb taking the position of the ACT-placeholder, what we call ACT-replacement) to replace the MASK token. We would call such a prediction an *exactly wrong prediction*.

4.2 Step 2: Fill in First Names and Professions

Once the templates such as the one given in (3) are available, we expand each of them into 9.1k unsaturated sentences by replacing the F/MNAME- and PROF-Placeholders with pre-set lists of male and female names and professions. [3]

Having completed step 2, our template (3) might have been developed into the unsaturated sentence shown in (4). The name and profession placeholders have been replaced by real names and professions; the only remaining placeholder is "ACT".

(4) Jessica is a printer who doesn't like to ACT. However, Jessica does like to [MASK].

4.3 Step 3: Extract Tailored ACT-Tokens of Specific Probability Ranks

In this third step, we replace the ACT-placeholders with verbs that are specific not only to the given unsaturated sentence (that is, specific to the given sentential context and to the specific combination of name and profession), but also to the model under scrutiny. We achieve this by individually extracting each model's predictions of the desired probability rank for the MASK in (5) and use it to replace the ACT-placeholder(s) in the unsaturated sentence at issue.

(5) Jessica is a printer and she likes to [MASK].

We run our first experiment with probability ranks 0, 50, 100, and 200. The goal of this procedure is to control for the overall probability of the ACT-token that the model might be tempted to repeat.

We expect that the models are more likely to wrongly repeat a negated ACT-token if it has a low probability rank: In this case, the model is inclined to predict it in contexts involving the given gender, first name, and profession; therefore, absent any understanding of negation, using an ACT-token of low probability rank makes it likely that the model will predict it to fill the MASK in patterns such as (3). In contrast, the model is very unlikely to predict an ACT-token of very high probability rank in these contexts. As a consequence, we expect the models to be less inclined to predict such ACT-tokens of high probability rank. However, the very occurrence even of such ACT-tokens might incline some models to predict them, despite both the overall low probability rank and the presence of negation.

For instance, assuming that we want to use probability rank 0 to fully specify unsaturated sentence (4) with regard to `roberta-large`, our method proceeds as follows. For `roberta-large`, the top three predictions to fill the MASK in (5) are: draw (prob. 0.21), write (prob. 0.16), and travel (prob. 0.15). Hence, we replace the ACT-placeholder in (4) with "draw", yielding (6). If we were running the experiment with probability rank 200, we would adapt the probability rank of the token used to replace the ACT-placeholder accordingly.

(6) Jessica is a printer who doesn't like to draw. However, she does like to <mask>.

Here, we have a fully-fledged, grammatical sentence with a MASK token. While "Jessica" and "printer" have been inserted using the lists, "draw" has been dynamically selected specific to both "Jessica" and "printer" as well as to the model under scrutiny by letting the model predict the MASK token in (5).

Unlike minimal pairs such as (1) and (2), this example (6) gives a minimal context: The situation in which the prediction of the MASK-token is to be made is one where Jessica does not like to draw.

---

[3] We use the top 100 male and female names in the USA between 1920 and 2019 according to the US social security administration. See here. For the professions, we use a list of 91 common professions.

As a consequence, if the model predicts "draw", it cannot be because of lack of understanding of context.

5 Experiments

For our experiments, we use the models provided by Huggingface (Wolf et al., 2019). We fine-tune the most promising models using a dataset that has been filtered from English Wikipedia with a rather simple regular expression, yielding 315 thousand sentences. For details, see the appendix, section D.

We have conducted three different experiments using the dataset creation method spelled out in the previous section. All of our experiments obey the basic pragmatic requirement to use micro-contexts, we pay attention to syntactic details that might matter for prediction, and we observe the maxim of relation for positive samples (requiring that we don't expect the models to merely repeat information). The first experiment forms the basis, it examines the ability of the models to correctly use information contained in negated sentences for prediction in a later sentence. In the second experiment, we use three kinds of misprimes to see whether this confuses the models, and in the final experiment, we test whether the models are sensitive to changes of referents. For a full list of the templates used in all experiments, see the appendix, section B; the scripts as well as these templates are also available on github.[4]

Experiment 1 In the first experiment, we used sentences of the form (7) and (8) to test the models' sensitivity to negation.

(7) MNAME is PROF who doesn't like to ACT. However, he does like to MASK.

(8) FNAME is PROF who tries to ACT as often as possible. So, she really does like to MASK.

Note that, with these templates, we made sure that the negated versions have a higher subsequence overlap than the corresponding positive versions, as the PLMs have a reputation for reacting strongly to such subsequences ("subsequence overlap" here refers to the overlap in tokens between the context where the ACT-token occurs and the context where the MASK occurs, see McCoy et al. 2019). This means that, if the results show that the models predict an ACT-token to fill the MASK more often with positive than with negated sentences, this cannot be because of the subsequence heuristic, as following this heuristic would pull the models ' prediction in the opposite direction. From a linguistic perspective, examples such as (8) obey Grice's maxim of relation by introducing new information in the second sentence.

Furthermore, we varied gender and the number of ACT-tokens in the first sentence (ranging from 1 to 3), and we also varied the extent to which we syntactically express the contrast in the negated version, motivated by pragmatic attention to syntactic detail. Starting from example (7), we first removed the conjunction ("However"), then we also removed the "does", which also marks a contrast. In the positive version, we added templates that do not have a conjunction signaling implication ("So"). Overall, this yields 30 different templates, which we expanded into sentences as described in the previous section. Then, we let the models predict the tokens to fill the MASK.

Experiment 2 In the second experiment, we wanted to further probe the robustness of the models' negation understanding by adding specific misprimes. Examples (9), (10), and (11) illustrate the patterns used here.

(9) MNAME is PROF who doesn't like to ACT. Of course, many people like to ACT. MNAME, in contrast, likes to MASK.

(10) MNAME is PROF who doesn't like to ACT. Many people, but not MNAME, like to ACT. MNAME likes to MASK.

(11) MNAME is PROF who doesn't like to ACT. Today is Tuesday and the Sun is shining. MNAME likes to MASK.

By varying gender as well as the presence or absence of a contrastive conjunction ("in contrast"), we obtained 10 templates, which we expanded and saturated as described above.

The basic idea behind templates of the kind of (9) and (10) is to bring to light shallow heuristics that are based on occurrence of the verbs in the context of the MASK to be filled. The expectation is that, if the models do not represent any logical structures involving negation, then the logically more explicit patterns of the form (10) are going to be more misleading to them than the less explicit ones of the form (9): in the former sentences, the proper

---

[4] https://github.com/retoj/transnegpaper_acl2022pub.

name appears again in the context of the activity that is not supposed to be predicted as a filler of the MASK. The random sentence inserted in (11), finally, is intended to test whether the models can transfer information contained in a negation across an unconnected sentence (one, notably, that might appear odd to humans as well, but which would not lead them to forget about the negated sentence).

Experiment 3 This third experiment, finally, is entirely dedicated to assessing whether the models are sensitive to changes in referents. By using templates of the form (12) (3 in total), we wanted to see whether the models are sensitive to obvious changes in referents.

(12) MNAME is PROF who doesn't like to ACT. Unlike MNAME, Cleopatra does like to MASK.

In templates such as (12), we included gender-incongruity and different proper names to clearly signal that the person of the first sentence that does not like to ACT is not the same as the Cleopatra of the second sentence.

6 Results

In the following, we report on the results of the experiments conducted as described in the previous section. The key figure that we are reporting is the percentage at which the model predicted an ACT-replacement token (in the following: "ACT-token"), for instance, "draw" in (6)) to fill the MASK. We call this figure "%-ACT-Repetition". Generally, a high percentage of ACT-repetitions implies poor performance with negated first sentences: these are the exactly wrong predictions. In contrast, a high percentage of ACT-repetitions is ok with positive first sentences; indeed, it is often a natural completion of the sentence, given the information in the first sentence. Furthermore, we report on results obtained by using ACT-tokens of probability rank 0 and 50 (for information on probability ranks, see above, section 4.3).

Finally, `xlnet-large-cased` performed so poorly that it has been excluded in the display of results in the present section. Since the predictions of this model were often ungrammatical, listing them along with the others would have given a false impression of equivalence; for instance, predicting ")" as an ACT-token in example (5) and "," to fill the MASK in example (6) would not count as an exactly wrong prediction, but it would of course be mistaken. In this sense, our approach requires that the predictions by the models be more or less sensible and grammatical, which all models except for this one fulfilled. However, `xlnet-large-cased`'s performance is given in detail in the appendix, section G, figure 12.

Experiment 1 Figure 1 displays the effect of negation on prediction. The values shown are percentages of cases where the model predicted (one of) the ACT-token(s) to fill the MASK in the final sentence.

As mentioned, in general, repeating such an activity token is correct if the activities are not in the scope of a negation, but exactly wrong if they are in such a scope, as in example (6). In figure 1, the red-to-reddish bars give the percentage at which the models wrongly predicted an ACT-token to fill the MASK, even though it was excluded by a negation in the first sentence. The green bars show the percentage at which the models predicted an ACT-token that has not previously been excluded via negation (which is perfectly fine).

In the first column of figure 1, the results of `neg-roberta-large` are displayed. This model wrongly predicts one of the ACT-tokens to fill the MASK in roughly 8% of cases if the first sentence is negated. The presence or absence of contrastive signals matter little. If the first sentence is not negated, the percentage goes up to some 52% on average, despite the fact that the lexical overlap is much smaller with positive templates. This yields a delta of 44% between negated and positive templates. Such a high delta indicates a sensitivity of the model for negation. In contrast, if both scores are low, they might be low simply because the model is unable to retain any information and hence predicts something completely unrelated to the context, or even something ungrammatical.

It is notable that fine-tuning does show a significant, albeit slightly unstable effect both regarding `roberta-large` and regarding `bert-large-cased`. Furthermore, as mentioned previously, the effect is much stronger with `xlnet-large`, as the vanilla version was simply predicting gibberish (closing brackets, for instance), while the fine-tuned version shows very strong performance.

Figure 2 shows further results from experiment one. We are here only showing the performance on negated templates. This means that, gener-

	neg-roberta-large	roberta-large	neg-xlnet-large	neg-bert-large	bert-large-cased	bert-base-cased	distilbert-base-cased
■ neg - N	8%	10%	11%	12%	7%	38%	78%
■ neg - d	8%	7%	5%	29%	43%	42%	83%
■ neg - c_d	8%	11%	6%	25%	30%	50%	86%
■ pos - N	39%	42%	50%	60%	58%	74%	81%
■ pos - i_d	64%	72%	81%	80%	87%	83%	89%

Figure 1: Percentages of prediction of ACT-token(s) ("neg": negated sentences, "pos": positive sentences, "N": no additional markers, "d": contrastive "does", "c_d" contrastive does with contrastive conjunction, "i_d": implicative conjunction plus "does" for emphasis). These predictions are ok if there is no negation in the first sentence (greenish bars) and exactly wrong if the first sentence is negated (red-reddish bars).

ally, an ACT-repetition is wrong here, as it has been explicitly excluded by negation (for example, compare (7)). Furthermore, we are showing the results categorized by probability rank of ACT-token chosen. This means that, for instance, `neg-roberta-large` wrongly predicts an ACT-token to fill the MASK in almost 14% of all cases if the probability rank of the ACT-token in question is 0, while it does so in less than 3% of cases for the lower probability ranks.

Figure 2 clearly shows that the BERT models (both large and base) react very strongly to high probability ranks: `neg-bert-large`'s error rate drops from almost 40% to about 2% if the probability rank of the act token is lowered from 0 to 50, 100, or 200. XLNET, in contrast (and quite surprisingly), has a lower error rate with probability rank 0 tokens than with tokens of lower probability ranks.

Experiment 1 has also shown some differences in performance of PLMs depending on the gender of the templates. In particular, the RoBERTas perform worse with male gender than with female gender. For details, see section F.

Experiment 2 Figure 3 shows percentages of ACT-repetition depending on the misprime or additional sentence inserted (for the interpretation of the Cleo-row, see below, experiment 3). Overall, the results show that all models are confused by the misprimes, but notably, `neg-roberta-large` only really loses performance with the one random sentence inserted. Furthermore, the results resemble the one presented above in figure 1 as far as the smaller models are performing worse, with distilbert being clearly at a loss. Fine-tuned XLNET loses much precision with the misprime with a "but", indicating a lack of representation of logical structure (see above, section 5).

	neg-roberta-large	roberta-large	neg-xlnet-large	neg-bert-large	bert-large-cased	bert-base-cased	distilbert-base-cased
■ 0	14%	13%	8%	42%	46%	69%	98%
■ 50	3%	5%	8%	2%	7%	18%	66%
■ 100	1%	3%	9%	2%	7%	16%	60%
■ 200	1%	2%	11%	1%	5%	14%	51%

Figure 2: Percentages of erroneous predictions of negated ACT-tokens by probability rank of ACT-tokens.

Experiment 3 With "Cleo", the templates used are such that it should be maximally clear that the person that does not like to ACT according to the first sentence is clearly different from the person that does like to MASK (see (12)). And the models are very sensitive to that, as figure 3 shows. The RoBERTas, for instance, repeat the ACT-token with some 86% probability, regardless of the presence of a contrastive conjunction or a contrastive "does" in the second sentence, while this figure has not exceeded 30% for any of the misprimes with `neg-roberta-large`.

7 Discussion

In the following, we first conduct a brief analysis of the predicted tokens, then we discuss four insights that flow from our results.

Analysis of Predicted Tokens Overall, per probability rank, each model issued 400k predictions of activities that persons might like to do; as it

	neg-roberta-large	roberta-large	neg-xlnet-large	neg-bert-large	bert-large-cased	bert-base-cased	distilbert-base-cased
None	8%	9%	8%	22%	27%	43%	82%
MP_but	12%	37%	72%	43%	57%	78%	95%
MP	11%	23%	49%	42%	57%	75%	97%
1rand	30%	37%	43%	82%	94%	84%	95%
Cleo	85%	88%	94%	55%	73%	67%	94%

Figure 3: Percentages of exactly wrong predictions by inserted element (probability ranks 0 and 50): Either a misprime (MP, see example (9)), a misprime with a but (MP_but, see example (10)), or a random sentence (1rand, see example (11)). Finally, “Cleo” refers to the clearly different referent in the second sentence (“Cleopatra”, see example (12)).

were, they made a guess as to what hobby a person with a specific gender, first name, and profession might have. Extensive inspection shows that in the clear majority of cases, with the stark exception of `xlnet-large-cased`, these predictions resulted in grammatical, sensible sentences, with some decline in grammaticality with higher probability ranks. Notably, the insertion of a random sentence (“Today is Tuesday and the sun is shining”) has not had any observable impact on the semantics of predictions. For instance, it did not lead to a higher rate of predictions of activities involving the outdoors, or generally requiring good weather.

For the runs conducted with `neg-roberta-large` and tokens of probability rank 0, the predicted tokens belong to just 108 verb types, five of which account for 57% of all predictions: read, write, cook, dance, and sing (read accounts for 22% alone).

Clear Sensitivity to Negation The first basic insight provided by experiment one is thoroughly positive: With the exception of `distilbert-base-cased`, all models show sensitivity to negation (see figure 1): they are much less inclined to ACT-repetition if the token has been negated, even if the ACT-token is highly probable, given the model, the gender, the first name and the profession, and even though there is much less subsequence overlap with the positive (not negated) templates than with the negated ones. Hence, almost all models showed sensitivity to negation despite the contrary pull exerted by several shallow heuristics.

Note also that the models are generally not overly sensitive to contrast-highlighting elements in the negated sentences, but very sensitive to implication-indicating elements in the positive sentences, which, considering examples such as (8), seems pragmatically sound: In the absence of such an element, one might think that the first and the second sentence in these templates have little connection except for the common referent. Furthermore, note that the BERT-models perform significantly worse with patterns containing contrast-highlighting elements. This is surprising as one would expect that such elements would make it easier for the models to realize that a prediction of an ACT-token to replace the MASK is inaccurate.

These results put the pioneering findings by Ettinger (2020), Kassner and Schütze (2020), Warstadt et al. (2020), and Ribeiro et al. (2020) in perspective: our study clearly shows that pre-trained transformer-based language models *do* show sensitivity to negation. In figure 1, `neg-roberta-large`’s tendency to repeat verbs that replace ACT-placeholders drops by some 44% if these replacements are in the scope of a negation. Clearly, this model does not simply ignore negation.

There are two explanations for this contrast with earlier research. The first one consists simply in a reminder that these earlier studies did not test models based on the RoBERTa or XLNET architectures. Furthermore, Ribeiro et al. (2020) only use base-sizes of the models they test. Still, even with `bert-large-cased` and `bert-base-cased`, the difference between previous findings and our result are stark.

This means that a second explanation is needed. We suggest that the best candidate for such an explanation is precisely our hypothesis that, in these early studies, the models are struggling less with negation and more with the contextualization of the tasks: they are not unable to represent negation; rather, they are unable to identify a default context that rules out certain predictions *ab initio*.

Inferences to the best explanations are always fallible (for the standard study of abductive inferences, see Lipton 2004): There could be another explanation that we have failed to consider that explains the difference in performance. However, given that, we are using highly controlled, synthetic, and relatively simple sentences, that we have extensively varied syntactic structure, gender, profession, and first name, and that we have tested a number of misprimes, all resulting in the same basic outcome, namely a sensibility to negation, we feel confident that we can rule out other explanations to the degree to which this is possible given current methods in BERTology. We therefore do take our results as providing strong support for our main hypothesis.

The Influence of Probability Ranks Furthermore, experiment one also shows that the model- and context-specific probability rank, which was controlled for in this experiment by a new method, is highly relevant for prediction (see figure 2). This effect is particularly pronounced for the BERT models, and much less for the RoBERTas and XLNET.

Another interesting aspect of the influence of probability ranks is that fine-tuning seems to reduce error rate less for highly probable tokens. Finally, the figures also show that the big drop in error rate occurs between probability ranks 0 and 50. Between 50 and 200, little further reduction occurs.

Robustness Against Misprimes & Random Insertions We have been testing the models' robustness against the insertion of two different misprimes as well as a random sentence in experiment 2. For results, see figure 3. These results show a very nuanced picture. First, `neg-roberta-large` is hardly disturbed by the misprimes, with the exception of the random sentence: its error rate doesn't surpass 12%. In stark contrast, `neg-xlnet-large`'s error rate skyrockets with all of the misprimes inserted: it shows an increase in error rate from 8 to 43%, and well beyond that. The other models are somewhere in between; notably, the BERT-models are struggling most with the random sentence inserted.

As robustness against misprimes indicates dependence on real understanding rather than shallow heuristics, these results further corroborate the finding of experiment 1 that the best performing models, `neg-roberta-large` in particular, understand negation.

Changes in reference The results of this experiment are surprising when the RoBERTas and fine-tuned XLNET are considered. All three models repeat the ACT-token with a probability of more than 85% if it is clear that the subject of the activity in question is clearly distinct from the subject of which the same activity has been negated in the first sentence. These results indicate that the models are clearly sensible to such changes in referents.

8 Conclusion

In this paper, we have examined the extent to which contemporary transformer-based PLMs understand negation. We have done so by presenting the models with tailored masked language modelling tasks that are structured in a way that is pragmatically sound and that ensures that the known shallow heuristics are of no help. We have found that all but two models are clearly sensitive to negation. It seems justified to say that the best-performing model understands negation, as it erroneously repeats a negated token in only 12% of cases even when strong misprimes are used (with the exception of the questionable insertion of a random sentence, where the figure is 30%), and it shows clear sensitivity to changes in reference. Our results complement and partly contrast earlier, semantics-based studies of PLMs' negation understanding.

A Our Concept of Real Understanding

It is a matter of dispute which conditions are sufficient to credit any being with "real" linguistic understanding. In philosophy of mind as well as in cognitive psychology there are two very broad camps. On the one hand, there is a representationalist one that emphasizes what is going on inside the mind or brain of the being in question (compare Searle, 1980, 417, who argues that "causal powers equal to those of the brain" are necessary, or Marr, 2010 [1982], whose pioneering monograph on vision science became one of the founding documents of cognitive science). On the other hand, there are neo-behaviorist researchers who emphasize the importance of the being's behavior for any judgment on its understanding (see Glock, 2019). This study sides with the neo-behaviorists in focusing on the behavior of the models in question rather than on their internal going-ons. Hence, to really understand negation, a being must be able to react to negated sentences competently in a variety of circumstances with a performance that is comparable to what humans are capable of.

Note that the representationalists generally agree that the neo-behaviorists requirements are necessary; they just doubt that they are sufficient for real understanding. Hence, if it should turn out that current models do not satisfy the neo-behaviorist's requirement, the representationalist would agree that, as a consequence, the models do not really understand negation.

Furthermore, note that this question is related to another one that Bender and Koller (2020) have raised forcefully: What kind of relation (if any) is expressed by meaning? Following Searle (1980), they argue that it is a relationship between a linguistic item, say a word, and something extralinguistic. On this view, understanding negation would require understanding the meaning of negation which, supposedly, involves a word-world-relation. Continuing our loosely Wittgensteinian neo-behaviorism, we disagree: the meaning of a word is given by its use in language (Wittgenstein, 2006/1953, § 43). Unfortunately, at this point, we can only point to this disagreement without properly engaging the arguments by Bender and Koller (2020).

B Full list of Templates

In tables 1, 2, and 3, we give the full list of templates with their features by experiment. "N-ACTs" refers to the number of activities used (that is, one, two or three verbs that the person in question is supposed to like or not to like doing), "Negtype" expresses whether the template is positive or contains a negation, "Conj" refers to the kind of conjunction used (if any), "Add. El." specifies whether an additional sentence between the first and the final sentence is inserted, or whether a shift in reference occurs ("Cleo"), and "MorF" specifies th gender of the first names and pronouns used.

C Analysis of Stylistic Proposals

As mentioned above, section 4, we have discussed all of the templates with a native speaker and philosopher of language, Dr. David Dolby. He has made the following suggestions, which we adopted for our main experiments. In addition, we carried out all of the experiments with the original templates as well. We here list his suggestions as well as the effect on model performance with regard to the six templates in total which were affected.

Proposal 1 (3 templates affected) In sentences as the following, it was proposed to replace "to swim, nor does she like to fish, and she also doesn't like to surf" with "to swim, fish, or surf": "Petra is an architect who doesn't like to swim, nor does she like to fish, and she also doesn't like to surf. She does like to MASK."

Proposal 2 (2 templates affected) In sentences as the following, it was proposed to replace "to swim, to fish, and to surf" with "to swim, fish, and surf": "Petra is an architect who tries to swim, to fish, and to surf as often as possible. So, she really does like to MASK."

Proposal 3 (1 template affected) In sentences as the following, it was proposed to replace "In contrast with Peter," with "Unlike Peter,": "Peter is an architect who doesn't like to swim. In contrast with Peter, Cleopatra does like to MASK."

We have run all the experiments with both of these variants, and the differences in performance are given in table 4.

In general, it seems that slight variation in performance between these variants is an indicator of a more profound understanding of the sentences in question (similar to a model's robustness against misprimes). A human evaluator would be able to understand that predicting either swim, fish, or surf in sentences such as the one quoted in proposal 1

Table 3: Templates used in experiment 3.

Model	**Delta Prop. 1 (3 templ. aff.)**	**Delta Prop. 2 (2 templ. aff.)**	**Delta Prop. 3 (1 templ. aff.)**
neg-roberta-large	1.40%	1.0%	14.14%
roberta-large	1.33%	1.3%	11.54%
neg-xlnet-large	5.19%	-0.4%	0.86%
neg-bert-large	10.51%	4.1%	22.31%
bert-large-cased	15.21%	6.6%	7.23%
bert-base-cased	1.08%	5.0%	3.40%
distilbert-base-cased	3.61%	5.0%	4.00%

Table 4: Difference in percentage of ACT-repetition for the templates affected, depending on whether or not Dolby's proposals were adopted (positive value means higher repetition without adopting Dolby's proposals). As usual, the average of probability ranks 0 and 50 was used. For instance, adopting proposal 1 leads to a decrease of ACT-repetition of 1.4% for neg-roberta-large with regard to the three templates affected.

is inadmissible, regardless of whether the sentence is phrased in the slightly clumsier phrasing before adopting Dolby's first proposal: The difference is in style, not in logical form.

In the specific cases at hand, it must be noted that only proposal 1 concerns templates that logically exclude certain predictions, while proposals 2 and 3 concern templates where certain predictions are suggested, e.g., swim, fish and surf in the example listed in the description of proposal 2, or swim in the example listed in the description of proposal 3. So, the substantial differences in performance caused by proposal 3 do not indicate that the models performed substantially worse without adopting the proposal. It merely means that they were less inclined to repeat the ACT-token in the sentence.

Furthermore, the results have minor impact on the results of the experiment as a whole, as even for the largest variation, found with `bert-large-cased`, the difference concerns only 3 out of 18 negated templates in total, implying that overall performance of the model improves by only 2.5%.

Finally, the figures fit with the findings from experiment 2 (see figure 3): the RoBERTas, in particular the fine-tuned version, show almost no susceptibility to these surface phenomena, whereas `bert-large-cased` reacts strongly, suggesting a shallower processing and less understanding of logical structure.

D Details on Fine-Tuning

To fine-tune the models to sentences involving negation, we use a regular expression to extract sentences containing a negation token together with a contrastive conjunction from English Wikipedia[5]; the goal was to filter for sentences that, in addition to containing a negation, also contain parts that can only be predicted correctly if the negation is taken into account. For instance, in sentence (13), taken from the fine-tuning corpus, a model that has no understanding whatsoever of negation is not going to predict a sensible token in the penultimate position ("play", right before ".").

(13) He was also selected by Zimbabwe for the 2014 African Nations Championship but didn't play.

By filtering for such patterns, we extract 351k sentences from English Wikipedia.

Based on some initial exploratory tests, we fine-tuned `roberta-large`, `xlnet-large-cased` as well as `bert-large-cased`. In view of the fine-tuning corpora used, we label the resulting models **neg-roberta-large**, **neg-bert-large** and **neg-xlnet-large** respectively. For fine-tuning, the scripts provided by Huggingface (Wolf et al., 2019) were adapted. Fine-tuning took place on 4 GPUs of a DGX-2. The fine-tuned models where then tested together with the vanilla ones in the experiments.

The python regular expression used to extract the sentences is the following (note that we are filtering out sentences with character length less than 65, as they are usually not full sentences):

```
re.search('( no )|( none* )|(n't)',sentence) and
re.search('rather|even|but',sentence) and len(sentence) >64
```

Fine-tuning occurred with the following settings (again taken from Huggingface):

- num_train_epochs=1,
- per_gpu_train_batch_size=64,

E Details on Experiments

The experiments were conducted on four GPUs of a DGX-2, processing time of one template (i.e. 9.1k sentences) per model varied widely depending on the model, from about 300 seconds for distilbert to 1500 seconds for the fine-tuned version of xlnet. The script used for these experiments as well as all necessary input-files is available on github.[6] The script builds on the standard scripts provided by Huggingface, see Wolf et al. (2019). For an illustration of the algorithm used, see algorithm 1.

F Results of Experiment 1 by Gender

Table 4 shows the results of experiments 1 and 2, restricted to negated templates, by gender. The RoBERTas perform slightly worse with male gender than with female, as they wrongly predict an ACT-token more often with male than with female templates. For the remaining models, there is no clear trend.

G Detailed Results of all models

In figures 5-12, we are giving all the results of all models, including vanilla `xlnet-large-cased`, which has been

                Obtain ACT1-3 by letting
                  MODEL predict [MASK]
                  in sentences like (5)
                Let MODEL predict the
                  [MASK] in the sentence
                  built from TEMPLATE,
                  NAME, PROF, ACT1-3.
            end
        end
    end
end
```

Algorithm 1: The method used to evaluate the models.

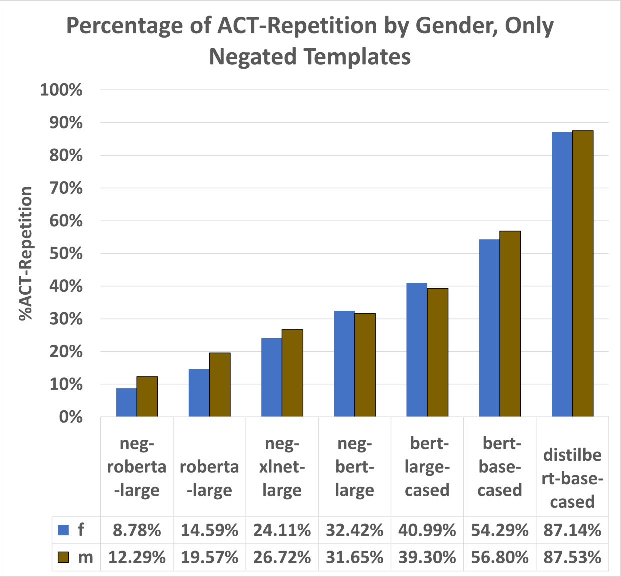

Figure 4: Performance in experiment 1 and 2, only negated templates and probability ranks 0 and 50, by gender.

excluded from the results in section 6 due to its extremely poor performance. As the final chart shows, the model repeats an ACT-token between 2% and 57% of cases. As a look at the prediction shows, this is because `xlnet-large-cased` often predicts ungrammatical and nonsensical tokens such as “that” or “.” to fill the MASK both in (5), which is used to extract the ACT-tokens of suitable rank, and in fully specified templates such as (6). Listing these nonsensical predictions on a par with the grammatical predictions by the other models would have given a false impression of equivalence.

To increase readability, we have replaced “contr_does” with “contr” and “implic._does” with “implic”.

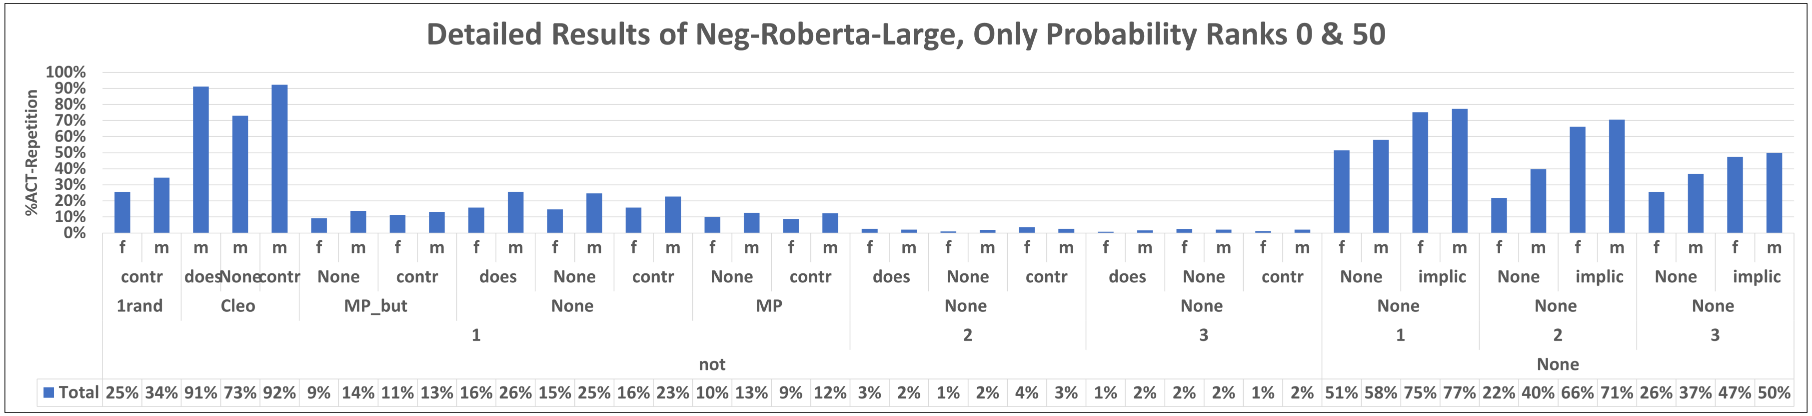

Figure 5: Performance of neg-roberta-large. Performance is shown only for probability ranks 0 and 50.

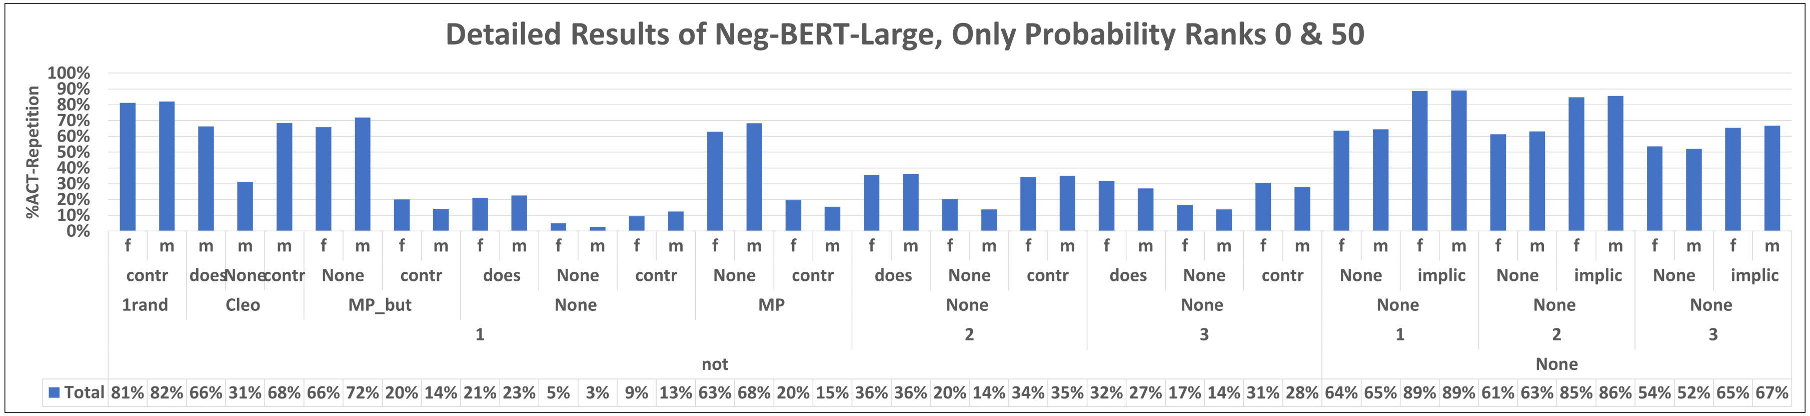

Figure 8: Performance of neg-bert-large. Performance is shown only for probability ranks 0 and 50.

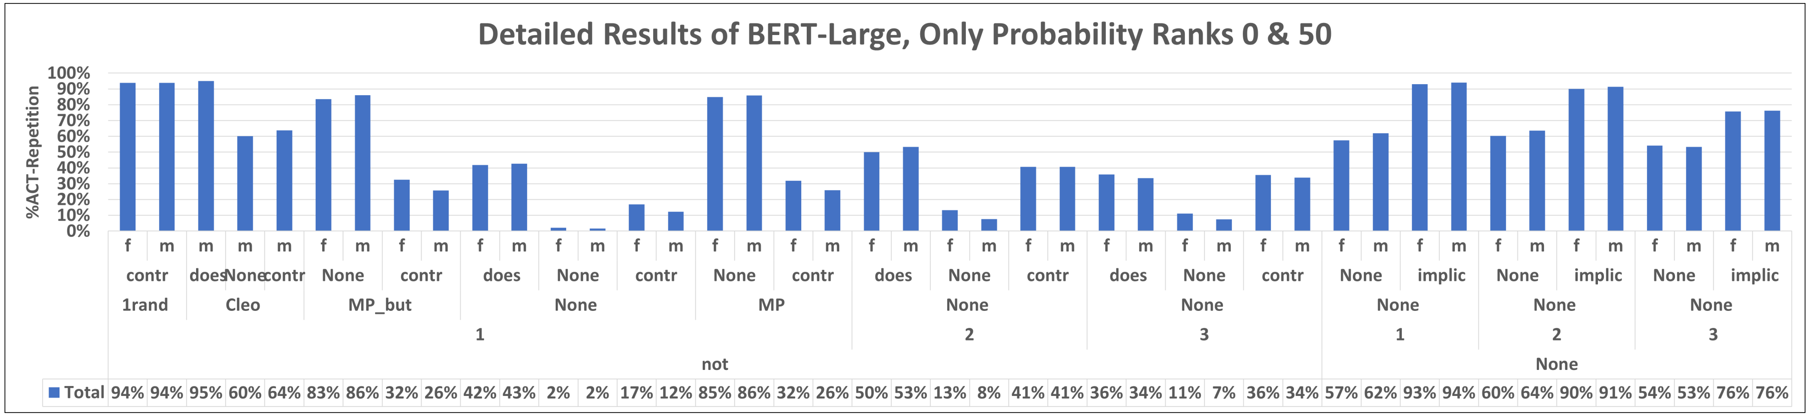

Figure 9: Performance of bert-large-cased. Performance is shown only for probability ranks 0 and 50.

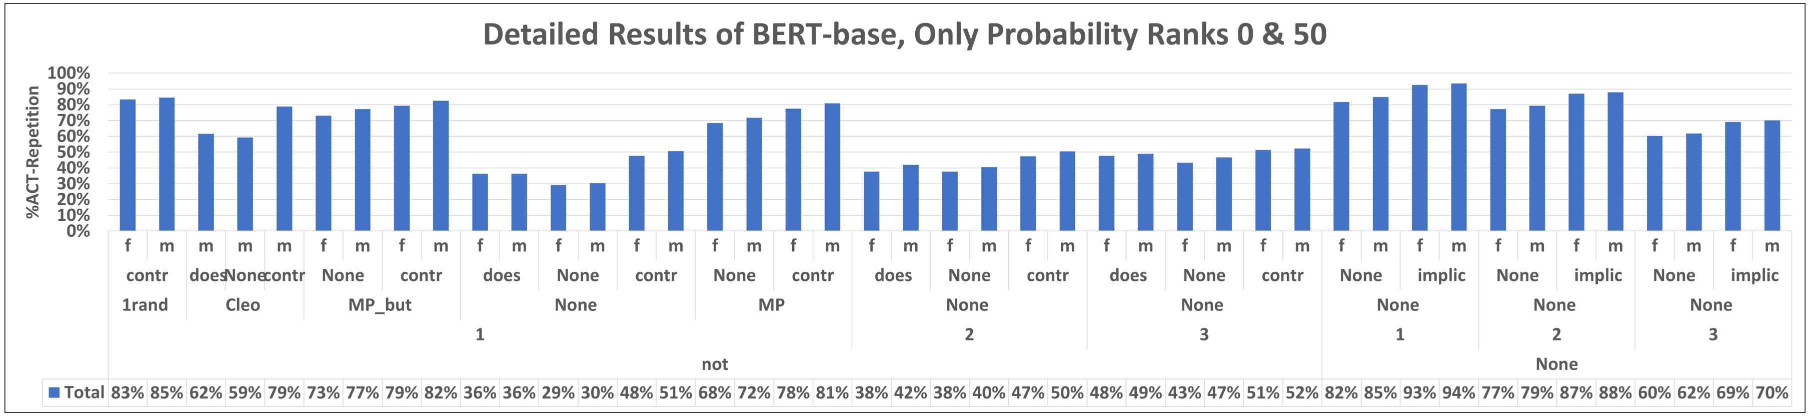

Figure 10: Performance of bert-base-cased. Performance is shown only for probability ranks 0 and 50.

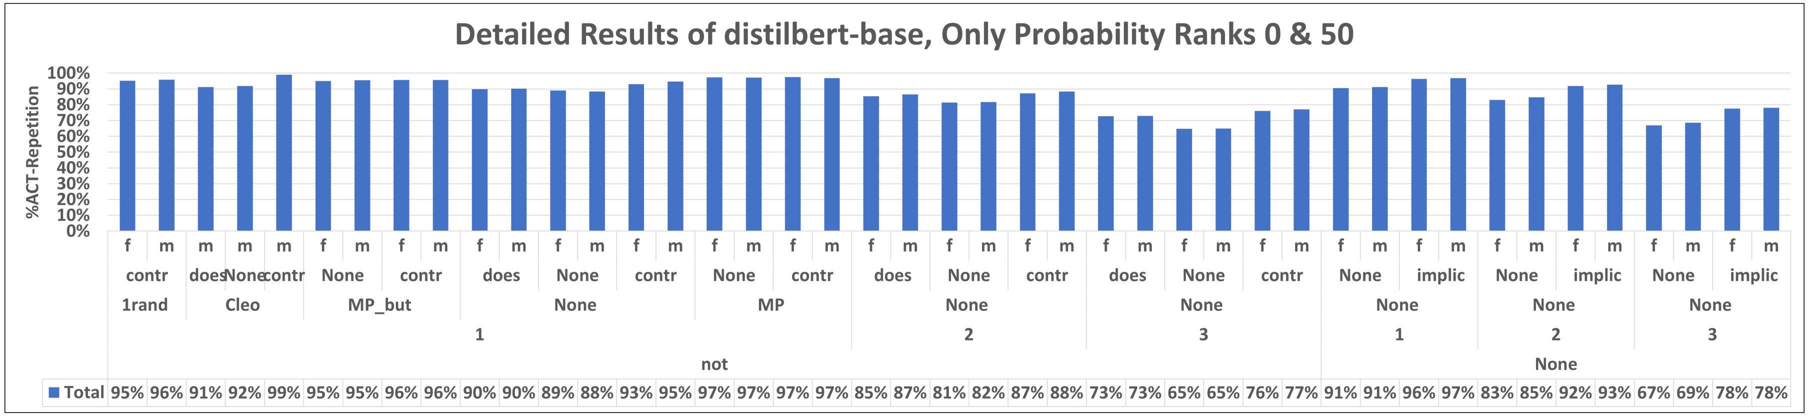

Figure 11: Performance of distilbert-base-cased. Performance is shown only for probability ranks 0 and 50.

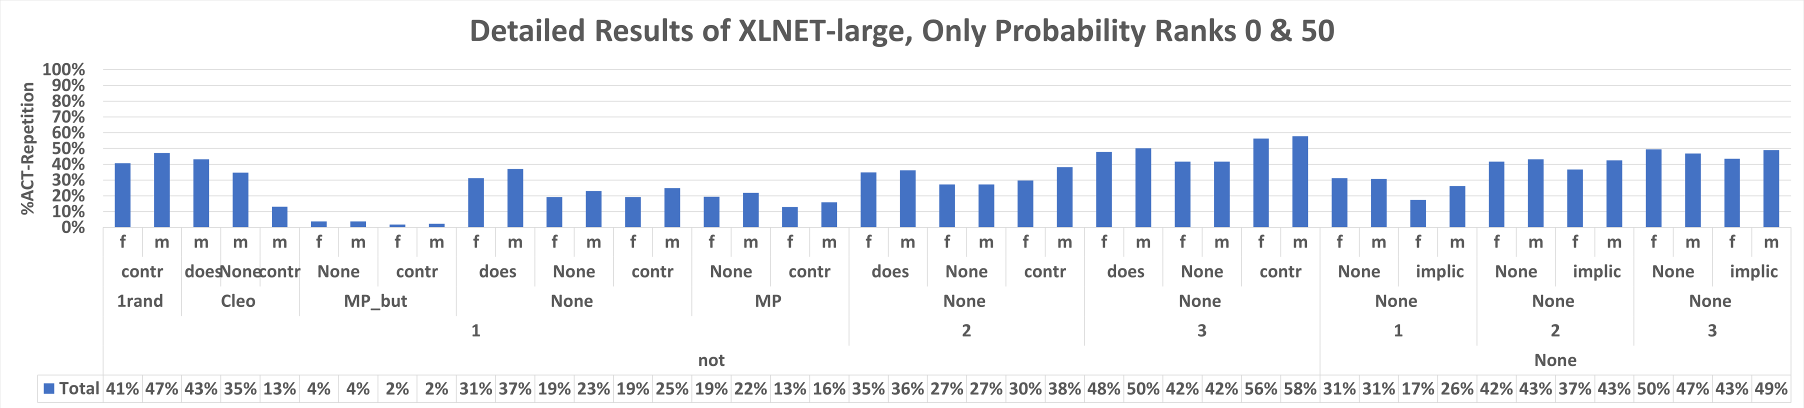

Figure 12: Performance of xlnet-large; as can be seen, the percentages of ACT-repetitions hardly differ between negated and positive sentences. Furthermore, note again that the model’s predictions are very poor, often predicting clearly wrong token such as closing brackets “)” or other non-alphabetic characters.

Probing for Predicate Argument Structures in Pretrained Language Models

Simone Conia[1] and **Roberto Navigli**[2]

Abstract

Thanks to the effectiveness and wide availability of modern pretrained language models (PLMs), recently proposed approaches have achieved remarkable results in dependency- and span-based, multilingual and cross-lingual Semantic Role Labeling (SRL). These results have prompted researchers to investigate the inner workings of modern PLMs with the aim of understanding how, where, and to what extent they encode information about SRL. In this paper, we follow this line of research and probe for predicate argument structures in PLMs. Our study shows that PLMs do encode semantic structures directly into the contextualized representation of a predicate, and also provides insights into the correlation between predicate senses and their structures, the degree of transferability between nominal and verbal structures, and how such structures are encoded across languages. Finally, we look at the practical implications of such insights and demonstrate the benefits of embedding predicate argument structure information into an SRL model.

1 Introduction

Semantic Role Labeling (SRL) is often defined informally as the task of automatically answering the question "*Who did What to Whom, Where, When and How?*" (Màrquez et al., 2008) and is, therefore, thought to be a fundamental step towards Natural Language Understanding (Navigli, 2018). Over the past few years, SRL has started to gain renewed traction, thanks mainly to the effectiveness and wide availability of modern pretrained language models (PLMs), such as ELMo (Peters et al., 2018), BERT (Devlin et al., 2019) and BART (Lewis et al., 2020). Current approaches have, indeed, attained impressive results on standard evaluation benchmarks for dependency- and span-based, multilingual and cross-lingual SRL (He et al., 2019; Li et al., 2019; Cai and Lapata, 2020; Conia and Navigli, 2020; Blloshmi et al., 2021; Conia et al., 2021).

Despite the remarkable benefits provided by the rich contextualized word representations coming from PLMs, the novelties introduced in recent state-of-the-art models for SRL revolve primarily around developing complexities on top of such word representations, rather than investigating what happens inside a PLM. For example, the SRL systems of He et al. (2019) and Conia and Navigli (2020) take advantage only of BERT's uppermost hidden layers to build their input word representations. However, the revolution that PLMs have sparked in numerous areas of Natural Language Processing (NLP) has motivated researchers in the community to investigate the inner workings of such models, with the aim of understanding how, where, and to what extent they encode information about specific tasks. This research has revealed that different layers encode significantly different features (Tenney et al., 2019; Vulić et al., 2020). In perhaps one of the most notable studies in this direction, Tenney et al. (2019) demonstrated empirically that BERT "rediscovers" the classical NLP pipeline, highlighting that the lower layers tend to encode mostly lexical-level information while upper layers seem to favor sentence-level information.

Although recent analyses have already provided important insights into which layers of a PLM are more relevant for SRL and how their relative importance is affected by the linguistic formalism of choice (Kuznetsov and Gurevych, 2020), not only do these analyses treat SRL as an atomic task but they also do not explore taking advantage of their insights to improve current state-of-the-art SRL systems. Indeed, the SRL pipeline is usually divided into four main steps: predicate identification and disambiguation, and argument identification and classification. To address this gap, in this paper we therefore take an in-depth look at how predicate senses and their predicate argument struc-

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 4622 - 4632
May 22-27, 2022

tures (PASs) are encoded across different layers of different PLMs. On the one hand, we provide new insights into the capability of these models to capture complex linguistic features, while on the other, we show the benefits of embedding such features into SRL systems to improve their performance.

Our contributions can be summarized as follows:

- We probe PLMs for PASs: do PLMs encode the argument structure of a predicate in its contextual representation?
- We show that, even though a PAS is defined according to a predicate sense, senses and argument structures are encoded at different layers in PLMs;
- We demonstrate empirically that verbal and nominal PASs are represented differently across the layers of a PLM;
- Current SRL systems do not discriminate between nominal and verbal PASs: we demonstrate that, although there exists some degree of transferability between the two, an SRL system benefits from treating them separately;
- We find that PAS information is encoded similarly across two very different languages, English and Chinese, in multilingual PLMs;
- We corroborate our findings by proposing a simple approach for integrating predicate-argument structure knowledge into an SRL architecture, attaining improved results on standard gold benchmarks.

We hope that our work will contribute both to the understanding of the inner workings of modern pretrained language models and to the development of more effective SRL systems. We release our software for research purposes at `https://github.com/SapienzaNLP/srl-pas-probing`.

2 Related Work

Probing pretrained language models. The unprecedented capability of modern PLMs to provide rich contextualized input representations took the NLP community by storm. Alongside the rising wave of successes collected by PLMs in an ever increasing number of areas, researchers started to question and investigate what happens inside these models and what they really capture, probing for knowledge and linguistic properties (Hewitt and Manning, 2019; Chi et al., 2020; Vulić et al., 2020). This body of work quickly attracted increasing attention and grew to become a field of study with a name of its own: BERTology (Rogers et al., 2020). Probing a PLM usually consists in defining a very precise task (e.g., identifying whether two words are linked by a syntactic or semantic relation), and then in designing and training a simple model, called a *probe*, to solve the task using the contextualized representations provided by the PLM. The idea is to design a probe that is as simple as possible, often consisting of a single-layer model: if the probe is able to address the task, then it must be thanks to the contextual information captured by the PLM as the expressiveness of the probe itself is limited by its simplicity. One could argue that some complex relations may require a non-linear probe (White et al., 2021) which can reveal hidden information as long as it is accompanied by control experiments (Hewitt and Liang, 2019) to verify that it is still extracting information from the underlying PLM, rather than merely learning to solve the probing task. Over the past few years, these probing techniques have been used to great effect and revealed that PLMs have been "rediscovering" the classical NLP pipeline (Tenney et al., 2019), and that they often encode distances between syntactic constituents (Hewitt and Liang, 2019), lexical relations (Vulić et al., 2020) and morphology (Chi et al., 2020), *inter alia*.

Probing techniques for SRL. As in several other fields of NLP, recent studies have aimed to shed some light on how, where and to what extent PLMs encode information relevant to SRL. Among others, Tenney et al. (2019) devised an edge probing mechanism aimed at ascertaining the capability of BERT to identify which semantic role ties a given predicate to a given argument span, and showed that this task is "solved" mainly by the middle layers of BERT. Toshniwal et al. (2020) proposed and compared several techniques for better combining the contextualized representations of a PLM, finding that applying max pooling or performing a weighted average are two robust strategies for SRL. More recently, Kuznetsov and Gurevych (2020) designed a probe to analyze how different linguistic ontologies – essential to the task in that they define predicate senses and semantic roles explicitly – require features that are encoded at different layers of a PLM. In this paper, we follow the line of research laid out by the aforementioned work, probing PLMs with the objective of understanding where and to what extent they encode a predicate argument structure into the contextualized representation of a predicate.

Recent advances in SRL. Thanks to their effectiveness, PLMs are now the *de facto* input representation method in SRL (He et al., 2019; Li et al., 2019; Conia and Navigli, 2020; Blloshmi et al., 2021). Recently proposed approaches have achieved impressive results on several gold benchmarks (Hajič et al., 2009; Pradhan et al., 2012), both in span-based and in dependency-based SRL, but also in multilingual and cross-lingual SRL, even though there still seems to be a significant margin for improvement in out-of-domain settings. The innovations put forward by such approaches, however, have mainly focused on architectural novelties built on top of PLMs: Cai et al. (2018) proposed the first end-to-end architecture; He et al. (2019) and Cai and Lapata (2019) successfully exploited syntax in multilingual SRL; Marcheggiani and Titov (2020) took advantage of GCNs to capture distant semantic relations; Conia and Navigli (2020) devised a language-agnostic approach to bridge the gap in multilingual SRL; Blloshmi et al. (2021) and Paolini et al. (2021) tackled the task as a sequence generation problem; Conia et al. (2021) introduced a model to perform cross-lingual SRL across heterogeneous linguistic inventories. However, if we look back at past work, it is easy to realize that we lack a study that provides an in-depth look into PLMs and a hint at how to better exploit them in future SRL systems.

3 Probing for Predicate Senses and Their Predicate-Argument Structures

As mentioned above, some studies have already investigated how semantic knowledge is distributed among the inner layers of current PLMs, finding that information useful for SRL is mainly stored in their middle layers (Tenney et al., 2019). However, such studies have considered SRL as an atomic task, while instead the SRL pipeline can be thought of as being composed of four different subtasks:

1. **Predicate identification**, which consists in identifying all those words or multi-word expressions that denote an action or an event in the input sentence;
2. **Predicate sense disambiguation**, which requires choosing the most appropriate *sense* or *frame* for each predicate identified, as the same predicate may denote different meanings or define different semantic scenarios depending on the context;
3. **Argument identification**, which consists in selecting the parts of the input text that are "semantically" linked as arguments to an identified and disambiguated predicate;
4. **Argument classification**, which is the task of determining which kind of semantic relation, i.e., semantic role, governs each predicate-argument pair.

For our study, it is important to note that, in many popular ontologies for SRL, predicate senses or frames are often tightly coupled to their possible semantic roles. In other words, the set of possible semantic roles that can be linked to a predicate p is defined according to the sense or frame of p. Hereafter, given a predicate p, we refer to its set of possible semantic roles as the *roleset* of p. For example, the predicate love as in "He loved everything about her" belongs to the FrameNet (Baker et al., 1998) frame *experiencer_focused_emotion* which defines a roleset composed of {Experiencer, Content, . . ., Degree}. The same predicate sense has different rolesets in other ontologies, for example {ARG0 (lover), ARG1 (loved)} in the English PropBank (Palmer et al., 2005) and {Experiencer, Stimulus, . . ., Cause} in VerbAtlas (Di Fabio et al., 2019).

3.1 Predicate Senses and Their Rolesets

Since rolesets are often defined according to predicate senses, it is interesting to investigate whether current pretrained language models store important features about senses and rolesets in their hidden layers. To this end, we formulate two simple probing tasks:

- **Sense probing**, which consists in predicting the sense s of a predicate p from the contextual vector representation $\mathbf{x}_p$ of p, where $\mathbf{x}_p$ is obtained from a pretrained language model.
- **Roleset probing**, which consists in predicting the semantic roles $\{r_1, r_2, \ldots, r_n\}$ that appear linked to a predicate p from its contextual representation $\mathbf{x}_p$, where $\mathbf{x}_p$ is obtained from a pretrained language model.

For the choice of $\mathbf{x}_p$, we compare four different options:

- **Random:** initializing the weights of the language model at random provides a simple control baseline to attest the ability of a probe to "learn the probing task", i.e. learning to associate random inputs to correct labels;

- **Static:** $\mathbf{x}_p$ is the input embedding of the pretrained language model corresponding to p, e.g., the non-contextual representation before the Transformer layers in BERT.[1]

- **Top-4:** $\mathbf{x}_p$ is the concatenation of the topmost four hidden layers of the language model: this is the configuration used in some of the recently proposed approaches for full SRL systems (Conia and Navigli, 2020);

- **W-Avg:** $\mathbf{x}_p$ is the weighted average of all the hidden layers of the language model, where the weights for each layer are learned during training (the larger the weight the more important its corresponding layer is for the probing task).

For each probing task, we train[2] two simple probes, a linear classifier and a non-linear[3] classifier, on the verbal predicate instances of the English training datasets provided as part of the CoNLL-2009 shared task for dependency-based SRL (Hajič et al., 2009).

3.2 Probing Results

Results on sense probing. Table 1 reports the results of our linear and non-linear probes on predicate sense disambiguation when using different types of input representations $\mathbf{x}_p$, namely, Static, Random, Last-4 and W-Avg, of an input predicate p in context. The Random baseline is able to disambiguate well (84.8% in Accuracy using BERT-base-cased), which is, however, unsurprising since CoNLL-2009 is tagged with PropBank labels and most of the predicates are annotated with their first sense (e.g., *buy.01*, *sell.01*). Interestingly, static representations from all four language models do not contain much more information about predicate senses than random representations. Using the topmost four hidden layers, instead, provides a substantial improvement over static representations for all language models (e.g., +6% in Accuracy for BERT-base-cased), lending credibility to the fact that context is key for the disambiguation process. Most notably, the best representation for the sense probing task is consistently obtained by performing a weighted average of all the hidden layers of the language model. This shows that important predicate sense information is not stored only in the topmost hidden layers and, therefore, also hints at the possibility that state-of-the-art architectures, such as those of He et al. (2019) and Conia and Navigli (2020), do not exploit pretrained language models to their fullest. Finally, it is interesting to note that linear and non-linear probes obtain similar results, showing that sense-related information can easily be extracted without the need for a complex probe.

		BERT	RoBERTa	m-BERT	XLM-R
Linear	Random	84.8	85.6	–	–
	Static	84.7	86.6	–	–
	Top-4	92.8	93.4	–	–
	W-Avg	**94.4**	**94.5**	–	–
Non-Linear	Random	84.3	83.6	83.7	84.2
	Static	86.4	86.6	86.1	86.1
	Top-4	93.2	93.6	92.3	93.3
	W-Avg	**94.2**	**94.8**	**93.4**	**94.2**

Table 1: Results on **sense probing** in terms of Accuracy (%) for the Random, Static, Top-4 and W-Avg probes using different pretrained language models, namely, BERT (base-cased), RoBERTa (base), multilingual BERT (base) and XLM-RoBERTa (base). Using a weighted average of all the hidden layers is a better choice than using the concatenation of the topmost four layers as in Conia and Navigli (2020).

Results on roleset probing. Table 2 reports the results on roleset identification obtained by our linear and non-linear probes when using different types of input representations $\mathbf{x}_p$, namely, Static, Random, Top-4 and W-Avg, of an input predicate p in context. For this task, we measure the performance of a probe in terms of micro-averaged F1 score, taking into account partially correct predictions, e.g., the system is partially rewarded for predicting $\{$ARG0, ARG1$\}$ instead of $\{$ARG0, ARG2$\}$. As is the case for sense probing, our simple Random baseline is able to identify the correct

---

[1] In case of a predicate composed of multiple subtokens, $\mathbf{x}_p$ is the average of the vector representations of its subtokens.

[2] We train each probe for 20 epochs using Adam (Kingma and Ba, 2015) as the optimizer with a learning rate of 1e-3. As is customary in probing studies, the weights of the pretrained language models are kept frozen during training. We use the pretrained language models made available by Huggingface's Transformers library (Wolf et al., 2020).

[3] We use the Swish activation function (Ramachandran et al., 2018) for our non-linear probes.

roleset for a predicate in context with a satisfactory performance (72.8% in F1 score using BERT-base-cased). Indeed, most predicates have at least one argument tagged with either ARG0 or ARG1, which in PropBank usually correspond to agentive and patientive proto-roles, respectively; we hypothesize that the Random probe merely learns to bias its predictions towards these very common semantic roles. Differently from in the sense probing task, the non-linear probe seems to perform better and achieve higher scores than the linear one. However, this does not mean that roleset-related features are "stored" non-linearly in PLMs. Indeed, one can notice that the random non-linear probe also performs better than its linear counterpart, suggesting that the higher score is due to the greater expressiveness of the probe, which "learns" the task rather than "extracting" information from the underlying PLM, i.e., the *selectivity* (Hewitt and Liang, 2019) of a non-linear probe is not greater than that of a linear probe in this task.

Despite the fact that the roleset probing task is more difficult than the sense probing one, we can observe a similar trend in the results: the Top-4 probe is substantially better than the Static probe, but W-Avg consistently outperforms Top-4, strongly suggesting that future approaches will need to use all the layers to take full advantage of the knowledge encoded within PLMs. We stress that not exploiting all the inner layers of a PLM is an illogical choice, since the cost of computing a weighted average of their hidden representations is negligible compared to the overall computational cost of a Transformer-based architecture.

On the correlation between senses and rolesets. Thus far, we have seen empirical evidence that PLMs encode important features about predicate senses and their rolesets across all their hidden layers, not just the topmost ones often used in the literature by current models for SRL. However, one may wonder how such features are distributed across these hidden layers. As we have already discussed above, predicate senses and their rolesets are tightly coupled: do PLMs distribute sense and roleset features similarly over their inner layers?

To answer this question, we resort to the W-Avg probe we introduced above. Indeed, its peculiarity is that it learns to assign a different weight to each hidden layer of a PLM: in order to minimize the training loss, the W-Avg probe will assign a larger weight to those layers that are most beneficial, i.e., to those layers that express features that are more relevant for the probing task. Therefore, we extract such layer weights learned by our probes for the two tasks we are studying – predicate sense disambiguation and roleset identification – and compare these learned weights, as shown in Figure 1 (top, blue charts). Interestingly, and perhaps surprisingly, the W-Avg probe learns a different weight distribution for the two probing tasks, even though rolesets are often defined on the basis of predicate senses in many popular ontologies for SRL. We can observe that predicate sense features are encoded more uniformly across the hidden layers of BERT or, equivalently, that the probe assigns similar weights to each hidden layer, slightly preferring the topmost ones (Figure 1, top-left). However, this is not the case for the roleset probing task, in which the probe mostly relies on the hidden layers going from the 6th to the 10th, almost disregarding the bottom and top ones. Furthermore, we can observe the same negative correlation within the distributions of the layer weights learned for senses and rolesets when using RoBERTa, albeit the divergence is slightly less accentuated (Figure 1, top-right).

		BERT	RoBERTa	m-BERT	XLM-R
Linear	Random	72.8	72.8	–	–
	Static	75.1	75.3	–	–
	Top-4	85.3	85.3	–	–
	W-Avg	**85.7**	**86.1**	–	–
Non-Linear	Random	75.9	75.9	75.8	75.7
	Static	76.3	76.5	76.2	76.3
	Top-4	89.2	88.8	88.0	88.9
	W-Avg	**89.4**	**89.3**	**88.8**	**89.1**

Table 2: Results on **roleset probing** in terms of F1 Score (%) for the Random, Static, Top-4 and W-Avg probes using different pretrained language models, namely, BERT (base-cased), RoBERTa (base), multilingual BERT (base) and XLM-RoBERTa (base). As for the sense probing task, using the a weighted average of all the hidden layers provides richer features to the probes.

3.3 Verbal and Nominal Predicates

One aspect that is often overlooked when designing and proposing novel architectures for SRL is that not all predicates are verbs. In English, it is easy to find examples of nouns that evoke or imply a predication, such as *producer*, *driver*, and *writer*. Most common nominal predicates are "verb-derived" or "deverbal" as their roleset is derived from their corresponding verbal predicates. This is why, per-

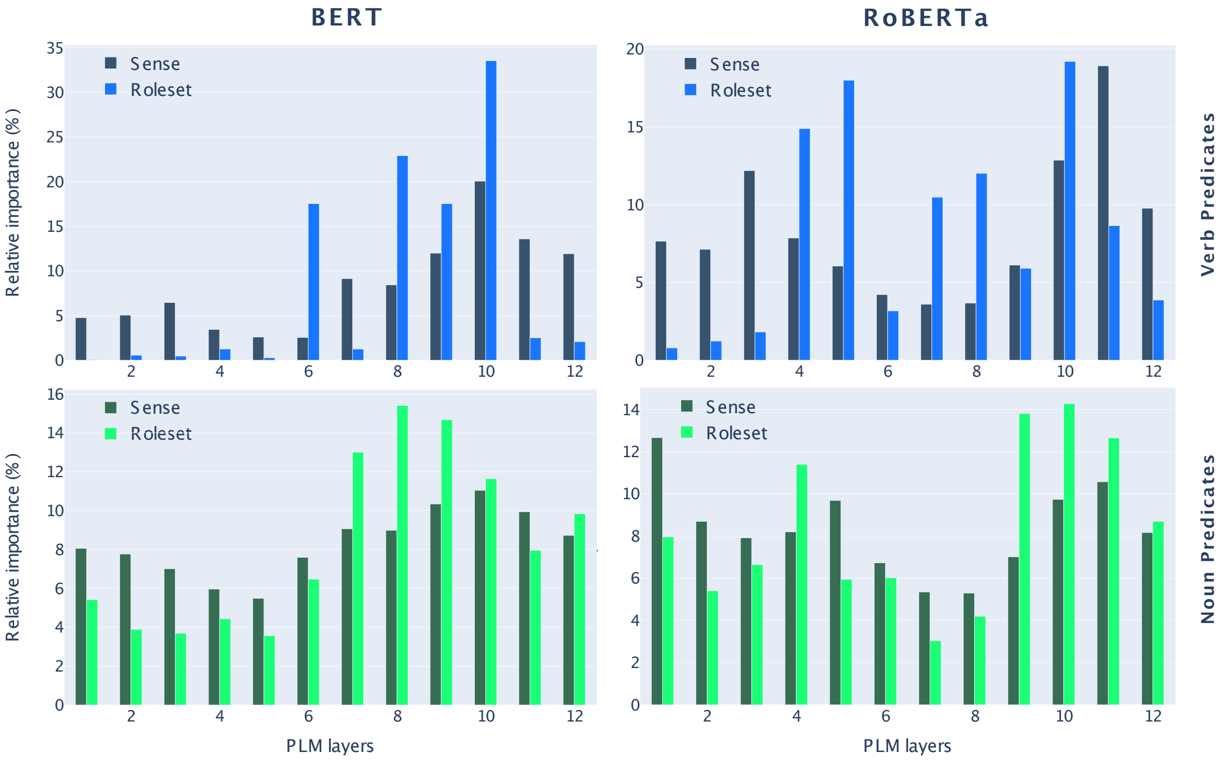

Figure 1: Relative importance (%) of each layer of BERT (left) and RoBERTa (right) for sense probing and roleset probing. Verbal predicates (top, blue): the most important layers of a PLM for roleset probing are the middle layers, especially for BERT, in which the top and the bottom layers are almost completely discarded. Nominal predicates (bottom, green): the importance of each layer follows the same trend for both sense and roleset probing.

PLM	Trained on	Verbs (F1)	Nouns (F1)
Random	Verbs	72.0	–
Random	Nouns	–	68.5
BERT	Verbs	85.7	63.3
BERT	Nouns	67.5	77.5
RoBERTa	Verbs	86.1	64.7
RoBERTa	Nouns	67.5	78.3

Table 3: Results in terms of F1 score (%) on zero-shot roleset identification when a probe is trained on verbal predicates and evaluated on nominal predicates, and vice versa. Interestingly, a probe trained on verbal predicates performs worse than a random probe on nominal predicates, demonstrating that knowledge transfer between predicate types is not trivial.

haps, current state-of-the-art approaches do not distinguish between verbal and nominal predicates.[4] However, nominal predicates also possess peculiarities that do not appear in their verbal counterparts; for example, a nominal predicate can be its own argument, e.g., *writer* is the agent itself of the action *write*.

We take this opportunity to investigate how nominal predicate senses and their rolesets are encoded by PLMs in their inner layers. We train a W-Avg probe on the sense and roleset probing tasks, focusing only on the nominal predicate instances in CoNLL-2009. Figure 1 (bottom, green charts) shows the weights learned for the sense and roleset probing tasks when using BERT (bottom-left) and RoBERTa (bottom-right): we can immediately observe that, differently from verbal predicates, the weight distributions learned for nominal senses and their rolesets follow the same trend in both PLMs. In other words, despite the fact that most nominal predicates are verb-derived, their information is encoded dissimilarly and distributed across different layers compared to those of verbal predicates.

We confirm our hunch by evaluating the ability of a W-Avg probe trained on roleset identification for verbal predicates only to also perform roleset identification for nominal predicates in a zero-shot fashion, and vice versa. Although, from a first glance at the results reported in Table 3, our simple model seems to be able to perform nominal roleset identification after being trained only on verbal

---

[4] We note that, in general, languages – English included – also possess, sometimes in extensive quantities, predicates that are neither verbal nor nominal. For example, Japanese prominently features adjectival predicates.

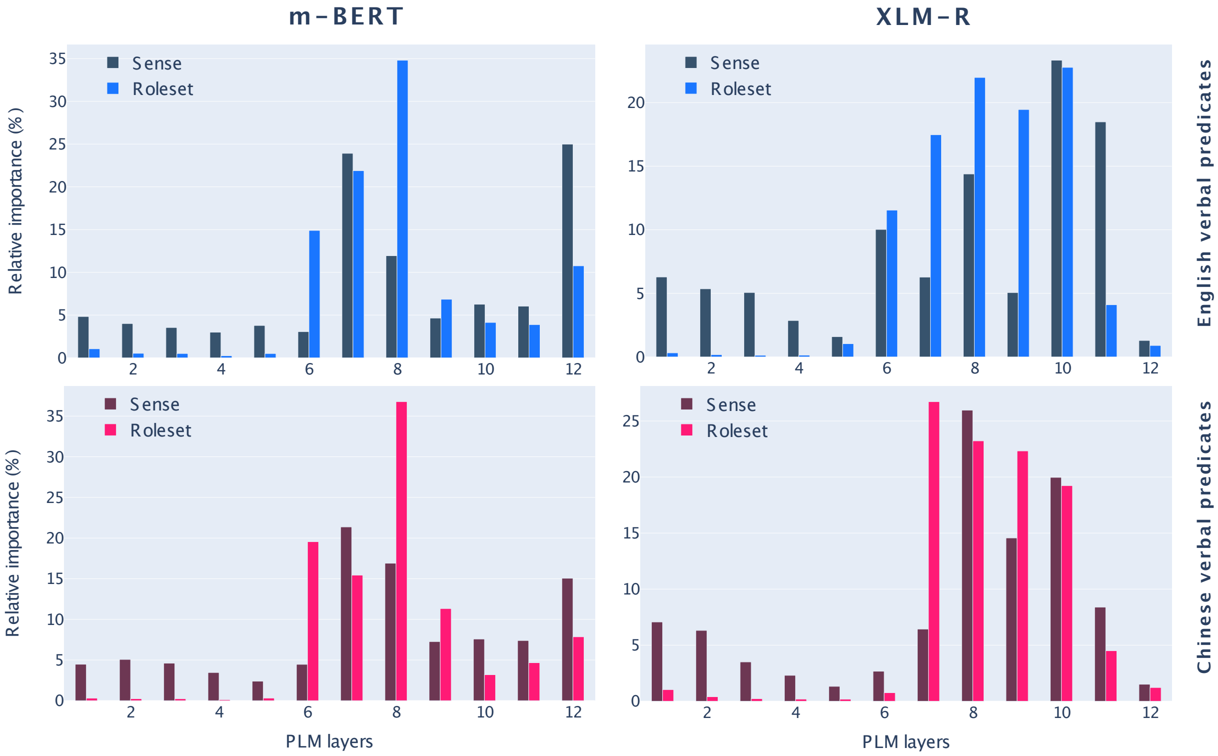

Figure 2: Relative importance (%) of each hidden layer of multilingual BERT (left) and XLM-RoBERTa (right) for sense probing and roleset probing. Results in English are in blue (top), whereas results in Chinese are in red (bottom).

rolesets, the performance is actually worse than a control probe, which is trained with a randomly initialized model on nominal roleset identification. In general, our analysis provides an empirical explanation for why recent approaches for nominal SRL adapted from verbal SRL are still struggling to learn general features across different predicate types, despite initial promising results (Klein et al., 2020; Zhao and Titov, 2020).

3.4 Senses and Rolesets Across Languages

We conclude our analysis on predicate senses and their rolesets with another important finding: multilingual PLMs encode both predicate sense and roleset information at similar layers across two very different languages, English and Chinese. In order to support this statement, we train an W-Avg probe on both sense disambiguation and roleset identification, first on the English verbal predicates from the training split of CoNLL-2009 and then on the Chinese verbal predicates from the training split of CoNLL-2009.

Figure 2 shows the distributions of the learned weights for each hidden layer of two language models, multilingual BERT (left) and XLM-RoBERTa (right). In particular, we observe that the probe learns to almost completely discard the first five layers of multilingual BERT for roleset identification in both English (top-left) and Chinese (bottom-left), while assigning similar weights across English and Chinese to the other hidden layers, with the 8th layer being relatively important in both languages. Overall, Figure 2 supports the evidence that both multilingual BERT and XLM-RoBERTa encode the same type of "semantic knowledge" at roughly the same hidden layers across languages, supporting the findings by Conneau et al. (2020) and indicating a possible direction for future work in cross-lingual transfer learning for SRL.

4 Integrating Predicate-Argument Structure Knowledge

Now that we have provided an in-depth look at how sense and roleset information is encoded at different inner layers of current PLMs (Section 3.2), highlighted the differences in how PLMs encode verbal and nominal predicates (Section 3.3), and revealed that multilingual PLMs capture semantic knowledge at similar layers across two diverse languages (Section 3.4), one may wonder how we can take advantage in a practical setting of what we have learned so far. In this Section, we study how we can improve a modern system for end-to-end SRL by integrating sense and roleset knowledge into its architecture.

4.1 Model Description

In what follows, we briefly describe the architecture of our baseline model, which is based on that proposed by Conia and Navigli (2020). Notice that, even though we refer to this model as our baseline, its end-to-end architecture rivals current state-of-the-art approaches, such as Blloshmi et al. (2021), Conia et al. (2021) and Paolini et al. (2021).

Given an input sentence $\mathbf{w}$, the model computes a contextual representation $\mathbf{x}_i$ for each word w_i in $\mathbf{w}$ by concatenating the representations obtained from the four topmost layers of a pretrained language model. These contextual word representations are then processed by a stack of "fully connected" BiLSTM layers in which the input to the i-th BiLSTM layer is the concatenation of the inputs of all previous BiLSTM layers in the stack, obtaining a sequence $\mathbf{h}$ of refined encodings. These encodings $\mathbf{h}$ are made "predicate-aware" by concatenating each $\mathbf{h}_i$ of w_i to the representation $\mathbf{h}_p$ of each predicate p in the sentence, and finally processed by another stack of fully-connected BiLSTMs, resulting in a sequence $\mathbf{a}$ of argument encodings. We refer to Conia and Navigli (2020) for further details about the architecture of our baseline model.

Enhancing the SRL model. Based on our observations and analyses in the Sections above, we put forward three simple enhancements to our strong baseline model:

- Representing words using a weighted average of all the inner layers of the underlying language model, since we now know that semantic features important for the task are scattered across all the layers of a PLM;
- Using two different sets of weights to compute different weighted averages for predicate senses and predicate arguments, as semantic features important for the two tasks are distributed differently across the inner layers of the underlying PLM;
- Adding a secondary task to predict rolesets from a predicate representation $\mathbf{h}_p$ in a multi-task learning fashion.

	P	R	F1
BERT$_{\text{base}}$ – baseline	91.8	91.9	91.8
BERT$_{\text{base}}$ – W-Avg	91.9	92.0	91.9
BERT$_{\text{base}}$ – 2×W-Avg	92.1	92.1	92.1
BERT$_{\text{base}}$ – 2×W-Avg + MT	92.2	92.2	92.2
BERT$_{\text{large}}$ – baseline	91.7	91.7	91.7
BERT$_{\text{large}}$ – W-Avg	91.9	92.0	92.0
BERT$_{\text{large}}$ – 2×W-Avg	92.5	92.5	92.5
BERT$_{\text{large}}$ – 2×W-Avg + MT	92.8	92.7	92.8

Table 4: Results in terms of micro-averaged precision, recall and F1 score on SRL over the verbal predicate instances in the standard gold benchmark of CoNLL-2009 for dependency-based SRL.

Results on SRL. Table 4 compares the results obtained on the verbal predicate instances in the standard gold benchmark of CoNLL-2009 for dependency-based SRL.[5] As we can see, each contribution provides an improvement over the previous one, both when using BERT-base-cased and BERT-large-cased (+0.4% and +1.1% in F1 score[6] over the baseline, respectively), the latter being one of the most used pretrained language models to achieve state-of-the-art results on the task. In general, not only did our analysis shed light on interesting properties of current PLMs through the lens of predicate senses and their rolesets, but it also provided practical hints on how to better exploit such properties in SRL.

Qualitative Analysis. Finally, we provide a look at what happens when our model is informed about predicate senses and their rolesets at training time. To inspect how the vector representations of predicates change as we inject more inductive bias towards predicate-argument information, in Figure 3 we use t-SNE to project and visualize on a bidimensional plane the representations of the predicate *close* when using: i) the baseline model, which is unaware of predicate-argument information and, therefore, does not show any significant clustering according to different rolesets; ii) the model when it can use different weighted averages to com-

---

[5] We trained our model for 30 epochs using Adam with an initial learning rate of 1e-3, leaving all parameters of the underlying language model frozen and using the parameter values used in the original paper by Conia and Navigli (2020).

[6] Scores were computed using the official CoNLL-2009 scorer provided during the shared task. This scoring script produces a unified F1 measure that takes into account both predicate senses and semantic roles.

Figure 3: t-SNE visualization of the representations for the predicate *close*. Different colors represent different rolesets, even though some rolesets are partially overlapping (e.g. {AM-EXT, AM-MNR} and {AM-EXT, AM-TMP}). From left to right: predicate representations from the baseline SRL model which is completely unaware of rolesets (left); predicate representations from an SRL model that can use two different weighted averages to create different representations for predicate senses and their arguments (center); predicate representations from an SRL model that is tasked to explicitly identify rolesets through a secondary learning objective in a multi-task fashion (right).

pute representations for predicate senses and their arguments; and iii) the model when it is explicitly tasked with the secondary training objective of learning to identify the roleset of each predicate. As one can see, as we inject more linguistic information into the model, the representations can be clustered better according to their corresponding predicate-argument structures.

5 Conclusion

In this paper, we probed PLMs for PASs: differently from past work, we dissected SRL into its core subtasks and analysed how PLMs encode predicate-argument structure information such as predicate senses and their rolesets. In our analysis, we observed that, despite the intrinsic connection between predicate senses and their rolesets that exists in several popular SRL inventories, different PLMs encode their features across significantly different layers. What is more, we also discovered that verbal and nominal predicates and their PASs are represented differently, making verbal-to-nominal SRL transfer far from trivial, and providing an empirical explanation for why previous attempts in this direction have struggled to obtain strong results. Furthermore, our analysis revealed that current multilingual language models encode PASs similarly across two very different languages, namely, English and Chinese.

Finally, in contrast to previous work on probing, we put together what we learned and demonstrated a practical application of our findings by devising simple yet effective techniques for the integration of predicate-argument structure knowledge into a state-of-the-art end-to-end architecture for SRL.

Abstract

We present a study on leveraging multilingual pre-trained *generative* language models for zero-shot cross-lingual event argument extraction (EAE). By formulating EAE as a *language generation* task, our method effectively encodes event structures and captures the dependencies between arguments. We design *language-agnostic templates* to represent the event argument structures, which are compatible with any language, hence facilitating the cross-lingual transfer. Our proposed model finetunes multilingual pre-trained generative language models to *generate* sentences that fill in the language-agnostic template with arguments extracted from the input passage. The model is trained on source languages and is then directly applied to target languages for event argument extraction. Experiments demonstrate that the proposed model outperforms the current state-of-the-art models on zero-shot cross-lingual EAE. Comprehensive studies and error analyses are presented to better understand the advantages and the current limitations of using generative language models for zero-shot cross-lingual transfer EAE.

1 Introduction

Event argument extraction (EAE) aims to recognize the entities serving as event arguments and identify their corresponding roles. As illustrated by the English example in Figure 1, given a trigger word *"destroyed"* for a *Conflict:Attack* event, an event argument extractor is expected to identify *"commando"*, *"Iraq"*, and *"post"* as the event arguments and predict their roles as *"Attacker"*, *"Place"*, and *"Target"*, respectively.

Zero-shot cross-lingual EAE has attracted considerable attention since it eliminates the requirement of labeled data for constructing EAE models in low-resource languages (Subburathinam et al., 2019; Ahmad et al., 2021; Nguyen and Nguyen, 2021). In this setting, the model is trained on the examples in the *source* languages and directly tested on the instances in the *target* languages.

Australian commandos, who have been operating deep in Iraq, destroyed a command and control post and killed a number of soldiers.

接近高级军官的消息灵通人士说，南斯拉夫军队不会离开军营去干涉反对派起义。

Figure 1: An illustration of cross-lingual event argument extraction. Given sentences in arbitrary languages and their event triggers (*destroyed* and 起义), the model needs to identify arguments (*commando*, *Iraq* and *post* v.s. 军队, and 反对派) and their corresponding roles (Attacker, Target, and Place).

Recently, generation-based models[1] have shown strong performances on monolingual structured prediction tasks (Yan et al., 2021; Huang et al., 2021b; Paolini et al., 2021), including EAE (Li et al., 2021; Hsu et al., 2021). These works fine-tune pre-trained generative language models to generate outputs following designed templates such that the final predictions can be easily decoded from the outputs. Compared to the traditional classification-based models (Wang et al., 2019; Wadden et al., 2019; Lin et al., 2020), they better capture the structures and dependencies between entities, as the templates provide additional declarative information.

Despite the successes, the designs of templates in prior works are language-dependent, which makes it hard to be extended to the zero-shot cross-lingual transfer setting (Subburathinam et al., 2019; Ahmad et al., 2021). Naively applying such models trained on the source languages to the target languages usually generates *code-switching* outputs, yielding poor performance for zero-shot

---

[*] The authors contribute equally.

[1] We use pre-trained *generative* language models to refer to pre-trained models with encoder-decoder structure, such as BART (Lewis et al., 2020), T5 (Raffel et al., 2020), and mBART (Liu et al., 2020). For models adapting these pre-trained generative models to generate texts for downstream applications, we denote them as *generation-based* models.

cross-lingual transfer,[2] as we will empirically show in Section 5.4. How to design *language-agnostic* generation-based models for zero-shot cross-lingual structured prediction problems is still an open question.

In this work, we present a study that leverage multilingual pre-trained generative models for zero-shot cross-lingual event argument extraction and propose X-GEAR (**Cross**-lingual **G**enerative **E**vent **A**rgument extracto**R**). Given an input passage and a carefully designed prompt that contains an event trigger and the corresponding language-agnostic template, X-GEAR is trained to generate a sentence that fills in a language-agnostic template with arguments. X-GEAR inherits the strength of generation-based models that captures event structures and the dependencies between entities better than classification-based models. Moreover, the pre-trained decoder inherently identifies named entities as candidates for event arguments and does not need an additional named entity recognition module. The *language-agnostic templates* prevents the model from overfitting to the source language's vocabulary and facilitates cross-lingual transfer.

We conduct experiments on two multilingual EAE datasets: ACE-2005 (Doddington et al., 2004) and ERE (Song et al., 2015). The results demonstrate that X-GEAR outperforms the state-of-the-art zero-shot cross-lingual EAE models. We further perform ablation studies to justify our design and present comprehensive error analyses to understand the limitations of using multilingual generation-based models for zero-shot cross-lingual transfer. Our code is available at `https://github.com/PlusLabNLP/X-Gear`

2 Related Work

Zero-shot cross-lingual structured prediction. Zero-shot cross-lingual learning is an emerging research topic as it eliminates the requirement of labeled data for training models in low-resource languages (Ruder et al., 2021; Huang et al., 2021a). Various structured prediction tasks have been studied, including named entity recognition (Pan et al., 2017; Huang et al., 2019; Hu et al., 2020), dependency parsing (Ahmad et al., 2019b,a; Meng et al., 2019), relation extraction (Zou et al., 2018; Ni and Florian, 2019), and event argument extraction (Subburathinam et al., 2019; Nguyen and Nguyen, 2021; Fincke et al., 2021). Most of them are *classification-based models* that build classifiers on top of a multilingual pre-trained *masked* language models. To further deal with the discrepancy between languages, some of them require additional information, such as bilingual dictionaries (Liu et al., 2019; Ni and Florian, 2019), translation pairs (Zou et al., 2018), and dependency parse trees (Subburathinam et al., 2019; Ahmad et al., 2021; Nguyen and Nguyen, 2021). However, as pointed out by previous literature (Li et al., 2021; Hsu et al., 2021), classification-based models are less powerful to model dependencies between entities compared to *generation-based models*.

Generation-based structured prediction. Several works have demonstrated the great success of generation-based models on monolingual structured prediction tasks, including named entity recognition (Yan et al., 2021), relation extraction (Huang et al., 2021b; Paolini et al., 2021), and event extraction (Du et al., 2021; Li et al., 2021; Hsu et al., 2021; Lu et al., 2021). Yet, as mentioned in Section 1, their designed generating targets are language-dependent. Accordingly, directly applying their methods to the zero-shot cross-lingual setting would result in less-preferred performance.

Prompting methods. There are growing interests recently to incorporate prompts on pre-trained language models in order to guide the models' behavior or elicit knowledge (Peng et al., 2019; Sheng et al., 2020; Shin et al., 2020; Schick and Schütze, 2021; Qin and Eisner, 2021; Scao and Rush, 2021). Following the taxonomy in (Liu et al., 2021), these methods can be classified depending on whether the language models' parameters are tuned and on whether trainable prompts are introduced. Our method belongs to the category that fixes the prompts and tunes the language models' parameters. Despite the flourish of the research in prompting methods, there is only limited attention being put on multilingual tasks (Winata et al., 2021).

3 Zero-Shot Cross-Lingual Event Argument Extraction

We focus on zero-shot cross-lingual EAE. Given an input passage and an event trigger, an EAE

---

[2] For example, TANL (Paolini et al., 2021) is trained to generate "`[Two soldiers|target] were attacked`" to represent *Two soldiers* being a *target* argument. When directly applying it to Chinese, the ground truth for TANL becomes "`[两位士兵|target]被攻击`", which is a sentence alternating between Chinese and English.

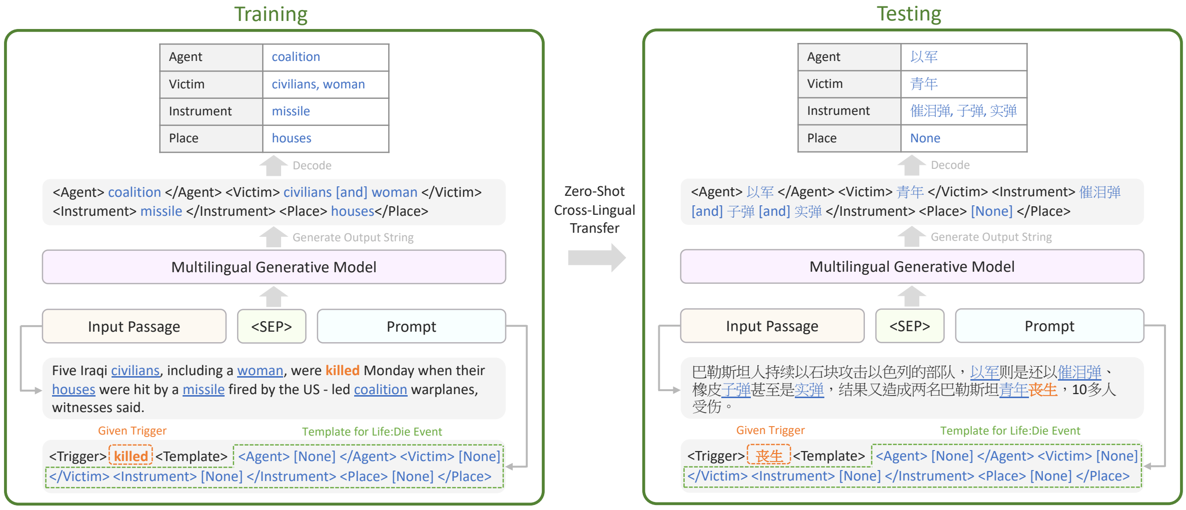

Figure 2: The overview of X-GEAR. Given an input passage and a carefully designed prompt containing an event trigger and a language-agnostic template, X-GEAR fills in the language-agnostic template with event arguments.

model identifies arguments and their corresponding roles. More specifically, as illustrated by the training examples in Figure 2, given an input passage $\mathbf{x}$ and an event trigger $\mathbf{t}$ (*killed*) belonging to an event type $\mathbf{e}$ (*Life:Die*), an EAE model predicts a list of arguments $\mathbf{a} = [a_1, a_2, ..., a_l]$ (*coalition*, *civilians*, *woman*, *missile*, *houses*) and their corresponding roles $\mathbf{r} = [r_1, r_2, .., r_l]$ (*Agent*, *Victim*, *Victim*, *Instrument*, *Place*). In the zero-shot cross-lingual setting, the training set $X_{train} = \{(\mathbf{x}_i, \mathbf{t}_i, \mathbf{e}_i, \mathbf{a}_i, \mathbf{r}_i)\}_{i=1}^{N}$ belongs to the source languages while the testing set $X_{test} = \{(\mathbf{x}_i, \mathbf{t}_i, \mathbf{e}_i, \mathbf{a}_i, \mathbf{r}_i)\}_{i=1}^{M}$ are in the target languages.

Similar to monolingual EAE, zero-shot cross-lingual EAE models are expected to capture the dependencies between arguments and make structured predictions. However, unlike monolingual EAE, zero-shot cross-lingual EAE models need to handle the differences (e.g., grammar, word order) between languages and learn to transfer the knowledge from the source languages to the target languages.

4 Proposed Method: X-GEAR

We formulate zero-shot cross-lingual EAE as a language generation task and propose X-GEAR, a **Cross**-lingual **G**enerative **E**vent **A**rgument ex-tracto**R** that is illustrated in Figure 2. There are two challenges raised by this formulation: (1) The input language may vary during training and testing; (2) The generated output strings need to be easily parsed into final predictions. Therefore, the output strings have to reflect the change of the input language accordingly while remaining well-structured.

We address these challenges by designing *language-agnostic templates*. Specifically, given an input passage $\mathbf{x}$ and a designed prompt that contains the given trigger $\mathbf{t}$, its event type $\mathbf{e}$, and a *language-agnostic template*, X-GEAR learns to generate an output string that fills in the language-agnostic template with information extracted from input passage. The language-agnostic template is designed in a structured way such that parsing the final argument predictions $\mathbf{a}$ and role predictions $\mathbf{r}$ from the generated output is trivial. Moreover, since the template is language-agnostic, it facilitates cross-lingual transfer.

X-GEAR fine-tunes multilingual pre-trained generative models, such as mBART-50 (Tang et al., 2020) or mT5 (Xue et al., 2021), and augments them with a copy mechanism to better adapt to input language changes. We present its details as follows, including the language-agnostic templates, the target output string, the input format, and the training details.

4.1 Language-Agnostic Template

We create one language-agnostic template $T_{\mathbf{e}}$ for each event type $\mathbf{e}$, in which we list all possible associated roles[3] and form a unique HTML-tag-style template for that event type $\mathbf{e}$. For example, in Figure 2, the *Life:Die* event is associated with four roles: *Agent*, *Victim*, *Instrument*, and *Place*. Thus, the template for *Life:Die* events is designed as:

---

[3] The associated roles can be obtained by skimming training data or directly from the annotation guideline if provided.

<Agent> `[None]` </Agent><Victim> `[None]` </Victim> <Instrument> `[None]` </Instrument><Place> `[None]` </Place>.

For ease of understanding, we use English words to present the template. However, these tokens (`[None]`, <Agent>, </Agent>, <Victim>, etc.) are encoded as special tokens[4] that the pre-trained models have never seen and thus their representations need to be learned from scratch. Since these special tokens are not associated with any language and are not pre-trained, they are considered as *language-agnostic*.

4.2 Target Output String

X-Gear learns to generate target output strings that follow the form of language-agnostic templates. To compose the target output string for training, given an instance $(\mathbf{x}, \mathbf{t}, \mathbf{e}, \mathbf{a}, \mathbf{r})$, we first pick out the language-agnostic template $T_{\mathbf{e}}$ for the event type $\mathbf{e}$ and then replace all "`[None]`" in $T_{\mathbf{e}}$ with the corresponding arguments in $\mathbf{a}$ according to their roles $\mathbf{r}$. If there are multiple arguments for one role, we concatenate them with a special token "`[and]`". For instance, the training example in Figure 2 has two arguments (*civilians* and *woman*) for the *Victim* role, and the corresponding part of the output string would be

<Victim> `civilians [and] woman` </Victim>.

If there are no corresponding arguments for one role, we keep "`[None]`" in $T_{\mathbf{e}}$. By applying this rule, the full output string for the training example in Figure 2 becomes

<Agent> `coalition` </Agent><Victim> `civilians [and] woman` </Victim><Instrument> `missile` </Instrument> <Place> `houses` </Place>.

Since the output string is in the HTML-tag style, we can easily decode the argument and role predictions from the generated output string via a simple rule-based algorithm.

4.3 Input Format

As we mentioned previously, the key for the generative formulation for zero-shot cross-lingual EAE is to guide the model to generate output strings in the desired format. To facilitate this behavior, we feed the input passage $\mathbf{x}$ as well as a *prompt* to X-Gear, as shown by Figure 2. The *prompt* contains all valuable information for the model to make predictions, including a trigger $\mathbf{t}$ and a language-agnostic template $T_{\mathbf{e}}$. Notice that we do not *explicitly* include the event type $\mathbf{e}$ in the prompt because the template $T_{\mathbf{e}}$ *implicitly* contains this information. In Section 6.1, we will show the experiments on explicitly adding event type $\mathbf{e}$ to the prompt and discuss its influence on the cross-lingual transfer.

4.4 Training

To enable X-Gear to generate sentences in different languages, we resort multilingual pre-trained generative model to be our base model, which models the conditional probability of generating a new token given the previous generated tokens and the input context to the encoder c, i.e,

$$P(x|c) = \prod_i P_{gen}(x_i|x_{<i}, c),$$

where x_i is the output of the decoder at step i.

Copy mechanism. Although the multilingual pre-trained generative models can generate sequences in many languages, solely relying on them may result in generating hallucinating arguments (Li et al., 2021). Since most of the tokens in the target output string appear in the input sequence,[5] we augment the multilingual pre-trained generative models with a copy mechanism to help X-Gear better adapt to the cross-lingual scenario. Specifically, we follow See et al. (2017) to decide the conditional probability of generating a token t as a weighted sum of the vocabulary distribution computed by multilingual pre-trained generative model P_{gen} and copy distribution P_{copy}

$$\begin{aligned} &P_{\text{X-Gear}}(x_i = t|x_{<i}, c) = \\ &\quad w_{copy} \cdot P_{copy}(t) + (1 - w_{copy}) \cdot P_{gen}(x_i = t|x_{<i}, c) \end{aligned}$$

where $w_{copy} \in [0, 1]$ is the copy probability computed by passing the decoder hidden state at time step i to a linear layer. As for P_{copy}, it refers to the probability over input tokens weighted by the cross-attention that the last decoder layer computed (at time step i). Our model is then trained end-to-end with the following loss:

$$\mathcal{L} = -\log \sum_i P_{\text{X-Gear}}(x_i|x_{<i}, c).$$

5 Experiments

5.1 Datasets

We consider two commonly used event extraction datasets: ACE-2005 and ERE. We consider En-

---

[4] In fact , the special tokens can be replaced by any other format, such as <–token1–> or </–token1–>. Here, we use <Agent> and </Agent> to highlight that arguments between these two special tokens are corresponding to the *Agent* role.

[5] Except for the special tokens `[and]` and `[None]`.

glish, Arabic, and Chinese annotations for **ACE-2005** (Doddington et al., 2004) and follow the preprocessing in Wadden et al. (2019) to keep 33 event types and 22 argument roles. **ERE** (Song et al., 2015) is created by the Deep Exploration and Filtering of Test program. We consider its English and Spanish annotations and follow the preprocessing in Lin et al. (2020) to keep 38 event types and 21 argument roles. Detailed statistics and preprocessing steps about the two datasets are in Appendix A.

Notice that prior works working on the zero-shot cross-lingual transfer of event arguments mostly focus on event argument role labeling (Subburathinam et al., 2019; Ahmad et al., 2021), where they assume ground truth entities are provided during both training and testing. In their experimental data splits, events in a sentence can be scattered in all training, development, and test split since they treat each event-entity pair as a different instance. In this work, we consider event argument extraction (Wang et al., 2019; Wadden et al., 2019; Lin et al., 2020), which is a more realistic setting.

5.2 Evaluation Metric

We follow previous work (Lin et al., 2020; Ahmad et al., 2021) and consider the *argument classification F1 score* to measure the performance of models. An argument-role pair is counted as correct if both the argument offsets and the role type match the ground truth. Given the ground truth arguments $\mathbf{a}$, ground truth roles $\mathbf{r}$, predicted arguments $\tilde{\mathbf{a}}$, and predicted roles $\tilde{\mathbf{r}}$, the argument classification F1 score is defined as the F1 score between the set $\{(\mathbf{a}_i, \mathbf{r}_i)\}$ and the set $\{(\tilde{\mathbf{a}}_j, \tilde{\mathbf{r}}_j)\}$. For every model, we experiment with three different random seeds and report the average results.

5.3 Compared Models

We compare the following models and their implementation details are listed in Appendix B.

- **OneIE** (Lin et al., 2020), the state-of-the-art for monolingual event extraction, is a classification-based model trained with multitasking, including entity extraction, relation extraction, event extraction, and *event argument extraction*. We simply replace its pre-trained embedding with XLM-RoBERTa-large (Conneau et al., 2020) to fit the zero-shot cross-lingual setting. Note that the multi-task learning makes OneIE require *additional annotations*, such as named entity annotations and relation annotations.
- **CL-GCN** (Subburathinam et al., 2019) is a classification-based model for cross-lingual event argument role labeling (EARL). It considers *dependency parsing annotations* to bridge different languages and use GCN layers (Kipf and Welling, 2017) to encode the parsing information. We follow the implementation of previous work (Ahmad et al., 2021) and add two GCN layers on top of XLM-RoBERTa-large. Since CL-GCN focuses on EARL tasks, which assume the ground truth entities are available during testing, we add one name entity recognition module jointly trained with CL-GCN.
- **GATE** (Ahmad et al., 2021), the state-of-the-art model for zero-shot cross-lingual EARL, is a classification-based model which considers *dependency parsing annotations* as well. Unlike CL-GCN, it uses a Transformer layer (Vaswani et al., 2017) with modified attention to encode the parsing information. We follow the original implementation and add two GATE layers on top of pre-trained multilingual language models.[6] Similar to CL-GCN, we add one name entity recognition module jointly trained with GATE.
- **TANL** (Paolini et al., 2021) is a generation-based model for monolingual EAE. Their predicted target is a sentence that embeds labels into the input passage, such as `[Two soldiers|target] were attacked`, which indicates that "*Two soldiers*" is a "*target*" argument. To adapt TANL to zero-shot cross-lingual EAE, we change its pre-trained generative model from T5 (Raffel et al., 2020) to mT5-base (Xue et al., 2021).
- **X-Gear** is our proposed model. We consider three different pre-trained generative language models: mBART-50-large (Tang et al., 2020), mT5-base, and mT5-large (Xue et al., 2021).

5.4 Results

Table 1 and Table 2 list the results on ACE-2005 and ERE, respectively, with all combinations of source languages and target languages. Note that all the models have similar numbers of parameters

---

[6] To better compare our method with this strong baseline, we consider three different pre-trained multilingual language models for GATE – (1) XLM-RoBERTa-large (2) mBART-50-large (3) mT5-base. For mBART-50-large and mT-base, we follow BART's recipe (Lewis et al., 2020) to extract features for EAE predictions. Specifically, the input passage is fed into both encoder and decoder, and the final token representations are elicited from the decoder output.

except for X-Gear with mT5-large.

Comparison to prior generative models. We first observe that TANL has poor performance when transferring to different languages. The reason is that its language-dependent template makes TANL easily generate code-switching outputs,[7] which is a case that pre-trained generative model rarely seen, leading to poor performance. In contrast, X-Gear considers the language-agnostic templates and achieves better performance for zero-shot cross-lingual transfer.

Comparison to classification models. X-Gear with mT5-base outperforms OneIE, CL-GCN, and GATE on almost all the combinations of the source language and the target language. This suggests that our proposed method is indeed a promising approach for zero-shot cross-lingual EAE.

It is worth noting that OneIE, CL-GCN, and GATE require an additional pipeline named entity recognition module to make predictions. Moreover, CL-GCN and GATE need additional dependency parsing annotations to align the representations of different languages. On the contrary, X-Gear is able to leverage the learned knowledge from the pre-trained generative models, and therefore no additional modules or annotations are needed.

Comparison to different pre-trained generative language models. Interestingly, using mT5-base is more effective than using mBART-50-large for X-Gear, although they have a similar amount of parameters. We conjecture that the use of special tokens leads to this difference. mBART-50 has different begin-of-sequence (BOS) tokens for different languages. During generation, we have to specify which BOS token we would like to use as the start token. We guess that this language-specific BOS token makes mBART-50 harder to transfer the knowledge from the source language to the target language. Unlike mBART-50, mT5 does not have such language-specific BOS tokens. During generation, mT5 uses the padding token as the start token to generate a sequence. This design is more general and benefit zero-shot cross-lingual transfer.

Larger pre-trained models are better. Finally, we demonstrate that the performance of X-Gear can be further boosted with a larger pre-trained generative language model. As shown by Table 1 and Table2, X-Gear with mT5-large achieves the best scores on most of the cases.

6 Analysis

6.1 Ablation Studies

Copy mechanism. We first study the effect of the copy mechanism. Table 3 lists the performance of X-Gear with and without copy mechanism. It shows improvements in adding a copy mechanism

---

[7] Such as the example shown in footnote 2.

Model	en ⇓ xx	ar ⇓ xx	zh ⇓ xx	xx ⇓ en	xx ⇓ ar	xx ⇓ zh	avg
mBART-50-large	**51.6**	39.8	47.2	48.2	43.2	47.2	46.2
- w/o copy	50.9	**42.2**	**49.6**	**50.6**	**43.5**	**48.7**	**47.6**
mT5-base	**54.3**	**41.4**	**51.4**	**49.4**	**46.7**	**51.0**	**49.1**
- w/o copy	52.1	39.5	47.6	48.1	42.7	48.5	46.4
mT5-large	**56.7**	44.8	**52.6**	**53.0**	**48.9**	52.1	**51.3**
- w/o copy	55.1	**45.0**	51.5	52.0	46.3	**53.2**	50.5

Table 3: Ablation study on copy mechanism for ACE-2005. "en ⇒ xx" indicates the average of "en ⇒ en", "en ⇒ zh", and "en ⇒ ar".

when using mT5-large and mT-base. However, interestingly, adding a copy mechanism is not effective for mBART-50. We conjecture that this is because the pre-trained objective of mBART-50 is denoising autoencoding (Liu et al., 2020), and it has already learned to copy tokens from the input. Therefore, adding a copy mechanism is less useful. In contrast, the pre-trained objective of mT5 is to only generate tokens been masked out, resulting in lacking the ability to copy input. Thus, the copy mechanism becomes beneficial for mT5.

Including event type in prompts. In Section 4, we mentioned that the designed prompt for X-GEAR consists of only the input sentence and the language-agnostic template. In this section, we discuss whether *explicitly* including the event type information in the prompt is helpful. We consider three ways to include the event type information:

- **English tokens**. We put the English version of the event type in the prompt even if we are training or testing on non-English languages, for example, using *Attack* for the event type *Attack*.
- **Translated tokens**. For each event type, we prepare the translated version of that event type token. For example, both *Attack* and 攻击 represents the *Attack* event type. During training or testing, we decide the used token(s) according to the language of the input passage. Since all the event types are written in English in ACE-2005 and ERE, we use an off-the-self machine translation tool to perform the translation.
- **Special tokens**. We create a special token for every event type and let the model learn the representations of the special tokens from scratch. For instance, we use `<-attack->` to represent the *Attack* event type.

Model	en ⇓ xx	ar ⇓ xx	zh ⇓ xx	xx ⇓ en	xx ⇓ ar	xx ⇓ zh	avg
X-GEAR (mT5-base)	**54.3**	**41.4**	51.4	49.4	**46.7**	**51.0**	**49.1**
w/ English Tokens	53.3	39.3	**52.3**	49.2	46.5	49.2	48.3
w/ Translated Tokens	51.7	40.4	52.2	**49.8**	45.6	48.8	48.1
w/ Special Tokens	52.3	39.7	51.8	49.0	45.4	49.3	47.9

Table 4: Ablation study on including event type information in prompts for ACE-2005. "en ⇒ xx" indicates the average of "en ⇒ en", "en ⇒ zh", and "en ⇒ ar".

Model	en ⇓ xx	ar ⇓ xx	zh ⇓ xx	xx ⇓ en	xx ⇓ ar	xx ⇓ zh	avg
X-GEAR (mT5-base)	54.3	**41.4**	**51.4**	49.4	**46.7**	**51.0**	**49.1**
w/ random order 1	**54.4**	38.9	50.8	48.7	45.1	50.1	48.0
w/ random order 2	52.1	40.4	**51.4**	48.3	45.9	49.7	48.0
w/ random order 3	53.7	40.8	50.7	**50.8**	45.8	48.6	48.4

Table 5: Ablation study on different orders of roles in templates for ACE-2005. "en ⇒ xx" indicates the average of "en ⇒ en", "en ⇒ zh", and "en ⇒ ar".

Table 4 shows the results. In most cases, including event type information in the prompt decreases the performance. One reason is that one word in a language can be mapped to several words in another language. For example, the *Life* event type is related to *Marry*, *Divorce*, *Born*, and *Die* four sub-event types. In English, we can use just one word *Life* to cover all four sub-event types. However, In Chinese, when talking about *Marry* and *Divorce*, *Life* should be translated to "生活"; when talking about *Born* and *Die*, *Life* should be translated to "生命". This mismatch may cause the performance drop when considering event types in prompts. We leave how to efficiently use event type information in the cross-lingual setting as future work.

Influence of role order in templates. The order of roles in the designed language-agnostic templates can potentially influence performance. When designing the templates, we intentionally make the order of roles close to the order in natural sentences.[8] To study the effect of different orders, we train X-GEAR with templates with different random orders and report the results in Table 5. X-GEAR with random orders still achieve good performance but slightly worse than the original order. It suggests that X-GEAR is not very sensitive to different templates while providing appropriate order of roles can lead to a small improvement.

Using English tokens instead of special tokens for roles in templates. In Section 4, we mentioned that we use language-agnostic templates

---

[8] For example, types related to subject and object are listed first and types related to methods and places are listed last.

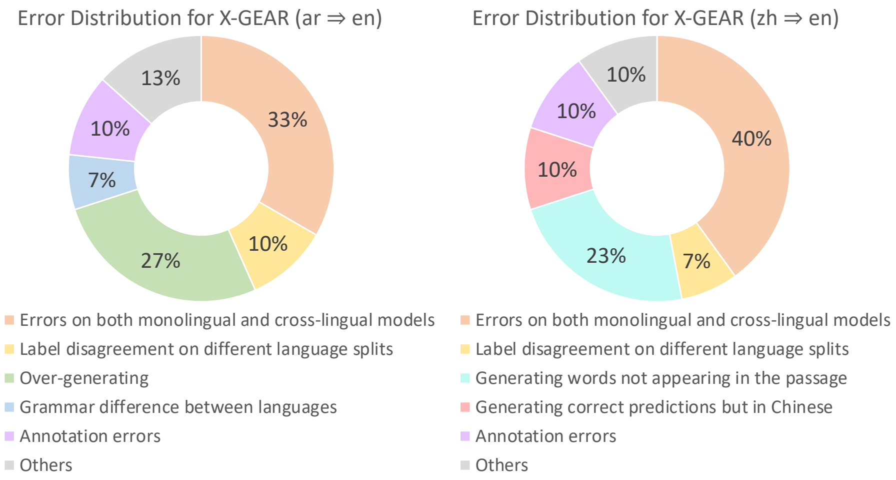

Figure 3: Distribution of errors that made by X-GEAR (mT5-base). ***Left:*** The distribution for our model that transfers from Arabic to English; ***Right:*** The distribution for our model trained on Chinese and tested on English.

Model	en ⇓ xx	ar ⇓ xx	zh ⇓ xx	xx ⇓ en	xx ⇓ ar	xx ⇓ zh	avg
X-GEAR (mT5-base)	**54.3**	**41.4**	**51.4**	**49.4**	**46.7**	**51.0**	**49.1**
w/ English Tokens	51.4	39.3	49.7	46.6	44.7	49.0	46.8

Table 6: Comparison of using English tokens and special tokens for roles in templates. "en ⇒ xx" indicates the average of "en ⇒ en", "en ⇒ zh", and "en ⇒ ar".

to facilitate the cross-lingual transfer. To further validate the effectiveness of the language-agnostic template. We conduct experiments using English tokens as the templates. Specifically, we set format

Agent: `[None]` <SEP> Victim: `[None]` <SEP> Instrument: `[None]` <SEP> Place: `[None]`

to be the template for *Life:Die* events. Hence, for non-English instances, the targeted output string is a code-switching sequence. Table 6 lists the results. We can observe that applying language-agnostic templates bring X-GEAR 2.3 F1 scores improvements in average.

6.2 Error Analysis

We perform error analysis on X-GEAR (mT5-base) when transferring from Arabic to English and transferring from Chinese to English. For each case, we sample 30 failed examples and present the distribution of various error types in Figure 3.

Errors on both monolingual and cross-lingual models. We compare the predicted results from X-GEAR(ar ⇒ en) with X-GEAR(en ⇒ en), or from X-GEAR(zh ⇒ en) with X-GEAR(en ⇒ en). If their predictions are similar and both of them are wrong when compared to the gold output, we classify the error into this category. To overcome the errors in this category, the potential solution is to improve monolingual models for EAE tasks.

Over-generating. Errors in this category happen more often in X-GEAR(ar ⇒ en). It is likely because the entities in Arabic are usually much longer than that in English when measuring by the number of sub-words. Based on our statistics, the average entity span length is 2.85 for Arabic and is 2.00 for English (length of sub-words). This leads to the natural for our X-GEAR(ar ⇒ en) to overly generate some tokens even though they have captured the correct concept. An example is that the model predicts *"The EU foreign ministers"*, while the ground truth is *"ministers"*.

Label disagreement on different language splits. The annotations for the ACE dataset in different language split contain some ambiguity. For example, given sentence *"He now also advocates letting in U.S. troops for a war against Iraq even though it is a fellow Muslim state."* and the queried trigger *"war"*, the annotations in English tends to label *Iraq* as the *Place* where the event happen, while similar situations in other languages will mark *Iraq* as the *Target* for the war.

Grammar difference between languages. An example for this category is *"... Blackstone Group would buy Vivendi's theme park division, including Universal Studios Hollywood ..."* and the queried trigger *"buy"*. We observe that X-GEAR(ar ⇒ en) predicts *Videndi* as the *Artifact* been sold and *division* is the *Seller*, while X-GEAR(en ⇒ en) can correctly understand that *Videndi* are the *Seller* and *division* is the *Artifact*. We hypothesize the reason being the differences between the grammar in Arabic and English. The word order of the sentence *"Vivendi's theme park division"* in Arabic is reversed with its English counterpart, that is, *"theme park division"* will be written before *"Vivendi"* in Arabic. Such difference leads to errors in this category.

Generating words not appearing in the passage. In X-Gear(zh ⇒ en), we observe several cases that generate words not appearing in the passage. There are two typical situations. The first case is that X-Gear(zh ⇒ en) mixes up singular and plural nouns. For example, the model generates *"studios"* as prediction while only *"studio"* appears in the passage. This may be because Chinese does not have morphological inflection for plural nouns. The second case is that X-Gear(zh ⇒ en) will generate random predictions in Chinese.

Generating correct predictions but in Chinese. This is a special case of *"Generating words not appearing in the passage"*. In this category, we observe that although the prediction is in Chinese (hence, a wrong prediction), it is correct if we translate the prediction into English.

6.3 Constrained Decoding

Among all the errors, we highlight two specific categories — *"Generating words not appearing in the passage"* and *"Generating correct predictions but in Chinese"*. These errors can be resolved by applying constrained decoding (Cao et al., 2021) to force all the generated tokens to appear input.

Table 7 presents the result of X-Gear with constrained decoding. We observe that adapting such constraints indeed helps the cross-lingual transferability, yet it also hurts the performance in some monolingual cases. We conduct a qualitative inspection of the predictions. The observation is that constrained decoding algorithm although guarantees all generated tokens appearing in the input, the coercive method breaks the overall sequence distribution that learned. Hence, in many monolingual examples, once one of the tokens is corrected by constrained decoding, its following generated sequence changes a lot, while the original predicted suffixed sequence using beam decoding are actually correct. This leads to a performance decrease.[9]

Model	monolingual	cross-lingual	average all
X-Gear (mBART-50-large)	**63.9**	37.4	**46.2**
w/ constrained decoding	62.4	**37.6**	45.9
X-Gear (mT5-base)	**67.8**	39.7	**49.1**
w/ constrained decoding	67.0	**39.9**	48.9
X-Gear (mT5-large)	**69.7**	42.2	51.3
w/ constrained decoding	68.8	**43.1**	**51.6**

Table 7: Results of applying constrained decoding. Breakdown numbers can be found in Appendix C. Based on whether the training languages are the same between training and testing, we classify the results into *monolingual* and *cross-lingual*, and we report the corresponding average for each category.

7 Conclusion

We present the first generation-based models for zero-shot cross-lingual event argument extraction. To overcome the discrepancy between languages, we design language-agnostic templates and propose X-Gear, which well capture output dependencies and can be used without additional named entity extraction modules. Our experimental results show that X-Gear outperforms the current state-of-the-art, which demonstrates the potential of using a language generation framework to solve zero-shot cross-lingual structured prediction tasks.

Acknowledgments

We thank anonymous reviewers for their helpful feedback. We thank the UCLA PLUSLab and UCLA-NLP group for the valuable discussions and comments. We also thank Steven Fincke, Shantanu Agarwal, and Elizabeth Boschee for their help on data preparation in Arabic. This work is supported in part by the Intelligence Advanced Research Projects Activity (IARPA), via Contract No. 2019-19051600007, and research awards sponsored by CISCO and Google.

Ethics Considerations

Our proposed models are based on the multilingual pre-trained language model that is trained on a large text corpus. It is known that the pre-trained language model could capture the bias reflecting the training data. Therefore, our models can potentially generate offensive or biased content learned by the pre-trained language model. We suggest carefully examining the potential bias before deploying our model in any real-world applications.

---

[9] Indeed, a similar situation happens to cross-lingual cases; however, since the original performance for cross-lingual transfer is not high enough, the benefits of correcting tokens are more significant than this drawback.

A Dataset Statistics and Data Preprocessing

Table 8 presents the detailed statistics for the ACE-2005 dataset and ERE dataset.

For the English and Chinese splits in ACE-2005, we use the setting provided by Wadden et al. (2019) and Lin et al. (2020), respectively. As for Arabic part, we adopt the setup proposed by Xu et al. (2021). Observing that part of the sentence breaks made from Xu et al. (2021) being extremely long for pretrained models to encode, we perform additional preprocessing and postprocessing procedures for Arabic data. Specifically, we split Arabic sentences into several portions that any of the portion is shorter than 80 tokens. Then, we map the models' predictions of the split sentences back to the original sentence during postprocessing.

B Implementation Details

We describe the implementation details for all the models as follows:

- **OneIE** (Lin et al., 2020). We use their provided code[10] to train the model with the provided default settings. It is worth mention that for the Arabic split in the ACE-2005 dataset, OneIE is trained with only entity extraction, event extraction, and event argument extraction since there is no relation labels in Xu et al. (2021)'s preprocessing script. All other parameters are set to the default values.
- **CL-GCN** (Subburathinam et al., 2019). We refer the released code from Ahmad et al. (2021)[11] to re-implement the CL-GCN method. Specifically, we adapt the baseline framework that described and implemented in OneIE's code (Lin et al., 2020), but we remove its relation extraction module and add two layers of GCN on top of XLM-RoBERTa-large. The pos-tag and dependency parsing annotations are obtained by applying Stanza (Qi et al., 2020). All other parameters are set to the be the same as the training of OneIE.
- **GATE** (Ahmad et al., 2021). We refer the official released code from Ahmad et al. (2021) to re-implement GATE. Similar to CL-GCN, we adapt the baseline framework that described and implemented in OneIE's code, but we remove its relation extraction module and add two layers of GATE on top of XLM-RoBERTa-large, mT5, or mBART-50-large. The pos-tag and dependency parsing annotations are also obtained by applying Stanza (Qi et al., 2020). The hyper-parameter of δ in GATE is set to be [2, 2, 4, 4, ∞, ∞, ∞, ∞]. All other parameters are set to the be the same as the training of OneIE.
- **TANL** (Paolini et al., 2021). To adapt TANL to zero-shot cross-lingual EAE, we adapt the public code[12] and replace its pre-trained based model T5 (Raffel et al., 2020) with mT5-base (Xue et al., 2021). All other parameters are set to their default values.
- **X-GEAR** is our proposed model. We consider three different pre-trained generative language models: mBART-50-large (Tang et al., 2020), mT5-base, and mT5-large (Xue et al., 2021). When fine-tune the pre-trained models, we set the learning rate to 10^{-4} for mT5, and 10^{-5} for mBART-50-large. The batch size is set to 8. The number of training epochs is 60.

C Constrained Decoding Detailed Results

Table 9 shows the detailed results for X-GEAR using constrained decoding algorithm during testing time. We directly apply constrained decoding algorithms on the trained models we have in Table 1.

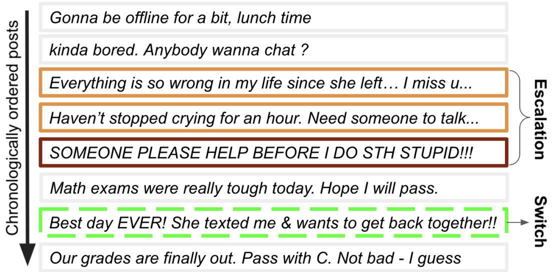
Abstract

Identifying changes in individuals' behaviour and mood, as observed via content shared on online platforms, is increasingly gaining importance. Most research to-date on this topic focuses on either: (a) identifying individuals at risk or with a certain mental health condition given a batch of posts or (b) providing equivalent labels at the post level. A disadvantage of such work is the lack of a strong temporal component and the inability to make longitudinal assessments following an individual's trajectory and allowing timely interventions. Here we define a new task, that of identifying moments of change in individuals on the basis of their shared content online. The changes we consider are sudden shifts in mood (switches) or gradual mood progression (escalations). We have created detailed guidelines for capturing moments of change and a corpus of 500 manually annotated user timelines (18.7K posts). We have developed a variety of baseline models drawing inspiration from related tasks and show that the best performance is obtained through context aware sequential modelling. We also introduce new metrics for capturing rare events in temporal windows.

1 Introduction

Linguistic and other content from social media data has been used in a number of different studies to obtain biomarkers for mental health. This is gaining importance given the global increase in mental health disorders, the limited access to support services and the prioritisation of mental health as an area by the World Health Organization (2019). Studies using linguistic data for mental health focus on recognising specific conditions related to mental health (e.g., depression, bipolar disorder) (Husseini Orabi et al., 2018), or identifying self-harm ideation in user posts (Yates et al., 2017; Zirikly et al., 2019). However, none of these works, even when incorporating a notion of time (Lynn et al., 2018; Losada et al., 2020), identify how an individual's mental health changes over time. Yet being able to make assessments on a longitudinal level from linguistic and other digital content is important for clinical outcomes, and especially in mental health (Velupillai et al., 2018). The ability to detect changes in individual's mental health over time is also important in enabling platform moderators to prioritise interventions for vulnerable individuals (Wadden et al., 2021). Users who currently engage with platforms and apps for mental health support (Neary and Schueller, 2018) would also benefit from being able to monitor their well-being in a longitudinal manner.



Gonna be offline for a bit, lunch time

kinda bored. Anybody wanna chat ?

Everything is so wrong in my life since she left… I miss u...

Haven't stopped crying for an hour. Need someone to talk...

SOMEONE PLEASE HELP BEFORE I DO STH STUPID!!!

Math exams were really tough today. Hope I will pass.

Best day EVER! She texted me & wants to get back together!!

Our grades are finally out. Pass with C. Not bad - I guess

Figure 1: Example of an Escalation (with a darker "peak") and a Switch within a user's timeline.

Motivated by the lack of longitudinal approaches we introduce the task of *identifying 'Moments of Change' (MoC) from individuals' shared online content*. We focus in particular on two types of changes: *Switches* – mood shifts from positive to negative, or vice versa – and *Escalations* – gradual mood progression (see Fig. 1, detailed in § 3). Specifically we make the following contributions:

- We present the novel task of identifying moments of change in an individual's mood by analysing linguistic content shared online over time, along with a longitudinal dataset of 500 user timelines (18.7K posts, English language) from 500 users of an online platform.
- We propose a number of baseline models for

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 4647 - 4660
May 22-27, 2022

automatically capturing Switches/Escalations, inspired by sentence- and sequence-level state-of-the-art NLP approaches in related tasks.

- We introduce a range of temporally sensitive evaluation metrics for longitudinal NLP tasks adapted from the fields of change point detection (van den Burg and Williams, 2020) and image segmentation (Arbelaez et al., 2010).
- We provide a thorough qualitative linguistic analysis of model performance.

2 Related Work

Social Media and Mental Health Online user-generated content provides a rich resource for computational modelling of wellbeing at both population and individual levels. Research has examined mental health conditions by analysing data from platforms such as Twitter and Reddit (De Choudhury et al., 2013; Coppersmith et al., 2014; Cohan et al., 2018) as well as peer-support networks such as TalkLife (Pruksachatkun et al., 2019). Most such work relies on proxy signals for annotations (e.g., self-disclosure of diagnoses, posts on support networks) and is characterised by a lack of standardisation in terms of annotation and reporting practices (Chancellor and De Choudhury, 2020). We have provided thorough annotation guidelines for Moments of Change that can aid mental health monitoring over time irrespective of the underlying condition.

Moments of Change (MoC) Little work has specifically focused on automatically capturing changes in user behaviour based on their social media posts. Within the health domain, Guntuku et al. (2020) showed that a user's language on Facebook becomes more depressed and less informal prior to their visit to an emergency department. With respect to mental health, De Choudhury et al. (2016) proposed to identify shifts to suicide ideation by predicting (or not) a transition from posting on a regular forum to a forum for suicide support. Pruksachatkun et al. (2019) examined moments of affective change in TalkLife users by identifying positive changes in sentiment at post-level with respect to a distressing topic earlier in a user's thread. In both cases MoC are overly specific and modelled through binary classification without any notion of temporal modelling.

NLP for Mental Health More advanced NLP methods have been used for predicting psychiatric conditions from textual data, including self-harm, suicide ideation, eating disorders, and depression (Benton et al., 2017; Kshirsagar et al., 2017; Yates et al., 2017; Husseini Orabi et al., 2018; Jiang et al., 2020; Shing et al., 2020). Researchers are increasingly adopting sequential modelling to capture temporal dynamics of language use and mental health. For example, Cao et al. (2019) encode microblog posts using suicide-oriented embeddings fed to an LSTM network to assess the suicidality risk at post level. Sawhney et al. (2020b, 2021) improves further on predicting suicidality at post-level by jointly considering an emotion-oriented post representation and the user's emotional state as reflected through their posting history with temporally aware models. The recent shared tasks in eRisk also consider sequences of user posts in order to classify a user as a "positive" (wrt self-harm or pathological gambling) or "control" case (Losada et al., 2020; Parapar et al., 2021). While such work still operates at the post- or user-level it highlights the importance of temporally aware modelling.

Related Temporal NLP Tasks Semantic change detection (SCD) aims to identify words whose meaning has changed over time. Given a set of word representations in two time periods, the dominant approach is to learn the optimal transformation using Orthogonal Procrustes (Schönemann, 1966) and measure the level of semantic change of each word via the cosine distance of the resulting vectors (Hamilton et al., 2016). A drawback of this is the lack of connection between consecutive windows. Tsakalidis and Liakata (2020) addressed this through sequential modeling by encoding word embeddings in consecutive time windows and taking the cosine distance between future predicted and actual word vectors. Both approaches are considered as baselines for our task. First story detection (FSD) aims to detect new events reported in streams of textual data. Having emerged in the Information Retrieval community (Allan et al., 1998), FSD has been applied to streams of social media posts (Petrović et al., 2010). FSD methods assume that a drastic change in the textual content of a document compared to previous documents signals the appearance of a new story. A baseline from FSD is considered in §4.2.

3 Dataset creation

We describe the creation of a dataset of individuals' *timelines* annotated with Moments of Change. A *user's timeline* $P^{(u)}_{s:e}$ is a subset of their history, a series of posts $[p_0, ..., p_n]$ shared by user u between dates s and e. A *"Moment of Change"* (MoC) is a particular point or period (range of time points) within $[s, e]$ where the behaviour or mental health status of an individual changes. While MoC can have different definitions in various settings, in this paper we are particularly interested in capturing MoC pertaining to an individual's mood. Other types of MoC can include life events, the onset of symptoms or turning points (e.g., moments of improvement, difficult moments or moments of intervention within therapy sessions).[1] We address two types of Moments of Change: **Switches** (sudden mood shifts from positive to negative, or vice versa) and **Escalations** (gradual mood progression from neutral or positive to more positive or neutral or negative to more negative). Capturing both sudden and gradual changes in individuals' mood over time is recognised as important for monitoring mental health conditions (Lutz et al., 2013; Shalom and Aderka, 2020) and is one of the dimensions to measure in psychotherapy (Barkham et al., 2021).

3.1 Data Acquisition

Individual's timelines are extracted from Talklife[2], a peer-to-peer network for mental health support. Talklife incorporates all the common features of social networks – post sharing, reacting, commenting, etc. Importantly, it provides a rich resource for computational analysis of mental health (Pruksachatkun et al., 2019; Sharma et al., 2020; Saha and Sharma, 2020) given that content posted by its users focuses on their daily lives and well-being.

A complete collection between Aug'11–Aug'20 (12.3M posts, 1.1M users) was anonymised and provided to our research team in a secure environment upon signing a License Agreement. In this environment, 500 user timelines were extracted (§3.2) and an additional anonymisation step was performed to ensure that usernames were properly hashed when present in the text. The 500 timelines were subsequently annotated using our bespoke annotation tool (§3.3) to derive the resulting longitudinal dataset (§3.4).

3.2 Timeline Extraction

Existing work extracts user timelines either based on a pre-determined set of timestamps (e.g., considering the most recent posts by a user) (Sawhney et al., 2020b) or by selecting a window of posts around mentions of specific phrases (e.g., around self-harm) (Mishra et al., 2019). The latter introduces potential bias into subsequent linguistic analysis (Olteanu et al., 2019), while the former could result into selecting timelines from a particular time period – hence potentially introducing temporally-dependent linguistic or topical bias (e.g., a focus on the COVID-19 pandemic). Here we instead extract timelines around points in time where a user's posting behaviour has changed. Our hypothesis is that such changes in a user's posting frequency could be indicative of changes in their lives and/or mental health. Such association between changes in posting behaviour on mental health fora and changes in mental health has been assumed in prior literature (De Choudhury et al., 2016).

Identifying changes in posting frequency We create a time series of each user's daily posting frequency based on their entire history. We then employ a change-point detection model to predict the intensity of daily post frequency by the given user. Bayesian Online Change-point Detection (Adams and MacKay, 2007) with a Poisson-Gamma underlying predictive model (Zachos, 2018) was chosen as our model, due to its highly competitive performance (van den Burg and Williams, 2020) and the fact that extracted timelines using this method had the highest density of MoC compared to a number of different timeline extraction (anomaly detection and keyword-based) methods for the same dataset.

Extracting timelines around change-points Upon detecting candidate MoC as change-points in posting frequency, we generated candidate timelines for annotation by extracting all of the user's posts within a seven-day window around each change-point. We controlled for timeline length (between 10 and 150 posts, set empirically) so that they were long enough to enable annotators to notice a change but not so long as to hinder effective annotation. This control for timeline length means that our subsequent analysis is performed (and models are trained and evaluated) on time periods during which the users under study are quite active; however, the upper bound of 150 posts in 15 days set for each timeline also ensures that we

---

[1] A limitation of our work stems from the fact that MoC are revealed to us by the user's shared content (i.e., we cannot identify changes in a user's well-being unless these are expressed online). We provide details on the limitations of our work in the Ethics Statement (§7).

do not bias (or limit) our analysis on extremely active users. Finally, to ensure linguistic diversity in our dataset, 500 timelines extracted in this way were chosen for annotation at random, each corresponding to a different individual. The resulting dataset consists of 18,702 posts (μ=35, SD=22 per timeline; range of timeline length=[10,124], see Fig. 2(a)).

3.3 Annotations of MoC

Annotation Interface An annotation interface was developed to allow efficient viewing and annotation of a timeline (see snippet in Fig. 3). Each post in a timeline was accompanied by its timestamp, the user's self-assigned emotion and any associated comments (color-coded, to highlight recurrent users involved within the same timeline). Given the context of the entire timeline, annotations for *MoC* are performed at post level: if an annotator marks a post as a *MoC*, then they specify whether it is (a) the beginning of a Switch or (b) the peak of an Escalation (i.e., the most positive/negative post of the Escalation). Finally, the range of posts pertaining to a MoC (i.e., all posts in the Switch/Escalation) need to be specified.

Label	Perfect Agreement	Majority
None (O)	0.69	0.89
Switch (IS)	0.08	0.30
Escalation (IE)	0.19	0.50

Table 1: Inter Annotator Agreement (IAA).

Data annotation After a round of annotations for guideline development with PhD students within the research group (co-authors of the paper), we recruited three external annotators to manually label the 500 timelines. They all have University degrees in humanities disciplines and come from three different countries; one of them is an English native speaker. Annotators were provided with a set of annotation guidelines containing specific examples, which were enriched and extended during iterative rounds of annotation.[3] Annotators completed 2 hands-on training sessions with a separate set of 10 timelines, where they were able to ask questions and discuss opinions to address cases of disagreement. Following the initial training phase, we performed spot checks to provide feedback and answer any questions while they labelled the full dataset (n=500 timelines). Annotators were encouraged to take breaks whenever needed, due to the nature of the content. On average, each annotator spent about 5 minutes on annotating a single timeline.

3.4 Deriving the final gold standard

The annotation of MoC is akin to assessment of anomaly detection methods since MoC (Switches and Escalations) are rare, with the majority of posts not being annotated (label ‘None’). Measuring the agreement in such settings is therefore complex, as established metrics such as Krippendorff's Alpha and Fleiss' Kappa would generally yield a low score. This is due to the unrealistically high expected chance agreement (Feinstein and Cicchetti, 1990), which cannot be mitigated by the fact that annotators do agree on the majority of the annotations (especially on the ‘None’ class). For this reason, we have used as the main indicator the per label positive agreement computed as the ratio of the number of universally agreed-upon instances (the intersection of posts associated with that label) over the total number of instances (the union of posts associated with that label). As highlighted

---

[3] Guidelines are available at `https://github.com/Maria-Liakata-NLP-Group/Annotation-guidelines`.

in Table 1, while perfect agreement for 'None' is at 69%, perfect agreement on Escalations and Switches is at 19% and 8%, respectively. However, if instead of perfect agreement we consider majority agreement (where two out of three annotators agree), these numbers drastically increase (30% for Switches and 50% for Escalations). Moreover, by examining the systematic annotation preferences of our annotators we have observed that the native speaker marked almost double the amount of Switches compared to the other two annotators, in particular by spotting very subtle cases of mood change. We have thus decided to generate a gold standard based on majority decisions, comprising only cases where at least two out of three annotators agree with the presence of a MoC. The rare cases of complete disagreement have been labelled as 'None'. We thus have 2,018 Escalations and 885 Switches from an overall of 18,702 posts (see Fig. 2(b) for the associated lengths in #posts). In future work we plan to consider aggregation methods based on all annotations or approaches for learning from multiple noisy annotations (Paun and Simpson, 2021).

4 Models & Experiment Design

Our aim is to detect and characterise the types of MoC based on a user's posting activity. We therefore treat this problem as a supervised classification task (both at post level and in a sequential/timeline-sensitive manner, as presented in §4.2) rather than an unsupervised task, even though we also consider effectively baselines with unsupervised components (FSD, SCD in §4.2). Contrary to traditional sentence or document-level NLP tasks, we incorporate timeline-sensitive evaluation metrics that account for the sequential nature of our model predictions (§4.1).

Given a user's timeline, the aim is to classify each post within it as belonging to a *"Switch"* (IS), an *"Escalation"* (IE), or *"None"* (O). At this point we don't distinguish between beginnings of switches/peaks of escalations and other posts in the respective ranges. While the task is sequential by definition, we train models operating both at the post level in isolation and sequential models at the timeline-level (i.e., accounting for user's posts over time), as detailed in §4.2. We contrast model performance using common post-level classification metrics as well as novel timeline-level evaluation approaches (§4.1). This allows us to investigate the impact of (a) accounting for severe class imbalance and (b) longitudinal modelling. We have randomly divided the annotated dataset into 5 folds (each containing posts from 100 timelines) to allow reporting results on all of the data through cross-validation.

4.1 Evaluation Settings

Post-level We first assess model performance on the basis of standard evaluation metrics at the post level (Precision, Recall, F1 score). These are obtained per class and macro-averaged, to better emphasize performance in the two minority class labels (IS & IE). However, post-level metrics are unable to show: (a) the expected accuracy at the timeline level (see example in Fig. 4) and (b) model suitability in predicting *regions* of change. These aspects are particularly important since we aim to build models capturing MoC over time.

Timeline-level Our first set of timeline-level evaluation metrics are inspired from work in change-point detection (van den Burg and Williams, 2020) and mirror the post-level ones, albeit operating on a window and timeline basis. Specifically, working on each timeline and label type independently, we calculate Recall $R_w^{(l)}$ (Precision $P_w^{(l)}$) by counting as "correct" a model prediction for label l if the prediction falls within a window of w posts around post labelled l in the gold standard. Formally:

$$R_w^{(l)} = \frac{|TP_w(M^{(l)},GS^{(l)})|}{|GS^{(l)}|}, P_w^{(l)} = \frac{|TP_w(M^{(l)},GS^{(l)})|}{|M^{(l)}|},$$

where TP_w denotes the true positives that fall within a range of w posts and $M^{(l)}$/$GS^{(l)}$ are the predicted/actual labels for l, respectively. Note that each prediction can only be counted once as "correct". $R_w^{(l)}$ and $P_w^{(l)}$ are calculated on every timeline and are then macro-averaged.

The second set of our timeline-level evaluation metrics is adapted from the field of image segmentation (Arbelaez et al., 2010). Here we aim at evaluating model performance based on its ability to capture *regions of change* (e.g., in Fig 4, 'GS' shows a timeline with three (two) such regions of Escalations (Switches)). For each such true region $R_{GS}^{(l)}$, we define its overlap $O(R_{GS}^{(l)}, R_M^{(l)})$ with each predicted region $R_M^{(l)}$ as the intersection over union between the two sets. This way, we can get recall and precision oriented *coverage* metrics as follows:

$$C_r^{(l)}(M \rightarrow GS) = \frac{1}{\sum_{R_{GS}^{(l)}} |R_{GS}^{(l)}|} \sum_{R_{GS}^{(l)}} |R_{GS}^{(l)}| \cdot max_{R_M^{(l)}} \{O(R_{GS}^{(l)}, R_M^{(l)})\},$$

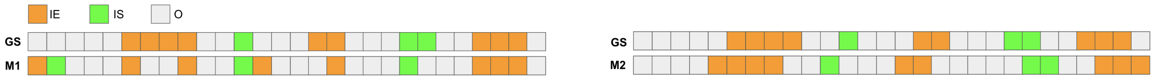

Figure 4: Actual (*GS*, shown twice) *vs* Predicted labels for each post (square) of a single timeline, by two models (*M1*, *M2*). Although *M2* provides a more faithful 'reconstruction' of the user's mood over time (the predictions are identical but shifted slightly in time), all post-level evaluation metrics for *M1* are greater or equal to those obtained by *M2* for the two minority classes (IE and IS).

$$C_p^{(l)}(M \rightarrow GS) = \frac{1}{\sum_{R_M^{(l)}} |R_M^{(l)}|} \sum_{R_M^{(l)}} |R_M^{(l)}| \cdot max_{R_{GS}^{(l)}} \{O(R_{GS}^{(l)}, R_M^{(l)})\}.$$

The coverage metrics are calculated on the timeline basis and macro-averaged similarly to $R_w^{(l)}$ and $P_w^{(l)}$. Using a set of evaluation metrics, each capturing a different aspect of the task, ensures assess to model performance from many different angles.

4.2 Baseline Models

We have considered different approaches to addressing our task:

(i) Naïve methods, specifically a Majority classifier (predicting always "None") and a "Random" predictor, picking a label based on the overall label distribution in the dataset. It has been shown that comparisons against such simple baselines is essential to assess performance in computational approaches to mental health (Tsakalidis et al., 2018).

(ii) Post-level supervised models operating on posts in isolation (i.e., ignoring post sequence in a user's timeline): (a) Random Forest (Breiman, 2001) on tfidf post representations (`RF-tfidf`); (b) BiLSTM (Huang et al., 2015) operating on sequences of word embeddings (`BiLSTM-we`);(c) `BERT(ce)` (Devlin et al., 2019) using the cross-entropy loss; and (d) `BERT(f)` trained using the alpha-weighted focal loss (Lin et al., 2017), which is more appropriate for imbalanced datasets.

(iii) Emotion Classification We used DeepMoji (`EM-DM`) (Felbo et al., 2017) and Twitter-roBERTa-base (`EM-TR`) from TweetEval '20 (Barbieri et al., 2020) operating on the post-level, to generate softmax probabilities for each emotion (64 for `EM-DM`, 4 for `EM-TR`). These provide meta-features to a BiLSTM to obtain timeline-sensitive models for identifying MoC.

(iv) First Story Detection `(FSD)`. We have used two common approaches for comparing a post to the *n* previous ones: representing the previous posts as (i) a single centroid or (ii) the nearest neighbour to the current post among them (Allan et al., 1998; Petrović et al., 2010). In both cases, we calculate the cosine similarity of the current and previous posts. The scores are then fed into a BiLSTM as meta-features for a sequential model. Results are reported for the best method only.

(v) Semantic Change Detection (SCD). Instead of the standard task of comparing word representations in consecutive time windows, we consider a user being represented via their posts at particular points in time. We follow two approaches. The first is an Orthogonal Procrustes approach (Schönemann, 1966) operating on post vectors (`SCD-OP`). Our aim here is to find the optimal transformation across consecutive representations, with higher errors being indicative of a change in the user's behaviour. In the second approach (`SCD-FP`) a BiLSTM is trained on the user's k previous posts in order to predict the next one (Tsakalidis and Liakata, 2020). Errors in prediction are taken to signal changes in the user. In both cases, we calculate the dimension-wise difference between the actual and the transformed/predicted representations (post vectors) and use this as a meta-feature to a BiLSTM to obtain a time-sensitive model.

(vi) Timeline-sensitive. From our (ii) post-level classifiers, `BERT(f)` tackles the problem of imbalanced data but fails to model the task in a longitudinal manner. To remedy this, we employ `BiLSTM-bert`, which treats a timeline as a sequence of posts to be modelled, each being represented via the `[CLS]` representation of `BERT(f)`. To convert the post-level scores/representations from (iii)-(v) above into time-sensitive models we used the same BiLSTM from (vi), operating at the timeline-level. Details for each model and associated hyperparameters are in the Appendix.

5 Results & Discussion

5.1 Quantitative Comparison

Model Comparison Table 2 summarises the results of all models; Fig. 5 further shows the P_w/R_w metrics for IE/IS for the best-performing models. `BiLSTM-bert` confidently outperforms all com-

Table 2: Post-level and Coverage-based evaluation for each model (**first** and **second** highest scores are highlighted).

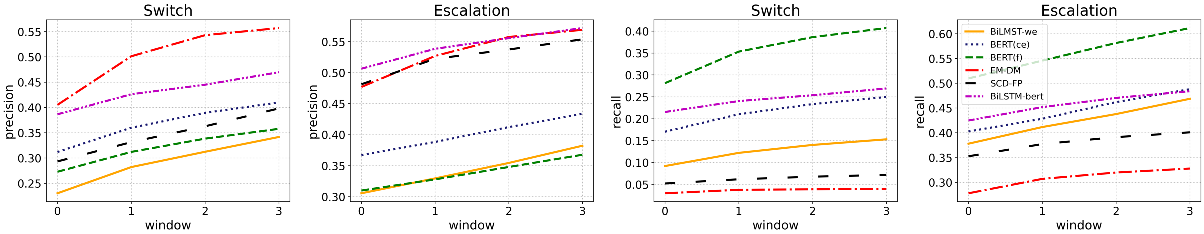

Figure 5: Timeline-level Precision P_w and Recall R_w of the best performing models.

peting models in terms of post-level macro-F1. It provides a 8.6% relative improvement (14% for the IS/IE labels) against the second best performing model (`BERT(f)`). Furthermore, it achieves a great balance between precision- and recall-oriented timeline-level metrics, being consistently the second-best performing model. This performance is largely attributed to two factors, which are studied further below: (a) the use of the Focal loss on BERT, generating `[CLS]` representations that are much more focused on the minority classes (IE/IS), and (b) its longitudinal aspect.

Post-level The BERT variants perform better than the rest in all metrics. Their coverage metrics though suggest that while they manage to predict better the regions compared to most timeline-level methods (i.e., high C_r), they tend to predict more regions than needed (i.e., low C_p) – partially due to their lack of contextual (temporal-wise) information. Finally, as expected, `BERT(f)` achieves much higher recall for the minority classes (IE/IS), in exchange for a drop in precision compared to `BERT(ce)` and in recall for the majority class (O).

Models from Related Tasks `EM-DM` achieves very high precision (P, P_w) for the minority classes, showing a clear link between the tasks of emotion recognition and detecting changes in a user's mood – indeed, emotionally informed models have been successfully applied to post-level classification tasks in mental health (Sawhney et al., 2020a); however, both `EM` models achieve low recall (R, R_w) for IE/IS compared to the rest. For the SCD inspired models, `SCD-FP` outperforms `SCD-OP` on most metrics. This is largely due to the fact that the former uses the previous k=3 posts to predict the next post in a user's timeline (instead of aligning it based on the previous post only. Thus `SCD-FP` benefits from its longitudinal component – a finding consistent with work in semantic change detection (Tsakalidis and Liakata, 2020).

Representation *vs* Fine-tuning *vs* Focal Loss While `BiLSTM-bert` yields the highest macro-F1 and the most robust performance across all metrics, it is not clear which of its components contributes the most to our task. To answer this, we perform a comparison against the exact same BiLSTM, albeit fed with different input types: (a) average word embeddings as in `BiLSTM-we`, (b) Sentence-BERT representations (Reimers and Gurevych, 2019) and (c) fine-tuned representations from `BERT(ce)`. As shown in Table 3, fine-tuning with `BERT(ce)` outperforms Sentence-BERT representations. While the contextual nature of all of the BERT-based models offers a clear improvement over the static word embeddings, it becomes evident that the use of the focal loss during training

	Post			Timeline		Coverage	
	P	R	F1	P_1	R_1	C_p	C_r
Word emb.	.589	.488	.508	.577	.450	.412	.282
Sent.-BERT	.610	.535	.546	.601	.499	.428	.333
BERT(ce)	.612	.518	.554	**.624**	.520	.434	.378
BERT(f)	**.621**	**.553**	**.580**	.622	**.545**	**.447**	**.398**

Table 3: Macro-avg performance of timeline-level BiLSTM operating on different input representations (see **Representation *vs* Fine-tuning *vs* Focal Loss** in §5.1).

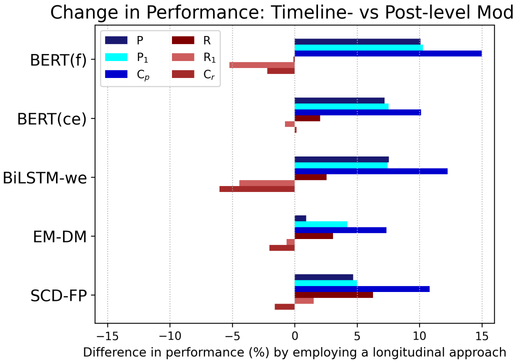

Figure 6: Gains/losses in performance (%) when incorporating a longitudinal component for each model (see **Timeline- *vs* Post-level Modelling** in §5.1).

the initial `BERT(f)` is vital, offering a relative improvement of 6% in post-level macro-F1 (13.7% for IS/IE). Calibrating the parameters in the focal loss could provide further improvements for our task in the future (Mukhoti et al., 2020).

Timeline- *vs* Post-level Modelling The importance of longitudinal modelling is shown via the difference between the BERT and BiLSTM variants when operating on single posts *vs* on the timeline-level (e.g., see the post-level results of `BERT(ce)/Word emb.` in Table 3 *vs* `BERT(ce)/BiLSTM-we` in Table 2, respectively). We further examine the role of longitudinal modelling in the rest of our best-performing models from Table 2. In particular, we replace the timeline-level BiLSTM in `EM-DM` and `SCD-FP` with a two-layer feed-forward network, operating on post-level input representations – treating each post in isolation. The differences across all pairwise combinations with and without the longitudinal component are shown in Fig. 6. Timeline-level models achieve much higher precision (6.1%/6.9%/11.1% for $P/P_1/C_p$, respectively) in return for a small sacrifice in the timeline-level recall-oriented metrics (-2.8%/1.9%/2.3% for $R/R_1/C_r$), further highlighting the longitudinal nature of the task.

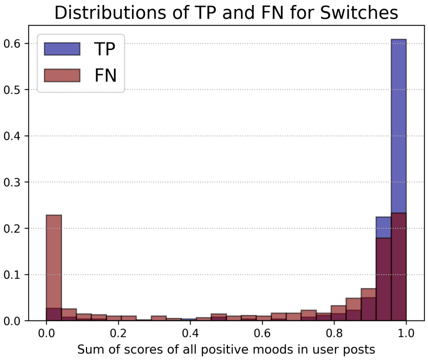

Figure 7: Histogram of positive emotion scores in True Positive & False Negative distributions, for the Switch label.

Table 4: Average probability of each emotion per classification case on ‘Switches’ (see **Switches** in §5.2).

5.2 Qualitative Analysis

Here we analyse the cases of Switches/Escalations identified or missed by our best performing model (`BiLSTM-bert`).

Switches (IS) are the most challenging to identify, largely due to being the smallest class with the lowest inter-annotator agreement. However, the `EM`-based models achieve high levels of precision on Switches, even during post-level evaluation (see Table 2). We therefore employ `EM-TR` (Barbieri et al., 2020), assigning probability scores for anger/joy/optimism/sadness to each post, and use them to characterise the predictions made by `BiLSTM-bert`. Fig. 7 and Table 4 show that our model predicts more often (in most cases, correctly) a ‘Switch’ when the associated posts express positive emotions (joy/optimism), but misses the vast majority of cases when these emotions are absent. The reason for this is that TalkLife users discuss issues around their well-being, with a negative mood prevailing. Therefore, `BiLSTM-bert` learns that the negative tone forms the users’ baseline and thus deviations from this constitute cases of ‘Switches’ (see example in Table 5). We plan to address this in the future by incorporating transfer learning approaches to our model (Ruder et al., 2019).

Escalations (IE) are better captured by our models. Here we examine more closely the cases of ‘Peaks’ in the escalations (i.e., the posts indicating the most

Oh, forgot :) Stay safe you lovely people all around the world!	O	IS
Hope you are all having a good night! Stay safe! :D	O	IS
Don't wanna deal with anyone.. Hope school finishes so I can go home soon	IS	O
Tired of my leg hurting so badly today. I really can't do any training :(	IS	O
Hope you're all great! <3 Love you all!	O	IS

Table 5: Example of a Switch in part of a user's (paraphrased) timeline, missed by `BiLSTM-bert`.

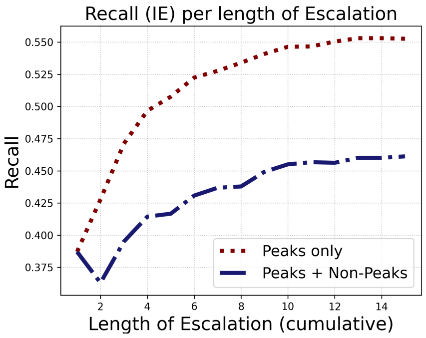

Figure 8: Recall for IE cases per cumulative length of Escalation (see **Escalations** in §5.2).

negative/positive state of the user within an escalation – see §3.3). As expected, the post-level recall of `BiLSTM-bert` in these cases is much higher than its recall for the rest of IE cases (.557 vs .408). In Fig. 8 we analyse the recall of our model in capturing posts denoting escalations, in relation to the length of escalations. We can see that our model is more effective in capturing longer escalations. As opposed to the Switch class, we found no important differences in the expressed emotion between TP and FN cases. By carefully examining the cases of Peaks in isolation, we found that the majority of them express very negative emotions, very often including indication of self-harm. A Logistic Regression trained on bigrams at the post-level to distinguish between identified *vs* missed cases of Peaks showed that the most positively correlated features for the identified cases were directly linked to self-harm (e.g., *"kill myself"*, *"to die"*, *"kill me"*). However, this was not necessarily the case with missed cases. Nevertheless, there were several cases of self-harm ideation that were missed by `BiLSTM-bert`, as well as misses due to the model "ignoring" the user's baseline, as is the case with Switches (see Table 6). Transfer learning and domain adaptation strategies as well as self-harm detection models operating at the post level could help in mitigating this problem.

Text
When my parents go out, I am gonna cut.
I feel so horrible. I really don't want to be here anymore.
Someone please text me... I swear I am about to harm myself... Please, anyone!'
Had an awesome day with my gf and she tagged me! I am not alone! :)
Have not cut for the past year!! Yay!!

Table 6: Examples of Peaks of Escalations (isolated paraphrased posts) missed by `BiLSTM-bert`.

6 Conclusion and Future Work

We present a novel longitudinal dataset and associated models for personalised monitoring of a user's well-being over time based on linguistic online content. Our dataset contains annotations for: (a) sudden shifts in a user's mood (switches) and (b) gradual mood progression (escalations). Proposed methods are inspired by state-of-the-art contextual models and longitudinal NLP tasks. Importantly, we have introduced temporally sensitive evaluation metrics, adapted from the fields of change-point detection and image segmentation. Our results highlight the importance of considering the temporal aspect of the task and the rarity of mood changes.

Future work could follow four main directions: (a) integrating longitudinal models of detecting changes, with post-level models for emotion and self-harm detection (see §5.2); (b) incorporating transfer learning methods (Ruder et al., 2019) to adapt more effectively to unseen users' timelines; (c) adjusting our models to learn from multiple (noisy) annotators (Paun and Simpson, 2021) and (d) calibrating the parameters of focal loss and testing other loss functions suited to heavily imbalanced classification tasks (Jadon, 2020).

7 Ethics Statement

Ethics institutional review board (IRB) approval was obtained from the corresponding ethics board of the University of Warwick prior to engaging in this research study. Our work involves ethical considerations around the analysis of user generated content shared on a peer support network (TalkLife). A license was obtained to work with the user data from TalkLife and a project proposal was submitted to them in order to embark on the project. The current paper focuses on the identification of moments of change (MoC) on the basis of content shared by individuals. These changes involve recognising sudden shifts in mood (switches or escalations). Annotators were given contracts and paid fairly in line with University payscales. They were alerted about potentially encountering disturbing content and were advised to take breaks. The annotations are used to train and evaluate natural language processing models for recognising moments of change as described in our detailed guidelines. Working with datasets such as TalkLife and data on online platforms where individuals disclose personal information involves ethical considerations (Mao et al., 2011; Kekü̈llüoğlu et al., 2020). Such considerations include careful analysis and data sharing policies to protect sensitive personal information. The data has been de-identified both at the time of sharing by TalkLife but also by the research team to make sure that no user handles and names are visible. Any examples used in the paper are either paraphrased or artificial. Potential risks from the application of our work in being able to identify moments of change in individuals' timelines are akin to those in earlier work on personal event identification from social media and the detection of suicidal ideation. Potential mitigation strategies include restricting access to the code base and annotation labels used for evaluation.

Limitations Our work in this paper considers moments of change as changes in an individual's mood judged on the basis of their self-disclosure of their well-being. This is faced by two limiting factors: (a) users may not be self-disclosing important aspects of their daily lives and (b) other types of changes related to their mental health (other than their mood/emotions, such as important life events, symptoms etc.) may be taking place. Though our models could be tested in cases of non-self-disclosure (given the appropriate ground truth labels), the analysis and results presented in this work should not be used to infer any conclusion on such cases. The same also holds for other types of 'moments of change' mentioned in §2 (e.g., transition to suicidal thoughts), as well as other types of changes, such as changes in an individual in terms of discussing more about the future, studied in Althoff et al. (2016), or changes in their self-focus (Pyszczynski and Greenberg, 1987) over time, which we do not examine in this current work.

Acknowledgements

This work was supported by a UKRI/EPSRC Turing AI Fellowship to Maria Liakata (grant EP/V030302/1) and the Alan Turing Institute (grant EP/N510129/1). The authors would like to thank Dana Atzil-Slonim, Elena Kochkina, the anonymous reviewers and the meta-reviewer for their valuable feedback on our work, as well as the three annotators for their invaluable efforts in generating the longitudinal dataset.

A Hyperparameters

Here we provide details on the hyperparameters used by each of our models, presented in §4.2:

- `RF`: Number of trees: [50, 100, 250, 500]
- `BiLSTM-we`: Two hidden layers ([64,128,256] units), each followed by a drop-out layer (rate: [.25, .5, .75]) and a final dense layer for the prediction. Trained for 100 epochs (early stopping if no improvement on 5 consecutive epochs) using Adam optimizer (lr: [0.001, 0.0001]) optimzing the Cross-Entropy loss with batches of size [128, 256], limited to modelling the first 35 words of each post.
- `BiLSTM-bert`: Two hidden layers ([64,128,256] and [124] units, respectively), each followed by a drop-out layer (rate: [.25, .5, .75]) and a final dense layer on each timestep for the prediction. Trained for 100 epochs (early stopping if no improvement on 5 consecutive epochs) using Adam optimizer (Kingma and Ba, 2015) (lr: [0.001, 0.0001]) optimizing the Cross-Entropy loss with batches of size [16, 32, 64].
- `EM-DM` & `EM-TR`: Same architecture as `BiLSTM-bert`, albeit operating on the `EM-DM`'s (`EM-TR`'s) output.
- `FSD`: Same architecture as `BiLSTM-bert`. For the FSD part, we experimented with word embeddings[4] and representations from Sentence-BERT. We extract features either by considering the nearest neighbor or by considering the centroid, on the basis of the previous [1,2,...,10] posts, as well as on the basis of the complete timeline preceding the current post (11 features, overall). The two versions (nearest neighbor, centroid) were run independently from each other.
- `SCD-OP` & `SCD-FP`: We experimented with average post-level word embeddings and representations from Sentence-BERT (results are reported for the latter, as it performed better). For `SCD-FP`, we stacked two BiLSTM layers (128 units each), each followed by a dropout (rate: 0.25), and a final dense layer for the prediction, with its size being the same as the desired output size (300 for the case of word embeddings, 768 for Sentence-BERT). We train in batches of 64, optimising the cosine similarity via the Adam Optimizer with a learning rate of .0001, and employing an early stopping criterion (5 epochs patience). The final model (i.e., after the SCD part) follows the exact same specifications as `BiLSTM-bert`, operating on the outputs from the SCD components.
- `BERT(ce)` & `BERT(f)`: We used BERT-base (uncased) as our base model and added a Dropout layer (rate: .25) operating on top of the `[CLS]` output, followed by a linear layer for the class prediction. We trained our models for 3 epochs using Adam (learning rate: [1e-5, 3e-5]) and perform five runs with different random seeds (0, 1, 12, 123, 1234). Batch sizes of 8 are used in train/dev/test sets. For the alpha-weighted Focal loss in `BERT(f)`, we used $\gamma = 2$ and $a_t = \sqrt{1/p_t}$, where p_t is the probability of class t in our training data. Results reported in the paper (as well as the results for BiLSTM-bert) are averaged across the five runs with the different random seeds.

We trained each model on five folds and selected the best-performing combination of hyperparameters on the basis of macro-F1 on a dev set (33% of training data) for each test fold.

B Libraries

The code for the experiments is written in Python 3.8 and relies on the following libraries: keras (2.7.0), numpy (1.19.5), pandas (1.2.3), scikit-learn (1.0.1), sentence_trasformers (1.1.0), spacy (3.0.5), tensorflow (2.5.0), torch (1.8.1), transformers (4.5.1).

C Infrastructure

All experiments were conducted on virtual machines (VM) deployed on the cloud computing platform Microsoft Azure. We have used two different VMs in our work:

- the experiments that involved the use of BERT were ran on a Standard NC12_Promo, with 12 cpus, 112 GiB of RAM and 2 GPUs;
- all other experiments were ran on a Standard F16s_v2, with 16 cpus and 32 GiB of RAM.

Multi-Task Pre-Training for Plug-and-Play Task-Oriented Dialogue System

Abstract

Pre-trained language models have been recently shown to benefit task-oriented dialogue (TOD) systems. Despite their success, existing methods often formulate this task as a cascaded generation problem which can lead to error accumulation across different sub-tasks and greater data annotation overhead. In this study, we present PPTOD, a unified plug-and-play model for task-oriented dialogue. In addition, we introduce a new dialogue multi-task pre-training strategy that allows the model to learn the primary TOD task completion skills from heterogeneous dialog corpora. We extensively test our model on three benchmark TOD tasks, including end-to-end dialogue modelling, dialogue state tracking, and intent classification. Experimental results show that PPTOD achieves new state of the art on all evaluated tasks in both high-resource and low-resource scenarios. Furthermore, comparisons against previous SOTA methods show that the responses generated by PPTOD are more factually correct and semantically coherent as judged by human annotators.[1]

1 Introduction

Task-oriented dialogue is often decomposed into three sub-tasks: (1) dialogue state tracking (DST) for tracking user's belief state; (2) dialogue policy learning (POL) for deciding which system action to take; (3) natural language generation (NLG) for generating dialogue response (Young et al., 2013).

Traditional approaches (Smith and Hipp, 1995; Young et al., 2013) adopt a modularized pipeline that addresses different sub-tasks with distinct dedicated modules. In contrast, recent systems (Wen et al., 2017; Eric et al., 2017; Lei et al., 2018; Shu et al., 2019) integrate all functionalities required to hold a dialogue into neural network models. With the advances in pre-trained language models (PLMs) (Radford et al., 2019; Devlin et al., 2019; Raffel et al., 2020), different systems based on PLMs have been proposed (Hosseini-Asl et al., 2020; Lin et al., 2020; Peng et al., 2021; Liu et al., 2021). Despite their differences, most existing methods formulate task-oriented dialogue as a cascaded generation problem, that is, the model can only solve latter sub-tasks by conditioning on the outputs of previous ones. For instance, to generate the response (NLG), the model must rely on the outputs of previous sub-tasks (i.e., DST and POL).

While impressive results are reported (Hosseini-Asl et al., 2020; Peng et al., 2021), we identify three major limitations in the cascaded formulation of their system design. (1) Firstly, as the model solves all sub-tasks in a sequential order, the errors accumulated from previous steps are propagated to latter steps (Li et al., 2017; Liu and Lane, 2018). (2) Secondly, the training data must be annotated for all sub-tasks. Such annotation requirement significantly increases the data curation overhead. More importantly, it precludes the model from using the large amount of existing data that is partially annotated (e.g., data only annotated with DST or NLG). (3) Thirdly, the results of different sub-tasks must be generated in a cascaded order which inevitably increases the system inference latency.

In this study, we propose a novel **P**lug-and-**P**lay **T**ask-**O**riented **D**ialogue (PPTOD) system. Figure 1 depicts an illustration of our approach. As seen, we integrate different dialogue modules (e.g. DST, POL, and NLG) into a unified model. Motivated by the concept of *in-context learning* (Brown et al., 2020), to steer the model to solve different TOD sub-task, we plug a task-specific natural language instruction, termed as *prompt*, into the dialogue context as the model input. This way, the generations of different sub-tasks are decoupled, leading to a greater flexibility of the model that brings us at least two advantages: (1) As different sub-tasks are

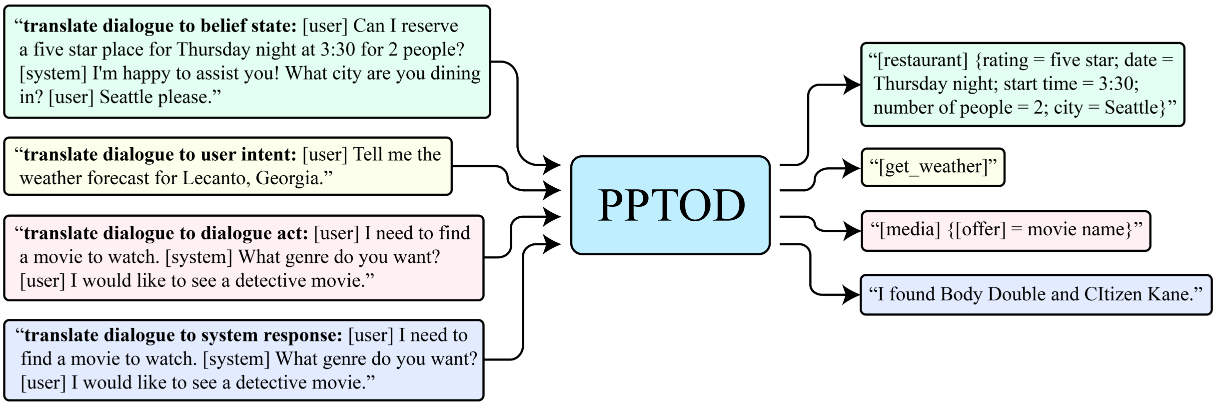

Figure 1: **Overview**: In the dialogue multi-task pre-training stage, we pre-train our model with four TOD-related tasks, including natural language understanding (NLU), dialogue state tracking (DST), dialogue policy learning (POL), and natural language generation (NLG). For each task, the model takes the dialogue context and the task-specific prompt as input and learns to generate the corresponding target text. Our learning framework allows us to train the model with partially annotated data across a diverse set of tasks. (best viewed in color)

solved separately, the model can learn from data that is partially annotated for different sub-tasks (e.g., DST and NLG). (2) The outputs of different sub-tasks are generated in parallel which alleviates the problem of error accumulation and reduces the system inference latency.

Inspired by recent success of dialogue language model pre-training (Zhang et al., 2020c; Wu et al., 2020; Peng et al., 2021), we propose a dialogue multi-task pre-training strategy that equips our model with the primary TOD task completion skills. Specifically, initialized with T5 (Raffel et al., 2020), we pre-train our model on a heterogeneous set of dialog corpora that consist of partially-annotated data. To build the pre-training corpora, we collect and combine eleven human-written multi-turn dialogue corpora. The collected datasets are partially annotated for some of the TOD-related tasks, including natural language understanding (NLU), dialogue state tracking (DST), dialogue policy learning (POL), and natural language generation (NLG). In total, the pre-training corpora contain over 2.3M utterances across over 80 domains (see more details in Table 1). When applying the pre-trained PPTOD to a new task, we fine-tune it using the same learning objective as in the pre-training stage.

We evaluate PPTOD on a wide range of benchmark TOD tasks, including end-to-end dialogue modelling, dialogue state tracking, and intent classification. Comparisons against previous state-of-the-art approaches show that PPTOD achieves better performance in both full-training and low-resource settings as judged by automatic and human evaluations. In summary, our contributions are:

- A novel model, PPTOD, that effectively leverages pre-trained language models for task-oriented dialogue tasks.
- A new dialogue multi-task pre-training strategy that augments the model's ability with heterogeneous dialogue corpora.
- Extensive evaluations on three benchmark TOD tasks reporting state-of-the-art results in both full-training and low-resource settings.
- In-depth analysis that further reveals the merits of our model design and the proposed multi-task pre-training strategy.

2 Related Work

Task-Oriented Dialogue. Task-oriented dialogue aims at accomplishing user's goal. Traditional systems (Williams and Young, 2007; Young et al., 2013) adopt a pipelined approach that requires dialogue state tracking for understanding user's goal, dialogue policy learning for deciding which system action to take, and natural language generation for generating dialogue responses.

Recently, to simplify the modelling effort, researchers have shifted their attention to building neural network models that address the TOD subtasks (Wen et al., 2017; Eric et al., 2017; Lei et al., 2018; Liang et al., 2020). With the advances in pre-trained language models (PLMs), Budzianowski and Vulić (2019) first applied the GPT-2 model for the NLG task. Lin et al. (2020) and Yang et al. (2021) moved one step forward and utilized pre-trained language models to solve all TOD sub-tasks conditioned on the history of oracle belief states. Based on the GPT-2 model, Hosseini-Asl et al. (2020) proposed a cascaded model, SimpleTOD, that addresses all TOD sub-tasks without using the oracle information. To improve the system performance, Peng et al. (2021) and Liu et al. (2021) applied dialogue pre-training over external dialogue corpora. However, both methods require the pre-training data to be fully annotated for all TOD sub-tasks (i.e., DST, POL, and NLG) which greatly limits the amount of data they can use. Additionally, Liu et al. (2021) achieved better results with noisy chanel model that requires two additional language models for outputs re-scoring. Unlike their approach, we address the task of task-oriented dialogue with a single unified model. Lastly, concurrent work by He et al. (2021) shows that adding an unified dialogue act prediction task for policy optimization helps to improve the performance of the pre-trained task-oriented dialogue model.

Language Model Pre-training. The research community has witnessed remarkable progress of pre-training methods in a wide range of NLP tasks, including language understanding (Peters et al., 2018; Devlin et al., 2019; Liu et al., 2019; Yang et al., 2019; Su et al., 2021a) and text generation (Radford et al., 2019; Lewis et al., 2020; Raffel et al., 2020; Su et al., 2021d,c,b, 2022).

In the dialogue domain, many models are pre-trained on open-domain conversational data like Reddit. Based on GPT-2, Transfertransfo (Wolf et al., 2019b) achieves good results on ConvAI-2 competition. As another extension of GPT-2, DialoGPT (Zhang et al., 2020c) performs well in generating open-domain dialogue response. ConveRT (Henderson et al., 2020) is a language model with dual-encoder built for the task of response selection. PLATO (Bao et al., 2020) pre-trains a model with discrete latent variable structure for the response generation task. Wu et al. (2020) adapts BERT with TOD pre-training and achieves strong performances on four dialogue understanding tasks.

Pre-training on Supplementary Data. Recent work (Phang et al., 2018; Aghajanyan et al., 2021) found that supplementary training on the tasks with intermediate-labelled data improves the performance of the fine-tuned models on GLUE natural language understanding benchmark (Wang et al., 2018). Our work studies a similar supplementary training setup with intermediate-labelled data for task-oriented dialogue systems. Unlike previous work, we use a single multi-task model for all relevant sub-tasks in task-oriented dialogue systems.

3 Methodology

In this section, we first discuss the datasets and learning objective used in the proposed dialogue multi-task pre-training. Then we introduce how to apply the pre-trained PPTOD for a new task.

3.1 Pre-training Datasets

To construct the pre-training corpus, we collect eleven human-written multi-turn task-oriented dialogue corpora, including MetaLWOZ (Lee et al., 2019b), SNIPS (Coucke et al., 2018), CLINC (Larson et al., 2019), ATIS (Amin, 2019), KVRET (Eric et al., 2017), WOZ (Mrkšić et al., 2017), MSR-E2E (Li et al., 2018), Frames (El Asri et al., 2017), TaskMaster (Byrne et al., 2019), and Schema-Guided (Rastogi et al., 2020). In total, there are over 2.3M utterances across 80 domains. In Table 1, we provide the details of data annotations and utterance/domain statistics of all datasets.[2]

3.2 Dialogue Multi-Task Pre-training

Motivated by previous work (McCann et al., 2018; Keskar et al., 2019; Raffel et al., 2020) that unify multiple NLP tasks into a common format, we cast all TOD-related tasks that we consider into the same plug-and-play text generation problem. To specify the target task, we plug a task-specific

    end
end
Output : Trained Model $\Theta$
```

prompt into the dialogue context as the model input. Figure 1 depicts an illustration of our approach.

In the multi-task pre-training stage, each training sample is represented as:

$$d = (z_t, x, y), \tag{1}$$

where t denotes the TOD task that the sample d belongs to, and $t \in \{\text{NLU}, \text{DST}, \text{POL}, \text{NLG}\}$. z_t is the task-specific prompt of the form "`translate dialogue to A:`", with `A` corresponding to "user intent", "belief state", "dialogue act", and "system response" for the tasks of NLU, DST, POL, and NLG, respectively. x denotes the input dialogue context which is a concatenation of all previous utterances in the dialogue - both system's and user's. And y denotes the target output text.

As an example presented in Figure 1, to perform the user intent classification task (i.e., NLU), the model is fed with the sequence *"translate dialogue to user intent: [user] Tell me the weather forecast for Lecanto, Georgia."* and is trained to generate the user intent label text *"[get_weather]"*.

Learning. The model is trained with a maximum likelihood objective. Given the training sample $d = (z_t, x, y)$, the objective $\mathcal{L}_\Theta$ is defined as

$$\mathcal{L}_\Theta = -\sum_{i=1}^{|y|} \log P_\Theta(y_i | y_{<i}; z_t, x), \tag{2}$$

where Θ is the model parameters.

In the multi-task pre-training stage, the model is trained to perform all TOD-related tasks with data annotated for different tasks. To optimize the model parameters Θ, we use mini-batch based optimization approach as shown in Algorithm 1.

3.3 Fine-Tuning to a New Task

When applying the pre-trained PPTOD to a new downstream task with task-specific labelled data, we use the same learning objective Eq. (2) as in the dialogue multi-task pre-training stage.

3.4 Implementation Details

In this work, we report results of PPTOD with three model sizes: $\text{PPTOD}_{\text{small}}$, $\text{PPTOD}_{\text{base}}$, and $\text{PPTOD}_{\text{large}}$. These three models are initialized with T5-small, T5-base, and T5-large models (Raffel et al., 2020) that contain ~60M, ~220M, and ~770M parameters, respectively. We pre-train the model with different configurations on our collected pre-training corpora for 10 epochs. The training samples are truncated to ensure a maximal length of 1024. The models are trained using Adam optimizer (Kingma and Ba, 2015) with a learning rate of 5e-5 and a batch size of 128. Our implementation is based on the Huggingface Library (Wolf et al., 2019a).

4 Experiments

We test PPTOD on three benchmark TOD tasks: (1) end-to-end dialogue modelling; (2) dialogue state tracking; and (3) user intent classification.

4.1 End-to-End Dialogue Modelling

End-to-end dialogue modelling aims at evaluating the model in the most realistic, fully end-to-end setting, where the generated dialogue states are used for the database search and response generation (Zhang et al., 2020b; Hosseini-Asl et al., 2020).

4.1.1 Dataset and Evaluation Metric

We conduct experiments on the benchmark MultiWOZ 2.0 (Budzianowski et al., 2018) and 2.1 (Eric et al., 2020) datasets.[3] In MultiWOZ, the generation of response is not only related to the dialogue context, but also grounded on the database (DB) state. The DB state is automatically retrieved from a pre-defined database using the generated dialogue state (DST). Following previous studies, during inference, PPTOD first predicts the DST result to retrieve the DB state. Then, based on the retrieved DB state and the dialogue context, the results of POL and NLG are generated in parallel. In Section §5, we further compare the performance of our model with or without using the DB state as input.

For evaluation, we follow the original MultiWOZ guidance for all individual metrics: **Inform**, **Success**, and **BLEU** (Papineni et al., 2002). An

overall measurement, i.e., combined score (Mehri et al., 2019), is also reported which is defined as **Combined** = (Inform + Success) × 0.5 + BLEU.

4.1.2 Baselines

We compare PPTOD with several strong baselines, including Sequicity (Lei et al., 2018), MD-Sequicity (Zhang et al., 2020b), DAMD (Zhang et al., 2020b), MinTL (Lin et al., 2020), HIER-Joint (Santra et al., 2021), LABES-S2S (Zhang et al., 2020a), SimpleTOD (Hosseini-Asl et al., 2020), UBAR (Yang et al., 2021), and SOLOIST (Peng et al., 2021), TOP and TOP+Noisy Online Decoding (TOP+NOD) (Liu et al., 2021).

4.1.3 Full Training Evaluation

Table 2 shows the main results. On both MultiWOZ 2.0 and 2.1 datasets, PPTOD performs better than previous SOTA methods on seven out of eight metrics. In particular, it is worth mentioning that our model is a single architecture that does not require additional language models for re-ranking the outputs as in TOP+NOD (Liu et al., 2021). Moreover, the results show that the large size PPTOD$_{\text{large}}$ underperforms PPTOD$_{\text{small}}$ and PPTOD$_{\text{base}}$. Our analysis is that the large size model is less capable when learning to generate the delexicalized tokens, which are not seen during its pre-training stage, for the NLG task.

4.1.4 Low-Resource Evaluation

To investigate the generalization ability of PPTOD, we evaluate it in a more challenging low-resource scenario. Following previous studies, we train our model on MultiWOZ 2.0 by varying the percentage of training data, ranging from 1% (~80 samples) to 20% (~1600 samples). We compare our model with several strong baselines, including MD-Sequicity, DAMD, SOLOIST, and MinTL.[4]

In each low-resource setting, we train our model five times with different random seeds and different selection of training data. The average scores over five runs are presented in Table 3.[5] As seen, PPTOD consistently outperforms all baseline models by a large margin. Notably, our performance gain is even larger when fewer samples are used for training. This indicates that PPTOD better leverages

---

[4] We did not compare results with TOP+NOD (Liu et al., 2021) since the authors did not release their code and models.

[5] Detailed numerical results can be found in Appendix B.

Table 4: DST results. †: the models require a full pre-defined ontology for all possible domain-slot pairs.

the prior knowledge from pre-training therefore achieving better results in the extreme low-resource settings. Furthermore, with 20% of training data, PPTOD can achieve results that are comparable to the scores of systems like SOLOIST that are trained with full dataset as reported in Table 2.

4.2 Dialogue State Tracking

Next, we evaluate PPTOD for the dialogue state tracking task. The experiments are conducted on the benchmark MultiWOZ 2.0 (Budzianowski et al., 2018) and 2.1 (Eric et al., 2020) datasets. For evaluation, the joint goal accuracy is reported.

4.2.1 Full Training Evaluation

We compare PPTOD with a wide range of existing methods that can be categorized into two classes: (1) classification-based approaches and (2) generation-based approaches. Table 4 shows the DST results. Compared to other generation-based approaches, PPTOD$_{\text{large}}$ obtains the highest accuracy on both datasets. The performance of our model is lower than the SOTA classification-based approaches. However, these methods operate on a fixed ontology and perform prediction over a pre-defined set of slot-value pairs (Zhang et al., 2019; Chen et al., 2020; Shan et al., 2020; Zhou et al., 2021). This idea of fixed ontology is not scalable, as in real world applications, the ontology is subject to constant change (Heck et al., 2020). In contrast, PPTOD directly generates the outputs, making it more adaptive and generalizable to new ontology labels in real world applications.

Model	Training Size (%)			
	1	5	10	20
SimpleTOD	7.91±1.07	16.14±1.48	22.37±1.17	31.22±2.32
MinTL	9.25±2.33	21.28±1.94	30.32±2.14	35.96±1.25
SOLOIST	13.21±1.97	26.53±1.62	32.42±1.13	38.68±0.98
PPTOD$_{\text{small}}$	27.85±0.77	39.07±0.85	42.36±0.29	45.98±0.38
PPTOD$_{\text{base}}$	29.72±0.61	40.20±0.39	43.45±0.64	46.96±0.40
PPTOD$_{\text{large}}$	**31.46±0.41**	**43.61±0.42**	**45.96±0.66**	**48.95±0.13**

Table 5: Low-resource DST Evaluation: The means and standard deviations over five runs are reported.

4.2.2 Low-Resource Evaluation

To investigate how well PPTOD performs with limited training samples on the downstream task, we evaluate it in a simulated low-resource setting. Specifically, we train the model on MultiWOZ 2.0 by varying the percentage of training data (i.e., 1%, 5%, 10%, and 20%). We compare PPTOD with three strong generation-based baselines, including SimpleTOD, MinTL, and SOLOIST, using the official code released by the authors.

Table 5 shows the experimental results. As seen, in all settings, PPTOD outperforms other baselines by a large margin. In the extreme scenario, with only 1% of training data, PPTOD surpasses the strongest SOLOIST model by 18 points of accuracy. This demonstrates that our model is more generalizable and can be better applied to new tasks where the amount of training data is limited.

4.3 Intent Classification

The goal of intent classification, i.e. NLU, is to classify the user's intent based on the user's utterance. We conduct experiments on the benchmark Banking77 dataset (Casanueva et al., 2020) that contains data with 77 different intents. Following previous studies (Casanueva et al., 2020; Peng et al., 2021), we test our model in both full training and low-resource settings. In the low-resource setting, we vary the number of training samples per intent from 10 to 30. The standard classification accuracy is reported for evaluation.

We compare PPTOD with several strong baselines, including BERT-Fixed, BERT-Tuned, USE+ConveRT (Casanueva et al., 2020), USE

Model	Generation Mode	DB	End-to-End Dialogue Modelling				Inference Measurement

PPTOD$_{large}$	84.12±0.23	**90.64±0.29**	**94.08±0.15**

Table 7: Results on Banking77 dataset. † and ‡ are cited from Casanueva et al. (2020) and Peng et al. (2021).

(Yang et al., 2020), ConveRT (Henderson et al., 2020), and SOLOIST (Peng et al., 2021). It is worth mentioning that all compared baselines are classification-based approach that uses a classifier with a softmax layer to make the prediction over the pre-defined intent set. In contrast, as described in section §3.2, PPTOD solves the classification task as a generation problem by directly generating the text of intent label. Therefore, when adapting to a new classification task, PPTOD is more flexible and no extra model parameters are required.

In the experiments, we train PPTOD for five runs with different selection of training data and random seeds. The average scores and standard deviations are reported in Table 7. We see that PPTOD is comparable with existing methods. On low-resource-30 and full training settings, PPTOD$_{large}$ achieves the best results. Our performance gains are even more remarkable given that PPTOD requires no extra parameters when solving the classification task.

5 Further Analysis

In this section, we present further discussions and empirical analyses of the proposed model.

5.1 Plug-and-Play vs Cascaded Generation

First, we compare our plug-and-play generation with the cascaded generation that is adopted by most existing studies. To this end, we fine-tune a T5-small model (without dialogue multi-task pre-training) on MultiWOZ 2.0 by either using the plug-and-play or the cascaded formulation. Moreover, we also examine the effect of DB state on the model performance. Specifically, for the plug-and-play model, when utilizing DB state, it first predicts the dialogue state (DST) to retrieve the DB state from the pre-defined database. Then, based on the DB state and dialogue context, the output of POL and NLG are generated in parallel. When ignoring the DB state, the plug-and-play model generates DST, POL, and NLG results in a fully paralleled fashion.

For evaluation, we report the results on end-to-end dialogue modelling task. In addition, we report the average inference latency and relative speedup of each model.[6] We compare our ablated models with two strong baselines, SOLOIST and MinTL.[7]

Table 6 presents the results. As seen, the plug-and-play models yield better results than their cascaded counterparts. One reason is that, for cascaded models, the previously generated results are explicitly used as model input for latter sub-tasks, which leads to error accumulation. Moreover, we see that using DB state generally improves the model performance for both plug-and-play and cascaded models as it provides the model with more grounding information. Furthermore, with DB state, our plug-and-play model achieves better overall score than MinTL with an around 4× speedup. This suggests that the plug-and-play formulation benefits the model both in terms of the generation accuracy as well as the inference latency.

5.2 Multi-Task Pre-Training Investigation

Next, we provide further analyses on the dialogue multi-task pre-training strategy. To quantify the importance of different pre-training data, we pre-train

---

[6] The latency of each model is measured on a single Nvidia V100 GPU with a batch size of 1.

[7] We did not include TOP+NOD (Liu et al., 2021) for comparison as the authors did not release their code.

Pre-training Data Annotation				End-to-End Dialogue Modelling						Dialogue State Tracking		Intent Classification	
NLU	DST	POL	NLG	1% training			full training			1% training	full training	10 samples	full training
				Inform	Success	BLEU	Inform	Success	BLEU	Accuracy	Accuracy	Accuracy	Accuracy
×	×	×	×	53.28	36.08	11.65	83.10	72.40	18.17	17.44	50.55	75.12	92.91

×	✓	×	×	66.10	46.40	11.26	86.30	74.90	18.52	**27.91**	51.48	75.97	93.03
×	×	✓	×	60.60	48.20	11.88	84.40	74.60	18.55	19.32	50.82	75.37	92.95
×	×	×	✓	59.38	40.78	12.34	83.60	74.70	**19.97**	17.82	50.58	75.61	92.97
✓	✓	✓	✓	**66.96**	**50.90**	**12.51**	**87.80**	**75.30**	19.89	27.85	**51.50**	**78.87**	93.27

Table 8: Performance of models pre-trained on data with different annotations. In the low-resource setting of different tasks, the average scores over five runs are reported. The last row reports the results of PPTOD$_{\text{small}}$.

the T5-small model using data that is annotated for individual TOD-related task (i.e., NLU, DST, POL, and NLG). After pre-training, we then evaluate the models on three downstream TOD tasks using MultiWOZ 2.0 and Banking77 datasets. For end-to-end dialogue modelling and dialogue state tracking, we test the model in both 1% and full training settings. For intent classification, we measure the accuracy of models trained with either 10 training samples per intent or full training samples.

Table 8 presents the results with the first row showing the performance of vanilla T5-small model. As seen, without any pre-training, the vanilla T5-small model performs poorly in the low-resource setting of all evaluated tasks. This suggests that the prior knowledge from pre-training is indispensable for the model to achieve strong performances in the low-resource scenarios.

Moreover, we see that pre-training with data annotated for individual TOD-related task helps the model to attain better result in the corresponding downstream task. For example, pre-training with DST data notably improves the model performance in the downstream DST task both in low-resource and full-training settings. Similarly, pre-training with NLG data helps the model to get better BLEU score in the end-to-end dialogue modelling task.

Lastly, we see that the PPTOD$_{\text{small}}$ model attains the best results on most of the evaluation metrics. This suggests that the pre-training data with different annotations are compatible with each other and the joint utilization of all pre-training data helps the model to achieve the best overall performance.

5.3 Human Evaluation

We also conduct a human evaluation with the help of graders proficient in English using an internal evaluation platform. For evaluation, we randomly selected 50 dialogue sessions from the test set of MultiWOZ 2.0 dataset. We compare the results generated by the PPTOD$_{\text{base}}$ model against the results from the SOLOIST model. All generated results, plus the reference, are evaluated by five graders on a 3-point Likert scale (0, 1, or 2) for each of the following features[8]:

	Understanding	Truthfulness	Coherency	Fluency
Agreement	0.641	0.598	0.668	0.806
Reference	1.92	2.00	1.93	1.98
SOLOIST	1.78	1.29	1.64	1.97
PPTOD	**1.86**	**1.51**	**1.83**	**1.99**

Table 9: Human Evaluation Results

- **Understanding**: Whether the system correctly understands the user's goal.
- **Truthfulness**: Whether the system's response is factually supported by the reference.[9]
- **Coherency**: Whether the system's response is semantically coherent with the context.
- **Fluency**: Whether the system's response is grammatically fluent and easy to understand.

Table 9 lists the results, with the first row showing strong inter-annotator agreements as measured by Fleiss′ kappa coefficient (Fleiss et al., 1971). Comparing with SOLOIST, our model achieves better scores on all metrics. Moreover, on the truthfulness and coherency metrics, our model significantly outperforms SOLOIST as judged by Sign Test (p-value < 0.05), suggesting that PPTOD generates more factually correct and semantically coherent responses. Finally, we note that on the fluency metric, both systems perform comparably with the reference (p-value > 0.4). This shows that the fluency of such systems is largely guaranteed by the prior syntactic knowledge from pre-trained language models, which suggests that future research should focus more on the other aspects of dialog systems.

---

[8] More evaluation details are provided in the Appendix C.

[9] For this metric, we only evaluate the results of PPTOD and SOLOIST. By definition, the reference gets a score of 2.0.

6 Conclusion

In this paper, we propose PPTOD, a unified model that supports both task-oriented dialogue understanding and response generation in a plug-and-play manner. In addition, we introduce a new dialogue multi-task pre-training strategy to further augment our model's ability in completing TOD-related tasks. Extensive experiments and analysis are conducted on three benchmark TOD tasks in both high-resource and low-resource settings. The automatic and human evaluations demonstrate that PPTOD outperforms the current SOTA systems in terms of various evaluation metrics.

Acknowledgments

The authors would like to thank Anna Currey, David Vandyke, and Dingmin Wang for their insightful discussions and support. Many thanks to our anonymous reviewers and area chairs for their suggestions and comments.

Ethical Statement

We honor and support the ACL code of Ethics. Task-oriented dialogue systems aim to interact and assist the users to fulfill their goals. The interaction and assistance process do not involve any bias towards to the participants. All datasets used in this work are from previously published works, and in our view, do not have any attached privacy or ethical issues.

A Dataset Details

We elaborate the details of the dialogue datasets contained in the pre-training dialogue corpora.

- **MetaLWOZ** (Lee et al., 2019b) is designed for improving models' ability in generating natural language responses in unseen domains. It contains annotations for natural language generation (NLG) spanning over 47 domains.
- **SNIPS** (Coucke et al., 2018) is designed to help developing models capable of understanding users' intent (i.e., natural language understanding (NLU)). Its data consists of users' utterances gathered by crowdsourcing with over 20 intent labels across 9 domains.
- **CLINC** (Larson et al., 2019) is built for improving model's ability in detecting out-of-scope users' intents. It contains data with NLU annotations for 150 intents across 10 different domains.
- **ATIS** (Amin, 2019) is used for building intent classification (NLU) model. It contains data with 22 user intents from the airline travel information domain.
- **KVRET** (Eric et al., 2017) is a in-car personal assistant dataset with dialogues from three domains: calendar scheduling, weather information retrieval, and point-of-interest navigation. It contains annotations for user belief state (DST) and system response (NLG).
- **WOZ** (Mrkšić et al., 2017) and **CamRest676** (Wen et al., 2017) are collected with Wizard-of-Oz procedure. They contains dialogues with DST and NLG annotations from the restaurant domain.
- **MSR-E2E** (Li et al., 2018) contains dialogues from three domains, including movie-ticket booking, restaurant reservation, and taxi booking. The data are annotated for three TOD-related tasks: DST, POL, and NLG.
- **Frames** (El Asri et al., 2017) contains dialogues from the trip booking domain. Its data are annotated for three TOD-related tasks, including DST, POL, and NLG.
- **TaskMaster** (Byrne et al., 2019) includes dialogues from six domains. Its data is collected with Wizard-of-Oz and self-dialogue approaches. The dataset is annotated with DST, POL, and NLG.
- **Schema-Guided** (Rastogi et al., 2020) is used for the DSTC8 (Kim et al., 2019) dialogue competition. It contains dialogues from 17 domains and it supports three TOD-related tasks, including DST, POL, and NLG.

B Low-Resource MultiWOZ Evaluation

In Table 10, we show the results of our model on MultiWOZ 2.0 under different low-resource settings. To get more confident results, for each setting, we train our model for five runs with different selection of training data and different random seeds. The complete results along with the mean and standard deviations are presented in Table 10.

C Human Evaluation Guidelines

Please evaluate the system's response with respect to the following features: (1) Understanding; (2) Truthfulness; (3) Coherency; and (4) Fluency. In the following, we provide some guidelines regarding how to judge the quality of the system's response in terms of different features.

C.1 Understanding

This metric measures whether the system's response shows that the system is able to understand the goal and intent of the user. The definition of different scores are:

- 2: The system completely understands the user's goal and intent.
- 1: The system partially understands the user's goal and intent.
- 0: The system does not understand the user's goal and intent at all.

C.2 Truthfulness

This metric measures whether the system's response is factually supported by the reference response. The definition of different scores are:

- 2: The facts in the system's response are all supported by or can be inferred from the reference response.
- 1: The facts in the system's response are partially supported by the reference response.
- 0: The system's response is contradicted to the facts contained in the reference response.

Table 10: Low-Resource Experiments on MultiWOZ: The average and std rows show the mean and standard deviation of results from five different runs. The Succ. and Comb. denote Success and Combined Score, respectively.

C.3 Coherency

This metric measures whether the system's response is logically coherent with the dialogue context. The definition of different scores are:

- 2: The system's response is logically coherent with the dialogue context.
- 1: The system's response contains minor information that is off the topic of the dialogue context.
- 0: The system's response is completely irrelevant to the dialogue context.

C.4 Fluency

The metrics measures the fluency of the system's response. The definition of different scores are:

- 2: The system's response is grammatically correct and easy to understand.
- 1: The system's response contains minor errors but they do not affect your understanding.
- 0: The system's response does not make sense and it is unreadable.

D Case Study

Table 11 presents a generated dialogue example from the PPTOD$_{\text{base}}$ model. The user starts the conversation by asking for an expensive restaurant that serves Indian food for dinner. PPTOD finds 14 restaurants that satisfy the user's goal and asks the user for a preferred location. We can see that, when the user states no preference on the restaurant location, PPTPD correctly updates the dialogue state by adding the area information which is missed by the oracle information. Then the user switches the dialogue topic for booking a hotel. Through the dialogue trajectory, we see that PPTOD completes the dialogue by successfully providing the user the necessary information such as number of hotel choices (at turn 3) and the booking reference number (at turn 6). When finding the user's booking request cannot be fulfilled (at turn 5), the models asks the user for an alternative option. Moreover, this example also demonstrates that PPTOD is able to deal with some NLU challenges displayed in the conversations. For example, at turn 4, the user already provides the information about the Gonville Hotel. But only after the user describes the intention of booking the hotel at turn 5, the model updates the name of hotel in the dialogue state based on the co-referenced information from the previous turn. Interestingly, the hotel name is ignored by the oracle dialogue state but our model correctly detects it. The dialogue understanding ability of PPTOD can also be observed in turn 6, in which it updates the hotel stay in the belief state from 2 days to 1 day after the user provides the corresponding information.

MUL0113		**Dialogue**
Turn 1	User Utterance	i am in need of an expensive indian restaurant for dinner .
	Generated Belief State	[restaurant] {food = indian, pricerange = expensive}
	Oracle Belief State	[restaurant] {food = indian, pricerange = expensive}
	Delexicalized Response	there are [value_choice] [value_price] [value_food] restaurants in cambridge . what area would you like to dine in ?
	Lexicalized Response	there are 14 expensive indian restaurants in cambridge . what area would you like to dine in ?
	Oracle Reference	there are 14 such restaurants . do you want to be in a specific part of town ?
Turn 2	User Utterance	i don't care what part of town it is in , i would like a phone number please .
	Generated Belief State	[restaurant] {food = indian, pricerange = expensive, area = don't care}
	Oracle Belief State	[restaurant] {food = indian, pricerange = expensive}
	Delexicalized Response	[value_name] is a [value_food] restaurant in the [value_area] part of town . their phone number is [value_phone] .
	Lexicalized Response	curry garden is a indian restaurant in the center part of town . their phone number is 01223302330 .
	Oracle Reference	sure , i am sorry . i have curry garden their phone number is 01223302330 . would you like me to reserve a table for you ?
Turn 3	User Utterance	not at this time . i am looking for a 3-star hotel , though . no guest house .
	Generated Belief State	[hotel] {stars = 3, type = hotel}; [restaurant] {food = indian, pricerange = expensive}
	Oracle Belief State	[hotel] {stars = 3, type = hotel}; [restaurant] {food = indian, pricerange = expensive}
	Delexicalized Response	i have [value_choice] [value_stars] star [value_type] in the [value_area] . [value_name] is a [value_stars] star [value_type] . would you like to book a room ?
	Lexicalized Response	i have 2 3-star hotel in the center . gonville hotel is a 3-star hotel . would you like to book a room ?
	Oracle Reference	i have found the gonville hotel . it is a 3 star hotel . would you like me to book it for you ?
Turn 4	User Utterance	not yet . is the gonville hotel in the same price range as the curry garden ?
	Generated Belief State	[hotel] {stars = 3, type = hotel}; [restaurant] {food = indian, pricerange = expensive}
	Oracle Belief State	[hotel] {stars = 3, type = hotel}; [restaurant] {food = indian, pricerange = expensive}
	Delexicalized Response	yes , it is in the [value_price] price range . would you like me to book it for you ?
	Lexicalized Response	yes , it is in the expensive price range . would you like me to book it for you ?
	Oracle Reference	yes , it is an expensive hotel .
Turn 5	User Utterance	can you book a room for 2 people for 2 nights starting on sunday ?
	Generated Belief State	[hotel] {stars = 3, type = hotel, name = gonville hotel, people = 2, day = sunday, stay = 2}; [restaurant] {food = indian, pricerange = expensive}
	Oracle Belief State	[hotel] {stars = 3, type = hotel, people = 2, day = sunday, stay = 2}; [restaurant] {food = indian, pricerange = expensive}
	Delexicalized Response	i am sorry , but the [value_name] is not available for that stay . would you like to try a shorter stay ?
	Lexicalized Response	i am sorry , but the gonville hotel is not available for that stay . would you like to try a shorter stay ?
	Oracle Reference	the booking was unsuccessful . would you like to try for another day or a shorter stay ?
Turn 6	User Utterance	could you try it for 1 night ? if that works , please book it and get the reference number .
	Generated Belief State	[hotel] {stars = 3, type = hotel, name = gonville hotel, people = 2, day = sunday, stay = 1}; [restaurant] {food = indian, pricerange = expensive}
	Oracle Belief State	[hotel] {stars = 3, type = hotel, people = 2, day = sunday, stay = 1}; [restaurant] {food = indian, pricerange = expensive}
	Delexicalized Response	i was able to successfully book your room . your reference number is [value_reference] . is there anything else i can help you with ?
	Lexicalized Response	i was able to successfully book your room . your reference number is 7rzme01z . is there anything else i can help you with ?
	Oracle Reference	you are all set for 1 night (sunday) , reference number is 6wvv053q . would you like to try another location for monday night ?
Turn 7	User Utterance	no . that is all i need , thank you .
	Generated Belief State	[hotel] {stars = 3, type = hotel, name = gonville hotel, people = 2, day = sunday, stay = 1}; [restaurant] {food = indian, pricerange = expensive}
	Oracle Belief State	[hotel] {stars = 3, type = hotel, people = 2, day = sunday, stay = 1}; [restaurant] {food = indian, pricerange = expensive}
	Delexicalized Response	you are welcome . have a great day !
	Lexicalized Response	you are welcome . have a great day !
	Oracle Reference	thank you , and goodbye .

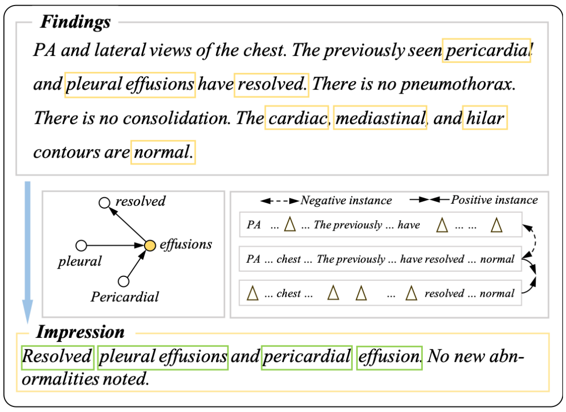
Abstract

The impression section of a radiology report summarizes the most prominent observation from the findings section and is the most important section for radiologists to communicate to physicians. Summarizing findings is time-consuming and can be prone to error for inexperienced radiologists, and thus automatic impression generation has attracted substantial attention. With the encoder-decoder framework, most previous studies explore incorporating extra knowledge (e.g., static pre-defined clinical ontologies or extra background information). Yet, they encode such knowledge by a separate encoder to treat it as an extra input to their models, which is limited in leveraging their relations with the original findings. To address the limitation, we propose a unified framework for exploiting both extra knowledge and the original findings in an integrated way so that the critical information (i.e., key words and their relations) can be extracted in an appropriate way to facilitate impression generation. In detail, for each input findings, it is encoded by a text encoder, and a graph is constructed through its entities and dependency tree. Then, a graph encoder (e.g., graph neural networks (GNNs)) is adopted to model relation information in the constructed graph. Finally, to emphasize the key words in the findings, contrastive learning is introduced to map positive samples (constructed by masking non-key words) closer and push apart negative ones (constructed by masking key words). The experimental results on OpenI and MIMIC-CXR confirm the effectiveness of our proposed method.[1]

1 Introduction

Radiology reports document critical observation in a radiology study and play a vital role in communication between radiologists and physicians. A radiology report usually consists of a findings section describing the details of medical observation and an impression section summarizing the most prominent observation. The impression is the most critical part of a radiology report, but the process of summarizing findings is normally time-consuming and could be prone to errors for inexperienced radiologists. Therefore, automatic impression generation (AIG) has drawn substantial attention in recent years, and there are many methods proposed in this area (Zhang et al., 2018; Gharebagh et al., 2020; MacAvaney et al., 2019; Shieh et al., 2019).



PA and lateral views of the chest. The previously seen pericardial and pleural effusions have resolved. There is no pneumothorax. There is no consolidation. The cardiac, mediastinal, and hilar contours are normal.

Resolved pleural effusions and pericardial effusion. No new abnormalities noted.

Figure 1: An example of the findings and corresponding impression, where the relation information, as well as positive and negative examples, are also shown in the figure. Note that △ represents the removed word.

Most existing studies focus on incorporating extra knowledge on the general encoder-decoder framework. For example, Zhang et al. (2018) utilized the background section in the radiology report through a separate encoder and then used it to guide the decoding process to enhance impression generation. Similarly, MacAvaney et al. (2019) and Gharebagh et al. (2020) proposed to extract the ontology information from findings and used an encoder to encode such information to promote the decoding process. Although these approaches have brought significant improvements, they only leverage extra knowledge and findings separately (i.e.,

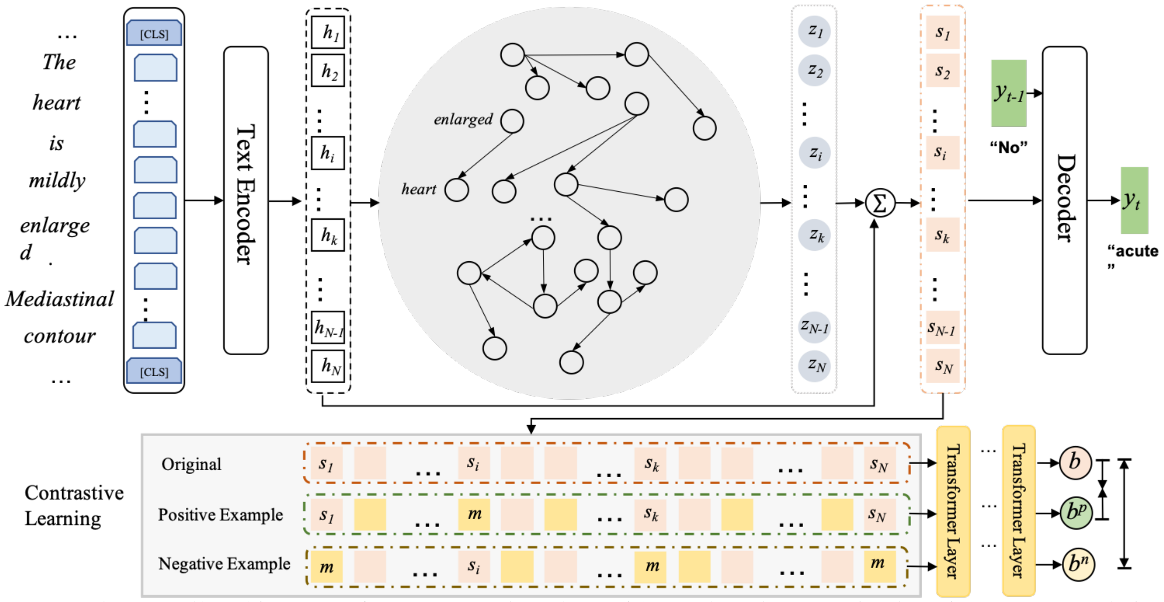

Figure 2: The overall architecture of our proposed method with graph and contrastive learning. An example input and output at $t-1$ and t step are shown in the figure, where the top is the backbone sequence-to-sequence paradigm with a graph to store relation information between critical words and the bottom is the contrastive learning module with specific positive and negative examples. $\mathbf{m}$ refer to a mask vector.

through an extra encoder). Thus, their performance relies heavily on the quality of extra knowledge, and the further relationships between extra knowledge and findings are not explored. In this paper, we propose a unified framework to exploit both findings and extra knowledge in an integrated way so that the critical information (i.e., key words and their relations in our paper) can be leveraged in an appropriate way. In detail, for each input findings, we construct a word graph through the automatically extracted entities and dependency tree, with its embeddings, which are from a text encoder. Then, we model the relation information among key words through a graph encoder (e.g., graph neural networks (GNNs)). Finally, contrastive learning is introduced to emphasize key words in findings to map positive samples (constructed by masking non-key words) closer and push apart negative ones (constructed by masking key words), as shown in Figure 1. In such a way, key words and their relations are leveraged in an integrated way through the above two modules (i.e., contrastive learning and the graph encoder) to promote AIG. Experimental results on two prevailing datasets (i.e., OpenI and MIMIC-CXR) show that our proposed approach achieves state-of-the-art results compared to existing studies.

2 Method

We follow the standard sequence-to-sequence paradigm for AIG. First, we utilize WordPiece (Wu et al., 2016) to tokenize original findings and obtain the source input sequence $\mathcal{X} = x_1, x_2, \cdots, x_N$, where N is the number of tokens in $\mathcal{X}$. The goal is to find a sequence $\mathbf{Y} = \{y_1, ...y_i, ..., y_L\}$ that summarizes the most critical observations in findings, where L is the length of impression and $y_i \in \mathrm{V}$ are the generated tokens and V is the vocabulary of all possible tokens. The generation process can be formalized as:

$$p(\mathbf{Y} \mid \mathcal{X}) = \prod_{t=1}^{L} p\left(y_t \mid y_1, \ldots, y_{t-1}, \mathcal{X}\right) \quad (1)$$

The model is then trained to maximize the negative conditional log-likelihood of $\mathcal{Y}$ given the $\mathcal{X}$:

$$\theta^* = \arg\max_{\theta} \sum_{t=1}^{L} \log p\left(y_t \mid y_1, ..., y_{t-1}, \mathcal{X}, A; \theta\right) \quad (2)$$

where θ is the parameters of the model, and A represents edges in the relation graph. An overview of our proposed method is presented in Figure 2. Our model contains three main components, i.e., the graph enhanced encoder, the contrastive learning module, and the decoder. The details are described in the following sub-sections.

2.1 Relation Graph

The impression usually describes critical abnormalities with more concise descriptions summarized from the corresponding findings and sometimes uses key phrases to express observations. For example, a sentence in findings texts *"There is a left pleural effusion which is small in size."*, is simplified as a key phrase *"Small left pleural effusion"* in the impression, where the relation between *"small"* and *"effusion"* is vital for describing the corresponding observation. Thus, the relation information in findings plays an essential role in accurate key phrase generation. Four types of medical entities, *anatomy*, *observation*, *anatomy modifier*, and *observation modifier*, are recognized from findings, which compose a majority of important medical knowledge in impression (Hassanpour and Langlotz, 2016). With WordPiece tokenization, we represent each entity by frequent subwords and connect any two subwords if they are adjacent in the same entity to enhance internal relations for keeping the entity complete. For example, the entity *"opacity"* is represented as *"op ##acity"* and then these two subwords connect to each other with both from *"op"* to *"##acity"* and from *"##acity"* to *"op"*. Besides, we need to consider the semantic relation between entities and other words, such as words used to describe the location and degree of symptoms, which is necessary for accurately recording abnormalities. For example, in a text span *"bilateral small pleural effusions"*, relations in <*"bilateral"*,*"effusions"*>, <*"small"*,*"effusions"*> are also important to describe the observation *"effusions"* and they can be extracted from the dependency tree. Therefore, we construct a dependency tree to extract the semantic relations between entities and other words, with the direction from their head words to themselves. We also employ the WordPiece to split these words as subwords and connect all the source subwords to the corresponding target words with the original direction. The constructed subword graph is then used to extract relation information, with edges represented by A.

2.2 Graph Enhanced Encoder

In recent years, pre-trained models have dominated not only general summarization tasks but also multi-modal tasks because of their strong ability in feature representation (Wu et al., 2021; Zhang et al., 2020a; Yuan et al., 2021, 2022). Thus, in our method, we utilize the pre-trained model BioBERT (Lee et al., 2020) trained on a large biomedical corpus as our text encoder. The hidden state $\mathbf{h}_i$ for each token x_i is generated by the text encoder

$$[\mathbf{h}_1, \mathbf{h}_2, \cdots, \mathbf{h}_n] = f_{te}(x_1, x_2, \cdots, x_n) \quad (3)$$

Herein, $f_{te}(\cdot)$ refers to the pre-trained Transformer-based text encoder (i.e., BioBERT (Lee et al., 2020)), and $\mathbf{h}_i$ is a d-dimensional feature vector for representing corresponding tokens x_i. Since GNNs are well known for extracting features from graph structure and have been shown promising in text generation tasks (Jia et al., 2020; Hu et al., 2021), we employ a GNN-based encoder to capture relation information from the corresponding subword graph. This process can be formulated as:

$$\mathbf{z} = f_{ge}(\mathbf{h}, A), \quad (4)$$

where $f_{ge}(\cdot)$ is the graph encoder, and $\mathbf{z}$ is the feature vector extracted from the graph. Next, to incorporate relation information into token representation, we concatenate $\mathbf{z}$ and $\mathbf{h}$ and utilize a fully connected layer to reduce it to the same dimensions as $\mathbf{z}$ and $\mathbf{h}$:

$$\mathbf{s} = \mathrm{MLP}([\mathbf{h}_1 \oplus \mathbf{z}_1, \mathbf{h}_2 \oplus \mathbf{z}_2, \cdots, \mathbf{h}_n \oplus \mathbf{z}_n]), \quad (5)$$

where s is the final token representation.

Algorithm 1: Generation of Examples

```
Input: $\mathbf{s}$: graph enhanced token representation
       $A$: edges in relation graph
Output: $\mathbf{s}^p$ Positive example
        $\mathbf{s}^n$ Negative example
Initialization: $\mathbf{s}^p \leftarrow \mathbf{s}$, $\mathbf{s}^n \leftarrow \mathbf{s}$
                $\mathbf{m} = [1e-6] \in \mathrm{R}^d$
$N, d = size(\mathbf{s})$
$V_{key} = Extract\_subword\_index(A)$
for $j = 0$ to $N$ do
    if j in $V_{key}$ then
        $\mathbf{s}^n_j \leftarrow \mathbf{m}$
    else:
        $\mathbf{s}^p_j \leftarrow \mathbf{m}$
    end if
end for
```

2.3 Contrastive Learning

Only relying on a GNN encoder to capture relation information still lacks the capability to fully grasp important word information from findings since the graph is pre-defined before training or testing. Recently, contrastive learning has shown strong power in learning and distinguishing significant knowledge by concentrating positive samples and contrasting with negative samples, and brought significant improvements in many tasks, such as improving the faithfulness of summarization and discriminating vital information to enhance representation (Cao and Wang, 2021; Zeng et al., 2021). We expect our model to be more sensitive to critical words contained in findings. For this purpose, we apply a contrastive learning module to concentrate positive pairs and push negative ones apart, which aims to help the model differentiate essential information from secondary information. We regard tokens with edges in the relation graph as critical tokens since they contain important information for describing key observations, as discussed in 2.1. To construct a positive example, we mask each non-key token representation in $\mathbf{s}$ as the constant vectors $\mathbf{m} \in \mathbb{R}^d$, with all elements $1e-6$, so that this instance can consolidate the critical information and remove unimportant words. Meanwhile, we utilize a similar way to mask important token representations in $\mathbf{s}$ as $\mathbf{m}$ to obtain a negative example $\mathbf{s}^n$. The details of generating positive and negative examples are shown in Algorithm 1. Note that in our model, we do not consider the other instances in the same mini-batch as the negative examples, which is different from many existing approaches (Kim et al., 2021; Giorgi et al., 2020) since we aim to identify the critical content in $\mathcal{X}$ instead of expanding differences between various findings in one mini-batch. In addition, radiology reports are not as diverse as ordinary texts, and they are mainly composed of fixed medical terms and some attributive words, where the former is used to record critical information and the latter is to keep sentences fluent and grammatically correct.

Afterward, we employ a randomly initialized Transformer-based encoder to model $\mathbf{s}$, $\mathbf{s}^p$, $\mathbf{s}^n$, respectively, which can be formulated as:

$$\mathbf{b} = f_{ce}(\mathbf{s}), \tag{6}$$

$$\mathbf{b}^p = f_{ce}(\mathbf{s}^p), \tag{7}$$

$$\mathbf{b}^n = f_{ce}(\mathbf{s}^n), \tag{8}$$

where $f_{ce}(\cdot)$ represents the contrastive encoder. $\mathbf{b}$, $\mathbf{b}^p$ and $\mathbf{b}^n$ are intermediate states extracted from the encoder, which are also d-dimensional vectors. Then, we calculate cosine similarity $sim(\mathbf{b}^1, \mathbf{b}^2) = \frac{\mathbf{b}_1^\top \mathbf{b}_2}{\|\mathbf{b}_1\| \cdot \|\mathbf{b}_2\|}$ for positive and negative pairs, denoted as $sim(\mathbf{b}, \mathbf{b}^p)$ and $sim(\mathbf{b}, \mathbf{b}^n)$. We follow Robinson et al. (2020) to formulate the training objective of contrastive module:

$$l_{con} = -\log \frac{e^{\mathrm{sim}(\mathbf{b}_i, \mathbf{b}^p)/\tau}}{\sum_{j=1}^{N} \left(e^{\mathrm{sim}(\mathbf{b}_i, \mathbf{b}^p)/\tau} + e^{\mathrm{sim}(\mathbf{b}_i, \mathbf{b}^n)/\tau} \right)}, \tag{9}$$

where τ is a temperature hyperparameter, which is set to 1 in this paper.

Data	Type	Train	Dev	Test
OpenI	Report #	2400	292	576
	Avg. wf	37.89	37.77	37.98

MIMIC -CXR	Report #	122,014	957	1,606
	Avg. wf	55.78	56.57	70.67
	Avg. sf	6.50	6.51	7.28
	Avg. wi	16.98	17.18	21.71
	Avg. si	3.02	3.04	3.49

Table 1: The statistics of the two benchmark datasets with random split for OpenI and official split for MIMIC-CXR, including the numbers of report, the averaged sentence-based length (Avg. sf, Avg. si), the averaged word-based length (Avg. wf, Avg. wi) of both Impression and Findings.

2.4 Decoder

The decoder in our model is built upon a standard Transformer (Vaswani et al., 2017), where the representation $\mathbf{s}$ is functionalized as the input of the decoder so as to improve the generation process. In detail, $\mathbf{s}$ is sent to the decoder at each decoding step, jointly with the generated tokens from previous steps, and thus the current output y_t can be computed by

$$y_t = f_e(\mathbf{s}_1, \mathbf{s}_2, \cdots, \mathbf{s}_n, y_1, \cdots, y_{t-1}), \tag{10}$$

where $f_e(\cdot)$ refers to the Transformer-based decoder and this process is repeated until the complete impression is obtained.

Besides, to effectively incorporate the critical word information into the decoding process, we sum the losses from the impression generation and contrastive objectives as

$$L = l_{ge} + \lambda l_{con}, \tag{11}$$

where l_{ge} is the basic sequence-to-sequence loss, and λ is the weight to control the contrastive loss.

3 Experimental Setting

3.1 Dataset

Our experiments are conducted on two following datasets: **OpenI** (Demner-Fushman et al., 2016) and **MIMIC-CXR** (Johnson et al., 2019) respectively, where the former contains 3268 reports collected by Indiana University and the latter is a larger dataset containing 124577 reports. Note that the number of reports we introduced is counted after pre-processing. We follow (Hu et al., 2021;

Data	Model	ROUGE			FC		
		R-1	R-2	R-L	**P**	**R**	**F-1**
OpenI	Base	62.74	53.32	62.86	-	-	-
	Base+CL	63.53	54.58	63.13	-	-	-
	Base+Graph	63.29	54.12	63.03	-	-	-
	Base+Graph+CL	**64.97**	**55.59**	**64.45**	-	-	-
MIMIC-CXR	Base	47.92	32.43	45.83	58.05	50.90	53.01
	Base+CL	48.15	33.25	46.24	58.34	51.58	53.70
	Base+Graph	48.29	33.30	46.36	57.80	51.70	53.50
	Base+Graph+CL	**49.13**	**33.76**	**47.12**	**58.85**	**52.33**	**54.52**

Table 2: Comparisons of baselines and our method on OpenI and MIMIC-CXR datasets. R-1, R-2 and R-L refer to ROUGE-1, ROUGE-2 and ROUGE-L, respectively. P, R and F-1 represent precision, recall, and F1 score.

Zhang et al., 2018) to filter the reports by deleting the reports in the following cases: (1) no findings or no impression sections; (2) the findings have fewer than ten words, or the impression has fewer than two words. For OpenI, we follow (Hu et al., 2021) to randomly divide it into train/validation/test set by 2400:292:576 in our experiments. For MIMIC-CXR, we apply two types of splits, including an official split and a random split with a ratio of 8:1:1 similar to (Gharebagh et al., 2020). We report the statistics of these two datasets in Table 1.

3.2 Baseline and Evaluation Metrics

To explore the performance of our method, we use the following ones as our main baselines:

- **Base** (Liu and Lapata, 2019): this is a backbone sequence-to-sequence model, i.e., a pre-trained encoder and a randomly initialized Transformer-based decoder.
- **Base+Graph** and **Base+CL**: these have the same architecture as **Base**, where the former incorporates an extra graph encoder to enhance relation information, and the latter introduces a contrastive learning module to help the model distinguish critical words.

Besides, we also compare our method with those existing studies, including both extractive summarization methods, e.g., **LexRank** (Erkan and Radev, 2004), **TransformerEXT** (Liu and Lapata, 2019), and the ones proposed for abstractive models. e.g., **TransformerABS** (Liu and Lapata, 2019), **OntologyABS** (Gharebagh et al., 2020), **WGSum (Trans+GAT)**, and **WGSum (LSTM+GAT)** (Hu et al., 2021).

Actually, factual consistency (FC) is critical in radiology report generation (Liu et al., 2019; Chen et al., 2020). Following Zhang et al. (2020c); Hu et al. (2021), we evaluate our model and three baselines by two types of metrics: summarization and FC metrics. For summarization metrics, we report F_1 scores of ROUGE-1 (R-1), ROUGE-2 (R-2), and ROUGE-L (R-L). Besides, for FC metrics, we utilize CheXbert (Smit et al., 2020)[2] to detect 14 observations related to diseases from reference impressions and generated impressions and then calculate the precision, recall, and F1 score between these two identified results.

3.3 Implementation Details

In our experiments, we utilize biobert-base-cased-v1.1[3] as our text encoder and follow its default model settings: we use 12 layers of self-attention with 768-dimensional embeddings. Besides, we employ stanza (Zhang et al., 2020d) to extract medical entities and the dependence tree, which is used to construct the graph and generate positive and negative examples. Our method is implemented based on the code of BertSum (Liu and Lapata, 2019)[4]. In addition, we use a 2-layer graph attention networks (GAT) (Veličković et al., 2017)[5] with the hidden size of 768 as our graph encoder and a 6-layer Transformer with 768 hidden sizes and 2048 feed-forward filter sizes for the contrastive encoder. The decoder is also a 6-layer Transformer with 768 dimensions, 8 attention heads, and 2048 feed-forward filter sizes. Note that λ is set 1 in all experiments, and more detailed hyperparameters are reported in A.1. During the training, we use Adam (Kingma and Ba, 2014) to optimize the trainable parameters in our model.

---

[2] FC is only applied to MIMIC-CXR since the CheXbert is designed for MIMIC-CXR. We obtain it from `https://github.com/stanfordmlgroup/CheXbert`

[3] We obtain BioBERT from `https://github.com/dmis-lab/biobert`

[4] We obtain the code of BertSum from `https://github.com/nlpyang/PreSumm`

[5] Since previous study (Hu et al., 2021) has shown that GAT (Veličković et al., 2017) is more effective in impression generation, we select GAT as our graph encoder.

4 Results and Analyses

4.1 Effect of Graph and Contrastive learning

To explore the effectiveness of our proposed method, we conduct experiments on two benchmark datasets, with the results reported in Table 2, where Base+graph+CL represents our complete model. We can obtain several observations from the results. First, both Base+graph and Base+CL achieve better results than Base with respect to R-1, R-2, and R-L, which indicates that graph and contrastive learning can respectively promote impression generation. Second, Base+graph+CL outperforms all baselines with significant improvement on two datasets, confirming the effectiveness of our proposed method in combining graph and contrastive learning. This might be because graphs and contrastive learning can provide valuable information from different aspects, the former mainly record relation information, and the latter brings critical words knowledge, so that an elaborate combination of them can bring more improvements. Third, when comparing these two datasets, the performance gains from our full model over three baselines on OpenI are more prominent than that on MIMIC-CXR. This is perhaps because compared to MIMIC-CXR, OpenI dataset is relatively smaller and has a shorter averaged word-based length, such that it is easier for the graph to record relation and more accessible for contrastive learning to recognize key words by comparing positive and negative examples. Fourth, we can find a similar trend on the FC metric on the MIMIC-CXR dataset, where a higher F1 score means that our complete model can generate more accurate impressions thanks to its more substantial power in key words discrimination and relationship information extraction.

4.2 Comparison with Previous Studies

In this subsection, we further compare our models with existing models on the aforementioned datasets, and the results are reported in Table 3. There are several observations. First, the comparison between our model and OntologyABS shows the effectiveness of our design in this task, where our model achieves better performance, though both of them enhance impression generation by incorporating crucial medical information. This might be because by comparing positive and negative examples for each findings, our model is more sensitive to critical information and more intelligent in distinguishing between essential information and secondary information, contributing to more accurate and valuable information embedded in the model. Second, we can observe that our model outperforms all existing models in terms of R-1, R-2, and R-L. On the one hand, effectively combining contrastive learning and graph into the sequence to sequence model is a better solution to improve feature extraction and thus promote the decoding process robustly. On the other hand, the pre-trained model (i.e., BioBERT) used in our model is a more powerful feature extractor in modeling biomedical text than those existing studies, e.g., TransformerABS, OntologyABS, and PGN, which utilize randomly initialized encoders. Third, when compared to those complicated models, e.g., WGSUM utilize stanza to extract entities and construct two extra graph encoders to extract features from a word graph, which are then regarded as background information and dynamic guiding information to enhance the decoding process for improving impression generation, our model can achieve better performance through a somewhat more straightforward method.

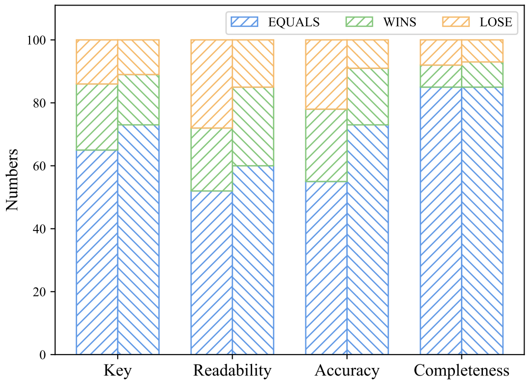

Figure 3: The results of human evaluation, where forward and backslash represent that BASE+GRAPH+CL versus the reference and BASE, respectively. Yellow, green and blue represent that our model loses, equal to competitors and wins.

4.3 Human Evaluation

We further conduct a human evaluation to understand the quality of the generated impression better and alleviate the limitation of the ROUGE metric. One hundred generated impressions on MIMIC-CXR from BASE and BASE+GRAPH+CL, along with their corresponding reference impressions, are randomly selected for expert evaluation (Gharebagh et al., 2020). Besides, we follow Hu et al. (2021) to utilize four metrics: Key, Readability, Accuracy, and Completeness, respectively. We invite three medical experts to score these generated impressions based on these four metrics, with the results shown in Figure 3. On the one hand, compared to BASE, we can find that our model outperforms it on all four metrics, where 16%, 25%, 18%, and 8% of impressions from our model obtain higher quality than BASE. On the other hand, comparing our model against reference impressions, our model obtains close results on key, accuracy, and completeness, with 86%, 78%, and 92% of our model outputs being at least as good as radiologists, while our model is less preferred for readability with a 10% gap. The main reason might be that many words removed in positive examples are used to keep sequence fluently, and our model tends to identify them as secondary information, leading that our model obtains relatively worse results on the readability metric.

4.4 Analyses

We conduct further analyses on Findings Length and Case Study.

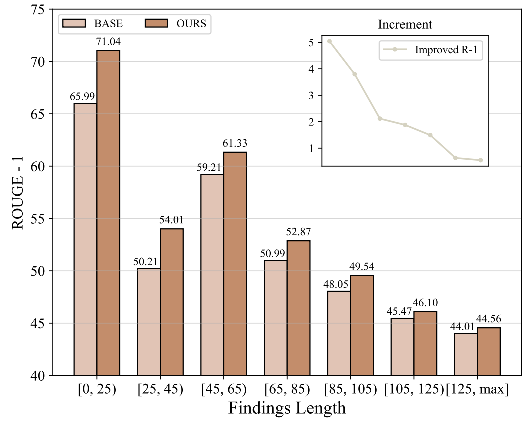

Figure 4: R-1 score of generated impressions from BASE and our model on the MIMIC-CXR test set, where OURS represent the BASE+GRAPH+CL.

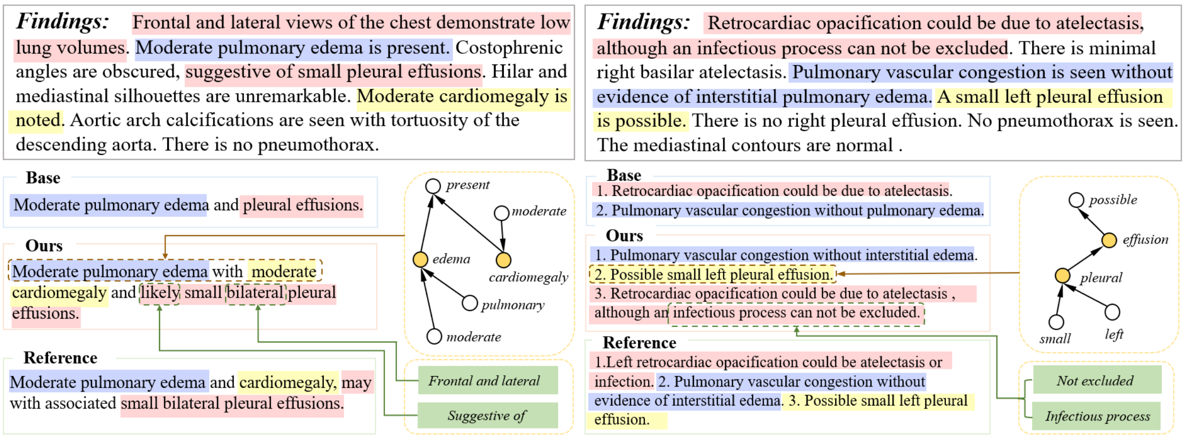
Findings Length To test the effectiveness of the word-based length of findings, we categorize the findings on the MIMIC-CXR test set into seven groups and present the R-1 score for each group in Figure 4. We have the following observations. First, as the findings length becomes long, the performance of BASE and our model tend to decrease, except for the second group, i.e., [25, 45], since short text are more accessible for the encoder to capture valid features, which is consistent with previous studies (Dai et al., 2019). Second, our model outperforms BASE in all the groups, further illustrating the effectiveness of our model regardless of the findings length. Third, we can observe a grey line with a downward trend from the incremental chart in the upper right corner of Figure 4, indicating that our model (i.e., BASE+GRAPH+CL) tends to gain better improvements over BASE on shorter findings than that on longer ones. This is because longer findings usually contain relatively more secondary information such that it is more challenging for contrastive learning to distinguish critical knowledge.

Case study To further demonstrate how our approach with graph and contrastive learning helps the generation of findings, we perform qualitative analysis on two cases, and the results are shown in Figure 5, where different colors on the texts indicate different critical information. Compared to BASE model, our model can generate more complete impressions which cover almost all the crucial abnormalities. In contrast, the BASE model fails to identify all the key information, e.g., (*"moderate cardiomegaly"* in the left example and *"possible*



Findings: Frontal and lateral views of the chest demonstrate low lung volumes. Moderate pulmonary edema is present. Costophrenic angles are obscured, suggestive of small pleural effusions. Hilar and mediastinal silhouettes are unremarkable. Moderate cardiomegaly is noted. Aortic arch calcifications are seen with tortuosity of the descending aorta. There is no pneumothorax.

Base

Moderate pulmonary edema and pleural effusions.

Ours

Moderate pulmonary edema with moderate cardiomegaly and likely small bilateral pleural effusions.

Reference

Moderate pulmonary edema and cardiomegaly, may with associated small bilateral pleural effusions.

Findings: Retrocardiac opacification could be due to atelectasis, although an infectious process can not be excluded. There is minimal right basilar atelectasis. Pulmonary vascular congestion is seen without evidence of interstitial pulmonary edema. A small left pleural effusion is possible. There is no right pleural effusion. No pneumothorax is seen. The mediastinal contours are normal .

Base

1. Retrocardiac opacification could be due to atelectasis.
2. Pulmonary vascular congestion without pulmonary edema.

Ours

1. Pulmonary vascular congestion without interstitial edema.
2. Possible small left pleural effusion.
3. Retrocardiac opacification could be due to atelectasis , although an infectious process can not be excluded.

Reference

1.Left retrocardiac opacification could be atelectasis or infection. 2. Pulmonary vascular congestion without evidence of interstitial edema. 3. Possible small left pleural effusion.

Figure 5: Examples of the generated impressions from BASE and BASE+GRAPH+CL as well as reference impressions. The yellow nodes in the graph indicate that these words are contained in entities.

small left pleural effusion" in the right case). Besides, our model can generate more accurate impressions with an appropriate word to represent possibility and a better modifier to describe the observation. On the one hand, in Figure 5, *"suggestive of"* in the left example and *"may"* in the right example imply a type of uncertainty, which means that doctors wonder whether the abnormal observation exists when writing findings, so that the corresponding word (i.e., *"likely"*) is used to describe this sensitive information. On the other hand, in the left case, according to the phrase *"Frontal and lateral"* in its original findings, our model can generate the synonym *"bilateral"* to depict the symptom *"pleural effusions"* more specifically.

5 Related Work

Recently, NLP technology has broadly applied in the medical domain, such as medical entity recognition (Liu et al., 2021b; Zhao et al., 2019), radiology report generation (Chen et al., 2021; Zhang et al., 2020b; Liu et al., 2021a), AIG, etc. Impression generation can be regarded as a type of summarization task that has drawn substantial attention in recent years, and there are many studies for addressing general abstractive summarization (See et al., 2017; Li et al., 2020; You et al., 2019; Huang et al., 2020). You et al. (2019) designed a novel focus-attention mechanism and saliency-selection network, equipped in the encoder and decoder to enhance summary generation. Li et al. (2020) proposed an abstractive sentence summarization method guided by the key words, which utilized a dual-attention and a dual-copy mechanism to integrate the semantics of both original sequence and key words. Many methods propose to introduce specific designs on the general summarization model to address radiology impression generation (Zhang et al., 2018; Gharebagh et al., 2020; MacAvaney et al., 2019; Hu et al., 2021; Abacha et al., 2021). MacAvaney et al. (2019); Gharebagh et al. (2020) extracted the salient clinical ontology terms from findings and then incorporated them into the summarizer through a separate encoder for enhancing AIG. Hu et al. (2021) further introduced pre-defined word graphs to record salient words as well as their internal relation and then employed two separate graph encoders to leverage graphs for guiding the decoding process. Most of these approaches exploit separate encoders to encode pre-defined knowledge (e.g., ontology terms and word graph), which are then utilized to enhance impression generation. However, they tend to over-rely on the quality of pre-extracted ontologies and word graphs and lack sensitivity to vital information of findings themselves. Compared to these models, our method offers an alternative solution to robustly improve key information extraction with the help of both graphs and contrastive learning.

6 Conclusion

In this paper, we propose to combine graphs and contrastive learning to better incorporate valuable features for promoting impression generation. Specifically, we utilize the graph encoder to extract relation information from the graph, constructed by medical entities and the dependence tree, for enhancing the representation from the pre-trained text encoder. In addition, we employ contrastive learning to assist the model in distinguishing between critical and secondary information, simultaneously improving sensitivity to important word representation by comparing positive and negative examples. Furthermore, we conduct experiments on two benchmark datasets, and the results illustrate the effectiveness of our proposed method, where new state-of-the-art results are achieved.

Abstract

Formality style transfer (FST) is a task that involves paraphrasing an informal sentence into a formal one without altering its meaning. To address the data-scarcity problem of existing parallel datasets, previous studies tend to adopt a cycle-reconstruction scheme to utilize additional unlabeled data, where the FST model mainly benefits from target-side unlabeled sentences. In this work, we propose a simple yet effective semi-supervised framework to better utilize source-side unlabeled sentences based on consistency training. Specifically, our approach augments pseudo-parallel data obtained from a source-side informal sentence by enforcing the model to generate similar outputs for its perturbed version. Moreover, we empirically examined the effects of various data perturbation methods and propose effective data filtering strategies to improve our framework. Experimental results on the GYAFC benchmark demonstrate that our approach can achieve state-of-the-art results, even with less than 40% of the parallel data[1].

1 Introduction

Formality style transfer (FST) (Rao and Tetreault, 2018) has garnered growing attention in the text style transfer community, which aims to transform an *informal*-style sentence into a *formal* one while preserving its meaning. The large amount of user-generated data from online resources like tweets often contain informal expressions such as slang words (e.g., *gonna*), wrong capitalization or punctuations, and grammatical or spelling errors. FST can clean and formalize such noisy data, to benefit downstream NLP applications such as sentiment classification (Yao and Yu, 2021a). Some examples of FST data are presented in Table 1.

Informal	*TITANIC I THINK IT COST ABOUT 300 MILLION*
Formal	*I think that Titanic cost around 300 million dollars.*
Informal	*being condiderate of her feelings and needs*
Formal	*I am being considerate of her personal needs and feelings.*

Table 1: Examples of informal-formal sentence pairs.

With the release of the FST benchmark Grammarly Yahoo Answers Corpus (GYAFC) (Rao and Tetreault, 2018), previous studies on FST tend to employ neural networks such as sequence-to-sequence (seq2seq) models to utilize parallel (informal and formal) sentence pairs. However, GYAFC only contains 100k parallel examples, which limits the performance of neural network models. Several approaches have been developed to address the data-scarcity problem by utilizing unlabeled sentences. In a previous study, Zhang et al. (2020) proposed several effective data augmentations methods, such as back-translation, to augment parallel data. Another line of research (Shang et al., 2019; Xu et al., 2019; Chawla and Yang, 2020) conducted semi-supervised learning (SSL) in a cycle-reconstruction manner, where both forward and backward transfer models were jointly trained while benefiting each other by generating pseudo-parallel data from unlabeled sentences. Under this setting, both additional informal and formal sentences are utilized; however, the forward informal→formal model mostly benefits from the *target*-side (formal) sentences, which are back-translated by the formal→informal model to construct pseudo training pairs. Conversely, the formal→informal model can only acquire extra supervision signals from informal sentences. Because the main objective of FST is the informal→formal transfer, the additional informal sentences were not well utilized in previous studies. In addition, these semi-supervised models incorporate many auxiliary modules such as style discriminators, to achieve state-of-the-art results, which result in rather complicated frameworks and more model parameters.

As noisy informal sentences are easier to ac-

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 4689 - 4701
May 22-27, 2022

quire from online resources, we attempt to take a different view from existing approaches, by adopting additional *source*-side (informal) sentences via SSL. We gain insights from the state-of-the-art approaches for semi-supervised image and text classification (Sohn et al., 2020; Xie et al., 2020; Berthelot et al., 2019; Zhang et al., 2021; Chen et al., 2020) and propose a simple yet effective SSL framework for FST using purely informal sentences. Our approach employs *consistency training* to generate pseudo-parallel data from additional informal sentences. Specifically, we enforce the model to generate similar target sentences for an unlabeled source-side sentence and its perturbed version, making the model more robust against the noise in the unlabeled data. In addition, a supervised loss is trained simultaneously to transfer knowledge from the clean parallel data to the unsupervised consistency training.

Data perturbation is the key component of consistency training and significantly affects its performance. To obtain a successful SSL framework for FST, we first empirically study the effects of various data perturbation approaches. Specifically, we explore easy data augmentation methods, such as random *word deletion*, and advanced data augmentation methods, such as *back-translation*. We also handcraft a line of rule-based data perturbation methods to simulate the features of informal sentences, such as *spelling error injection*. Furthermore, we propose three data filtering approaches in connection with the three evaluation metrics of FST: style strength, content preservation, and fluency. Specifically, we adopt *style accuracy*, *source*-BLEU, and *perplexity* as three metrics to filter out low-quality pseudo-parallel data based on a threshold. We also propose a dynamic threshold algorithm to automatically select and update the thresholds of source-BLEU and perplexity.

We evaluate our framework on the two domains of the GYAFC benchmark: *Entertainment & Music* (E&M) and *Family & Relationships* (F&R). We further collect 200k unpaired informal sentences for each domain to perform semi-supervised training. Experimental results verify that our SSL framework can enhance the performance of the strong supervised baseline, a pretrained T5-large (Raffel et al., 2020) model, by a substantial margin, and improve the state-of-the-art results by over 2.0 BLEU scores on both GYAFC domains. Empirically, we also deduce that simple word-level data augmentation approaches are better than advanced data augmentation methods that excessively alter the sentences, and *spelling error injection* is especially effective. In addition, our evaluation-based data filtering approach can further improve the performance of the SSL framework. Furthermore, we also conduct low-resource experiments by reducing the size of parallel data. Surprisingly, our framework could achieve the state-of-the-art results with only less than 40% of parallel data, demonstrating the advantage of our method in low-resource situations.

2 Related Work

Formality style transfer FST is an important branch of text style transfer. For FST, Rao and Tetreault (2018) released a high-quality parallel dataset - GYAFC, comprising two sub-domains and approximately 50k parallel data for each domain. Previous studies (Rao and Tetreault, 2018; Niu et al., 2018; Xu et al., 2019; Zhang et al., 2020) typically train seq2seq encoder-decoder models on this benchmark. Recent studies (Wang et al., 2019; Yao and Yu, 2021b; Chawla and Yang, 2020; Lai et al., 2021) have deduced that fine-tuning large-scale pretrained models such as GPT-2 (Radford et al., 2019) and BART (Lewis et al., 2020) on the parallel corpora can improve the performance. To address the data-scarcity problem of parallel datasets, Zhang et al. (2020) proposed three data augmentation techniques to augment pseudo-parallel data for training. Similar to prior research on text style transfer that adopt back-translation (Zhang et al., 2018; Lample et al., 2018; Prabhumoye et al., 2018; Luo et al., 2019), some other approaches on FST (Shang et al., 2019; Xu et al., 2019; Chawla and Yang, 2020) adopt a cycle-reconstruction scheme, where an additional backward transfer model is jointly trained together with the forward transfer model, and the two models generate pseudo-paired data for each other via iterative back-translation. Although Xu et al. (2019) and Chawla and Yang (2020) train a single model to perform bidirectional transfer, the generation of both directions remain disentangled by a control variable, making each direction rely on the unlabeled data of its target side. Therefore, the unlabeled informal sentences exert no direct effects on the informal→formal transfer. In contrast, our work focuses on how to better utilize source-side unlabeled data (i.e., informal sentences) using SSL and does not introduce any extra models.

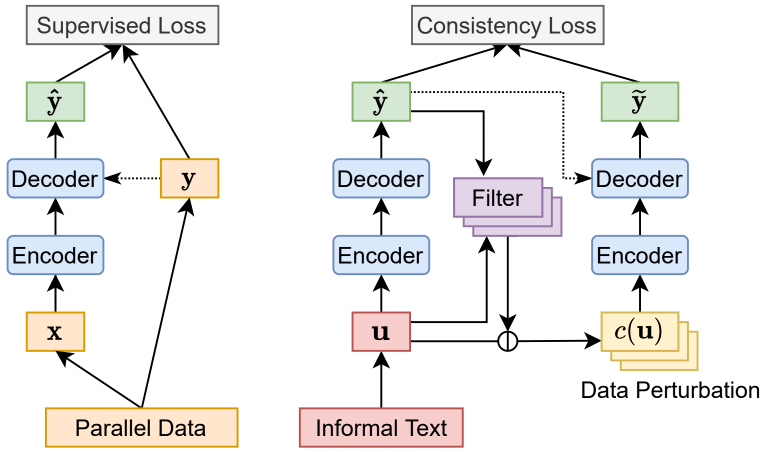

Figure 1: Overview of our semi-supervised consistency training framework which jointly optimizes two losses: (1) a supervised loss trained on parallel data; (2) a consistency training loss, where the model first generates a pseudo target $\hat{\mathbf{y}}$ for an additional informal text, then it is combined with a perturbed input $c(\mathbf{u})$ to train the model if passing the data filter. The dotted arrows indicate teacher forcing in the encoder-decoder model.

SSL with consistency regularization SSL is popular for its advantage in utilizing unlabeled data. Consistency regularization (also known as consistency training) (Sajjadi et al., 2016) is an important component of recent SSL algorithms on image and text classification (Miyato et al., 2018; Tarvainen and Valpola, 2017; Berthelot et al., 2019; Sohn et al., 2020). It enforces a model to produce invariant predictions for an unlabeled data and its perturbed version. These studies developed different data perturbation (Xie et al., 2020; Berthelot et al., 2019) or data filtering (Zhang et al., 2021; Xu et al., 2021) approaches to improve the performance. However, few studies have been made on how to apply consistency training in natural language generation (NLG) tasks such as FST because of the different target spaces, i.e., instead of single class labels or probabilities, the output of NLG is the combination of discrete NL tokens. This renders the experiences in classification tasks not applicable to FST. For instance, classification probabilities are typically adopted as the metric to filter high-confidence pseudo-examples for consistency training in classification tasks (Sohn et al., 2020; Xie et al., 2020; Zhang et al., 2021), which is implausible in FST. A similar study (He et al., 2019) improved self-training by injecting noise into unlabeled inputs and proved its effectiveness on machine translation and text summarization; however, self-training involves multiple iterations to collect pseudo-parallel data and retrain the model, hence the training is not end-to-end. In this study, we explore various data perturbation strategies and propose effective data filtering approaches to realize a successful consistency-based framework for FST, which may also provide useful insights for future studies on semi-supervised NLG.

3 Method

3.1 Base Model

FST involves rewriting an informal sentence into a formal one. Formally, given a sentence $\mathbf{x} = (x_1, x_2, \ldots, x_n)$ of length n with style S, our objective is to transform it into a target sentence $\mathbf{y} = (y_1, y_2, \ldots, y_m)$ of length m and style T, while preserving its content.

Following prior studies (Rao and Tetreault, 2018; Zhang et al., 2020; Chawla and Yang, 2020; Lai et al., 2021) on FST, we employ the supervised baseline as a seq2seq encoder-decoder model that directly learns the conditional probability $P(\mathbf{y}|\mathbf{x})$ from parallel corpus $\mathcal{D}$ comprising $(\mathbf{x}, \mathbf{y})$ pairs. The objective is the cross-entropy loss between the decoder outputs and the ground-truth target sentences:

$$\begin{aligned}\mathcal{L}_{sup} &= \mathbb{E}_{(\mathbf{x},\mathbf{y})\sim D}[-\log P(\mathbf{y}|\mathbf{x};\theta)] \\ &= \mathbb{E}_{(\mathbf{x},\mathbf{y})\sim D}[-\sum_i \log P(y_i|y_{1:i-1}, \mathbf{x};\theta)],\end{aligned} \tag{1}$$

where θ denotes the model parameters.

3.2 Consistency Training

Our approach leverages the idea of consistency regularization (Sajjadi et al., 2016) and enforces a model to generate similar target sentences for an original and perturbed unlabeled sentence. Simultaneously, the model is also trained on the supervised data. Accordingly, the knowledge garnered from supervised training can be gradually transferred to unsupervised training. An overview of our framework is presented in Figure 1. Typically, the consistency training loss is computed on the divergence between predictions on an unlabeled input $\mathbf{u}$ and its perturbed version $\tilde{\mathbf{u}} = c(\mathbf{u})$, where $c(\cdot)$ is the perturbation function and $\mathbf{u} \in \mathcal{U}_S$ represents a source-side unlabeled sentence (in our case, an informal sentence). Formally, consistency training can be defined as minimizing the following unsupervised loss:

$$\mathbb{E}_{\mathbf{u} \sim \mathcal{U}_S} D\left[P(\mathbf{y}|\mathbf{u};\theta)||P(\mathbf{y}|c(\mathbf{u});\theta)\right], \quad (2)$$

where $D[\cdot||\cdot]$ denotes a divergence loss. In practice, we adopt pseudo-labeling (Lee et al., 2013) to train the unsupervised loss, for which we fix the model parameter θ to predict a "hard label" (pseudo target sentence) $\hat{\mathbf{y}}$ for $\mathbf{u}$ and enforce the consistency of model prediction by training θ with $(c(\mathbf{u}), \hat{\mathbf{y}})$. Hence the unsupervised objective can be optimized as a standard cross-entropy loss as follows:

$$\mathcal{L}_{unsup} = \mathbb{E}_{\mathbf{u} \sim \mathcal{U}_S} \mathbb{E}_{\hat{\mathbf{y}} \sim P(\mathbf{y}|\mathbf{u};\hat{\theta})} [-\log P(\hat{\mathbf{y}}|c(\mathbf{u});\theta)], \quad (3)$$

where $\hat{\theta}$ denotes a fixed copy of θ. This training process does not introduce additional model parameters. The entire additional training cost to supervised learning is a training pass and a generation pass for each unlabeled sentence.

As the overall objective, we train a weighted sum of the supervised loss in Equation (1) and the unsupervised loss in Equation (3):

$$\mathcal{L} = \mathcal{L}_{sup} + \lambda \mathcal{L}_{unsup}, \quad (4)$$

where λ represents a hyper-parameter for balancing the effects of supervised and unsupervised training. To achieve a good initial model for consistency training, we first pretrain the model on the supervised loss for several warm-up steps.

3.3 Data Perturbation Strategies

Data perturbation is the key component of consistency-based SSL algorithms (Xie et al., 2020; Chen et al., 2020) and significantly affects the performance. In this section, we briefly introduce a collection of different data perturbation methods explored in this research.

First, we consider some easy data augmentation methods commonly used for supervised data augmentation, which includes

- **word deletion (drop)**[2]: to randomly drop a proportion of words in the sentence.
- **word swapping (swap)**: to randomly swap a proportion of words with their neighbouring words.
- **word masking (mask)**: to randomly replace words with a mask token "_".
- **word replacing with synonym (synonym)**: to randomly replace some words with a synonym based on WordNet (Fellbaum, 1998).

In addition, we consider advanced data augmentation methods that have proven effective in semi-supervised text classification (Xie et al., 2020):

- **back-translation**: to translate a sentence into a pivot language, then translate it back to obtain a paraphrase of the original one.
- **TF-IDF based word replacing (tf-idf)**: to replace uninformative words with low TF-IDF scores while retaining those with high TF-IDF values.

Furthermore, we handcraft a set of rule-based data perturbation for FST. There are some typical informal expressions in the parallel corpus, such as the use of slang words and abbreviations, capitalized words for emphasis, and spelling errors. Some existing studies (Wang et al., 2019; Yao and Yu, 2021b) adopt editing rules to revise such informal expressions as a preprocessing step. Inspired by these, we propose the adoption of opposite rules to synthesize such noises. We consider the following methods:

- **spelling error injection (spell)**: to randomly inject spelling errors to a proportion of words by referring to a spelling error dictionary.
- **word replacing with abbreviations (abbr)**: to replace all the words in the sentence with their abbreviations or slang words (e.g., "are you" → "r u") by referring to an abbreviation dictionary.
- **word capitalization (capital)**: to randomly capitalize a proportion of words.

---

[2] We abbreviate each method for ease of denotation.

These rule-based methods can inject noise into the unlabeled informal sentences without changing its informality, but strengthening it instead.

3.4 Evaluation-Based Data Filtering

In the consistency training loss, the noisy pseudo-target $\hat{\mathbf{y}}$ is generated from the decoder model and may exert negative effects on the training. Therefore, we propose three evaluation-based data filters in connection with the evaluation metrics of FST.

Specifically, we attempt to measure the quality of pseudo-target sentences by considering the three most important evaluation criteria of text style transfer: **style strength**, **content preservation**, and **fluency**. Next, we comprehensively explain each evaluation metric and the corresponding data filter.

Style strength measures the formality of generated sentences. Typically, people adopt binary classifiers such as TextCNN (Chen, 2015) classifiers to judge the formality of a sentence (Lai et al., 2021). Inspired by this, we pretrain a TextCNN formality classifier on the parallel training corpus (i.e., GYAFC) to distinguish between informal and formal sentences. For an unlabeled informal sentence $\mathbf{u}$ and its pseudo target sentence $\hat{\mathbf{y}}$, we maintain $(c(\mathbf{u}), \hat{\mathbf{y}})$ for unsupervised training only when

$$p_{cls}^{+}(\hat{\mathbf{y}}) - p_{cls}^{+}(\mathbf{u}) > \sigma, \qquad (5)$$

where $p_{cls}^{+}(\cdot)$ represents the probability of the sentence being formal, predicted by the style classifier and σ is a threshold of the probability. This guarantees that only the sentence pairs with strong style-differences are used for consistency training.

Content preservation is another important evaluation metric of FST, typically measured with BLEU between the ground-truth target sentence and the model generations. In unsupervised text style transfer where no ground-truth target exists, *source*-BLEU is adopted as an alternative, i.e., the BLEU scores between the source input sentence and the generated target sentence. Similarly, we propose the adoption of *source*-BLEU between $\mathbf{u}$ and $\hat{\mathbf{y}}$ as the metric to filter out pseudo targets that present poor content preservation.

Fluency is also used to evaluate the quality of generated sentences. We follow (Hu et al., 2020) to pretrain an N-gram language model on the training data to estimate the empirical distributions of formal sentences. Then, the *perplexity* score is calculated for the pseudo target sentence $\hat{\mathbf{y}}$ by the language model. The motivation is that the sentences with lower perplexity scores match the empirical distribution of formal sentences better, and are thus considered as more fluent.

A natural idea is to filter out pseudo-parallel data based on a *source*-BLEU or a *perplexity* threshold. However, it is infeasible to determine the optimal threshold for the two metrics beforehand because the pseudo paired data are generated on-the-fly during the training and we cannot know the distribution of the BLEU or perplexity scores. In addition, choosing the BLEU/perplexity threshold is not as easy as tuning the style probability σ because they heavily depend on the data distribution and exhibit varying ranges of values.

3.5 Dynamic Threshold Selection

To realize the selection of thresholds for the BLEU- and perplexity- based filters, we propose a dynamic threshold strategy based on the distribution of the scores computed for already generated pseudo-paired sentences. Specifically, we maintain an ordered list L to store the scores calculated for previously generated pseudo data and update it continuously following the training. At each iteration, a batch of new scores are inserted into L while maintaining the decreasing order of the list. Subsequently, we update the threshold as the value at a certain position $L[\phi \times len(L)]$ in the score list, where $len(L)$ denotes the length of the current score list and $\phi \in [0, 1]$ represents a ratio that determines the threshold's position in the list. We only keep pseudo data with scores higher (or lower for perplexity scores) than the threshold for consistency training. This actually makes ϕ approximately the proportion of pseudo data we keep for training, making it more convenient to control the trade-off between the qualities and quantities of selected pseudo data. More details are provided in Appendix B, C.

4 Experiments

We introduce the experimental settings in Section 4.1. To obtain relevant findings on how to build an effective consistency training framework for FST, we first empirically study the effects of multiple data perturbation methods in Section 4.2 and prove the effectiveness of consistency training via comparisons with the base model. Then, we validate our consistency training model with different data filtering methods in Section 4.3 and demonstrate their additional effects on the SSL frame-

Dataset	Train	Val	Test	Unlabeled
E&M	52595	2877	1416	200k
F&R	51967	2788	1432	200k

Table 2: The statistics of datasets.

work. Based on the findings in these two experiments, we further compare our best models with previous state-of-the-art models in Section 4.4. We also include case studies in Section 4.4 to present some qualitative examples. Finally, we conduct low-resource experiments (Section 4.5) to demonstrate our method's advantage when less parallel data are available.

4.1 Experimental Settings

Datasets We evaluate our framework on the GYAFC (Rao and Tetreault, 2018) benchmark for formality style transfer. It comprises crowdsourced informal-formal sentence pairs split into two domains, namely, E&M and F&R. The informal sentences in the dataset were originally selected from the same domains in Yahoo Answers L6 corpus[3]. We focus on the *informal-formal* style transfer because it is more realistic in applications. We further collected massive amounts of informal sentences from each of the two domains in Yahoo Answers L6 corpus as the unsupervised data. The statistics of the datasets are presented in Table 2.

Implementation Details We employ PyTorch (Paszke et al., 2019) for all the experiments. We pretrain a TextCNN style classifier on the supervised data for each domain of GYAFC, following the setting in (Lai et al., 2021). The same classifier is adopted for both the style accuracy evaluation and the style strength filter in our SSL framework. We adopt HuggingFace Transformers (Wolf et al., 2020) library's implementation of pretrained T5-Large (Raffel et al., 2020) as the base model. We adopt the Adam (Kingma and Ba, 2014) optimizer with the initial learning rate 2×10^{-5} to train all the models. More details of hyper-parameters and model configurations are provided in Appendix A.

Evaluation Metrics The main evaluation metric for FST is the BLEU score between the generated sentence and four human references in the test set. We adopt the corpus BLEU in NLTK (Loper and Bird, 2002) following (Chawla and Yang, 2020). In addition, we also pretrained a TextCNN formality classifier to predict the formality of transferred sentences and calculate the accuracy (Acc.). Furthermore, we compute the harmonic mean of BLEU and style accuracy as an overall score, following the settings in (Lai et al., 2021).

4.2 Effects of Data Perturbation Methods

In this experiment, we validate the effectiveness of our consistency training framework and compare the effects of different data perturbation methods. Specifically, we adopt the nine data perturbation methods introduced in Section 3.3 and include the *no-perturbation* variant that indicates directly using an unlabeled sentence and its pseudo target to train the unsupervised loss. We adopted no data filtering strategy in this experiment to simplify the comparison.

As shown in Table 3, our framework could consistently improve the base model by using different perturbation methods; however, back-translation resulted in mostly lower results than the base model. This contradicts the conclusion in (Xie et al., 2020) that back-translation is especially powerful for semi-supervised text classification. We attribute this to the fact that back-translation tends to change the entire sentence into a semantically similar but syntactically different sentence. Compared with other word-level perturbation strategies, back-translation triggers a larger mismatch between the perturbed input and the pseudo-target sentence generated from the unperturbed input, leading to a poor content preservation ability of the model. In contrast, simple word-level noises achieved consistently better results, especially spell error (*spell*), random word swapping (*swap*), and abbreviation replacing (*abbr*). These three methods tend to alter the words but do not lose their information while other methods eliminate the entire word by deleting (*drop, mask*) or replacing it with another word (*synonym, tf-idf*). This may also cause a larger mismatch between the pseudo input and output.

Hence, we draw the conclusion that *simple word-level perturbations tend to bring more effects*. This differs from the observations in text classification (Xie et al., 2020) because content preservation is important in FST. In particular, we also found that *spell* achieved the highest BLEU scores on both datasets. However, adding no perturbation even resulted in a worse performance than the base model. Moreover, *capital* is also relatively weaker than the other two rule-based methods because it

only changes the case of a chosen word. This suggests that the perturbation should not be too simple either.

4.3 Effects of Data Filtering

In this section, we analyze whether our proposed data filters are beneficial to the performance of our consistency training framework. Specifically, we chose the most effective data perturbation method *spell* to analyze the effects of adding the three data filters: style strength (*style*), content preservation (*bleu*), and fluency (*lm*) filters. As presented in Table 4, the results for different datasets and different filters have different tendencies. For example, adding the *style* filter on the E&M dataset caused negative effects while contributing the best results to the F&R domain.

Although a filter does not necessarily improve the result, this is reasonable because filters result in less pseudo data for model training and it is difficult to control the trade-off between the quality and the quantity of selected data. Nevertheless, we still observe that the *bleu* filter contributes to the highest performance of *spell* for all the metrics on the E&M domain, while *style* benefits the performance of *spell* the most on F&R, leading to the best performing models of our approach[4].

4.4 Comparison with Previous Works

We compare our best model with the following previous studies on GYAFC.

- **NMT** (Rao and Tetreault, 2018) is an LSTM-based encoder-decoder model with attention.
- **GPT-CAT** (Wang et al., 2019) adopts GPT-2 and rule-based pre-processing for informal sentences.
- **NMT-Multi-task** (Niu et al., 2018) jointly solves monolingual formality transfer and formality-sensitive machine translation via multi-task learning.
- **Hybrid Annotations** (Xu et al., 2019) trains a CNN discriminator in addition to the transfer model and adopts a cycle-reconstruction loss to utilize unsupervised data.
- **Transformers (DA)** (Zhang et al., 2020) uses three data augmentation methods, includ-

---

[4] Empirically, we also found that mixing up three filters achieved no better results than a single filter, possibly because this filtered out too much pseudo data.

Table 7: Experimental results on test sets under low-resource settings with varied parallel data size.

ing back-translation, formality discrimination, and multi-task transfer.

- **CARI** (Yao and Yu, 2021b) improves GPT-CAT by using BERT (Devlin et al., 2018) to select optimal rules to pre-process the informal sentences.

- **Chawla's** (Chawla and Yang, 2020) uses language model discriminators and maximizing mutual information to improve a pretrained BART-Large (Lewis et al., 2020) model, along with a cycle-reconstruction loss to utilize unlabeled data.

- **BART-large+SC+BLEU** (Lai et al., 2021) improves BART-large by incorporating reinforcement learning rewards to enhance style change and content preservation.

We also report the results of **Ours (base)**, our backbone T5-large model, and **Ours (best)**, our best performing models selected from Table 4.

As observed in Table 5, **Ours (best)** outperforms previous state-of-the-art models by a substantial margin and improves the BLEU scores from 76.17 and 79.92 to 78.75 and 81.37, respectively, on the E&M and F&R domains of the GYAFC benchmark. Although **BART-large+SC+BLEU** achieved better results on the Acc. of F&R, the only released official outputs of **BART-large+SC+BLEU** were obtained from a model that was trained on the training data of both domains and adopted rewards to directly optimize style accuracy; hence, it is not directly comparable to our model. **Ours (best)** improves the fine-tuned T5-large baseline by a large margin as well, demonstrating the effectiveness of our SSL framework.

Human Evaluation We also conduct human evaluation to better capture the quality of the models' outputs. Following (Zhang et al., 2020), we measure the *Formality*, *Fluency*, and *Meaning Preservation* of generated sentences by asking two human annotators to assign a score ranging from {0, +1, +2} regarding each aspect. We randomly sampled 50 examples from the test set of each domain and compare the generated outputs of **Ours (base)**, **Ours (best)**, and the previous state-of-the-art **Chawla's** model trained on the single-domain data. In addition, the annotators were unaware of the corresponding model of each output. As shown

Example 1	Source	*I like natural / real girls, I don't like fake looking prissy drama queens.*
	Ours(best)	*I like natural looking girls, not pretentious drama queens.*
	Ours(base)	*I like natural, real girls, I do not like fake looking, prissy drama queens.*
	Chawla's	*I like natural and real girls , I do not like fake looking prissy drama queens .*
	Human-Annotation	*I like natural and real girls, not fake-looking, prissy drama queens.*
Example 2	Source	*That's like Broke Back Mountain for little John Wanye.*
	Ours(best)	*That is similar to "Broke Back Mountain" for John Wayne.*
	Ours(base)	*That is like "Broke Back Mountain" for John Wayne.*
	Chawla's	*That is like Broke Back Mountain for little John Wanye .*
	Human-Annotation	*That is similar to "Brokeback Mountain" for young John Wayne.*
Example 3	Source	*You guys don't have any reason to hate each other.*
	Ours(best)	*You do not have any reason to hate each other.*
	Ours(base)	*You guys do not have any reason to hate each other.*
	Chawla's	*You guys do not have any reason to hate each other .*
	Human-Annotation	*There is no reason for you two to dislike each other.*

Table 8: Examples sampled from the test set outputs.

in Table 6, the human evaluation results are consistent with the automatic evaluation results: **Ours (base)** is competitive compared with **Chawla's**, while **Ours (best)** improves over the base model and outperforms the previous state-of-the-art on all the metrics, except that it presents lower results on *Meaning* than **Ours (base)** on F&R. More details on human evaluation can be found in Appendix D.

Qualitative Examples We present some of the generated outputs of **Ours (base)**, **Ours (best)**, and **Chawla's** in Table 8. It can be observed that all the models can produce high-quality outputs with considerable formality, meaning preservation and fluency. Nevertheless, **Ours (best)** exhibits a stronger capability to modify the original sentence, especially for some informal expressions, leading to the best performance on the *Formality* metric. For example, it replaced "like" with "similar to" in Example 2 and deleted the informal word "guys" in Example 3. However, it may alter the original sentence so much that the meaning of the sentence is changed to some extent (Example 1). This may explain why **Ours (best)** achieves a lower *Meaning* score than **Ours (base)** on F&R.

4.5 Low-Resource Experiments

We also simulate the low-resource settings by further reducing the size of available parallel data. Specifically, we randomly sample from the original training data with a size in the range of {100, 1000, 5000, 20000} and compare the results of the base model T5-Large with our SSL model. The size of unlabeled data remains 200k for each domain. We adopt the *spell* data perturbation without any data filter and avoid exhaustive hyper-parameter tuning. Table 7 demonstrates that our framework is especially effective under few-shot settings when only 100 parallel data are available. By comparing with previous state-of-the-art results on FST, we can observe that our approach can achieve competitive results with only 5000 ($< 10\%$) parallel training data, and even better results with only 20000 ($< 40\%$) parallel examples.

5 Conclusion

In this study, we proposed a simple yet effective consistency-based semi-supervised learning framework for formality style transfer. Unlike previous studies that adopted cycle-reconstruction to utilize additional target-side sentences for back-translation, our method offers a different view, to leverage source-side unlabeled sentences. Without introducing additional model parameters, our method can easily outperform the strong supervised baseline and achieve the new state-of-the-art results on formality style transfer datasets. For future work, we will attempt to generalize our approach to other text generation scenarios.

A Detailed Experimental Settings

A.1 Hyper-Parameters

We set the max length of input sentences to 50 Byte-Pair Encoding (Sennrich et al., 2016) tokens. The weight of unsupervised loss λ is set to 1.0 in all our experiments, which is an empirical choice from previous studies (Sohn et al., 2020). The batch size is 8 for the supervised objective and 56 for the unsupervised objective, such that the model can leverage more unlabeled data for training. The threshold σ for the style strength filter is set to 0.8 and the threshold ratio ϕ is set to 0.4 for both the content preservation and fluency filters. We tested σ in the discrete range between 0.5 and 0.9 and for

ϕ, we searched over the values between 0.1 and 0.8. Although the chosen values of σ and ϕ are not necessarily the best for all the datasets, we fix them in later experiments for their reasonable results.

A.2 Training Details

We train two binary style classifiers on each domain of GYAFC. The training data are the formal and informal sentences in the original training sets of the E&M and F&R domain. The classifiers are validated on the formal sentences in the original validation set. The classifier for E&M could achieve 95.69% accuracy on the validation set, while the classifier for F&R achieved 94.70%. We adopt a 4-gram Kneser-Ney language model to compute perplexity scores for the fluency data filter. During semi-supervised training, we first pretrain the model solely on the supervised data for 2000 steps to achieve a good initialization of the model parameters. Then, we jointly train the supervised and consistency losses simultaneously. The model checkpoint is validated with an interval of 1000 steps and selected based on the best BLEU score on the validation set. Early stopping is also adopted with patience 10. We employ beam search with beam width 5 for the model's generations and pseudo-target prediction[5]. All our experiments are conducted on NVIDIA A100 (40GB) GPUs.

A.3 Details of Unlabeled Data Collection

We collected 200k from each of the E&M and F&R domains of Yahoo Answers L6 corpus. The collection procedure is as follows. (1) We chose the passages labeled "<bestanswer>" in the corpus and tokenized them into separate sentences. (2) We filtered out sentences with formality scores larger than 0.5 (i.e. judged as formal) predicted by the style classifier we built for model evaluation. (3) We built an N-gram language model by training on the informal sentences in the original training data of GYAFC, and used it to generate perplexity scores for these sentences. We kept 200k sentences with lowest perplexity scores, such that we obtained a collection of the most informal sentences in the corpus. We only observed one overlapping sentence with the test set of each domain, which we considered negligible and kept in the data.

A.4 Details of Data Perturbation

All our data perturbation methods are implemented based on the nlpaug[6] library. We set the ratio of perturbed words in a sentence to 0.1 for all word-level perturbation methods and deduced that increasing the ratio could often result in lower results, as that will enhance the difference between the original and perturbed sentences, which is consistent with our conclusion in Section 4.2. We present examples of all data perturbation methods in Table 9.

We also attempted mixing different perturbations with *spell*, but did not obtain better results than single *spell*. This can also be attributed to the conclusion that simple perturbations are even better.

B Formal Description of the Algorithm

Here, we provide a formal algorithmic description of our consistency training framework in Algorithm 1 and assume that we adopt content preservation (BLEU) data filtering or fluency (perplexity) data filtering in this algorithm to include the formal description of our dynamic threshold strategy. We omit the case when we adopt style strength filtering because it does not use the dynamic threshold and is more straightforward to understand.

C Details of Dynamic Threshold Selection

Here, we provide more details of the dynamic threshold strategy for the content preservation and fluency filters. In practice, we do not filter any pseudo data in the initial warm-up steps of consistency training, to initialize the score list. Furthermore, after iterating an epoch of the unsupervised data, we keep the current threshold fixed and do not update the score list any more. The score list is implemented as a skiplist to enable $O(\log N)$ insertion into an ordered list. The overall time complexity of the data filtering is $O(\log 1 + \log 2 + \cdots + \log N) = O(\log N!) = O(N \log N)$, where N is the number of unlabeled data.

D Details of Human Evaluation

We describe the rating criteria in the human evaluation. We ask two well-educated annotators to rate the *formality*, *fluency*, and *meaning preservation* on a discrete scale from 0 to 2 for the model outputs, following (Zhang et al., 2020). During the annotation, we randomly shuffle the sentences

Finetune $\theta$ on $\mathcal{D}$ via Equation (1).
                                                                    ▷ Semi-supervised training
repeat
    Sample a batch $\mathcal{B}_D = \{(\mathbf{x}_i, \mathbf{y}_i)\}_{i=1}^{B}$ from $\mathcal{D}$.
    Sample a batch $\mathcal{B}_U = \{\mathbf{u}_i\}_{i=1}^{\mu B}$ from $\mathcal{U}_S$.
    Obtain $\mathcal{B}_U' = \{\tilde{\mathbf{u}}_i | \tilde{\mathbf{u}}_i = c(\mathbf{u}_i)\}_{i=1}^{\mu B}$.
    Generate pseudo targets $\mathcal{B}_Y = \{\hat{\mathbf{y}}_i | \hat{\mathbf{y}}_i = \text{argmax} P(\mathbf{y}|\mathbf{u}_i; \theta)\}_{i=1}^{\mu B}$.
    Compute a batch of data filter scores $L_B = \{b_i | b_i = f(\mathbf{u}_i, \hat{\mathbf{y}}_i)\}_{i=1}^{\mu B}$
    Insert $L_B$ into $L$ while maintaining the decreasing order of $L$.
    Obtain $s = L[\sigma \times len(L)]$ as the threshold.
    if $ft$ = BLEU then
        Obtain a filtered pseudo-parallel batch $\mathcal{B}_f = \{(\tilde{\mathbf{u}}_i, \hat{\mathbf{y}}_i) | b_i > s, i = 1, , \ldots, \mu B\}$
    else if $ft$ = perplexity then
        Obtain a filtered pseudo-parallel batch $\mathcal{B}_f = \{(\tilde{\mathbf{u}}_i, \hat{\mathbf{y}}_i) | b_i < s, i = 1, , \ldots, \mu B\}$
    end if
    Compute consistency loss $\mathcal{L}_{unsup} = \mathbb{E}_{(\tilde{\mathbf{u}}, \hat{\mathbf{y}}) \sim \mathcal{B}_f}[-\log P(\hat{\mathbf{y}}|\tilde{\mathbf{u}}; \theta)]$.
    Compute supervised loss $\mathcal{L}_{sup} = \mathbb{E}_{(\mathbf{x}, \mathbf{y}) \sim \mathcal{B}_D}[-\log P(\mathbf{y}|\mathbf{x}; \theta)]$.
    Optimize $\mathcal{L} = \mathcal{L}_{sup} + \lambda \mathcal{L}_{unsup}$ and update $\theta$.
until CONVERGE
```

from the three models and make the model names invisible to annotators.

Formality The annotator are asked to rate the formality change level given a source informal sentence and the generated output sentence, regardless of the fluency and meaning preservation. If the output sentence improves the formality of the source sentence significantly, the score will be 2 points. If the output sentence improves the formality but still keeps some informal expressions, or the improvement is minimal, it will be rated 1 point. If there is no improvement on the formality, it will be rated 0 points.

Fluency The fluency is rated 2 points if the output sentence is meaningful and has no grammatical error. If the target sentence is meaningful but contains some minor grammatical errors, it will be rated 1 point. If the sentence is incoherent, it will be rated 0 points.

Meaning Preservation Given a source sentence and a corresponding output sentence, the raters are asked to ascertain how much information is preserved in the output sentence compared to the input sentence. If the two sentences are exactly equivalent, the output obtains 2 points. If they are mostly equivalent but different in some trivial details, the output will receive 1 point. If the output omits important details that alter the meaning of the input sentence, it is rated 0 points.

Cross-Lingual Ability of Multilingual Masked Language Models: A Study of Language Structure

Yuan Chai[1,*], **Yaobo Liang**[2], **Nan Duan**[2]

[1]`chaiyuan@buaa.edu.cn`
[2]`{yalia, nanduan}@microsoft.com`

Abstract

Multilingual pre-trained language models, such as mBERT and XLM-R, have shown impressive cross-lingual ability. Surprisingly, both of them use multilingual masked language model (MLM) without any cross-lingual supervision or aligned data. Despite the encouraging results, we still lack a clear understanding of why cross-lingual ability could emerge from multilingual MLM. In our work, we argue that cross-language ability comes from the commonality between languages. Specifically, we study three language properties: constituent order, composition and word co-occurrence. First, we create an artificial language by modifying property in source language. Then we study the contribution of modified property through the change of cross-language transfer results on target language. We conduct experiments on six languages and two cross-lingual NLP tasks (textual entailment, sentence retrieval). Our main conclusion is that the contribution of constituent order and word co-occurrence is limited, while the composition is more crucial to the success of cross-linguistic transfer.

1 Introduction

Zero-Shot Cross-Lingual transfer aims to build models for the target language by reusing knowledge learned from the source language. In this way, models can be efficiently implemented in multilingual as well as low-resource language scenarios. Traditionally, it is solved by a two-step pipeline (Ruder et al., 2019): a shared multilingual textual representation is first built and then supervised data from the source language is used on the top of it to train task-specific models. With the recent emergence of multilingual language models, the standard paradigm in this field has shifted to the pre-trained fine-tuning paradigm. Multilingual pre-trained language models, such as mBERT (Devlin et al., 2019) and XLM-R (Conneau et al., 2020a), have proven effective for cross-lingual transfer with better results on a large number of downstream tasks and languages (Pires et al., 2019; Conneau et al., 2020a).

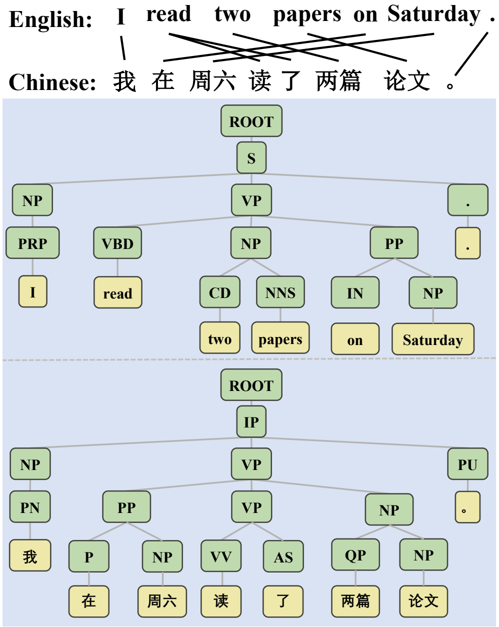

Figure 1: Example of two sentences in different languages, which are different in constituent order, but are very similar in constituent tree. Note that we simplify the constituent tree for better understanding.

The most surprising part is that mBERT and XLM-R are both trained without using any parallel corpus. Previous work (Pires et al., 2019; Wu and Dredze, 2019) attribute this success to the shared anchor words. But recent work (Conneau et al., 2020b; K et al., 2020) shows that cross-lingual transfer still could emerge even corpus of languages are from different domain, or don't share any common words. For cross-lingual model, sharing transformer encoder weight is critical, while whether having language specific word embedding or language identity marker is not important. This makes us more curious about what kind of common prop-

May 22-27, 2022 ©2022 Association for Computational Linguistics

erty of languages could make cross-lingual transfer successful.

In our work, we study three language structure properties: 1) Constituent order. Specifically, we study three common constituent orders: order of verb and object, adposition and noun phrase, adjective and noun. 2) Composition. Composition means that we could combine two or several simple meanings and build a new more complicated meaning. For example, two words could form a phrase, and more composition could form a sentence recursively. 3) Word co-occurrence. We take the bag of words assumption and study the word co-occurrence in a sentence.

We use Figure 1 to better show the composition similarity between two sentences. Although the English sentence and Chinese sentence have different word order, but they are both first divided into a noun phrase and a verb phrase, and the verb phrase is then divided into three parts that are identical in meaning but inconsistent in order.

To better analyze the contribution of these three properties, we use the control variable method. Based on a successful transfer between the source and target languages, we change or remove only one structure property in the source language. We measure the importance of this property by testing the change in performance of the cross-language transfer from the modified source language to the target language. The results show that the effect of constituent order and word co-occurrence is small, while composition has a greater effect.

The main contributions are summarized as follows: (1) We analyze the source of cross-linguistic ability from shared properties in language structure and propose three candidate answers. (2) We used the control variable method, modifying only the target property in the corpus and keeping the other settings identical, thus better quantifying the contribution of the studied properties. (3) Our experiments clearly show that constituent order and word co-occurrence make very limited contributions to cross-lingual ability, while composition is the key to cross-lingual transfer.

2 Study Design

In this section, we introduce the design of our study, including the three language structure properties, and the overall setup. We also detail the pre-training and fine-tuning settings for better reproduction.

2.1 Dissecting Language Structure

Constituent Order In constituent tree, the constituents in a grammar rule are often ordered. For example in English, "`S->NP VP`" means that we should put the noun phrase at beginning of sentence and put the verb phrase after it. There are many linguistic studies to summarize and compare the constituent order of different languages, such as WALS (Dryer and Haspelmath, 2013). We mainly study three WALS features, 83A (Order of Object and Verb), 85A (Order of Adposition and Noun), and 87A (Order of Adjective and Noun).

Composition Composition means to combine two or several meanings and build a new more complicated meaning. As shown in Figure 1, "two" and "papers" could form a new meaning "two papers". And we could further combine it with "read" to form "read two papers". To better dissect the language structure, the composition in our study doesn't have order. By recursively combining meanings, we could express infinite meanings with finite words. The combination process forms an unordered tree.

Word Co-Occurrence In our paper, we study the word co-occurrence at the sentence level. Some words often co-occur in a context window or a sentence. As shown in Figure 1, the word co-occurrence of sentences with same meaning may also be similar in different languages, which may be a source of cross-lingual ability.

The natural language sentences of most languages are composed of a list of ordered words. But different languages may have different word order. We argue that most research about word order, for example research in WALS, are studying constituent order. The term "word order" hypothesis that any word could have any neighboring word. But "constituent order" hypothesis that some words should always group together and form a constituent and the order between groups are the object of study. The words from two constituents are unlikely to be neighboring words. Based on this, we dissect the "word order" into two concepts "constituent order" and "composition". "composition" is the rules to group words to phrase, clause and sentence. If we remove all the word order information, we will only have a set of unordered words and we name this feature as word co-occurrence. Bag-of-Word assumption only takes word co-occurrence information and has achieved great success in topic modeling and word embedding. We also hope to study its influence to cross-lingual ability of MLM.

2.2 Overall Setup

Bilingual Pre-training Following previous studies (Conneau et al., 2020b; K et al., 2020), our experiments were done on the corpus of only two languages, source (English) and target (multiple languages). By involving only one pair of languages, we can ensure that the performance of a given target language is only affected by the source language, without worrying about interference from a third language. In our work, we select English as source language because it has best constituent parser and most of cross-lingual benchmarks only have English training data.

Only Modify Source Language We believe the source of cross-lingual ability is the commonality between languages, and it can be destroyed by modifying either language in the pair. We decide to only modify source language and leave target language unmodified. This makes results on target language comparable to each other and ensures that changes in the results only come from changes of language property rather than modifications in the target language. By keeping the other settings the same and modifying only the source language, we exclude the interference of extraneous factors. This setup follows the control variable method and allows a more precise quantification.

Consistent in Pre-training and Evaluation We study the different commonality by creating a new language. So we make modifications both in pre-training and downstream evaluation. This consistency could help to generalize our conclusions to new languages beyond the 100 human natural languages. For example, the new languages could be other modalities like image, audio and video. Or programming languages like Python, Java and Lisp. We may meet extra-terrestrial someday and could access their unlabeled textual corpus. We still hope cross-lingual research could help us to understand their languages.

2.3 Multilingual Masked Language Model

Our multilingual masked language model pre-training follows the standard setup such as mBERT, XLM-R. Specifically, we mask 15% of the input tokens, of which 80% are replaced with mask tokens, 10% keep the original words, and 10% are randomly replaced with sampled words from the multilingual vocabulary. The training objective is to recover the masked tokens. We use the entire Wikipedia for each language as pre-training data and the model parameters are shared across languages. Unlike standard multilingual pre-trained models, the vocabulary in our experiments is not shared across languages. To remove confounding factors, our vocabulary is learned individually on each language using BPE (Sennrich et al., 2016), as (Conneau et al., 2020b; K et al., 2020) have demonstrated that sharing vocabulary has a very limited effect on cross-lingual transfer. Note the softmax prediction layer shared across languages is still preserved.

Implementation Details We use base size model in each experiment, which is a Transformer (Vaswani et al., 2017) with 12 layers, 12 heads, and GELU activation functions. The vocabulary size is 32k for each language, the embedding dimension is 768, the hidden dimension of the feed-forward layer is 3072, and the dropout rate is 0.1. We use the Adam optimizer and the polynomial decay learning rate scheduler with 3×10^{-4} learning rate and 10k linear warm-up steps during training. We train each model with 8 NVIDIA 32GB V100 GPUs and use total batch size 2048 with gradient accumulation strategy. We stop pre-training at 160k steps and evaluate the pre-trained model on downstream tasks every 8k steps and report the best result.

2.4 Downstream Cross-lingual Evaluation

We consider Cross-lingual Natural Language Inference (XNLI) dataset (Conneau et al., 2018) and Tatoeba dataset (Artetxe and Schwenk, 2019) in XTREME benchmark (Hu et al., 2020) to evaluate performance.

XNLI is a standard cross-lingual textual entailment dataset, which asks whether a premise sentence entails, contradicts, or is neutral toward a hypothesis sentence in the same language. We use the **zero-shot cross-lingual transfer** setting, where we first fine-tune the pre-trained model with source (English) language and then directly test the model with target language. XNLI is a three-category classification task which uses accuracy as its metric. The three categories in the test set are uniformly distributed, so the score of random guesses is 33.33%.

Tatoeba is a cross-lingual sentence retrieval dataset which consists of up to 1,000 English-aligned sentence pairs covering 122 languages. Tatoeba uses the source to target Top-1 accuracy as its metric. Note that Tatoeba only has test set so we use the pre-trained model directly without fine-tuning.

Evaluation Details For XNLI, the task-specific layer is a two layer linear mapping with tanh function between them, which takes the `[cls]` token as input. We use the Adam optimizer and linear decay learning rate scheduler with 7×10^{-6} learning rate and 12.5k linear warmup steps during fine-tuning. We fine-tune each model with batch size 32 for 10 epochs and evaluate on the English dev set every 3k steps to select the best model. We report the result on average of four random seed. For Tatoeba, we use the average pooling subword representation (excluding special token) of sentences at the 8-th layer as sentence representations following XTREME settings (Hu et al., 2020). Evaluation is done by finding the nearest neighbor for each sentence in the other language according to cosine similarity.

3 Constituent Order

Previous work(Pires et al., 2019) has argued that the cross-lingual transfer performance between languages with same constituent order is 10%-20% better than languages with different constituent order. So we further conduct control variate experiments to study the influence of constituent order. First we introduce the constituent order we studied and experiment setup. Then we analyze the effects of constituent order through the results. Our main conclusion is that the contribution of constituent order is about 1%.

3.1 Constituent Order Modification

Following (Naseem et al., 2012; Pires et al., 2019), we use a subset of order-related features from WALS to study constituent order. Specifically, we examine:

- **Order of Object and Verb.** Corresponding to 83A in WALS and grammar "`VP->VB NP`" in the constituent tree. Two orders are defined in WALS, OV for Object-Verb order and VO for Verb-Object order. English is an OV language and we change it to VO by changing the grammar to "`VP->NP VB`". Note that we consider all tags starting with `VB` (`VBZ`, `VBD`) as `VB`.
- **Order of Adposition and Noun Phrase.** Corresponding to 85A in WALS and grammar "`PP->IN NP`" in the constituent tree. Two orders are defined in WALS, Prepositions (Pre) for Preposition-Noun Phrase order and Postpositions (Post) for Noun Phrase-Postposition order. English is a Prepositions language and we change it to Postpositions by changing the grammar to "`PP->NP IN`".
- **Order of Adjective and Noun.** Corresponding to 87A in WALS and grammar "`NP->JJ NN`" in the constituent tree. Two orders are defined in WALS, AN for Adjective-Noun order and NA for Noun-Adjective order. English is a AN language and we change it to NA by changing the grammar to "`NP->NN JJ`".

Specifically, we use the Constituency Parsing tool in Stanford's CoreNLP (Manning et al., 2014) to obtain the constituent trees. For each order-related feature, we filter out the parent node and children nodes satisfy the feature's grammar. For example, the grammar for order of object and verb is "`VP->VB NP`". We filter out the parent node, whose constituent label is VP, with and only with two children nodes, whose constituent labels are VB and NP respectively. Then we will change the order of the two children nodes. After we recursively check and modify all tree nodes, we in-order traverse the tree and get the sentence with constituent order modified. In Figure 2, we show examples of modifying constituent order.

We select Spanish, Russian, Hindi, Turkish, Thai, and Vietnamese as target languages, considering the variance of script, typological features and pre-training resources.

Unlike the analysis of correlations between constituent order and results of target languages (Pires et al., 2019), we follow the principle of control variables and modify the constituent order directly in the corpus. In this way, we can ensure that the differences in results come from constituent order modifications only.

3.2 Effect of Constituent Order

Table 1 and Table 2 show the results on XNLI and Tatoeba. With the results of modifying three features and test on six different target languages, we can draw the following three conclusions:

Modifying constituent order barely affects source language. As shown in 1, modifying constituent order in the source language barely change

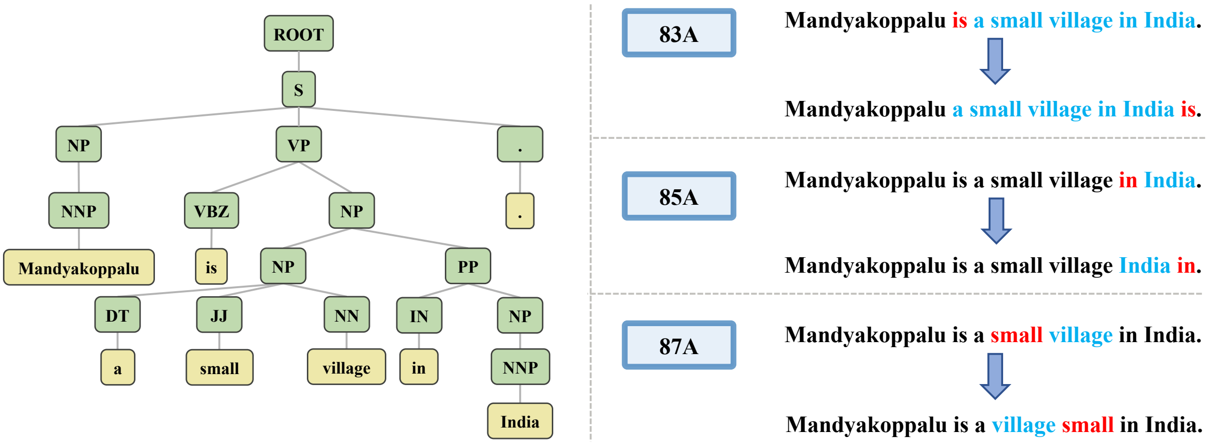

Figure 2: Example of constituent tree and constituent order modification based on WALS features. 83A, 85A and 87A represent order of object and verb, order of adposition and noun phrase and order of adjective and noun.

en-NA	76.8	52.6	78.5

Table 2: Comparison of Tatoeba results before and after modification of constituent order.

its XNLI results (basically 0.3%). This means that our modifications do not affect the overall meaning of the language. The modified language is still a reasonable language for both humans and models.

Changing source language's constituent order to same as target language could improve cross-lingual transfer. In Tables 1 and 2, we find that modifying constituent order achieves consistent gains on most low-resource languages. For example, modifying 83A in Turkish achieves gains 0.79% on XNLI and 5.6% on Tatoeba , 85A in Hindi gains 0.74% on XNLI and 4.4% on Tatoeba , 87A in Vietnamese gains 0.31% on XNLI and 2.5% on Tatoeba . However, this pattern is not very stable in high-resource languages. For example, 87A in Spanish gains only 0.08% on XNLI and decreases by 5.4% on Tatoeba instead.

The overall effect of modifying constituent order to cross-lingual transfer is limited. No matter what modification is made, the results on six different target languages showed very limited changes (basically within 1% on XNLI and 8% on Tatoeba). This further suggests that constituent order has limited effect on cross-lingual transfer. In other words, constituent order is not the key component of language structure. As for the magnitude of the variation, it is slightly higher on Tatoeba than on XNLI. We believe there are two main reasons. First, the average sentence length of Tatoeba is lower than XNLI, so the effect of modification will be magnified. Second, Tateoba doesn't have training data and the zero-shot evaluations are highly unstable. For example, (Phang et al., 2020) achieved more than 20% gains by fine-tuning the model on XNLI at first.

3.3 Comparison to Previous Work

The "conflict" conclusion between our work and Pires et al. 2019 is because of the difference of experiment design. In the experiment about object and verb order, Pires et al. 2019 change the source language to totally different language, and test on target languages. For example train on English (VO) or Hindi (OV), and test on French (VO). And they found the transfer from VO to VO is much better than transfer from OV to VO. While our experiments use modified English. We argue that the verb and object order isn't the only difference of source language in their experiment. For example, most of Europe languages are VO and most of Central Asia languages are OV. Languages in the same region are more similar than languages in different region. Our work conduct control variate experiments and could analysis the importance of constituent order better.

4 Composition: The Key to Zero-Shot Cross-Lingual Transfer

In this section, we study the contribution of constituent order, composition and word co-occurrence respectively. We first present how to completely remove constituent order and composition step-by-step from the corpus, and then analyze the results. Subsequently, by controlling the rate of composition retention, we further quantified its contribution to cross-lingual transfer.

4.1 Language Ablation of Removing Constituent Order and Composition

First, we introduce several experiments settings:

Constituent Shuffle: Removing Constituent Order. When removing the constituent order, we should be careful to keep the composition untouched. As shown in Figure 3, we shuffle the children nodes of same intermediate node in the constituent tree, while preserving the parent-children relation between nodes unchanged. By comparing its results with the baseline, we can quantify the contribution of constituent order.

Word Shuffle: Removing Constituent Order and Composition. To further remove the composition, we randomly shuffle the words in sentence. This "Word Shuffle" operation will remove constituent order and composition together. By comparing it with the results of "constituent shuffle", we can quantify the contribution of composition.

Baselines Without Pre-training: Removing Constituent Order, Composition and Word Co-occurence. We also provide a "Without Pre-training" baseline in XNLI and "Word Embedding Average" baseline in Tatoeba to quantify the contribution of word co-occurrence by comparing with "Word Shuffle". On XNLI, "Without Pre-training" represents a Transformer model with same structure as pre-trained model but with random initialized weights. Then we fine-tune it with source language and test on target languages. Because Tatoeba doesn't have any training data, we use the average of word embedding as a baseline. The word embedding is extracted from the embedding layer of "word shuffle" setting. The performance of word embedding average baseline still credits to word-occurrence but not to pre-training.

Second, to quantify the modification degree, we define two metrics. Inversion Ratio is the number of inverse pairs in the modified sentence, which normalized by the number of total word pairs in the sentence. Word Move Distance is the average distance of each word moved in sentence, which normalized by length of each sentence. As shown in Table 3, the sentences after constituent shuffle and word shuffle are almost identical in two metrics and both much higher than sentences modifying local constituent order. This shows that constituent shuffle also makes lots of word order modifications and has high randomness.

source type	IR (%)	WMD (%)
en-OV	3.04	2.71
en-Post	4.26	3.66
en-AN	0.49	0.35
Constituent Shuffle	50.44	31.1
Word Shuffle	51.89	33.54

Table 3: Inversion Ratio (IR) and Word Move Distance (WMD) of the modifications used in the experiments.

4.2 Contribution of Each Part

We present the results in Table 4 and Table 5. we can draw the following three conclusions:

On monolingual pre-training and fine-tuning,

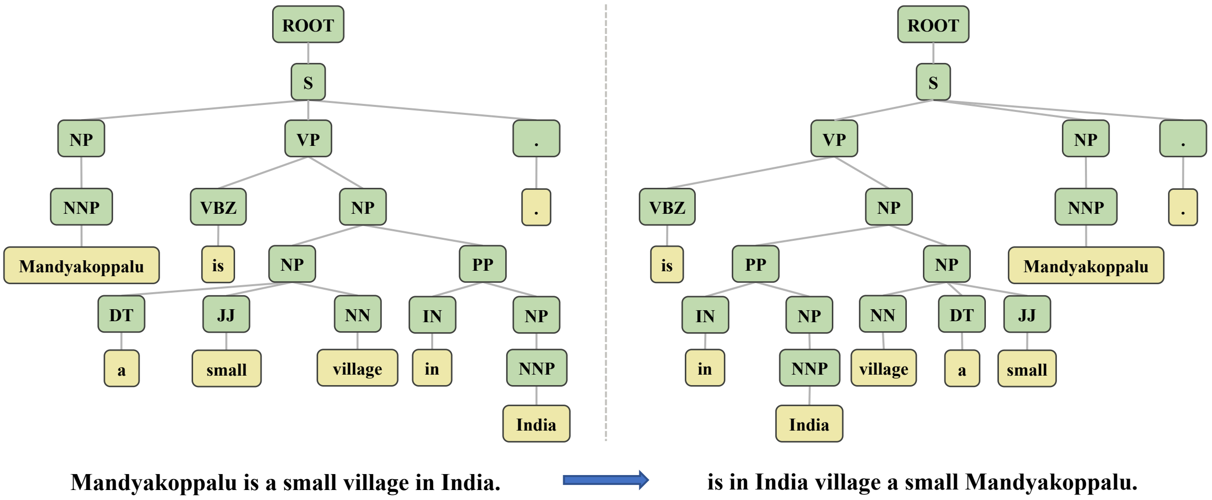

Figure 3: Example of constituent shuffle by disordering children of each intermediate node in constituent tree.

source type	es		ru		hi	
	source	target	source	target	source	target
Original Language	83.97	78.11	83.93	73.90	83.83	69.46
Constituent Shuffle	81.88	76.42	81.40	71.25	81.97	70.18
Word Shuffle	70.45	39.84	71.34	35.14	70.37	39.16
Without Pre-training	56.67	34.27	56.43	35.20	56.71	34.44
Random Guess	33.33	33.33	33.33	33.33	33.33	33.33

Table 4: Comparison of XNLI results before and after removing constituent order and composition.

source type	es	ru	hi
Original Language	82.2	78.1	60.6
Constituent Shuffle	68.3	49.4	55.2
Word Shuffle	37.0	10.6	15.7
Word Embedding Average	32.3	8.5	13.5
Random Guess	0.1	0.1	0.1

Table 5: Comparison of Tatoeba results before and after removing constituent order and composition.

pre-training without composition still achieve good results. We can observe that whether removing constituent order or removing composition in the source language, it still shows meaningful results (much higher than random guess) on XNLI. This illustrates that textual entailment of monolingual languages can have good performance relying only on word co-occurrence.

Cross-lingual transfer works with composition and doesn't work without composition. When the constituent order is removed, only a limited performance loss (within 3%) is shown on both the source and target languages, and it is almost constant on the performance gap between source and target languages. This shows again that the contribution of constituent order to cross-language transfer is very limited and it is not a critical component of the language structure. However, when composition is removed, the cross-lingual transfer results on target language are only slightly higher than random guess. This clearly shows that composition is the key to cross-lingual transfer. As for word co-occurrence, it only contributes 5% on XNLI and 10% to 15% on Tatoeba. These results show that it does make some contribution but the contribution is very limited. Relying on word co-occurrence alone is not enough for a reasonable cross-lingual performance.

Removing constituent order and keeping composition may improve cross-lingual transfer. We observe an interesting result in Table 4. There is about 2% drop on both Spanish and Russian after removing constituent order. However, the results show a 0.7% improvement on Hindi while English dropped 2%. We think this is because that model relies on every possible feature to solve English task but only relies on the commonality between language to achieve cross-lingual transfer. The model will use constituent order and composition feature to solve XNLI in unmodified English but only could use composition feature in constituent shuffled English. For languages with similar constituent order to English, more language features may lead to better performance. But for languages

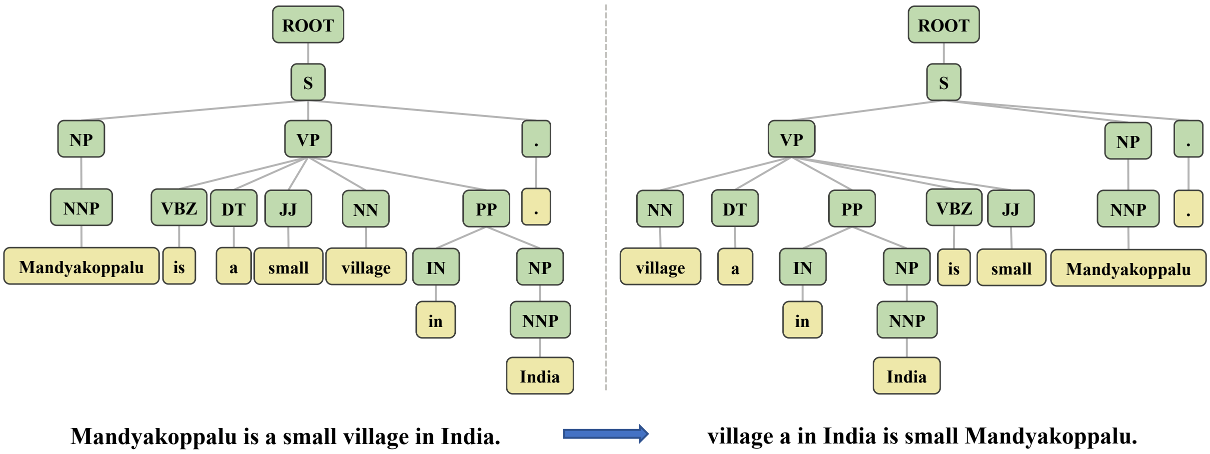

Figure 4: Example of removing intermediate nodes and disordering on the constituent tree.

with different constituent order to English, only rely on composition will lead to better generalization ability. This further shows that constituent order is not key to cross-lingual transfer, and composition is the most important commonality between all languages.

4.3 Detailed Analyze Composition

To further quantify the effect of composition, we remove it in different degrees. As shown in Figure 4, we randomly remove the ratio α of intermediate nodes in the constituent tree. For each removed node, all its children are connected to its father. Note that an intermediate node is defined as a non-root node with more than one children. We show Spanish results only due to space limitation.

α		0	0.25	0.5	0.75	1
XNLI	source	82.36	81.44	81.09	80.66	70.45
	target	76.61	76.19	75.22	74.17	39.84
Tatoeba		83.1	69.8	62.9	54.8	47.7

Table 6: Comparison of XNLI and Tatoeba results on Spanish at different ratio in removing composition similarity.

In Table 6, We observe that when we remove 75% of the composition, the results on XNLI are still higher than when we completely remove it. While on Tatoeba, there is a significant decrease in the results as more compostion is removed. We argue this is due to the difference in sentence length, which is much higher in XNLI than Tatoeba. Even with 75% removed, the absolute value of retained composition is still much higher in XNLI. This result shows that only a certain ratio composition is required for reasonable performance, which shows again that composition is crucial for cross-linguistic transfer.

5 Related Work

Multilingual Pre-Training mBERT and XLM-R train multilingual MLM without using any parallel corpus and show strong cross-lingual ability. mBERT is an extension of BERT which is pre-trained on Wikipedia data over 100 languages to learn a language-invariant feature space shared across multiple languages. XLM-R (Conneau et al., 2020a) is trained on 2.5T data over 100 languages extracted from Common Crawl (Wenzek et al., 2020), which demonstrates the effect of the model trained on a large-scale corpus. Results of XLM-R on a large number of downstream cross-lingual tasks show that a large-scale training corpus can significantly improve the performance of multilingual models.

Other methods use parallel corpus in multilingual pre-training. XLM (Conneau and Lample, 2019) introduces a Translation Language Model (TLM) based on the parallel corpus which shows significant improvement on downstream tasks. Unicoder (Huang et al., 2019) introduces a multitask learning framework to learn cross-lingual representations with monolingual and parallel corpora, achieving further gains. ALM (Yang et al., 2020) allows the model to learn cross-lingual code-switch sentences, enhancing the transfer ability. Recent studies INFOXLM (Chi et al., 2021), HICTL (Wei et al., 2021), VECO (Luo et al., 2021) and ERNIE-M (Ouyang et al., 2021) use contrastive learning, back translation and other tricks further enhancing the performance of the multilingual model. Our work focus on studying the model only with multilingual MLM, and leave the study of works with parallel data as future work.

Probing Multilingual MLM mBERT and XLM-R have successfully achieved excellent cross-lingual transfer performance without using any parallel corpus. Researchers have wondered what the source of this cross-lingual ability is. (Pires et al., 2019) examines the zero-shot cross-lingual transfer performance on NER (Pan et al., 2017) and part-of-speech (POS) tagging. They believe this success comes from the shared anchor words between languages. Not coincidentally, similar conclusion is reached by (Wu and Dredze, 2019). However, this conclusion is proven inaccurate by (Conneau et al., 2020b; K et al., 2020). Their experiments show that the model still learns cross-lingual transfer ability on the corpus without anchor words at all. Besides, (Conneau et al., 2020b; K et al., 2020; Artetxe et al., 2020; Libovický et al., 2020; Muller et al., 2021) have analyzed the cross-lingual ability of multilingual masked language models in terms of language similarity, shared model parameters cross languages, model structure, training objectives, language marker. The results suggest that structure similarity and shared parameters between languages are crucial for cross-lingual transfer. In this paper, we focus on analyzing language structure. We decompose it into constituent order, composition, and word co-occurrence and study the effect of each part separately.

Word Order in Machine Translation and Masked Language Model Finding the appropriate word ordering in target languages significantly influences the machine translation quality for statistical machine translation (Tillmann, 2004; Chiang, 2007), neural machine translation (Kawara et al.; Zhao et al., 2018) and non-autoregressive neural machine translation (Ran et al., 2019). This is because the input and output sentence for machine translation have different order and the evaluation metrics also consider the output word order. While our study is different because we only focus on classification tasks and their outputs don't need to consider word order.

Ji et al. 2021 shows that adapting word order could get about 1% gain. While our composition reordering also could get about 1% gain. But all these gains still show that constituent order is not important for cross-lingual transfer because that removing composition will lead to more than 30% difference. Sinha et al. 2021 shows that word order is not important for English monolingual pre-training. After removing composition, our experiments also show that the performance on source languages won't drop a lot. But the performance on target language will drop more than 30%. This proves that composition is not the key for English monolingual pre-training but the key for cross-lingual transfer.

6 Conclusion

In this paper, we study the source of cross-lingual ability in the multilingual masked language model in the view of language structure. We study three language structure properties: constituent order, composition and word co-occurrence. The experiments are conducted using control variable method. we create an artificial language by modifying property in source language. We quantify the contribution of these three properties separately through cross-language transfer performance changes from the modified language to the target language. The results show that the contribution of constituent order and word co-occurrence are very limited, while composition is actually the key to cross-lingual transfer. How to use this finding to enhance pre-trained multilingual language models and improve performance on cross-lingual NLP tasks will be our focus for future work.

Abstract

Word sense disambiguation (WSD) is a crucial problem in the natural language processing (NLP) community. Current methods achieve decent performance by utilizing supervised learning and large pre-trained language models. However, the imbalanced training dataset leads to poor performance on rare senses and zero-shot senses. There are more training instances and senses for words with top frequency ranks than those with low frequency ranks in the training dataset. We investigate the statistical relation between word frequency rank and word sense number distribution. Based on the relation, we propose a Z-reweighting method on the word level to adjust the training on the imbalanced dataset. The experiments show that the Z-reweighting strategy achieves performance gain on the standard English all words WSD benchmark. Moreover, the strategy can help models generalize better on rare and zero-shot senses.

1 Introduction

Word sense disambiguation (WSD) has been a long-standing problem in natural language processing community. The task can benefit many downstream applications (Navigli, 2009), including but not limited to machine translation (Vickrey et al., 2005; Pu et al., 2018) and information retrieval (Stokoe et al., 2003; Zhong and Ng, 2012).

The goal of the WSD task is to disambiguate word senses given contexts. For example, the word "*lift*" in the context "*Lift* a load" and "The detective carefully *lifted* some fingerprints from the table" has different meanings. The former one means "raise from a lower to a higher position" and the latter one means "remove from a surface". From semantic recognition of human being, the former sense is easier to disambiguate as it is the most common sense of the word while the latter one is a relatively rare one.

A skewed distribution exists in SemCor (Miller et al., 1993), a commonly used human-labeled dataset for the WSD task, where most common senses have many training examples while rare senses have much fewer examples. A large coverage of senses are not accompanied with training examples, which are called zero-shot senses. Many deep neural-networks-based methods are affected by this imbalanced training corpora (Luo et al., 2018; Huang et al., 2019b).

Previous approaches attempt to address this problem by designing a new dataset or task specifically for the rare senses and zero-shot senses (Holla et al., 2020; Blevins et al., 2021; Barba et al., 2021) or enriching the sense embeddings by incorporating external lexical knowledge (Kumar et al., 2019; Scarlini et al., 2020; Blevins and Zettlemoyer, 2020). Different from these methods, we address the unbalanced training issue from the perspective of adjusting the learning process.

An interesting human language phenomenon is that it follows a statistical distribution described by Zipf's law (Zipf, 1949), which also exists in many corpora including SemCor. From the linguistic perspective, an explanation for Zipf's law is that people tend to use more common words to minimize the communication effort (Zipf, 1949). Inspired by this, we consider a word with top rank in frequency should be assigned high training weight.

From the statistical perspective, two laws have been proposed to explain Zipf's law in word frequency, namely the meaning-frequency law (Zipf, 1945) and Zipf's law of abbreviation (Florence, 1950; Grzybek, 2006). The meaning-frequency law proposes that more frequent words have larger number of word senses, which we also denote as larger word #sense. Based on this, we calculate the word #sense distribution in SemCor and use a mathematical function to fit the relation between word rank and word #sense. Based on the relation, we design the Z-reweighting strategy on the word

May 22-27, 2022

level to help models generalize better to rare and zero-shot senses.

To the best of our knowledge, we are the first to leverage linguistic distribution to address the training bias on the WSD task. Our method improves the generalization ability of deep neural models on rare senses and zero-shot senses. Results on all English words WSD evaluation benchmarks show that our system achieves improvement on rare and zero-shot senses by 2.1% and 3.6% on F1 score. Furthermore, our strategy outperforms the system without any reweighting strategy and achieves a performance gain on the F1 score on all senses. We open source our code.[1]

2 Related works

2.1 Word Sense Disambiguation

Word sense disambiguation is to distinguish the sense of a specific word given a context sentence. Current methods can be broadly classified into two streams, supervised-learning-based and knowledge-based. Supervised-learning-based approaches view the WSD task as a classification problem. For example, Zhong and Ng (2010) learn classifiers independently for each word. Knowledge-based methods, such as (Banerjee et al., 2003; Basile et al., 2014), mainly exploit two kinds of knowledge: 1) the gloss, usually in the form of a sentence defining the word sense; 2) graph structure of lexical resources.

Recent researches integrate supervised learning and knowledge into a unified system and achieve better performance than systems relying on knowledge only. For utilizing gloss, GlossBert (Huang et al., 2019b) constructs context-gloss pairs and conducts sentence-pair classification training. Bi-encoder (Blevins and Zettlemoyer, 2020) proposes an end-to-end learning system to train the embedding space of context words and senses together. For utilizing structure properties, EWISE (Kumar et al., 2019) injects gloss and knowledge graph embedding into sense embeddings. EWISER (Bevilacqua and Navigli, 2020) further injects relational knowledge as additional supervision.

Different with the previous approaches, we focus on addressing training bias caused by the imbalanced distribution in the training dataset. In this paper, we analyze the formulation of the distribution and propose the Z-reweighting method to improve performance on rare and unseen senses.

2.2 Zipf's Law in Word Frequency

Power law distribution widely exists in human language, where the word frequency can be described by Zipf's law (Zipf, 1949). Previous works show that the linguistic law exists in many corpora, including SemCor (Miller et al., 1993), CHILDES (MacWhinney, 2000), and Wikipedia (Grefenstette, 2016). SemCor is also one of the largest training datasets for the WSD task, which also includes Ontonotes (Marcus et al., 2011) and OMSTI (Taghipour and Ng, 2015).

Manin (2008) argues from the semantic view and proposes that the word semantics are influenced by the expansion of word meanings and competition of synonyms results in the law. Zipf (1945) proposes that word frequency is related to its word #sense, in which more frequent words have larger word #sense. Recently, Casas et al. (2019) investigates the law from the perspective of both word #sense and word length. Similarly, our work takes consideration of word #sense distribution and utilizes it for balanced training on the WSD task.

2.3 Learning Imbalanced Dataset

There are many approaches to address the influence on learning brought by imbalanced training data under a supervised setting. Most of the algorithms belong to re-weighting (Huang et al., 2016, 2019a) or re-sampling (Buda et al., 2018; Cui et al., 2019). Re-weighting methods adjust the weights of different classes. Re-sampling methods balance the learning by over-sampling minority classes or under-sampling the frequent classes. Another line of works incorporates the idea of angular margin, aiming to enlarge the intra-class margin (Liu et al., 2016; Wang et al., 2018; Cao et al., 2019).

Our work follows the line of re-weighting. We take consideration of the word #sense distribution and propose Z-reweighting method for the WSD task, which is quite different with previous reweighting methods.

3 Distribution Analysis in SemCor

In this section, we first show the overall word and sense distribution in SemCor[2] (Miller et al., 1993). Since we propose to utilize the word #sense distribution as the basis for the Z-reweighting strategy,

we further look into the relationship between word rank, frequency, and word #sense.

3.1 Imbalanced Data Distribution in SemCor

As mentioned in (Kilgarriff, 2004), a Zipfian distribution exists in the word senses of human language. In this part, we investigate the details of the distribution in training data of SemCor on both the word level and the sense level.

Senses in WordNet are generally ordered from most to least frequently used [3]. The most common sense is ranked first, denoted as **MCS**. We denote other senses of a word as least common senses **LCS**. Following this definition, we calculate the distribution of training data in the SemCor corpus, and the resulting distribution is shown in Table 1. SemCor contains 226,036 training instances, where each instance is a sentence with a labeled sense of one word. Among all the instances, 73.5% are training instances for MCS, belonging to 22,320 words and the rest are for LCS. LCS has 5.43 training instances for each sense, much lower than MCS which has 7.45 instances on average.

We further investigate the word #sense distribution of training words labeled with MCS and LCS respectively. The word #sense defined in WordNet[4] is utilized to calculate the distribution. The average word #sense for training words labeled with LCS is 4.77, much greater than that of MCS. This shows that words labeled with LCS have a larger coverage of senses to distinguish. The words with LCS in training data SemCor has higher word #sense while with fewer training instances. Therefore, we can see that disambiguating LCS is much more challenging than MCS in the WSD task.

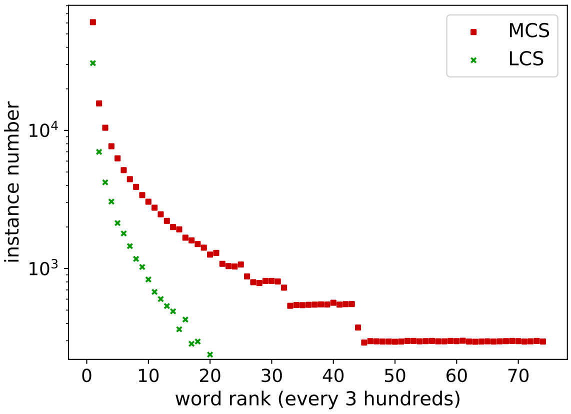

Figure 1: Word frequency distribution for MCS and LCS with sorted rank. One point represents the total instance number of three hundred words.

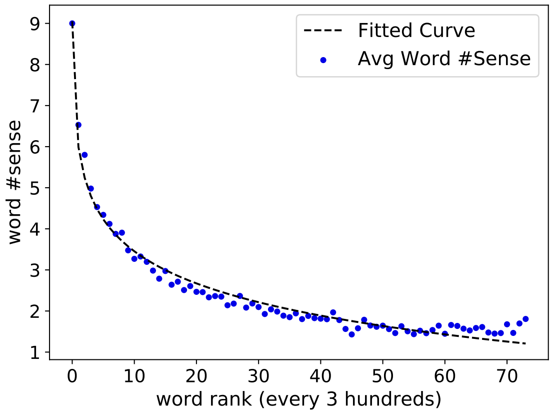

Figure 2: Average word #sense distribution with sorted rank. One point represents the average #sense of three hundred words.

3.2 Word Rank, Frequency, and Word #Sense

To investigate the details of the Zipfian distribution in SemCor, we calculate the number of training instances and word #sense for each word and sort them by frequency in descending order.

We apply a binning technique to reduce noise and get a better view of Zipf's law on word distribution. Specifically, every adjacent 300 words belong to a bin for clear analysis in this part. The distribution of instance number with sorted word rank by decreasing frequency is shown in Figure 1. As we can see, top ranked words have much more training cases than low ranked words both for training words labeled with MCS and LCS.

To get a deeper understanding of the statistical law in word frequency, we further analyze the relation between word #sense and sorted word rank. Similar to training instances, we calculate the average #sense of every 300 words in a bin and get the distribution of word #sense with the sorted word rank by decreasing frequency. As shown in Figure 2, the words with top rank have larger #sense than

---

[3] https://wordnet.princeton.edu/documentation/wndb5wn

[4] https://wordnet.princeton.edu

words with low rank. This shows that words with the top frequency rank have more senses to disambiguate. Moreover, words with LCS are mostly with top ranks.

4 Algorithms

In this section, we first introduce the terminology for the WSD task. Then we illustrate our Z-reweighting strategy on adjusting the training loss for the imbalanced training dataset.

4.1 Terminology

The WSD task is to disambiguate the meanings of a set of words $w = \{w_1, w_2, ..., w_n\}$ given a context sentence S. Each context word $w_i, i \in [1, n]$ in a sentence S has several candidate senses $\{s_1, s_2, ..., s_m\}$. Each sense is described by a definition sentence, also called gloss in WordNet (Miller, 1998). The candidate senses have a corresponding gloss set $\{g_1, g_2, ..., g_m\}$.

4.2 Z-Reweighting Strategy

To alleviate the influence brought by the imbalanced training dataset, we propose the Z-reweighting strategy to balance the learning between MCS and LCS during training, resulting in a stronger capability of the model in disambiguating rare and zero-shot senses while maintaining comparable performance on MCS at the same time.

Training words in SemCor are denoted in form $W = \{W_1, W_2, ..., W_N\}$ with descending order of frequency. The #sense of a word represents the number of senses belonging to the word. $P = \{p_1, p_2, ..., p_N\}$ is the #sense array of the words.

To facilitate the analysis of word #sense, we use a bin parameter K to group the words. Average #sense array is calculated for every K words as:

$$p'_o = \sum_{d=oK}^{o(K+1)} \frac{p_d}{K}, o \in [1, \frac{N}{K}], d \ \in [1, N], \quad (1)$$

$$P' = \{p'_1, ..., p'_{\frac{N}{K}}\}, \quad (2)$$

As analyzed in (Casas et al., 2019), a power law exists between word frequency and #sense in the corpora CHILDES (MacWhinney, 2000). Similarly, we utilize a function $f(x) = a\ln(x + b) + c$ to fit the relation between word #sense P' and word rank $o = [1, 2, ..., \frac{N}{K}]$ in SemCor mathematically, where a, b, c are parameters. The fitting function is monotonic decreasing with word rank. An example of the fitting curve and original word #sense distribution with word frequency at $K = 300$ is shown in Figure 2.

With the same word ranks, a smoothed word #sense array can be calculated from the fitting curve as:

$$P^f = \{p^f_1, ..., p^f_{\frac{N}{K}}\}, \quad (3)$$

The discrete fitting word #sense array is normalized for further processing:

$$P^r = \frac{P^f}{\max(P^f)}, \quad (4)$$

Since the number of words is too large to assign each word a weight, the $\frac{N}{K}$ bins of words are further split into M groups. For word in k-th bin, $k \in [1, \frac{N}{K}]$, belonging to group $j \in [1, M]$, the regularized #sense satisfies:

$$p^t_{j+1} \le p^r_k < p^t_j, \quad (5)$$

where $P^t = \{p^t_1, ..., p^t_M\}$ is the threshold array to split the groups. The words in group $j \in [1, M]$ are assigned weight:

$$\alpha_j = (p^t_j)^\eta, \quad (6)$$

where η is a power parameter.

Assume the predicted output probabilities from a model for candidate sense set as $z = [z_1, z_2, ..., z_m]$, the standard cross entropy loss given true word sense label y is:

$$loss(w_i, y) = -\log(\frac{\exp(z_y)}{\sum_{l=1}^{m} \exp(z_l)}). \quad (7)$$

In Z-reweighting strategy, the weight α_j is used to adjust the training on word level. The new weighted training loss is:

$$loss(w_i, j, y) = -\alpha_j \log(\frac{\exp(z_y)}{\sum_{l=1}^{m} \exp(z_l)}), \quad (8)$$

where $i \in [1, N]$ and $j \in [1, M]$, representing the word with rank i in group j has training weight α_j.

5 Experiments

In this section, we first introduce the training dataset and evaluation metrics. Then we show different baseline methods. Finally, details of the training process are presented.

5.1 Dataset

SemCor 3.0 is used as the training dataset. Five standard WSD datasets from Senseval and SemEval competitions are used as evaluation set. Among them, semeval 2007 (Pradhan et al., 2007) is used as development dataset for selecting the best model. Other four datasets including senseval-2 (Palmer et al., 2001), senseval-3 (Snyder and Palmer, 2004), semeval2012 (Navigli et al., 2013) and semeval2015 (Moro and Navigli, 2015) are used as test datasets. We select F1 as the evaluation metric. We also follow previous works (Raganato et al., 2017) to report the overall performance on all datasets. For further analysis, F1 scores on MCS, LCS, and zero-shot senses are also calculated.

5.2 Baselines

BEM framework (Blevins and Zettlemoyer, 2020) without any balanced strategy is a baseline system. In addition, different balanced training methods applied on BEM framework are used as three more baseline systems. The balanced methods are classified into two levels, namely, the sense-level (balanced reweighting and margin based method LDAW (Cao et al., 2019)), and the word-level (balanced resampling).

Biencoder Model (BEM). The model utilizes the gloss knowledge from WordNet. The two encoders are initialized with the same pre-trained language model. The encoders take a context sentence and glosses as input, generating representations for word w_i and corresponding gloss set $\{g_1, g_2, ..., g_m\}$ as E_i and $\{G_1, G_2, ..., G_m\}$ separately. Based on the representations, the similarity score between words and glosses are calculated as:

$$z_j = E_i \cdot G_j, j \in [1, m]$$

A standard cross-entropy loss is used in training as Equation 7.

Balanced Reweighting Method (B-reweighting). The B-reweighting strategy is applied on the sense level. For each word, the weights of senses is proportional to the inverse of training instances.

$$loss_{bal}(w_i, y) = -\beta_y \log \frac{\exp(z_y)}{\sum_{l=1}^{m} \exp(z_l)},$$

where $\beta_l = \frac{\sum_{l=1}^{m} n_l}{n_l}$ for $l \in [1, ..., m]$ and n_l is the number of training instances on sense l of w_i.

Balanced Resampling Method (B-resampling). The B-resampling method is applied on the word level. Firstly each word is sampled with the same probability. Then the training cases of the selected word are sampled randomly. Standard cross-entropy loss is used in this method.

LDAM. The margin-based method adjusts the training on the sense level. The goal of LDAM is to solve the class-imbalance problem by utilizing a label-distribution-aware margin loss. We apply the LDAW loss on the sense level as another baseline.

The smoothed relaxation of LDAM in the cross-entropy loss with enhanced margins is as follows:

$$loss_{margin}(w_i, y) = -\log \frac{e^{z_y - \Delta_y}}{e^{z_y - \Delta_y} + \sum_{l \neq y} e^{z_l}},$$

where $\Delta_l = \frac{C}{n_l^{1/4}}$, for $l \in \{1, \ldots, m\}$ and C is a constant. n_l is the training instances number of sense j for word w_i.

Standard LDAW is trained in two stages. Firstly the label-distribution-aware margin loss is applied to train the model for three epochs and B-reweighting loss is used for further training. In both stages, the learning rate is always 1e-5. For first stage training, C is set as 0.5.

5.3 Implementation details

Baseline Systems. Each system is trained for 20 epochs. AdamW (Kingma and Ba, 2015) is selected as the optimization algorithm. The learning rate is fixed at 1e-5 during training. The encoders in the biencoder framework both are initialized with bert-base (110M parameters) or bert-large (336M parameters) (Kenton and Toutanova, 2019). The experiments in which encoders initialized with bert-base are run on RTX 2080 and the experiments in which encoders initialized with Bert-large are run on RTX 3090. Average running hours is 30 hours for Bert-base and 40 hours for Bert-large.

Z-reweighting. To simplify the mathematical function fitting of word #sense distribution, we first split the words into bins by setting a fixed group number K. For the second grouping stage, to simplify the reweighting strategy on word level, we use thresholds to group the smoothed values calculated by fitting curve given word rank. In the experiments, we use weights of 1 decimal place as thresholds. The defined threshold array is as

model	Test Datasets

Table 3: F1(%) score on MCS, LCS and zero-shot senses on the ALL test dataset. The mean scores and standard deviation values of three experiments are reported for each system.

$P^t = [1.0, 0.9, ..., 0.1]$, where the gap between thresholds is 0.1. For assigning weights, $\eta = 1, 2$ is used to adjust the value of weight. For example, words with regularized word #sense in $[0.3, 0.4)$ are in a group, assigning weight 0.16 when $\eta = 2$. The weight is further rounded with one decimal number as 0.2. If the rounding weight is less than 0.1, we use a weight of 0.1. For comparison with baselines, we set $K = 300, \eta = 2$ in the Z-reweighting strategy.

6 Results

In this section, we first analyze the overall performance on the test datasets using different training strategies. Then the details of improvement on MCS, LCS, and zero-shot senses for word groups are presented. Finally, we analyze the influences brought by hyper-parameters in Z-reweighting and influences brought by backbone models.

6.1 Overall Performance

The performance on test datasets by different systems are shown in Table 2. WordNet S1 uses the most common sense in WordNet and MFS uses the most frequent sense in the training dataset. Both the baselines achieve much lower performances than previous learning based systems, including BERT-base (Kenton and Toutanova, 2019), GlossBERT (Huang et al., 2019b) and BEM[5]. The sense embeddings in EWISE is fixed during training, which explains its much lower performance than GlossBERT and BEM.

The F1 score on MCS, LCS and zero-shot senses in ALL testset, with 4,603, 2,650, and 1,139 test instances respectively, are reported in Table 3. Comparing BEM with systems with balancing strategies, only Z-reweighting achieves performance gain on LCS and zero-shot senses while maintaining comparable performance on overall performance at the same time. Details show that though Z-reweighting slightly drops on MCS, performance on LCS and zero-shot senses increases 2.1% and 3.6% separately.

Besides the Z-reweighting method, B-reweighting and LDAW also show performance improvement on LCS and zero-shot senses, comparing with the BEM baseline. However, these balanced strategies deteriorate the system ability in

---

[5] We use original open source code for paper (Blevins and Zettlemoyer, 2020): https://github.com/facebookresearch/wsd-biencoders.

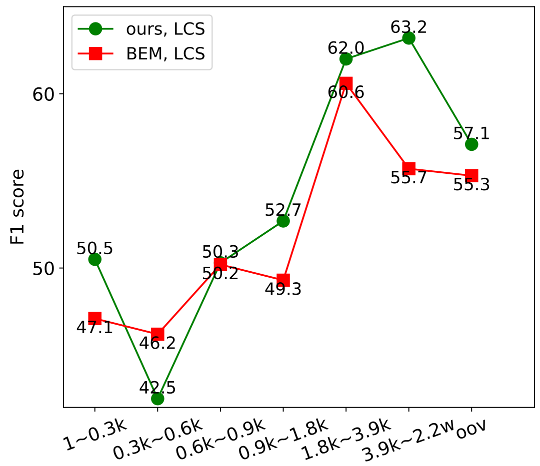

Figure 3: F1(%) score on LCS on ALL test dataset. *1-0.3k* means words with rank from 1 to 0.3k belongs to first group. *oov* means the group of words not appearing in SemCor.

disambiguating MCS, resulting in the drop of F1 score on the ALL dataset.

Among all the balanced training strategies, B-resampling performs the worst. Equally sampling the words leads to insufficient training of top-ranked words, which results in poor performance. Our Z-reweighting strategy outperforms all the other balanced training strategies, indicating that our method is effective in improving the generalization ability of the model.

6.2 LCS, Zero-shot Senses in Word Groups

Among all the balanced strategies, only Z-reweighting outperforms baseline system BEM on the F1 score of ALL dataset. To look into how the Z-reweighting strategy works, we analyze the details of performance in the word groups. Noting that according to the Z-reweighting strategy, words in each group are assigned the same weight. The hyper-parameters are $K = 300, \eta = 2$ for our results. Under the setting, there are six groups of words from training dataset. These six groups of words are sorted by decreasing frequency order. The left words belong to a *oov* group in which words are not shown in the training dataset.

We calculate the F1 score of LCS and zero-shot senses of ALL test set and plot the results in Figure 3 and Figure 4 separately. In Figure 3, our system outperforms BEM on group one, in which the words are with highest frequency. The Z-reweighting strategy assigns the largest weight in this group and the F1 score improves 3.4%. For group 4 to group 7, our algorithm also shows consistent improvements. The performance gain drops in group 2. The reason behind this is that we manage to improve the performance of all words on the WSD task and use semeval2007 as development set for model selection.

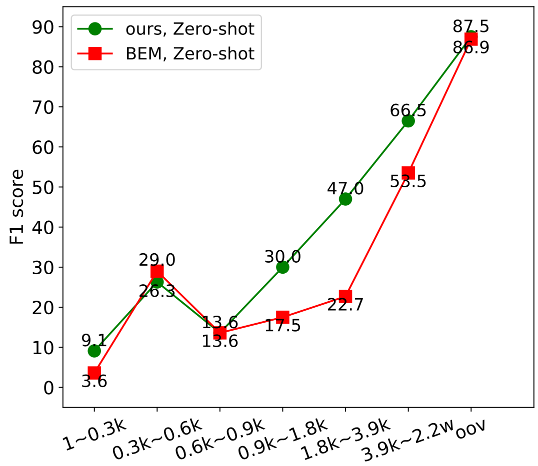

Figure 4: F1(%) score of zero-shot senses on ALL test dataset.

For zero-shot senses shown in Figure 4, our system achieves improvement in five out of seven word groups, at most 24.3% for group five. The results show that the Z-reweighting strategy enables the model to generalize better to unseen senses. For words in group seven, the performance of zero-shot senses also improves, which shows that our method can further generalize better to senses of unseen words.

6.3 Impact of K and η in Z-reweighting

Each different bin number K results in a set of distinct weights for training words. In our experiments, we set $K = 50, 100, 200, 300, 400$ and $\eta = 1, 2$.

The performances of our system under different hyper-parameter settings are shown in Figure 5 and Table 4. In Figure 5, we can see that $\eta = 2$ achieves higher performance than $\eta = 1$ in most settings. This shows that the training weights with larger disparity on top and low ranked words result in higher performance on the overall score. The best performance achieves at $K = 300, \eta = 2$. It is interesting to see that with different hyper-parameters, the system has various overall scores. When $K = 400$, the overall score achieves lowest both for $\eta = 1$ and $\eta = 2$. It indicates that large K eliminates the weight distinctness between words during training, leading to drop on overall performance.

To explore the details of effects brought by

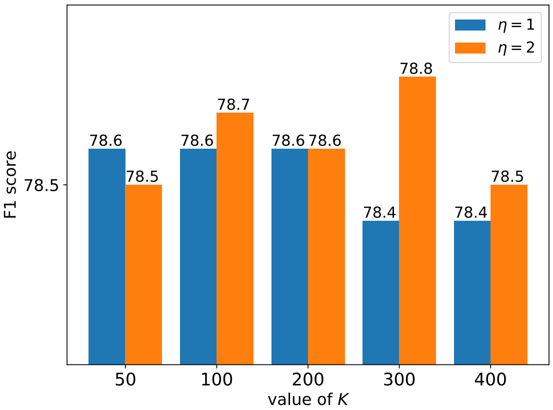

Figure 5: F1(%) score on ALL test dataset for different group parameter K and η.

hyper-parameters, we further show the F1 score of MCS, LCS, and zero-shot senses in Table 4. The accuracy of MCS varies from 92.8% to 93.3% under different settings. For most of the groups, MCS achieves higher performance with $\eta = 1$ than $\eta = 2$. When the gap between weights becomes larger with $\eta = 1$ changing to $\eta = 2$, the influences on LCS and zero-shot senses are greater than those on MCS. LCS achieves the best score 54.3%, 1.4% higher than the lowest score. Zero-shot senses achieve the best score of 72.3%, 1.4% higher than the lowest score. For all the combinations, we can see improvements on LCS and zero-shot senses compared to baseline BEM, demonstrating the effectiveness of our strategy.

6.4 Impact of Backbone Models

In this section, we show the influences brought by backbone models in BEM. The encoders of BEM are initialized by Bert-base and Bert-large models respectively for comparison. For Z-reweighting strategy, we use $K = 300, \eta = 2$. Training parameter settings are the same with the two backbone models. We experiment with different balanced training strategies. The results are presented in Figure 6. From the figure we can see that Bert-large achieves better performance on BEM and LDAM systems. For B-reweighting and Z-reweighting systems, the overall scores remain almost the same. However, for the B-resampling strategy, the performance drop 1%. Since the performances on Bert-large are nearly the same or even worse than Bert-base, we use Bert-base as the backbone model for training efficiency.

	Senses		
Parameter	MCS	LCS	Zero-shot
K=50, η=1	**93.3**	53.0	70.9
K=50, η=2	93.0	53.5	71.6
K=100, η=1	**93.3**	53.1	71.5
K=100, η=2	93.1	53.7	**72.3**
K=200, η=1	93.2	53.4	71.6
K=200, η=2	92.9	54.0	71.9
K=300, η=1	92.9	53.4	71.5
K=300, η=2	93.0	**54.3**	72.2
K=400, η=1	93.2	52.9	71.3
K=400, η=2	92.8	53.7	72.2

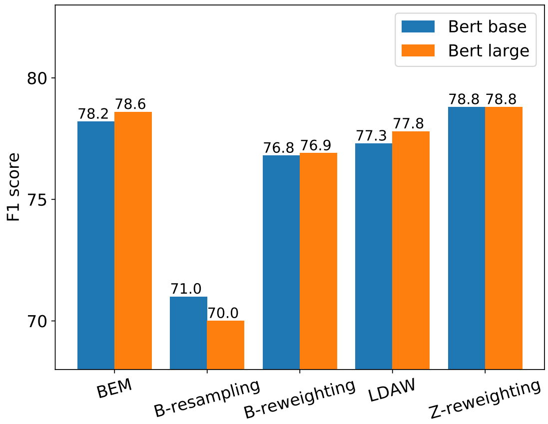

Figure 6: F1(%) score on ALL test dataset for balanced training strategies with different pretrained language models in BEM framework.

7 Conclusion

In this paper, we address the problem in learning imbalanced training dataset on the WSD task. Words with top frequency rank have more senses to disambiguate both for MCS and LCS. We assume these words should be assigned larger weights during training. Specifically, we use a mathematical function to fit the relation between word rank and word #sense, and utilize smoothed #sense to design the Z-reweighting strategy for all words English WSD task. The strategy leads to improvement on the performance of LCS and zero-shot senses on standard English WSD evaluation benchmarks. Furthermore, our method achieves performance gain on the F1 score for all senses. The results demonstrate the effectiveness of our methods.

Abstract

With state-of-the-art systems having finally attained estimated human performance, Word Sense Disambiguation (WSD) has now joined the array of Natural Language Processing tasks that have seemingly been solved, thanks to the vast amounts of knowledge encoded into Transformer-based pre-trained language models. And yet, if we look below the surface of raw figures, it is easy to realize that current approaches still make trivial mistakes that a human would never make. In this work, we provide evidence showing why the F1 score metric should not simply be taken at face value and present an exhaustive analysis of the errors that seven of the most representative state-of-the-art systems for English all-words WSD make on traditional evaluation benchmarks. In addition, we produce and release a collection of test sets featuring (a) an amended version of the standard evaluation benchmark that fixes its lexical and semantic inaccuracies, (b) 42D, a challenge set devised to assess the resilience of systems with respect to least frequent word senses and senses not seen at training time, and (c) hardEN, a challenge set made up solely of instances which none of the investigated state-of-the-art systems can solve. We make all of the test sets and model predictions available to the research community at `https://github.com/SapienzaNLP/wsd-hard-benchmark`.

1 Introduction

In recent years, Natural Language Processing (NLP) has witnessed a quantum leap in benchmark task performance, mainly thanks to the adoption of two major technical innovations: the Transformer architecture (Vaswani et al., 2017) and transfer learning from language models pre-trained on massive amounts of textual data (Devlin et al., 2019; Lewis et al., 2020). The impact of these breakthroughs was so strong that, on many benchmarks, the performance of human non-experts was surpassed (Wang et al., 2019b), prompting researchers to release new, more challenging benchmarks (Wang et al., 2019a).

Word Sense Disambiguation (WSD), the task of automatically assigning a meaning to an ambiguous word in context (Bevilacqua et al., 2021), is undergoing a similar process: current state-of-the-art systems are now capable of attaining and surpassing the F1 score of 80%[1] on standard test datasets (Bevilacqua and Navigli, 2020; Barba et al., 2021a; Conia and Navigli, 2021; Kohli, 2021), a figure often reported as the estimated human performance, because it corresponds to the highest recorded inter-annotator agreement (Edmonds and Kilgarriff, 2002; Navigli et al., 2007; Palmer et al., 2007).

Matching and/or surpassing human performance reasonably triggers the assumption that systems are capable of carrying out tasks in real-world scenarios as effectively as their human counterparts (Kiela et al., 2021), to the point where non-practitioners would regard such tasks as “solved”. And yet, once systems are investigated beyond sheer accuracy figures, their flaws become readily apparent (Ribeiro et al., 2016; Belinkov and Bisk, 2018; Ribeiro et al., 2020; Card et al., 2020; Zhou et al., 2020). Following this trend of research, our work provides evidence showing why traditional evaluation measures for WSD, such as the F1 score, should not be taken at face value, hence corroborating the thesis that the problem of disambiguation is far from solved (Emelin et al., 2020; Loureiro et al., 2021).

To provide context, consider the following example, where the sense prediction[2] of the currently state-of-the-art ESCHER model (Barba et al., 2021a) for the word <u>wind</u> is compared with the gold answer from the test set of SemEval-2013 Task 12 (Navigli et al., 2013):

---

[1] Unless specified, for the remainder of this work, we will use “F1 score” to refer to the micro-averaged F1 score.

[2] According to the most commonly employed sense inventory for WSD, i.e., WordNet 3.0 (Fellbaum, 1998).

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 4724 - 4737
May 22-27, 2022

context: The banks battling against a strong wind in the USA several years later. Investors and regulators (. . .)

gold: A tendency or force that influences events.

ESCHER: Air moving (. . .) from an area of high pressure to an area of low pressure.

Here, the contextual meaning of the word wind is clear to any English speaker, with no cues in the sentence that would lead a human reader to pick the "air" meaning. This is an illustrative case of why, despite having achieved (on paper) *superhuman* performance, systems continue to make mistakes that the inter-annotator agreement would not justify. Similarly, in the context below, another system which breaks the 80% performance ceiling (Conia and Navigli, 2021) makes a trivial mistake on a standard test instance (Snyder and Palmer, 2004), and fails to label the word couple properly:

context: I was just sitting down to meet with some new therapy clients, a couple, and the building started shaking (. . .)

gold: A pair of people who live together.

Conia and Navigli (2021): A small indefinite number.

With a view to gaining a better understanding of the nature of what systems still fail to disambiguate, in this work we provide the following main contributions: (i) we put forward a detailed quantitative and qualitative analysis of errors shared among seven state-of-the-art systems for English WSD, including systems that have surpassed the 80% human estimate in terms of F1 score (Bevilacqua and Navigli, 2020; Barba et al., 2021a), (ii) we produce an amended version of the English all-words WSD evaluation benchmarks featured in Senseval and SemEval tasks (Agirre et al., 2009; Raganato et al., 2017a), (iii) we devise "42D" (pron. [for·ti·tude]), the first manually-curated test bed made available to the research community after a hiatus of seven years since SemEval-2015 (Moro and Navigli, 2015), and a powerful evaluation tool for estimating system resilience in contexts featuring least frequent word senses, (iv) we establish a new human performance threshold for assessing actual *superhuman* scores on WSD test sets, and propose macro-averaged F1 score as an alternative to micro-averaged F1 score to better account for least frequent word senses in WSD evaluation, (v) we release "hardEN", a challenge set for English all-words WSD on which state-of-the-art systems under investigation achieve exactly 0.0% F1 score, and (vi) we set up an experimental setting to show the impact sense distribution has over the aforementioned datasets.

2 Related Work

WSD has witnessed the creation of many different evaluation benchmarks, most notably as part of the Senseval (now SemEval) evaluation campaigns (Kilgarriff, 1998). Since the release of the popular Unified Evaluation Framework by Raganato et al. (2017a), the experimental setting has become quite standard, with most systems being evaluated on ALL, i.e., the concatenation of Senseval-2 (Edmonds and Cotton, 2001), Senseval-3 Task 1 (Snyder and Palmer, 2004), SemEval-2007 Task 17 (Pradhan et al., 2007), SemEval-2013 Task 12 (Navigli et al., 2013), and SemEval-2015 Task 13 (Moro and Navigli, 2015). Besides reporting results split by part of speech, which has not been particularly insightful, no specific finer-grained analysis is usually performed.[3] This trend runs the risk of promoting a sort of collective hill-climbing behavior, which, in turn, makes it unclear how much the improvement in performance has been due to genuinely stronger generalization power, as opposed to overfitting to increasingly stale test sets.

In opposition to this measure-centered style of evaluation, one possible alternative is that of behavioral testing, as proposed by Ribeiro et al. (2020). In their proposal (which does not address WSD explicitly), the benchmark evaluates separately minimum testable units of behavior, each of which addresses one specific skill required by a usable system. WSD, however, is a tricky problem to address in this way, as it is, in fact, a collection of idiosyncratic, diverse classification problems, which are hard to cluster in a meaningful way.

A different kind of analysis, perhaps more specific to WSD, has tackled the problem of the strong imbalance of sense distributions, which makes learning difficult for automatic algorithms, and monitors how this imbalance affects performance (Calvo and Gelbukh, 2015; Izquierdo et al., 2015; Postma et al., 2016; Wang and Wang, 2021). We

---

[3] Partial exceptions are Kumar et al. (2019), Bevilacqua et al. (2020), Blevins et al. (2021), Chen et al. (2021), and Barba et al. (2021a), which have paid particular attention to least frequent senses and data efficiency.

follow this line of research in that we also take sense distribution skewness as the core issue in the development of WSD algorithms. Therefore, both in the analysis of current WSD systems and in the creation of our new benchmarks, we check for the excessive influence of the most frequent output classes.

3 Systems at Issue

In an effort to make our analysis as thorough and comprehensive as possible, we consider a set of seven representative cutting-edge approaches for WSD.[4] With the exception of SyntagRank (Scozzafava et al., 2020), all systems are supervised neural architectures exploiting pre-trained language models. Below, we describe each of these systems:[5]

ARES (Scarlini et al., 2020)[6] is a semi-supervised approach to producing contextualized sense embeddings that share the same space as those from BERT (Devlin et al., 2019). It enables a simple 1 Nearest-Neighbour algorithm to attain high performance both in the English and multilingual settings despite relying on English training data only. We use the ARES English vectors freely available at `http://sensembert.org`.

BEM (Blevins and Zettlemoyer, 2020) is a bi-encoder model with high accuracy for the disambiguation of rare word senses. BEM maps the target in context and its word senses (as represented by glosses) independently into a shared embedding space, by means of jointly learned context and gloss encoders. Disambiguation is then performed simply by predicting the sense whose encoding is most similar to that of the target. We employ the model and code available at `https://github.com/facebookresearch/wsd-biencoders`.

ESCHER (Barba et al., 2021a, ESR) frames WSD as a span extraction task similar to SQuAD (Rajpurkar et al., 2016), in which a system is asked to detect the span matching the gloss of the correct sense for a target word from a pseudo-document constructed by concatenating the context of the target word with all the glosses of its possible senses. At the time of writing, ESCHER represents the state of the art in WSD.[7] We employ the model and code available at `https://github.com/SapienzaNLP/esc`.

EWISER (Bevilacqua and Navigli, 2020, EWR) is a WSD classifier that exploits relational information included in WordNet by incorporating a sparse adjacency matrix within the architecture. We employ the model and code available at `https://github.com/SapienzaNLP/ewiser`.

Generationary (Bevilacqua et al., 2020, GEN) reframes WSD as definition modeling, i.e., the task of generating a gloss from static or contextual embeddings (Noraset et al., 2017), therefore recasting disambiguation as a generative problem. We use the GEN-UNI (MBRR) model reported in the original paper. While the only exposure of the model to WordNet-tagged data was through SemCor (Miller et al., 1993), i.e., the most widely employed training set for WSD, the model was also trained on other lexicographic resources, such as the Oxford Dictionary (Chang and Chen, 2019).

GlossBERT (Huang et al., 2019, GLB) formulates WSD as a gloss ranking task, with a cross-encoder scoring context-gloss pairs. The model is trained with a simple learning-to-rank (He et al., 2008) approach, simply predicting whether a gloss is relevant to the context or not. We employ the model and code available at `https://github.com/HSLCY/GlossBERT`.

SyntagRank (Scozzafava et al., 2020, SYN) is a knowledge-based system that jointly exploits the Personalized PageRank algorithm and the wealth of syntagmatic information contained in SyntagNet (Maru et al., 2019) to perform disambiguation in multiple languages. We accessed SyntagRank by means of its APIs which are freely available at `http://api.syntagnet.org/`.

4 The Hard Core

To consider WSD as solved, it would be reasonable to expect disambiguation errors to be little more than mismatches between the reference ground truth and another different, but still reasonable interpretation. For example, if we consider the word

---

[4] To ensure a fair comparison, we only consider systems/settings that are not exposed to the Princeton WordNet Gloss Corpus (`https://wordnetcode.princeton.edu/glosstag.shtml`).

[5] For an extensive overview of state-of-the-art system backbones and trends in WSD, see Bevilacqua et al. (2021).

[6] For ease of reading, we will henceforth use abbreviations to identify some of the systems under investigation.

[7] Contemporary to this work, ConSeC (Barba et al., 2021c), which extends ESCHER, has now attained the new state of the art.

Table 2: F1 scores for the reported systems on ALL and its subsets analyzed in Section 4.1. Top to bottom: ALL (Raganato et al., 2017a), the subset of ALL with no WN1st instances (ALL$_{no1st}$), the subset of ALL with no instances whose ground truth is in SemCor (ALL$_{noSC}$), and the subset of ALL featuring predictions errors shared by all systems (ALL$_{HC}$). Left to right: dataset, number of instances (#inst) of which monosemous (#mono), system performances (ARES, BEM, ESR, EWR, GEN, GLB, SYN) on macro (M-F1) and micro F1 (m-F1), respectively. **Bold** is M-F1 best.

chestnuts in "my aunt grows chestnuts", the two senses "any of several attractive deciduous trees yellow-brown in autumn" and "edible nut of any of various chestnut trees of the genus Castanea" would both be good, albeit slightly different interpretations, but the sense "the brown color of chestnuts", instead, is clearly not. To show that the current state of the art is nowhere near this level of performance, we select as a case study the set of instances in the Unified Evaluation Framework for English WSD of Raganato et al. (2017a) (ALL) which are wrongly disambiguated by all of the considered systems (see Section 3). We analyze this "hard core" (henceforth, ALL$_{HC}$)—where performances are 0.0% in F1 score across the board by design—from both a quantitative and a qualitative perspective.

4.1 Quantitative Analysis

Sense distribution is a central problem for WSD. In our quantitative study, therefore, we analyze performances on the hard core by dividing test instances into frequency-based partitions. While performances are virtually always computed in terms of micro-averaged F1 scores, here we choose to report macro-averaged F1 (aggregated by sense), as the former gives more weight to frequent senses simply because they occur more often—thus hiding mediocre performances on least frequent senses.

Most Frequent Sense Bias. The most frequent class (in WSD, the most frequent sense, or MFS) can be overpredicted by machine learning algorithms (Postma et al., 2016; Blevins and Zettlemoyer, 2020; Loureiro et al., 2021). To quantify this phenomenon, in Table 1 (top), we report how many times our systems at issue predict the MFS in WordNet (henceforth, WN1st) on ALL$_{HC}$, as well as on ALL itself.[8]

As can be seen, systems show a clear bias towards WN1st senses on ALL, predicting them much more often (at least 69%) than the WN1st rate on the ground truth (65.2%). The distribution divergence becomes dramatic on ALL$_{HC}$, where systems predict WN1st at least 62.7% of the times, but the true WN1st rate is now just 2.0%. Overall, systems show a mostly comparable bias towards WN1st, with two notable exceptions: (i) GEN, likely due to the fact that in its UNI setting the system is exposed to multiple resources and hence is less biased; on the other hand, and perhaps counterintuitively (but see Calvo and Gelbukh, 2015) (ii) SYN, which is unsupervised, is the most biased

---

[8] We consider a test set instance to be a WN1st instance if at least one of the word senses assigned to disambiguate it coincides with the WN1st.

towards WN1st. Finally, we note that ESR, despite being the state of the art, does not behave differently from other systems in this respect, suggesting that there is much room for improvement.

In Table 2, we report both micro- and macro-averaged F1 scores on ALL, a subset of ALL without WN1st instances (ALL$_{no1st}$), and ALL$_{HC}$. As a consequence of the reduced importance of frequent senses, macro-averaged F1 scores are always lower than micro-averaged counterparts. Moreover, we can see that the reduced bias on WN1st by GEN results in a partial divergence between the system ranking on ALL and that on ALL$_{no1st}$, with GEN, which has a much lower WN1st bias, now outperforming GLB on the latter.

Training Dataset Bias. In addition to the WN1st bias, it is also useful to examine how much the lack of extrapolative capabilities is a reason for the existence of such a large set of unanswerable items. Thus, we classify instances and predictions according to whether the sense occurs at least once in SemCor (see also Kumar et al., 2019; Wang and Wang, 2021). Predicting a sense that never occurs at training time not only requires zero-shot capabilities, but also the ability to overcome the bias that a system learns from the training data for other senses of the same word. In Table 1 (bottom), we report the frequency with which our systems at issue predict a word sense that occurs at least once in SemCor. If we look at the raw percentages for ALL, there seems to be a slight bias towards senses that were seen at training time. However, such values do not take into account monosemous words for which the model always outputs the correct answer. In ALL$_{HC}$, where by construction there cannot be any monosemous sense, occurring senses are predicted at least 95% of the times, while they make up only 67.1% of the ground truth.

We refer back to Table 2 for the F1 scores on ALL$_{noSC}$, i.e., the subset of ALL with no instances whose gold sense is found in SemCor. The divergence between the ranking on ALL and ALL$_{noSC}$ is even wider than that between ALL and ALL$_{no1st}$. In this case, GEN, which obtains rather unremarkable results on ALL, becomes the second-to-best on ALL$_{noSC}$, supporting the notion that gloss modeling is beneficial for WordNet-based WSD, even when using data outside of WordNet. Indeed, the gloss-centric approach of ESR offers the best results across the board, even though its bias on SemCor-attested (and WN1st) senses is still strong—hinting that a possible way forward could be combining ESR (or any equally strong baseline) with strategies meant to mitigate the bias.

4.2 Qualitative Analysis

Determining why a sizeable subset of instances cannot be disambiguated by any of the systems we take into consideration requires a finer-grained, qualitative level of analysis to check whether, i) annotation errors, or ii) gaps in WordNet, are an important factor. At the same time, iii) we also want to see if we replicate previous inter-annotator agreement figures (Edmonds and Kilgarriff, 2002; Navigli et al., 2007; Palmer et al., 2007). In order to achieve these objectives, we ask an expert linguist with extensive experience in tagging with the WordNet inventory[9] to revise the test instances in ALL, the main test set first provided by Raganato et al. (2017a),[10] as well as in the dataset released as part of SemEval-2010 in-domain WSD Task 17 of Agirre et al. (2009), by tagging each instance with one of the following labels:

- **unchanged**, to indicate that the annotator agreed with the existing ground truth;
- **fine-grained**, to indicate that one or more senses need to be added to the ground truth, without removing the existing ones;
- **error:token-lemma**, to indicate that the test instance was originally assigned a wrong lemma, or was improperly tokenized;
- **error:pos**, to indicate that the test instance was originally assigned a wrong part of speech (PoS);
- **error:sense**, to indicate that one or more senses in the ground truth are wrong;
- **error:inventory**, to indicate that the ground truth is wrong, but there is no appropriate sense for the target word in the inventory of WordNet 3.0.

Table 3 showcases an excerpt of instances as tagged by our linguist according to the aforementioned set of labels. Additionally, in Table 4, we

---

[9] All our annotators have effective operational proficiency in English and received a wage in line with their country of residence. Annotation was carried out by means of a user-friendly, in-house interface.

[10] We exclude SemEval-2007, since this dataset is often used as development set (Pasini et al., 2021).

tag (id)	**fine-grained** (semeval2010.d003.s043.t001)

provide a broader look and report the frequency of appearance (percentage) for each label, as assigned to (a) the concatenation of datasets in Raganato et al. (2017a) with the exception of monosemous words and SemEval-2007 instances (ALL-), (b) its subset of shared errors making up the hard core described in Section 4 (ALL$_{HC}$-), (c) ALL- not including instances featured in ALL$_{HC}$- (ALL$_{NS}$-), and (d) SemEval-2010 with no monosemous instances (S10-).

Two interesting results emerge from this analysis. On the one hand, the hard core seems to be "hard" for the human annotator too, since the majority of instances are labeled as either disambiguation errors (**error:sense**), or as lacking equally valid word senses (**fine-grained**). Indeed, the shared error subset (ALL$_{HC}$-) features the lowest level of **unchanged** instances and, at the same time, the highest rate of **error:sense** instances, meaning that the linguist had a significantly higher disagreement with respect to the original test set in ALL$_{HC}$- than in ALL$_{NS}$-. Furthermore, the percentage of cases in which the linguist deemed necessary the use of (i) additional word senses to disambiguate a certain instance (**fine-grained**) or (ii) the use of a word sense not featured in the inventory (**error:inventory**) is more than double that of the rest of the dataset. On the other hand, if we sum the percentage of **unchanged** instances with that of **fine-grained**, and exclude from the set of all instances the samples where disagreements do not depend on disambiguation choices (**error:pos**, **error:token-lemma**, **error:inventory**), the agreement of the linguist with respect to the gold standard is far superior to what is traditionally reported in the literature, reaching a high ceiling of 91.1%, more than 10% above traditional estimates (Edmonds and Kilgarriff, 2002; Navigli et al., 2007;

Palmer et al., 2007). Indeed, **fine-grained** instances do not involve a disambiguation error, but merely extend the instance with additional possible meanings. This can only *increase* performances, since the standard evaluation scorer provided as part of the framework of Raganato et al. (2017a) gives the system full score if the predicted sense is in the ground truth set.

5 New Benchmarks

Results from the quantitative and qualitative analysis carried out on the hard core reveal two main reasons why F1 scores can be potentially misleading indicators of the actual capabilities of current systems: (i) scores are actually a long way from estimated human performance when observed in challenging, but nevertheless real-world scenarios, and (ii) errors found in traditional test beds compromise insightful model evaluations. Against this background, we put forward a set of evaluation tools to enable a more robust appraisal of system performance in English WSD, namely, (i) 42D, a multi-domain challenge set, (ii) amended versions of ALL (ALL$_{NEW}$) and SemEval-2010 Task 17 (S10$_{NEW}$), and (iii) the new hardEN/softEN benchmark.

5.1 42D

Thus far, we have only considered existing evaluation benchmarks for WSD. In view of this—and with the purpose of showing that the issues highlighted in Section 4.1 are not artifacts of the data taken into account, but a general problem with current WSD systems—we introduce “42D”, a novel test set for English WSD, built from scratch by manually annotating paragraphs taken from the British National Corpus (Leech, 1992, BNC).[11] 42D, with its 370 test instances, is specifically designed to be a challenge set (Belinkov and Glass, 2019), since for each of the instances the ground truth, i) does not occur in SemCor, and ii) is not the first sense in WordNet. In addition to this, 42D’s source texts are sampled so as to be representative of different text domains, specifically, the 42 domains defined in BabelNet[12] 4.0 (Navigli and Ponzetto, 2012; Navigli et al., 2021).[13]

5.2 ALL$_{NEW}$ and S10$_{NEW}$

With the aim of providing a cleaner test set, one in which non-system-dependent issues have been removed, we ask the same linguist who performed the error analysis of Section 4.2 to complete the task by also updating the instances from ALL and SemEval-2010 based on the labels assigned during the first phase: additional word senses are assigned for instances labeled as **fine-grained** and existing annotations are amended for **error:sense** cases; PoS tagging, lemmatization, and tokenization errors are fixed, and the instance updated with suitable word senses (see Table 3 for an excerpt of changes applied to the original test sets).

As a result, we obtain two test sets: ALL$_{NEW}$, featuring $4,917$ polysemous instances amending the original ALL dataset of Raganato et al. (2017a)[14], and S10$_{NEW}$, with 955 polysemous test instances amending the original SemEval-2010 Task 17 of Agirre et al. (2010).

5.3 hardEN and softEN

Besides an analysis of the current WSD evaluation datasets, in this paper we also want to make available one comfortable-to-use benchmark that addresses the discussed issues. For this reason, we derive a new intersection of 476 test instances that the systems at issue were not able to solve, this time, from the concatenation of the amended sets ALL$_{NEW}$ and S10$_{NEW}$, as well as 42D. We name this challenge set “hardEN”, in contrast to its counterpart, “softEN”, which, instead, features the remaining $5,766$ test instances for which at least one system is able to provide a correct prediction. The hardEN/softEN benchmark is useful in that it sets a new “starting line” for WSD systems, one that concurrently accounts for what they still fail to do, while keeping track of what they can already do.

5.4 Evaluation

Table 5 compares the results obtained on our revised ALL$_{NEW}$ dataset by the current state-of-the-art systems, with respect to the original ALL test set of Raganato et al. (2017a)—filtered to include only instances featured in ALL$_{NEW}$ (ALL$*$), showing that the ranking of the systems taken into account

Table 5: F1 scores for the reported systems on the datasets described in Section 5. Left to right: dataset/subdataset (dataset), number of instances (#inst), system performances (ARES, BEM, ESR, EWR, GEN, GLB, SYN) measured using both macro (M-F1) and micro F1 (m-F1). **Bold** is M-F1 best. $*$ indicates the subset of ALL (Raganato et al., 2017b) that includes only those instances that are also featured in ALL$_{NEW}$.

does not change as a result of the amending process. However, we can appreciate the significant difference in terms of performance when this is measured using the macro-averaged F1 score as opposed to the micro-averaged F1 score used in the literature. For example, the performance of ESCHER drops by almost 3 points on ALL$_{NEW}$, from 81.6% to 78.7%. Indeed, the macro-averaged F1 score is better suited to highlighting the weaknesses of a system with imbalanced class distributions, as is the case for word senses, whose distribution follows Zipf's Law. We argue, therefore, that future systems should also report their results using this measure in order to better enable their strengths and weaknesses to be determined.

Table 5 also shows the performance of each system on our revised SemEval-2010 (S10$_{NEW}$), 42D, and the hardEN/softEN benchmark. 42D is of particular interest as it showcases how the state of the art still struggles in challenging settings, including rare word senses and out-of-domain instances: the best system, ESR, only manages to score 54.1% in micro F1, a value that is very distant from the 80% figure originally estimated for human experts. As a last remark, it is worth noting how the performances on softEN for EWR and ESR reach and surpass the threshold of 85%, hence showing figures closer to the new, higher human performance ceiling we described in Section 4.2.

dataset	ESCHER		Uniform E.		Ranked E.	
	M-F1	m-F1	M-F1	m-F1	M-F1	m-F1
ALL$_{NEW}$	78.7	81.6	77.8	81.6	**78.8**	82.3

Table 6: Macro- (M-F1) and micro-averaged F1 (m-F1) scores of our Uniform and Ranked ensemble strategies compared against the best performing systems, ESCHER. Best macro-averaged F1 scores are in **bold**.

6 Where to go?

In this work, we dived deep into what the current state of the art in WSD can achieve and what the main roadblocks to overcome in the future are. With hardEN as the new frontier to surpass and softEN as a milestone to preserve, in this Section, we take the opportunity to briefly discuss possible directions for achieving both ends.

Joining forces. One might wonder whether putting together multiple systems can be a viable approach for achieving progress in WSD, as preliminarily explored in the past by (Brody et al., 2006). Here we provide a provisional answer by investigating two simple ensemble strategies with the aim of understanding if it is possible to improve the results by making different and diverse systems agree. In the first ensemble strategy, i.e., uniform ensemble, we apply majority voting among the predictions of each of the seven systems; in the second strategy, i.e., ranked ensemble, each voting system is ranked according to its performance rank on ALL$_{NEW}$, e.g., the vote of ESCHER (the best system on ALL$_{NEW}$) is worth seven times that of SyntagRank (the seventh and worst system), in order to favor systems that are more likely to predict correct senses.

Interestingly, as Table 6 shows, even though re-

dataset	SemCor		K1		SemCor+K1	
	M-F1	m-F1	M-F1	m-F1	M-F1	m-F1
ALL$_{NEW}$	**78.7**	81.6	61.0	60.8	75.9	80.0
S10$_{NEW}$	**78.0**	82.1	68.5	67.4	76.2	80.1
42D	58.9	54.1	63.0	60.3	**65.2**	60.5
softEN	**83.7**	86.8	65.1	64.3	80.4	84.6
hardEN	0.0	0.0	**35.3**	33.6	16.8	14.5

Table 7: Macro- (M-F1) and micro-averaged F1 (m-F1) scores of ESCHER: trained only on SemCor, only on K1 (automatically-generated dataset containing one example per sense), and on SemCor + K1. Improving on hardEN decreases scores on softEN. Best macro-averaged F1 scores are in **bold**.

sults for ALL$_{NEW}$ are slightly higher when using ranked ensembling, this strategy appears to be impairing performance in challenging settings such as 42D. Furthermore, by construction, if hardEN features all and only those instances that all the systems at issue fail to provide a correct answer for, then ensembles cannot represent a solution for hardEN, no matter the strategy employed.

Data augmentation. A renowned problem in WSD is the knowledge acquisition bottleneck: we have thousands of senses for which we have no available training data, but manual sense tagging is an expensive process (Pasini, 2020). What happens when a system is trained with automatically generated usage examples? To find out, we employ the examples generated via the ExMaker encoder-decoder architecture (Barba et al., 2021b), to train ESCHER in two configurations: the first, in which the system is trained only with one automatically generated example per sense (K1), and the second, in which ESCHER is trained on the concatenation of SemCor and K1 (SemCor+K1).

As shown in Table 7, although ESCHER, when using K1, successfully "nibbles" at hardEN (achieving 35.3% in terms of macro-averaged F1 score), it does so at the expense of its performance on softEN (dropping more than 18% in macro-averaged F1 score), which is clearly undesirable. This is further proof that flattening the sense distribution on the training set is not sufficient to deal with hard test instances while at the same time preserving performance on the easier ones (see also Postma et al. (2016) and Loureiro et al. (2021)).

7 Conclusion

Although traditional metrics indicate that WSD systems have attained human-level performances, the actual capabilities of state-of-the-art models are poorly reflected by the current evaluation benchmarks. In this paper, we analyzed the intersection of errors made by a heterogeneous set of seven state-of-the-art systems for English WSD from a quantitative and qualitative perspective, detailing two main reasons why they still falter when compared to their human counterparts, namely, their strong bias towards most frequent word senses and towards senses featured in the training data, as well as the presence of an array of lexical and semantic fallacies in traditional evaluation benchmarks. With the aim of providing a test bench that is more effective in reflecting the actual capabilities of WSD systems, we introduced (i) an amended version of the most popular test bed for WSD, and (ii) the 42D challenge set. As a result of the aforementioned work, we also present the hardEN/softEN benchmark, a unified test bed aimed at moving forward with the disambiguation of so far unresolved instances, while keeping track of the current strong points of WSD systems. We make our test sets and model predictions available at `https://github.com/SapienzaNLP/wsd-hard-benchmark`.

A Building and Annotating 42D

Building 42D. As a first step, we pre-processed the whole BNC raw text by means of the Stanford CoreNLP pipeline (Manning et al., 2014). Then, we split the corpus into chunks of less than 250 adjacent tokens (including punctuation). We exploited a straightforward unsupervised technique to automatically tag paragraphs from the BNC with domain labels from BabelDomains (Camacho-Collados and Navigli, 2017). Given that each BabelDomain label is associated with a set of synsets, with each synset having its own lexicalizations (e.g., car, automobile, and machine, for the WordNet synset "a motor vehicle with four wheels"), we assigned each paragraph to a specific domain, simply by determining which, among the 42 domains, showed the highest number of distinct lexicalizations within a paragraph.[15] As the the automatic domain classification method is error-prone, we asked a linguist to check whether the top chunk for each domain, ranked by highest number of lexicalizations, was fluent and representative of conventional descriptive or narrative discourse, e.g., filtering out lists of countries for the `geography_geology_and_places` domain. The dataset was therefore assembled as a result of the concatenation of the 42 chosen paragraphs, with an average paragraph length of 208 tokens (including punctuation).

Annotating 42D. We asked a linguist to annotate the pre-processed data from the BNC. For the annotation process, the linguist was asked to consider *all* the lexical clues available in WordNet, namely, lexicalizations, glosses, examples, and hypernymy/hyponymy relations, which often act as complementary sources of evidence (Joshi et al., 2013; Kanojia et al., 2014; Dhungana and Shakya, 2015). As a case in point, WordNet 3.0 defines two senses of the verb *say* as "utter aloud" and "express in words", respectively. Such glosses can be deemed similar when the verb is used to introduce direct speech. However, it is by looking at the usage examples that it can be noted how the direct speech is only featured for the word sense glossed as "utter aloud". In view of the above, the annotator was asked to (i) tag all content words in 42D, (ii) use multiple sense tags where appropriate, (iii) manually fix errors caused by the automatic nature of the pre-processing stage, and (iv) treat multiwords that appear in WordNet as a single instance. Finally, annotations featuring WN1st or monosemous senses were discarded. As a result, we collected an overall total of 370 manually annotated, challenging instances.

Once collected, we asked a second linguist to perform a blind annotation over the whole dataset and, consequently, computed a raw agreement of 79.6%. While this figure is lower than that computed for the ALL test set by Raganato et al. (2017a), 42D is much harder, as evidenced in Section 5.4.

---

[15] To ensure a significant inter-domain ambiguity, we only considered lexicalizations featured in more than one domain.

Large Scale Substitution-based Word Sense Induction

Matan Eyal[1] **Shoval Sadde**[1] **Hillel Taub-Tabib**[1] **Yoav Goldberg**[1,2]

Abstract

We present a word-sense induction method based on pre-trained masked language models (MLMs), which can cheaply scale to large vocabularies and large corpora. The result is a corpus which is sense-tagged according to a corpus-derived sense inventory and where each sense is associated with indicative words. Evaluation on English Wikipedia that was sense-tagged using our method shows that both the induced senses, and the per-instance sense assignment, are of high quality even compared to WSD methods, such as Babelfy. Furthermore, by training a static word embeddings algorithm on the sense-tagged corpus, we obtain high-quality static senseful embeddings. These outperform existing senseful embeddings methods on the WiC dataset and on a new outlier detection dataset we developed. The data driven nature of the algorithm allows to induce corpora-specific senses, which may not appear in standard sense inventories, as we demonstrate using a case study on the scientific domain.

1 Introduction

Word forms are ambiguous, and derive meaning from the context in which they appear. For example, the form "bass" can refer to a musical instrument, a low-frequency sound, a type of voice, or a kind of fish. The correct reference is determined by the surrounding linguistic context. Traditionally, this kind of ambiguity was dealt via *word sense disambiguation* (WSD), a task that disambiguates word forms in context between symbolic sense-ids from a sense inventory such as WordNet (Miller, 1992) or, more recently, BabelNet (Navigli and Ponzetto, 2010). Such sense inventories rely heavily on manual curation, are labor intensive to produce, are not available in specialized domains and inherently unsuitable for words with emerging senses.[1] This can be remedied by *word sense induction* (WSI), a task where the input is a given word-type and a corpus, and the output is a derived sense inventory for that word. Then, sense disambiguation can be performed over the WSI-derived senses.

The introduction of large-scale pre-trained LMs and Masked LMs (MLM) seemingly made WSI/WSD tasks obsolete: instead of representing tokens with symbols that encode sense information, each token is associated with a contextualized vector embeddings that captures various aspects of its in-context semantics, including the word-sense. These contextualized vectors proved to be very effective as features for downstream NLP tasks. However, contextualized embeddings also have some major shortcomings: most notably for our case, they are expensive to store (*e.g.* BERT embeddings are 768 or 1024 floating point numbers for each token), and are hard to index and query at scale. Even if we do manage to store and query them, they are not interpretable, making it impossible for a user to query for a particular sense of a word without providing a full disambiguating context for that word. For example, consider a user wishing to query a dataset for sentences discussing *Oracle* in the mythology-prophet sense, rather than the tech company sense. It is not clear how to formulate such a query to an index of contextualized word vectors. However, it is trivial to do for an index that annotates each token with its derived sense-id (in terms of UI, after a user issues a query such as "Oracle", the system may show a prompt such as "did you mean Oracle related to IBM; Sun; Microsoft, or to Prophet; Temple; Queen", allowing to narrow the search in the right direction).

Amrami and Goldberg (2018, 2019) show how contextualized embeddings can be used for achieving state-of-the-art WSI results. The core idea of their WSI algorithm is based on the intuition, first proposed by Başkaya et al. (2013), that occurrences of a word that share a sense, also share in-context

---

[1] For example, in current WordNet version, *Corona* has 6 synsets, none of them relates to the novel *Coronavirus*.

Figure 1: Examples of induced word-senses for various words. For each sense we list the top-5 representatives, as well as the 5 closest neighbours in the static embeddings space.

substitutes. An MLM is then used to derive top-k word substitutes for each word, and these *substitute-vectors* are clustered to derive word senses.

Our main contribution in this work is proposing a method that scales up Amrami and Goldberg (2018)'s work to *efficiently* annotate all tokens in a large corpus (e.g. Wikipedia) with automatically derived word-senses. This combines the high-accuracy of the MLM-based approach, with the symbolic representation provided by discrete sense annotations. The discrete annotations are interpretable (each sense is represented as a set of words), editable, indexable and searchable using standard IR techniques. We show two applications of the discrete annotations, the first one is sense-aware information retrieval (§7), and the second is high-quality senseful *static* word embeddings we can derive by training a static embeddings model on the large sense annotated corpus (§8).

We first show how the method proposed by Amrami and Goldberg (2018) can be adapted from deriving senses of individual lemmas to efficiently and cheaply annotating *all the corpus occurrences* of *all the words in a large vocabulary* (§3). Deriving word-sense clusters for all of English Wikipedia words that appear as single-token words in BERT-LARGE's (Devlin et al., 2019) vocabulary, and assigning a sense to each occurrence in the corpus, required 100 hours of cheap P100 GPUs (5 hours of wall-clock time on 20 single GPU machines) followed by roughly 4 hours on a single 96-cores CPU machines. The whole process requires less than 50GB of disk space, and costs less than 150$ on Google Cloud platform.

After describing the clustering algorithm (§4), we evaluate the quality of our system and of the automatic sense tagging using SemEval datasets and a new manually annotated dataset we created (§5). We show that with the produced annotated corpora it is easy to serve sense-aware information retrieval applications (§7). Another immediate application is feeding the sense-annotated corpora to a static embedding algorithm such as word2vec (Mikolov et al., 2013), for deriving *sense-aware static embeddings* (§8). This results in state-of-the-art sense-aware embeddings, which we evaluate both on an existing WiC benchmark (Pilehvar and Camacho-Collados, 2019) and on a new challenging benchmark which we create (§9).

In contrast to WSD which relies on curated sense inventories, our method is data-driven, therefore resulting senses are corpus dependent. The method can be applied to any domain for which a BERT-like model is available, as we demonstrate by applying it to the PubMed Abstracts of scientific papers, using SCIBERT (Beltagy et al., 2019). The resulting senses cover scientific terms which are not typically found in standard sense inventories (§6).

Figure 1 shows examples of induced senses for selected words from the English Wikipedia corpus. For each sense we list 5 community-based representatives (§3), as well as the 5 closest neighbours in the sense-aware embedding space (§8). Additional examples are available in Appendix A. Code and resources are available in github.com/allenai/WSIatScale.

2 Related Work

Word Sense Induction and Disambiguation Previous challenges like Jurgens and Klapaftis (2013) focused on word sense induction for small sized datasets. To the best of our knowledge we are the first to perform large-scale *all-words* WSI. The closest work to our method is the substitution-based method proposed in Amrami and Goldberg (2018, 2019) which is the starting point to our paper. In that paper, the authors suggested a WSI algorithm designed for a small dataset (SemEval 2010, 2013) with a predefined set of ambiguous target words (See (§3) for more details on the algorithm). In our work, we change Amrami and Goldberg (2019) such that we can efficiently run sense induction on all the words in very large corpora.

An alternative approach for sense tagging is based on Word Sense Disambiguation (WSD). The two main WSD methods are Supervised WSD and Knowledge-based WSD. Supervised WSD suffers from the difficulty of obtaining an adequate amount of annotated data. Indeed, even SemCor, the largest manually annotated tagged corpus, consists of only 226,036 annotated tokens. Among different supervisied WSD methods, Zhong and Ng (2010) suggested a SVM based approach and Melamud et al. (2016); Yuan et al. (2016) suggested LSTMs paired with nearest neighbours classification. Knowledge-base WSD (Moro et al., 2014; Pasini and Navigli, 2017), on the other hand, avoids the reliance on large annotated word-to-sense corpus and instead maps words to senses from a closed sense inventory (*e.g.* WordNet (Miller, 1992), BabelNet (Navigli and Ponzetto, 2010)). As such, the quality of knowledge-based WSD heavily depends on the availability, quality and coverage of the associated annotated resources.

Sense Embeddings In §8 we exploit the sense-induced corpus to train sense embeddings. Reisinger and Mooney (2010) were the first to suggest creating multiple representations for ambiguous words. Numerous recent papers (Chen et al., 2014; Rothe and Schütze, 2015; Iacobacci et al., 2015; Pilehvar and Collier, 2016; Mancini et al., 2017; Iacobacci and Navigli, 2019) aim to produce similar embeddings, all of which use either WordNet or BabelNet as semantic network. Our method is similar to Iacobacci et al. (2015), with the difference being that they rely on semantic networks (via Babelfy (Moro et al., 2014)). In contrast and similarly to us, Pelevina et al. (2016) does not rely on lexical resources such as WordNet. The authors proposed splitting pretrained embeddings (such as word2vec) to a number of prototype sense-embeddings. Yet in our work, we directly learn the multi-prototype sense-embeddings which is only possible due to the large-scale corpus annotation. When comparing both methods in §9.1 we infer it is better to directly learn multi-prototype sense-embeddings.

3 Large Scale Sense Induction

3.1 Definition

We define large-scale sense induction as deriving sense clusters for all words in a large vocabulary and assigning a sense cluster to each corpus occurrence of these words.[2]

3.2 Algorithm

Contextualized BERT vectors contain sense information, and clustering the contextualized vectors results in sense clusters. However, storing a 1024 dimensional vector of 32bit floats for each relevant token in the English Wikipedia corpus requires over 8TB of disk-space, making the approach cumbersome and not-scalable. However, as shown by Amrami and Goldberg (2019), MLM based word-substitutes also contain the relevant semantic information, and are much cheaper to store: each word-id in BERTLARGE's vocabulary can be represented by 2 bytes, and storing the top-5 substitutes for each corpus position requires less than 20GB of storage space.[3]

---

[2] In *BERT-large-cased-whole-word-masking* this corresponds to 16k vocabulary items, that match to 1.59B full words in English Wikipedia, or 92% of all word occurrences. Analyzing the remaining words, only 0.01% appear in Wikipedia more than 100 times. We derive word senses to a substantial chunk of the vocabulary, which also corresponds to the most ambiguous words as less frequent words are substantially less polysemous (Hernández-Fernández et al., 2016; Fenk-Oczlon et al., 2010; Zipf, 1945).

[3] The size can be reduced further using adaptive encoding techniques that assign fewer bits to frequent words. We did not implement this in this work.

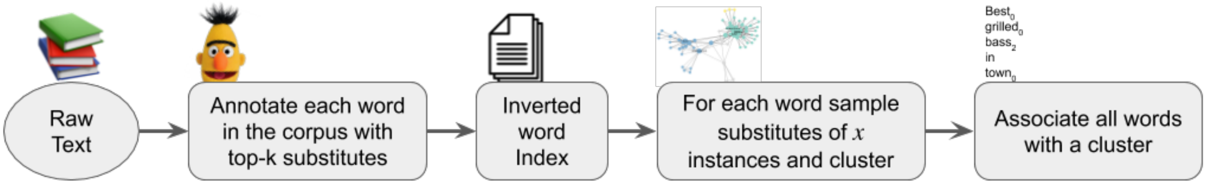

Figure 2: *Scalable WSI* flow. Given raw text, we annotate each word with its top-k substitutes, create inverted word index, find best clusters for each distinct lemma and associate all corpus words with a matching cluster.

In order to perform WSI at scale, we keep the main intuition from Amrami and Goldberg (2019), namely to cluster sparse vectors of lemmas of the top-k MLM-derived word substitutions. This results in vast storage saving, and also in a more interpretable representations. However, for scalability, we iterate over the corpus sentences and collect the top-k substitutes for all words in the sentence at once based on a single BERT call for that sentence. This precludes us from using the dynamic-patterns component of their method, which requires separately running BERT for each word in each sentence. However, as we show in Section §5.1 we still obtain sufficiently high WSI results.

The steps for performing Scalable WSI are summarized in Fig. 2. We elaborate on each step below, using English Wikipedia as a running example.[4]

Annotation: We run *BERT-large-cased-whole-word-masking* on English Wikipedia, inferring substitutes for all corpus positions. For positions that correspond to single-token words,[5] we consider the predicted words, filter stop-words, lemmatize the remaining words (Honnibal et al., 2020), and store the top-5 most probable lemmas to disk. This step takes 5 hours on 20 cloud-based GPU machines (total of 100 GPU hours), resulting in 1.63B tokens with their corresponding top-5 lemmas.

Inverted Word Index: We create an inverted index mapping from each single-token word to its corpus occurrences (and their corresponding top-5 lemmas). This takes 5 minutes on a 96 cores CPU machine, and 10GB of disk.

Sense Induction: For each of 16,081 lemmas corresponding to single-token words, we retrieve random 1000 instances,[6] and induce senses using the community-based algorithm described in §4. This process requires 30 minutes on the 96-core CPU machine, and uses 100MB of disk space. The average number of senses per lemma is 3.13. Each sense is associated with up to 100 representative words, which represent the highest-degree words in the sense's community. Table 1 shows the 5 senses found for the word *bass* with their top-5 representative words. See additional examples in Fig. 1 and Appendix A.

bass$_0$	**bass**$_1$	**bass**$_2$	**bass**$_3$	**bass**$_4$
bassist	double	fish	tenor	trap
guitar	second	bottom	baritone	swing
lead	tail	perch	voice	heavy
drum	steel	shark	soprano	dub
rhythm	electric	add	singer	dance

Table 1: Top 5 representatives of the sense-specific communities of word *bass*. The communities roughly match to bass as a musical instrument, register, fish species, voice and in the context of Drum&Bass

Tagging: Each of the remaining word-occurrences is associated with a sense cluster by computing the Jaccard similarity between the occurrences' top-5 lemmas and the cluster representatives, and choosing the cluster that maximizes this score. For example, an occurrence of the word *bass* with lemmas *tenor, baritone, lead, opera, soprano* will be associated with bass$_3$. This takes 100 minutes on 96-core machine, and 25GB of storage.

4 Sense Clustering Algorithm

We replace the hierarchical clustering algorithm used by Amrami and Goldberg (2018, 2019) with a community-detection, graph-based clustering algorithm. One major benefit of the community detection algorithms is that they naturally produces a dynamic number of clusters, and provide a list of interpretable discrete representative lemmas for each cluster. We additionally found this method to be more stable.

Graph-based clustering for word-sense induction typically constructs a graph from word occurrences

---

[4] The Wikipedia corpus is based on a dump from August 2020, with text extracted using WikiExtractor (Attardi, 2015).

[5] We exclude single-character tokens, stopwords and punctuation.

[6] The clustering algorithm scales super-linearly with the number of instances. To reduce computation cost for tokens that appear more than 1000 times in the dataset, we sample $\min(\text{numOccur}, 1000)$ instances for each token word, and cluster given the subset of instances. We then associate each of the remaining instances to one of the clusters as explained in the final step of the algorithm.

or collocations, where the goal is to identify sense-specific sub-graphs within the graph that best induce different senses (Klapaftis and Manandhar, 2008, 2010). We instead construct the graph based on word substitutes. Following Jurgens (2011), we pose identifying sense-specific clusters as a *community detection problem*, where a community is defined as a group of connected nodes that are more connected to each other than to the rest of the graph.

Graph construction For each word w in the vocabulary, we construct a graph $G_w = (V_w, E_w)$ where each vertex $v \in V_w$ is a substitute-word predicted by the MLM for w, and an edge $(u, v) \in E_w$ connects substitutes that are predicted for the same instance. The edge is weighted by the number of instances in which both u and v were predicted. More formally, let $X = \{x_w^i\}_{i=1}^n$ bet the set of all top-k substitutes for n instances of word w, and $x_w^i = \{w'^{j}_{x_w^i}\}_{j=1}^k$ represents the k top substitutes for the ith instance of word w. The graph G_w is defined as follows:

$$\begin{aligned} V_w &= \{u : \exists i \; u \in x_w^i\} \\ E_w &= \{(u, v) : \exists i \; u \in x_w^i \wedge v \in x_w^i\} \\ W(u, v) &= |\{i : (u, v) \in x_w^i\}| \end{aligned}$$

Community detection A community in a sub-graph corresponds to a set of tokens that tend to co-occur in top-k substitutes of many instances, and not co-occur with top-k substitutes of other instances. This corresponds well to senses and we take community's nodes as sense's representatives.

We identify communities using the fast *"Louvain"* method (Blondel et al., 2008). Briefly, Louvain searches for an assignment of nodes to clusters such that the *modularity score* Q—which measures the density of edges inside communities compared to edges between communities—is maximized:

$$Q = \frac{1}{2m} \sum_{u \; v} \left[W(u, v) - \frac{k_u k_v}{2m} \right] \delta(c_u, c_v)$$

m is the sum of all edge weights in the graph, $k_u = \sum_v W(u, v)$ is the sum of the weights of the edges attached to node u, c_u is the community to which u is assigned, and δ is Kronecker delta function. This objective is optimized using an iterative heuristic process. For details, see Blondel et al. (2008).

5 Intrinsic Evaluation of Clustering Algorithm

We start by *intrinsically evaluating* the WSI clustering method on: (a) SemEval 2010 and SemEval 2013; and (b) a new test set we develop for large-scale WSI. In section 9, we additionally *extrinsically evaluate* the accuracy of static embeddings derived from a sense-induced Wikipedia dataset.

When collecting word-substitutes, we lemmatize the top-k list, join equivalent lemmas, remove stop-words and the target word from the list, and keep the top-5 remaining lemmas.

5.1 SemEval Evaluation

We evaluate the community-based WSI algorithm on two WSI datasets: SemEval 2010 Task 14 (Manandhar et al., 2010) and SemEval 2013 Task 13 (Jurgens and Klapaftis, 2013). Table 2 compares our method to Amrami and Goldberg (2018, 2019) and AutoSense (Amplayo et al., 2019), which is the second-best available WSI method. Bert-noDP/DP are taken from Amrami and Goldberg (2019). Bert-DP uses "dynamic patterns" which precludes wide-scale application. We follow previous work (Manandhar et al., 2010; Komninos and Manandhar, 2016; Amrami and Goldberg, 2019) and evaluate SemEval 2010 using F-Score and V-Measure and SemEval 2013 using Fuzzy Normalized Mutual Information (FNMI) and Fuzzy B-Cubed (FBC) as well as their geometric mean (AVG). Our method performs best on SemEval 2010 and comparable to state-of-the-art results on SemEval 2013. The algorithm performs on-par with the Bert-noDP method, and does not fall far behind the Bert-DP method. We now turn to assess the end-to-end induction and tagging over Wikipedia.

5.2 Large Scale Manual Evaluation

We evaluate our method on large corpora by randomly sampling 2000 instances from the sense-induced Wikipedia, focusing on frequent words with many senses. We manually annotate the samples' senses without access to the automatically induced senses, and then compare our annotations to the system's sense assignments. We publicly release our manual sense annotations.

Sampling and Manual Annotation We used a list of 20 ambiguous words from *CoarseWSD-20* (Loureiro et al., 2021). The full list and per-word results can be found in Appendix C. For each word we sampled 100 passages from English Wikipedia

Model	F-S	V-M	AVG
AutoSense	61.7	9.8	24.59
Bert-noDP	70.9 (0.4)	37.8 (1.5)	51.7 (1.2)
Ours	**70.95 (0.63)**	**40.79 (0.19)**	**53.79 (0.31)**
Bert-DP	71.3 (0.1)	40.4 (1.8)	53.6 (1.2)

Model	FNMI	FBC	AVG
AutoSense	7.96	61.7	22.16
Bert-noDP	19.3 (0.7)	**63.6 (0.2)**	**35.1 (0.6)**
Ours	**19.42 (0.39)**	61.98 (0.12)	34.69 (0.33)
Bert-DP	21.4 (0.5)	64.0 (0.5)	37.0 (0.5)

Table 2: Evaluation on the SemEval 2010 (top) and SemEval 2013 (bottom) datasets. We report mean (STD) scores over 10 runs.

with the target word, including inflected forms (case insensitive). Unlike *CoarseWSD-20*, we sampled examples without any respect to a predefined set of senses. For example, the only two senses that appear in *CoarseWSD-20* for the target word *arm* are *arm (anatomy)*, and *arm (computing)*, leaving out instances matching senses reflecting *weapons, subdivisions, mechanical arms* etc.

With the notion that word sense induction systems should be robust to different annotations schemes, we gave two fluent English speakers 100 sentences for each of the 20 ambiguous words from *CoarseWSD-20*. Annotators were not given a sense inventory. Each annotator was asked to label each instance with the matching sense *according to their judgment*. For example, for the target word *apple* in the sentence *"The iPhone was announced by Apple CEO."*, annotators can label the target sense with *Apple Inc.*, *Apple The Company* etc. Annotation Guidelines are available in Appendix B.

On average annotators labeled 6.65 senses per word (5.85 and 7.45 average clusters per word for the two annotators). This is more than the 2.65 average senses according to *CoarseWSD-20* and less than WordNet's 9.85.

Results We report our system's performance alongside two additional methods: A strong baseline of the most frequent sense (MFS), and Babelfy (Moro et al., 2014)—the sense disambiguation system used in BabelNet (Tested using Babelfy live version April 2021). Differently from the latter, our system does not disambiguates but induces senses, therefore, clusters are not labeled with a sense tag from a sense inventory. Instead, we represent senses to annotators using a list of common substitute words and a few examples. Thus, after annotating the Wikipedia passages, we additionally asked annotators to name the system's clusters with the same naming convention as in their annotations.

	MFS	Babelfy	Ours
Ann #1	49.55	41.5	**89.05**
Ann #2	49.9	41.95	**85.95**
average	49.72	41.72	**87.50**

Table 3: Classification F1 scores for MFS, Babelfy and our proposed system by annotator on our manually annotated dataset.

Given a similar naming convention between systems and annotators, we report F1 scores of systems' tagging accuracy with respect to the manual annotations. We report F1 averaged over words in Table 3. Our system outperforms both baselines, despite Babelfy having access to a list of predefined word senses. A full by-word table and comprehensive results analysis are in Appendix C.

While a 1-to-1 mapping between system clusters and manual senses is optimal, our system sometimes splits senses into smaller clusters, thus annotators will name two system clusters with the same label. Therefore it is also important to report the number of clusters produced by the system comparing to the number of senses after the annotators merged similar clusters. Our system produced 7.25 clusters with 2.25 clusters on average merged by the annotators.[7] Additionally, in rare cases our system encapsulates a few senses in a single cluster: this happened 3 and 5 times for both annotators across all the dataset.

6 Application to Scientific Corpora

A benefit of a WSI approach compared to WSD methods is that it does not rely on a pre-specified sense inventory, and can be applied to any corpus for which a BERT-like model is available. Thus, in addition to the Wikipedia dataset that has been presented throughout the paper, we also automatically induce senses over a corpus of 31 million PubMed Abstracts,[8] using SciBERT (Beltagy et al., 2019). As this dataset is larger than the Wikipedia dump, the process required roughly 145 GPU hours and resulting in $14,225$ sense-annotated lemmas, with an average number of 2.89 senses per lemma.

This dataset highlights the data-driven advantages of sense-induction: the algorithm recovers many senses that are science specific and are not represented in the Wikipedia corpora. While performing a wide-scale evaluation of the scientific WSI is beyond our scope in this work, we do show

---

[7] This is partially due to using clusters from two casing (*e.g. bank* and *Bank*), some of the merges share sense meaning but of different casing.

[8] www.nlm.nih.gov/databases/download/pubmed_medline

a few examples to qualitatively demonstrate the kinds of induced senses we get for scientific texts.

For each of the words *mosaic, race* and *swine* we show the induced clusters and the top-5 cluster representatives for each cluster.

mosaic$_0$	**mosaic**$_1$	**mosaic**$_2$	**mosaic**$_3$
virus	partial	mixture	mixed
dwarf	chimeric	landscape	genetic
mild	congenital	combination	spatial
cmv	heterozygous	pattern	functional
stripe	mutant	matrix	cellular

While senses mosaic$_0$ (the common mosaic virus of plants) and mosaic$_2$ ("something resembling a mosaic", "mosaic of..") are represented in Wikipedia, senses mosaic$_1$ (the mosaic genetic disorder) and mosaic$_3$ (mosaic is a quality, e.g., "mosaic border", "mosaic pattern") are specific to the scientific corpora (The Wikipedia corpora, on the other hand, includes a sense of mosaic as a decorative art-form, which is not represented in Pubmed).

race$_0$	**race**$_1$	**race**$_2$	**race**$_3$
racial	exercise	class	pcr
ethnicity	run	group	clone
black	training	state	sequence
rac	competition	population	rt
gender	sport	genotype	ra

Senses race$_0$ (ethnic group), race$_1$ (competition) and race$_2$ (population/civilization) are shared with wikipedia, while the sense race$_3$ ("Rapid amplification of cDNA ends", a technique for obtaining the sequence length of an RNA transcript using reverse transcription (RT) and PCR) is Pubmed-specific.

swine$_0$	**swine**$_1$	**swine**$_2$
pig	seasonal	patient
porcine	avian	infant
animal	influenza	group
livestock	pandemic	case
goat	bird	myocardium

Here swine$_1$ captures the Swine Influenza pandemic, while swine$_2$ refers to swine as experimental Pigs.

7 Sense-aware Information Retrieval

An immediate application of a high quality sense-tagged corpus is sense-aware retrieval. We incorporate the sense information in the SPIKE extractive search system (Shlain et al., 2020)[9] for Wikipedia and Pubmed datasets. When entering a search term, suffixing it with @ triggers sense selection allowing to narrow the search for the specific sense. Consider a scientist looking for PubMed occurrences of the word *"swine"* in its influenza meaning. As shown in Figure 3, this can be easily done by writing "swine@" and choosing the second item in the resulting popup window. The outputs are sentences with the word *"swine"* in the matching sense. As far as we know, SPIKE is the first system with such WSI capabilities for IR. Similarly, Blloshmi et al. (2021) suggested to enhance IR with sense information, but differently from us, this is done by automatically tagging words with senses from a predefined inventory.

8 Sense-aware Static Embeddings

Learning static word embeddings of sense-ambiguous words is a long standing research goal (Reisinger and Mooney, 2010; Huang et al., 2012). There are numerous real-world tasks where context is not available, precluding the use of contextualized-embeddings. These include Outlier Detection (Camacho-Collados and Navigli, 2016; Blair et al., 2016), Term Set Expansion (Roark and Charniak, 2000) the Hypernymy task (Breit et al., 2021), etc. Additionally, static embeddings are substantially more efficient to use, can accommodate larger vocabulary sizes, and can accommodate efficient indexing and retrieval. Yet, despite their flexibility and success, common word embedding methods still represent ambiguous words as a single vector, and suffer from the inability to distinguish between different meanings of a word (Camacho-Collados and Pilehvar, 2018).

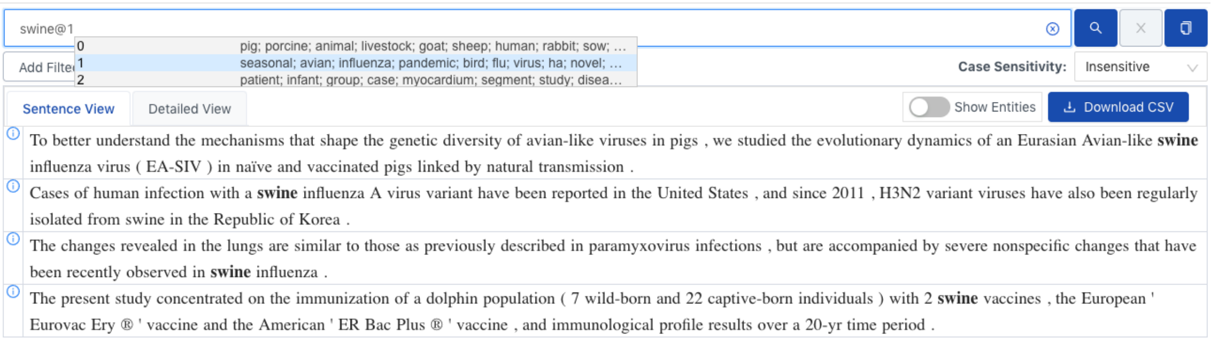
Using our sense-tagged corpus we suggest a simple and effective method for deriving sense-aware static embeddings: We run an off-the-shelf embedding algorithm,[10] on the corpus where single-token words are replaced with a concatenation of the word and its induced sense (*e.g. "I caught a bass."* becomes *"I caught@0 a bass@2."*). This makes the embedding algorithm learn embeddings for all senses of each word out-of-the-box.[11] An integral property of the embedding algorithm is that it represents both the sense-annotated tokens and the other vocabulary items in the same embedding space —

---

[9] spike.apps.allenai.org

[10] We use the CBOW variant of the word2vec algorithm (Mikolov et al., 2013) as implemented in Gensim (Řehůřek and Sojka, 2010). We derive 100-dimensional embeddings using the negative-sampling algorithm and a window size of 5.

[11] A similar approach was used by Iacobacci et al. (2015) over a corpus which was labeled with BabelNet and WordNet senses.



0 pig; porcine; animal; livestock; goat; sheep; human; rabbit; sow; …
1 seasonal; avian; influenza; pandemic; bird; flu; virus; ha; novel; …
2 patient; infant; group; case; myocardium; segment; study; disea…

To better understand the mechanisms that shape the genetic diversity of avian-like viruses in pigs , we studied the evolutionary dynamics of an Eurasian Avian-like **swine** influenza virus (EA-SIV) in naïve and vaccinated pigs linked by natural transmission .

Cases of human infection with a **swine** influenza A virus variant have been reported in the United States , and since 2011 , H3N2 variant viruses have also been regularly isolated from swine in the Republic of Korea .

The changes revealed in the lungs are similar to those as previously described in paramyxovirus infections , but are accompanied by severe nonspecific changes that have been recently observed in **swine** influenza .

The present study concentrated on the immunization of a dolphin population (7 wild-born and 22 captive-born individuals) with 2 **swine** vaccines , the European ' Eurovac Ery ® ' vaccine and the American ' ER Bac Plus ® ' vaccine , and immunological profile results over a 20-yr time period .

Figure 3: User interaction in SPIKE when looking for the word *"swine"* in its *"swine flu"* sense. (Unlike the animal/experimental pig senses)

this helps sense inferring about words that are represented in the MLM as multi-tokens words (Even though these correspond to less-frequent and often less ambiguous words (Hernández-Fernández et al., 2016; Fenk-Oczlon et al., 2010; Zipf, 1945)). For example, in the top-5 nearest neighbours for the different *bass* senses as shown below, *smallmouth* and *pumpkinseed*, multi-token words in BERTLARGE's vocabulary, are close neighbours the *bass* instances that correspond to the *fish* sense.

bass$_0$	**bass$_1$**	**bass$_2$**	**bass$_3$**	**bass$_4$**
guitar$_0$	tuba	crappie	baritone$_0$	synth
drums$_0$	trombone$_0$	smallmouth	tenor$_0$	drum$_1$
guitar$_3$	horn$_0$	pumpkinseed	alto$_0$	synths
keyboards$_0$	flute$_0$	sunfish	bassoon	breakbeats
keyboard$_0$	trumpet$_0$	perch$_0$	flute$_0$	trap$_4$

Note that some neighbours are sense annotated (single-token words that were tagged by our system), while others are not (multi-token words).

For English Wikipedia, we obtain a total vocabulary of 1.4M forms, $90,023$ of which are sense-annotated. Compared to the community-based representative words, the top neighbours in the embedding space tend to capture members of the same semantic class rather than direct potential replacements.

9 Sense-aware Embeddings Evaluation

9.1 WiC Evaluation

Pilehvar and Camacho-Collados (2019) introduced the WiC dataset for the task of classifying word meaning in context. Each instance in WiC has a target word and two contexts in which it appears. The goal is to classify whether the word in the different contexts share the same meaning. *e.g.* given two contexts: *There's a lot of trash on the <u>bed</u> of the river* and *I keep a glass of water next to my <u>bed</u> when I sleep*, our method should return *False* as the sense of the target word *bed* is different.

Method	**Acc.**
JBT (Pelevina et al., 2016)	53.6
Sense-aware Embeddings (this work)	**58.3**
SW2V* (Mancini et al., 2017)	58.1
DeConf* (Pilehvar and Collier, 2016)	58.7
LessLex* (Colla et al., 2020)	**59.2**

Table 4: Accuracy scores on the WiC dataset. Systems marked with * make use of external lexical resources.

Word Embeddings	**OPP**	**Acc.**
GloVe	93.31	65
word2vec	93.31	68
DeConf	93.37	73
Ours (Skip-gram)	96.31	83.5
Ours (CBOW)	**96.68**	**86**

Table 5: OPP and Accuracy on the *25-7-1-8* dataset.

Our method is the following: Given the sense-aware embeddings, a target word w and two contexts, we calculate the context vector as the average of the context words. The matching sense vector is the closest out of all w embeddings. We then classify the contexts as corresponding to the same meaning if the cosine distance of the found sense embedding is more than threshold apart. We do not use the train set. The threshold is optimized over the development set and fixed to 0.68.

This task has a few tracks, we compare our embeddings systems to the best performing methods from the *Sense Representations* track. Of these, JBT (Pelevina et al., 2016), a lexical embedding method, is the only one that does not use an external lexical resource (induction). The results in Table 4 show accuracy on this task. We outperform the induction method, and are on-par with the lexicon-based methods, despite not using any external lexical resource.

9.2 Evaluation via Outlier Detection

Another setup for evaluating word embeddings is that of *outlier detection*: given a set of words, identify which one does not belong to the set (Blair et al., 2016). Outlier detection instances are composed of in-group elements and a set of outliers from a related semantic space. In each evaluation round, one outlier is added to the in-group items, and the algorithm is tasked with finding the outlier. Existing outlier detection datasets either did not explicitly target sense-ambiguous words (*8-8-8* (Camacho-Collados and Navigli, 2016), *WikiSem500* (Blair et al., 2016)) or explicitly *removed* ambiguous words altogether (*25-8-8-sem* (Brink Andersen et al., 2020)).

Ambiguity-driven Outlier Detection. We construct a challenge set for outlier detection that specifically targets ambiguous cases. In order to account for sense ambiguity, we add a *distractor* to each of the in-group sets: the distractor is an item which has multiple senses, where the most salient sense does not belong to the group, while another sense does belong to the group. For example:

In-group: *zeus, hades, poseidon, aphrodite, ares, athena, artemis*
Outliers: *mercury, odysseus, jesus, sparta, delphi, rome, wrath, atlanta*
Distractor: *nike*

Here, a model which does not explicitly represent the greek-god sense of *nike* is likely to place it far away from the in-group instances, causing it to be mistakenly marked as the outlier.

The starting point for our dataset is *25-8-8-Sem* (Brink Andersen et al., 2020). This dataset contains 25 test groups, each with 8 in-group elements and 8 outliers, resulting in 200 unique test cases. The outliers are sorted in a decreasing degree of relatedness to the in-group elements. In our dataset we replace one of the in-group elements with an ambiguous distractor. For example, in the Greek-gods case above, we replaced the original 8th item (*"hera"*) with the ambiguous distractor *nike*. [12] The dataset consists of 25 groups of 7 non ambiguous group elements, 1 distractor and 8 outliers (*25-7-1-8*), similarly resulting 200 unique test cases.

Method Following Camacho-Collados and Navigli (2016), we rank each word likelihood of being the outlier by the average of all pair-wise semantic similarities of the words in $W \backslash \{w\}$. Therefore if w is an outlier, this score should be low. See Appendix D for additional details.

Metrics Camacho-Collados and Navigli (2016) proposed evaluating outlier detection using the accuracy (The fraction of correctly classified outliers among the total cases) and Outlier Position Percentage (OPP) metric. OPP indicates how close outliers are to being classified correctly:

$$OPP = \frac{\sum_{W \in D} \frac{OP(W)}{|W|-1}}{|D|} \times 100$$

where $OP(W)$ is the position of the outlier according to the algorithm.

Results In Table 5 we report performance of on the *25-7-1-8* set. Word2vec and GloVe accuracy scores are low while having high OPP scores. This is the expected behaviour for embeddings without sense awareness. These will position the distractor and the outlier furthest away from the group items while not designed to make the hard decision required for high Accuracy. Our sense-aware embeddings strongly outperform GloVe and word2vec which do not include senses. Our embeddings also outperform the word embeddings proposed in DeConf (Pilehvar and Collier, 2016), which are the best performing sense embeddings on WiC which are also publicly available.

10 Conclusion

We show that substitution-based word-sense induction algorithms based on word-substitutions derived from MLMs are easily scalable to large corpora and vocabulary sizes, allowing to efficiently obtain high-quality sense annotated corpora. We demonstrate the utility of such large-scale sense annotation, both in the context of a scientific search application, and for deriving high-quality sense-aware static word embeddings.

As a secondary contribution, we also develop a new variant of the Outlier Detection evaluation task, which explicitly targets ambiguous words.

A Additional Examples

Due to limit of space we provide additional examples in the appendix. We start with the senses found for the word *face*:

Representatives

face$_0$	**face**$_1$	**face**$_2$	**face**$_3$
confront	head	look	side
meet	front	address	line
encounter	name	point	wall
suffer	cheek	serve	surface
experience	body	toward	slope

Neighbours

face$_0$	**face**$_1$	**face**$_2$	**face**$_3$
meet$_3$	hand$_0$	faced$_2$	slope$_0$
challenge$_3$	forehead$_0$	sit$_1$	rim$_0$
suffer$_0$	hands$_0$	hang$_1$	flank$_2$
confront$_0$	nose$_0$	facing$_2$	ridge$_4$
lose$_1$	eyes$_3$	rotate$_0$	slope$_1$

The face senses refer to meeting/confronting, the body part, turn/look and side, respectively.

Here we present two senses of the word *orange*, corresponding to the color and fruit:

Representatives		**Neighbours**	
orange$_0$	**orange**$_1$	**orange**$_0$	**orange**$_1$
yellow	apple	yellow$_0$	apple$_0$
red	lemon	purple$_0$	avocado
amber	lime	amber$_0$	almond
pink	fruit	blue$_0$	apple$_1$
olive	banana	orangish	apricot

Finally we present the senses for *Jordan*:

Representatives

Jordan$_0$	**Jordan**$_1$	**Jordan**$_2$	**Jordan**$_3$
Johnson	Jerusalem	David	River
Jones	Palestine	Jason	Zion
Jackson	Israel	Joel	Water
Murray	Yemen	Justin	City
Mason	Turkey	Jonathan	water

Neighbours

Jordan$_0$	**Jordan**$_1$	**Jordan**$_2$	**Jordan**$_3$
Jones$_1$	Kuwait$_1$	Jeremy$_1$	Huleh
Kramer$_1$	Lebanon$_0$	Aaron$_0$	Yarkon
Allen$_0$	Syria$_0$	Justin$_0$	Arabah
Mack$_0$	Iraq$_0$	Brandon$_0$	Khabur
Robinson$_0$	Sudan$_1$	Josh$_0$	Tyropoeon

Here the clusters correspond to Jordan the surname, the country, first name and the Jordan River, respectively.

B Annotation Guidelines for Manual Evaluation

The objective of this task is to annotate word-meanings of 20 ambiguous words in a total of 2000 different contexts.

What is word-meaning? Words have different meanings in different contexts, for example, in the sentence: *"there is a light that never goes out"*, the word *"light"* refers to any device serving as a source of illumination. While *"light"* in the sentence *"light as a feather"* refers to the comparatively little physical weight or density of an object.

Step 1:

In this dataset we examine 20 ambiguous words as targets. For each of these words we collected 100 sentences in which the target word appears. For every sentence in the 100 set per target word, you will be asked to write a short label expressing the meaning of the target word in that particular context.

For example, here are three sentences with the target word *"light"*, each with its possible annotation.

1. *"there is a light that never goes out"* → visible light.
2. *"light as a feather"* → light as in weight.
3. *"magnesium is a light metal"* → light as in weight.

Note that in this example the annotator found the second and third meanings of the word *"light"* to be the same and therefore labeled them with the same label.[13]

While some annotations are indeed intuitive, labeling word-meanings when the target word is part of a name can be challenging. Here are a few guidelines for such use case:

Whenever a target word appeared as part of a name (Person, Organization etc.), one of three heuristics should be used[14]:

1. If the target word is the surname of a person, the example should be tagged *surname*.[15]

2. If the entity (as a whole) refers to one of the word-meanings, it should be labeled as such. For example, *Quitobaquito Springs* label should refer to a natural source of water.

3. If the target word is part of a name different from the original word-meaning, it should be tagged as *Part of Name*. This includes song names, companies (*Cold Spring Ice*), restaurants etc. Possible exceptions for this case are when a specific named entity is significantly frequent.

Step 2: [16]

---

[13] For ease of use for future evaluators, at the end of this step, both annotators picked a single naming convention when two labels referred to the same sense. Names of labels that were used only by one annotator were not changed.

[14] Some of the dissimilarities between the annotations are with respect the tension between the second and third guidelines.

[15] As opposed to Babelfy, there was no attempt for entity linking, so all persons were tagged the same.

[16] This step is presented to annotators once step 1 is done

For each of the target words you labeled, you will now receive a short list of indirect word-meaning definitions. Indirect word-meanings are composed of:

(a) A list of 10 words that may appear instead of the target word in specific contexts

(b) A list of 5 sentences in which the target word has this specific word-meaning.

For example, this is a possible indirect word-meaning for the target word *"Apple"*, representing the fruit, as opposed to the tech company:

Alternatives: orange, olive, cherry, lime, banana, emerald, lemon, tomato, oak, arrow,

Sentences in which Apple appears in this word-meaning:

"He and his new bride planted apple trees to celebrate their marriage."

"While visiting, Luther offers Alice an apple."

"When she picks the apple up, it is revealed that Luther has stolen a swipe card and given it to Alice to help her escape."

You will be asked to label the indirect word-meanings with one of the labels you used in step 1. If no label matches the indirect word-meaning you are allowed to propose a new label or define it to be "Unknown". Additionally, if you find several indirect word-meanings too close in meaning, label them the same.

C Analysis of Manual Evaluation

In table 6 we report a by-word analysis of our manual evaluation results. For each word we detail F1 scores of the most frequent sense (MFS), Babelfy, and our proposed system. Similarly to Loureiro et al. (2021), we report the ratio of the first sense with respect to the rest (F2R) and normalized entropy[17] to reflect sense balance. All of which are reported per annotator.

Analysis Analysis of our system's error shows that for some words the system could not create a matching cluster for specific senses (to name a few examples, "yard" as a ship identifier and "impound/enclosure" sense for the word "pound"). It appears that a matching cluster was not created due to the low tally of these senses in the English Wikipedia, and indeed the two senses appeared only two and three times respectively in the 100 passages sample. Additionally, annotator 2 annotated in a more fine-grained manner that does not correspond to our system tendency to merge capitalized instances of the target word into a sense that corresponds to "part of named entity".

As described above, in rare cases our system merged two senses into a single cluster. For example, the same cluster of the word "trunk" contained occurrences which annotator 1 tagged either "human torso" or "tube-like organs" (like the pulmonary trunk). While such annotation was uncommon (3 out of 117 senses for annotator 1 and 5 out of 149 senses for annotator 2), it does affect our system's micro F1 score for the better. In case we do not allow such annotation our overall score drops from 87.52 to 86.65.

A comparison between Babelfy and our gold annotation shows a common mistake in its labeling where Babelfy attributes the vast majority of sentences to the same non-salient sense. For example, Babelfy attributes 77 out of 100 instances of *hood* to "An aggressive and violent young criminal" - a sense that was not found even once in the manual annotation. While in a number of cases Babelfy used finer-grained sysnset groups than in our annotations we took into account any senses that are a subset of our annotated senses. For examples, Babelfy's *"United States writer who lived in Europe; strongly influenced the development of modern literature (1885-1972)"* synset was attribute any instances from the senses *surname* that refer to the writer Ezra Pound.

D Outlier Detection Method

When using a single-prototype vector-space models, Camacho-Collados and Navigli (2016) proposed a procedure for detecting outliers based on semantic similarity using *compactness score*:

$$c(w) = \frac{1}{n^2 - n} \sum_{w_i \in W \setminus \{w\}} \sum_{\substack{w_j \in W \setminus \{w\} \\ w_i \neq w_j}} sim(w_i, w_j)$$

Where D is the entire dataset and W is defined as $\{w_1, w_2, \cdots, w_n, w_{n+1}\}$ where w.l.o.g. $\{w_1, w_2, \cdots, w_n\}$ are the group elements (including the distractor) and w_{n+1} is the outlier. We use the same procedure with an additional nuance, we expanded the procedure to receive more than a single vector representation per word such that it will fit multi-prototype embeddings (*e.g.* our embeddings and DeConf) and case sensitive embeddings

---

for all words

[17] Computed as $\frac{-\sum_{i=1}^{k} \frac{c_i}{n} \log \frac{c_i}{n}}{log(k)}$, where k is the number of annotated senses, each of size c_i and n is the size of annotated examples per word, in our case $n = 100$.

	Annotator #1					Annotator #2

Average	49.55	41.5	**89.05**	2.11	0.74	49.9	41.95	**85.95**	2.13	0.65

Table 6: Manually annotated set scores by annotator. The first three columns for each annotator reflect disambiguation and induction scores with respect to the most frequent sense, Babelfy and our proposed system. We also report F2R and normalized entropy (Ent).

(*e.g.* word2vec). When given as set of words (like $W \setminus \{w\}$ when calculating $c(w)$) we first find the relevant sense for each element before inferring the outlier. Camacho-Collados and Navigli (2016) suggested calculating $c(w)$ using the *pseudo inverted compactness score*.

Can Synthetic Translations Improve Bitext Quality?

Eleftheria Briakou and **Marine Carpuat**
Department of Computer Science
University of Maryland
College Park, MD 20742, USA
`ebriakou@cs.umd.edu`, `marine@cs.umd.edu`

Abstract

Synthetic translations have been used for a wide range of NLP tasks primarily as a means of data augmentation. This work explores, instead, how synthetic translations can be used to *revise* potentially imperfect reference translations in mined bitext. We find that synthetic samples can improve bitext quality without any additional bilingual supervision when they replace the originals based on a semantic equivalence classifier that helps mitigate NMT noise. The improved quality of the revised bitext is confirmed intrinsically via human evaluation and extrinsically through bilingual induction and MT tasks.

1 Introduction

While human-written data remains the gold standard to train Neural Machine Translation (NMT) and Multilingual NLP models, there is growing evidence that synthetic bitext samples—sentence-pairs that are translated by NMT—benefit a wide range of tasks. They have been used to enable semi-supervised MT training from monolingual data (Sennrich et al., 2016a; Zhang and Zong, 2016; Hoang et al., 2018), to induce bilingual lexicons (Artetxe et al., 2019; Shi et al., 2021), and to port models trained on one language to another (Conneau et al., 2018; Yang et al., 2019).

While synthetic bitexts are useful additions to original training data for downstream tasks, it remains unclear how they differ from naturally occurring data. Some studies suggest that synthetic samples might be simpler and easier to learn (Zhou et al., 2020; Xu et al., 2021). Recognizing that naturally occurring bitext can be noisy, for instance, when they are mined from comparable monolingual corpora (Resnik and Smith, 2003; Fung and Yee, 1998; Esplà et al., 2019; Schwenk et al., 2021), we hypothesize that synthetic bitext might also directly improve the equivalence of the two bitext sides. Thus synthetic samples might be useful not only for data augmentation but also to revise potentially noisy original bitext samples.

In this paper, we present a controlled empirical study comparing the quality of bitext mined from monolingual resources with a synthetic version generated via MT. We focus on the widely used WikiMatrix bitexts for a distant (i.e, EN-EL) and a similar language-pair (i.e, EN-RO), since it has been shown that this corpus contains a significant proportion of erroneous translations (Caswell et al., 2021). We generate synthetic bitext by translating the original training samples using MT systems trained on the bitext itself and therefore do not inject any additional supervision in the process. We also consider selectively replacing original samples with forward and backward synthetic translations based on a semantic equivalence classifier, which is also trained without additional supervision.

We show that the resulting synthetic bitext improves the quality of the original intrinsically using human assessments of equivalence and extrinsically on bilingual induction (BLI) and MT tasks. We present an extensive analysis of synthetic data properties and of the impact of each step in its generation process. This study brings new insights into the use of synthetic samples in NLP. First, intrinsic evaluation shows that synthetic translations, in addition to "normalizing" the bitext (Zhou et al., 2020; Xu et al., 2021), could potentially provide reference translations that are more semantically equivalent to the source than the original ones.

Furthermore, the improved bitext provides more useful signals for BLI tasks and NMT training in two settings (training from scratch; continued training), as confirmed by our extrinsic evaluations. Finally, ablation analyses that compare different ways to combine synthetic translations show that using *both translation directions* and *filtering using semantic equivalence* is key to improving bitext quality and calls for further exploration of best practices for using synthetic translations in NLP tasks.

2 Background

Synthetic Translations Generating synthetic translations has mainly been studied as a means of data augmentation for NMT through forward translation (Zhang and Zong, 2016) or back-translation (Sennrich et al., 2016a; Marie et al., 2020) of monolingual resources. Moreover, recent lines of work use synthetic translations to augment the original parallel data: Nguyen et al. (2020) diversify the parallel data via translating both sides using multiple models and then merging them with the original to train a final NMT model; Jiao et al. (2020) employ a similar approach to rejuvenate inactive examples that contribute the least to the model performance. Sequence-level knowledge distillation (Kim and Rush, 2016) can also be viewed as replacing original bitext with synthetic translations. While its original goal was to guide the training of a student model of small capacity with the output of a teacher of high capacity, distillation is also necessary to effectively train some categories of MT architectures such as non-autoregressive models (Gu et al., 2018). While it is not entirely clear why synthetic distilled samples are superior to original bitext in this case, recent studies suggest that the synthetic samples are simpler and thus easier to learn from (Zhou et al., 2020; Xu et al., 2021).

Synthetic Data Selection Prior work covers a wide spectrum of different selection strategies on top of synthetic translations generated from monolingual samples. Each of them focuses on identifying samples with specific properties: Axelrod et al. (2011) sample sentences that are most relevant to a target domain with the goal of creating pseudo in-domain bitext; Hoang et al. (2018) generate synthetic parallel data iteratively from increasingly better back-translation models for improving unsupervised NMT; Fadaee and Monz (2018) focus on the diversity of synthetic samples and sample synthetic translations containing words that are difficult to predict using prediction losses and frequencies of words. By contrast, our empirical study investigates whether synthetic translations can be used to ***selectively replace*** original references to improve bitext quality rather than augmenting it.

Bitext Quality Mining bitext from the web results in large-scale corpora that are usually collected without guarantees about their quality. For instance, they contain noisy samples, ranging from untranslated sentences to sentences with no linguistic content (Khayrallah and Koehn, 2018; Caswell et al., 2020). Some of this noise is typically filtered out automatically using heuristics (Ramírez-Sánchez et al., 2020) or NMT model scores (Junczys-Dowmunt, 2018; Koehn et al., 2019). Yet, even after this noise filtering, a wide range of the remaining samples contains fine-grained semantic divergences (Briakou and Carpuat, 2020). Our past work explored strategies to mitigate the impact of these divergences on MT models by incorporating divergence tags as token-level factors (Briakou and Carpuat, 2021), and designing an approach to automatically edit divergent samples with noisy supervision from monolingual resources (Briakou et al., 2021). By contrast, this work explores whether synthetic translations can be used to replace potentially fine-grained divergences using only the bitext we seek to revise.

Algorithm 1 Revising Bitext: Given a bitext $\mathcal{D} = (S, T)$, a divergent scorer $\mathbf{R}$, and a margin score t, return revised bitext $\tilde{\mathcal{D}}$

```
procedure TRAIN($\mathcal{D} = (S,T)$)
    Train $M_{S\to T}$ on $\mathcal{D}$ until convergence
    return $M_{S\to T}$
end procedure
procedure EQUIVALIZE($\mathcal{D} = (S,T)$)
    $M_{S\to T} \leftarrow$ TRAIN($\mathcal{D} = (S,T)$)
    $M_{T\to S} \leftarrow$ TRAIN($\mathcal{D} = (T,S)$)
    $\tilde{\mathcal{D}} \leftarrow \varnothing$
    for $i \in 1,...,|\mathcal{D}|$ do
        $(S_i, \hat{T}_i) \leftarrow (S_i, M_{S\to T}(S_i))$
        $(\hat{S}_i, T_i) \leftarrow (M_{T\to S}(T_i), T_i)$
        $d_F \leftarrow \mathbf{R}(S_i, \hat{T}_i) - \mathbf{R}(S_i, T_i)$
        $d_B \leftarrow \mathbf{R}(\hat{S}_i, T_i) - \mathbf{R}(S_i, T_i)$
        if $\max(d_F, d_B) > t$ then
            if $\max = d_F$ then
                $\tilde{\mathcal{D}} \leftarrow \tilde{\mathcal{D}} \cup \{(S_i, \hat{T}_i)\}$
            else
                $\tilde{\mathcal{D}} \leftarrow \tilde{\mathcal{D}} \cup \{(\hat{S}_i, T_i)\}$
            end if
        else
            $\tilde{\mathcal{D}} \leftarrow \tilde{\mathcal{D}} \cup \{(S_i, T_i)\}$
        end if
    end for
    return $\tilde{\mathcal{D}}$
end procedure
```

3 Approach

This section describes the methods and data we use to produce revised bitexts for our empirical study.

3.1 Methods for Revising Bitext

We rely on established techniques that can be applied using only the bitext that we seek to revise. First, we train NMT models on the original bitext to translate in both directions. For each original sentence-pair, we generate a pool of synthetic translations using NMT and apply a divergence ranking criterion to decide whether and how to replace the original references with a better translation. Algorithm 1 gives an overview of the process, and we describe each step below.

Generating synthetic translations We train NMT models $M_{S \to T}$ and $M_{T \to S}$ on the original bitext to translate in each direction (lines 2-3). For each sentence-pair, they are used to generate two candidates for replacement by forward and backward translation (lines 6-7): $(S_i, M_{S \to T}(S_i))$ and $(M_{T \to S}(T_i), T_i)$. As a result, NMT models translate the exact same data that they are trained on. We thus expect translation quality to be high , and that local errors in the original bitext might be corrected by the translation patterns learned by NMT models on the entire corpus.

Selective Replacement We propose to replace an original pair by a candidate *only if* the candidate is predicted to better convey the meaning of the source than the original, which we refer to as the *semantic equivalence condition*. We implement this by ranking the original sample (S_i, T_i), its revision by forward translation $(S_i, M_{S \to T}(S_i))$ and its revision by back-translation $(M_{T \to S}(T_i), T_i)$, according to their degree of semantic equivalence. If none of the synthetic samples score higher than the original, it is not replaced (line 17). Otherwise, the original is replaced by the highest scoring synthetic sample (lines 10-15). As a result the cardinality of the bitext remains constant. The semantic equivalence condition (d_F and d_B (lines 8-9)) is implemented using divergentmBERT, a divergent scorer introduced in our prior work (Briakou and Carpuat, 2020) that is trained on synthetic samples generated by perturbations of the original bitext (e.g., deletions, lexical or phrasal replacements) performed without any bilingual information.

3.2 Experimental Set-Up

Bitext We evaluate the use of synthetic translations for revising bitext on two language pairs of the WikiMatrix corpus (Schwenk et al., 2021). WikiMatrix consists of sentence-pairs mined from Wikipedia pages using language agnostic sentence embeddings (LASER) (Artetxe and Schwenk, 2019). Prior work indicates that, as expected, the corpus as a whole comprises many samples that are not exact translations: Caswell et al. (2021) report that for more than half of the audited low-resource language-pairs, mined pairs are on average misaligned; Briakou and Carpuat (2020) find that 40% of a random sample of the English-French bitext are not semantically equivalent, and include fine-grained meaning differences in addition to alignment noise. We focus on bitexts with fewer than one million sentence pairs in Greek↔English (EL↔EN, with 750,585 pairs) and Romanian↔English (RO↔EN, with 582,134 pairs), because improving bitext is particularly needed in this data regime. In much higher resource settings, filtering strategies might be sufficient as there might be more high quality samples overall. In much lower resource settings, the data is likely too noisy or too small to effectively revise bitexts using NMT. We filter out noisy pairs in the training data using `bicleaner` (Ramírez-Sánchez et al., 2020) so that our empirical study excludes the most obvious forms of noise, and focuses on the harder case of revising samples that standard preprocessing pipelines consider to be clean.[1]

Preprocessing We use Moses (Koehn et al., 2007) for punctuation normalization, true-casing, and tokenization. We learn 32K BPEs (Sennrich et al., 2016b) per language using `subword-nmt` [2].

NMT Models We use the base Transformer architecture (Vaswani et al., 2017) and include details on the exact architecture and training in Apendix C.

Selective Replacement The divergence ranking models are trained using our public implementation of divergentmBERT (Briakou and Carpuat, 2020).[3] Synthetic divergences are generated starting from the 5,000 top scoring WikiMatrix sentences based on LASER score (i.e., seed equivalents). We fine-tune the "BERT-Base Multilingual Cased" model (Devlin et al., 2019) and set the margin equal to 5 as per our original implementation. We use the same margin value for the margin score of Algorithm 1. [4]

4 Intrinsic Evaluation of Bitext Quality

4.1 Human evaluation

We ask 3 bilingual speakers to evaluate the quality of the EN-EL bitexts. Given an original source sentence, they are asked to rank the original target and the candidate target in the order of their equivalence to the source. They are asked "Which sentence conveys the meaning of the source better?", and ties are allowed. A random sample of 100 pairs from forward and backward MT is annotated.

As can be seen in Table 2, 60% of ALL synthetic candidates are better translations of the WikiMatrix reference, which confirms the potential of NMT for improving over original translations. Further ablations confirm the benefits of selecting these synthetic candidates with the semantic equivalence condition. When the divergent scorer ranks a candidate higher than the original by a small margin (i.e., $0 \leq d \leq 5$ given $d = R(S_i, M_{S\rightarrow T}(T_i)) - R(S_i, T_i))$), human evaluation shows that the candidate is actually better than the original only 51% of the times. When using our exact semantic equivalence condition ($d > 5$), candidates are judged as more equivalent than the original 87.5% of the times, and annotations within this set have a stronger agreement (i.e., 0.688 Kendall's τ). This indicates that the condition $d > 5$ identifies more clear-cut examples of synthetic translations that fix semantic divergences in the original data and can be thus used for selective replacement of imperfect references by better quality translations.

Candidate set	% Equivalized	Kendall's τ
ALL	60.0%	0.321
$d < 0$	26.4%	0.157
$0 \leq d \leq 5$	51.0%	0.234
$d > 5$	**87.5%**	**0.688**

Table 2: Human evaluation results for all evaluated pairs and ablation sets for different thresholds on divergent score differences between candidates and originals (i.e., d).

Further inspection of the annotations reveals that most source-target WikiMatrix examples contain fine meaning differences (56%). In those cases, we observe that most of the content between the sentences is shared, but either small segments are

mistranslated (e.g., "London" instead of "Athens" in the first example of Table 1), or some information is missing from either side of the pair (e.g., "all six" missing from the target side in the third example of Table 1). Furthermore, more coarse-grained divergences are found less frequently (12%)—in those cases, we notice that sentences are usually either topically related or structurally similar (e.g., length, syntax) with a few anchor words (e.g., last example in Table 1). Finally, 32% of the times the original WikiMatrix pairs are perfect translations of each other.

4.2 How do synthetic translations differ from originals?

Figure 1 presents the distribution of lexical differences (i.e., computed using LeD—a score that captures lexical differences based on the percentages of tokens that are not found in two sentences (Niu and Carpuat, 2020)) between original and synthetic translations (in EN) for candidates that replace and do not replace the originals. [5] First, we observe that a substantial amount of synthetic translations that do not replace original references (40%) corresponds to small LED scores (< 0.1), suggesting that the equivalence criterion could fall back to the original sentence not because of the poor quality of candidate references, but rather due to them being already close to the originals. Furthermore, all synthetic translated instances are represented in almost all bins, with fewer instances found on the extreme bins of > 0.7 LED scores. Finally, synthetic translations that replace original references are mostly concentrated within the range $[0.2, 0.6]$ of LeD scores. This indicates that they share lexical content with the original, which further supports the hypothesis that synthetic translations revise fine-grained meaning differences in WikiMatrix in addition to alignment noise.

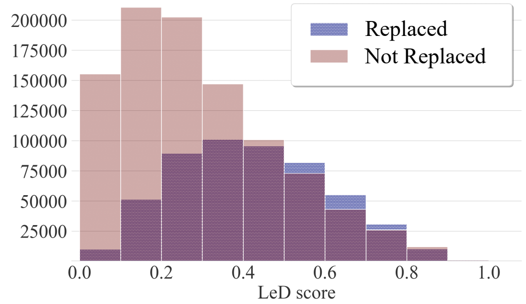

Figure 1: LeD differences of original vs. synthetic translations (EL→EN). Replaced candidates share lexical content with the originals.

4.3 How does the revised bitext differ from the original?

Table 3 presents differences in statistics of the original vs. revised WikiMatrix EN-EL bitexts to shed more light on the impact of selectively using synthetic translation for bitext quality improvement. [6] The refined bitext exhibits higher coverage (i.e., ratio of source words being aligned by any target words; rows 5 and 13) and smaller complexity (i.e.,

---

[5] LeD details are in Appendix A.

[6] Details on the metrics are in Appendix A.

the diversity of target word choices given a source word (Zhou et al., 2020)) compared to the original bitext. Moreover, the use of synthetic translations introduces small decreases in the lexical types covered in the final corpus (i.e., rows 3 and 11), which is expected as the additional coverage in the original corpus might be a result of divergent texts. Those observations are in line with prior work that seeks to characterize the nature of synthetic translations used in other settings, such as knowledge distillation (Zhou et al., 2020; Xu et al., 2021).

While fixing divergent references contributes to this simplification effect, NMT translations might also reinforce unwanted biases from the original bitext. For instance, the distribution of two grammatical gender pronouns on the English side is a little more imbalanced in the improved bitext than in the original (rows 6-7 and 14-15), [7] likely due to gender bias in NMT (Stanovsky et al., 2019). This calls for techniques to mitigate such biases (Saunders and Byrne, 2020; Stafanovičs et al., 2020) for NMT and other downstream tasks.

5 Extrinsic Evaluation of Bitext Quality

Our previous analysis suggests that selective replacement of divergent references with synthetic translations results in bitext of *improved quality*, with reduced level of noises and easier word-level mappings between the two languages, when compared to the original WikiMatrix corpus. To better understand how those differences impact downstream tasks, we contrast the improved bitext with the original through a series of extrinsic evaluations for EN-EL and EN-RO languages that rely on parallel texts as training samples (see §5.2). First, we focus on the recent state-of-the-art unsupervised BLI approach of Shi et al. (2021) that relies on word-alignments of extracted bitexts. Second, we follow the recent bitext quality evaluation frameworks adopted by the "Shared Task on Parallel Corpus Filtering and Alignment" (Koehn et al., 2020) and built neural machine translation systems from scratch and by continued training on a multilingual pre-trained transformer model. Finally, we conduct extensive ablation experiments to test the impact of using synthetic translations without the semantic equivalence condition and contrast with familiar techniques used by prior work (see §5.3).

5.1 Experimental Set-Up

BLI The task of BLI aims to induce a bilingual lexicon consisting of word translations in two languages. We experiment with the recently proposed method of Shi et al. (2021) that combines extracted bitext and unsupervised word alignment to perform fully unsupervised induction based on extracted statistics of aligned word pairs. The induced lexicons are evaluated based on MUSE (Lample et al., 2018) consisting of 45,515 and 80,815 dictionary entries for EL-EN and EN-RO, respectively.[8] We extract word alignments using mBERT-based *Simalign*[9] (Jalili Sabet et al., 2020) and statistics based on the implementation of Shi et al. (2021).[10]

MT We experiment with MT tasks following two approaches: (1) training standard transformer seq2seq models from scratch; (2) continued training for mT5 (Xue et al., 2021), a multilingual pretrained text-to-text transformer. We evaluate translation quality with BLEU (Papineni et al., 2002)[11] on the official development and test splits of the TED corpus (Qi et al., 2018). [12] For (1) we follow the experimental settings described in §3.2. For (2) we initialize the weights of transformer with "mT5-small" which consists of 300M parameters,[13]. We use the `simpletransformers` implementation.[14] We fine-tune for up to 5 epochs and include the parameter settings in Appendix D.

Ablation Settings We compare the NMT models trained on the variants of the synthetic bitext to isolate the impact of replacement criteria and different candidates.[15] For the former, we experiment with the **rejuvenation** approach of Jiao et al. (2020) that replaces original references with forward translated candidates for the 10% least active original samples measured by NMT probability scores. Moreover, we experiment with **forward** and **backtranslation** baselines trained on bitexts that consist solely from target- or source-side candidate sentences (i.e., original references are entirely excluded) and with ablations that consider either forward or backward

Table 4: Unsupervised BLI extrinsic evaluation results on MUSE for the entire dataset (*All*) and on subsets binned by frequency (i.e., right-most highlighted columns). Revised bitexts yield statistically significant ($*$) improvements over the original bitexts overall and for low-to-medium frequency dictionary entries.

candidates for the proposed semantic equivalence condition. Finally, we consider two alternatives to the **semantic equivalence** condition based on divergent scores: the **ranking** condition replaces a candidate if it scores higher than the original (i.e., margin with $d = 0$) and the **thresholding** condition adds the additional constraint that candidates should rank higher than a threshold to replace the original pair.

5.2 Extrinsic Evaluation Results

BLI Table 4 presents results for unsupervised BLI on the MUSE gold-standard dictionaries, for EL-EN and EN-RO. Across languages, the revised bitexts induce better lexicons compared to the original WikiMatrix. Crucially, improvements are reported both in terms of Recall—which connects to the observation that the revised bitext exhibits higher coverage than the original and in terms of Precision—which connects to the noise reduction effect that impacts the extracted word alignments. Additionally, a break-down on the Precision of the induced lexicons binned by the frequency of MUSE source-side entries (i.e., last 3 columns in Table 4) reveals that the improvements come from better induction of low- and medium-frequency words, which we expect are more sensitive to noisy misalignments that result from divergent bitext. Finally, those improvements are reported despite the small increase of the OOV rate in the revised lexicons that results from the decrease in the lexical types covered in it, as mentioned in the analysis (i.e., §4.3).

Furthermore, following the advice of Kementchedjhieva et al. (2019) who raise concerns on BLI evaluations based on gold-standard pre-defined dictionaries, we accompany our evaluation with manual verification to confirm that our conclusions are consistent with those of the automatic evaluation. Concretely, we manually check the *false positives* induced translation pairs from the original vs. the improved bitext. We found that $65/80$ are *false false positives* (due to incompleteness of pre-defined dictionaries) for the improved bitext and $51/80$ for the original (see Appendix F for the complete list). This confirms that the metric improvements we observe are meaningful and suggests that the improved bitext help learn better mappings between source and target words.

Table 6: BLEU results (averages of 3 seeds) on EN↔EL NMT. δ denotes average improvements over the original bitext. Bitext statistics give percentage of original ($\mathcal{O}$), forward ($\mathcal{F}$), and backward ($\mathcal{B}$) translated candidates. First column shows the selective replacement condition for candidate replacement (when applicable).

mT5 continued training across epochs. Across tasks and settings, the revised bitext yields better translation quality than the original WikiMatrix data. The consistent improvements we observe across the two settings suggest that the properties of the synthetic translations that replace original samples and bring those improvements are invariant to specific models. Moreover, the magnitude of improvements is larger in the continued training setting compared to training from scratch (e.g., $\sim +0.8$ vs. $\sim +1.5$, for EN→EL; $\sim +0.2$ vs. $\sim +1.5$, for RO→EN). The latter suggests that improvements from using synthetic samples do not only come from the normalization effect (i.e., synthetic samples are easier to model by NMT) but also connect to the reduced noise in the training samples. This further complements our hypothesis that synthetic translations can improve the quality of imperfect references that should, in principle, yield noisy training signals—and thus impact the resulting quality—of different MT models.

5.3 Ablation Study

Table 6 compares the translation quality (BLEU) of NMT systems trained on different synthetic translations. By forcing the semantic equivalence condition when deciding whether a synthetic translation replaces an original, we revise 50% of the latter yielding the best results across directions with significant improvements (i.e, increases do not lie within 1 stdev of the original's bitext performance) of +0.81 (EN→EL, row 9) and +1.49 (EL→EN, row 18) points over the original bitext.

Impact of semantic equivalence condition Table 6 shows that naively disregarding the original references and training only on synthetic translations gives mixed results: training on *forward-translated* references only (i.e., row 2) gives small improvements (+0.36) over the model trained on WikiMatrix for EN→EL, while it performs comparably to it for EL→EN (i.e., row 11). On the other hand, training on *backward* data only (i.e., row 12) improves BLEU by a small margin (+0.23) for MT into EN while it hurts BLEU when translating into EL (i.e., row 3). This indicates that the good quality of the synthetic translations cannot be taken for granted and motivates replacing original pairs under conditions that account for semantic controls.

The latter is further confirmed by results on the rejuvenation baseline: replacing candidates for the 10% of the most inactive WikiMatrix samples results in small and insignificant increases in BLEU when compared to models trained on original WikiMatrix data (i.e., rows 1-4 and 10-13). This indicates that rejuvenation might not be well-suited to lower resource settings than the ones it was originally tested on (Jiao et al., 2020). The rejuvenation technique might be affected by the decreased NMT quality and calibration in lower resource settings. By contrast, using synthetic translations with semantic control mitigates their impact.

Finally, all three semantic control variants based on divergent scores yield bitexts that improve BLEU compared to the original WikiMatrix (i.e., rows 5-8 and 14-18). Among them, the *margin* condition is the most successful, followed by the *thresholding* variant. The breakdown of training statistics reveals the reason behind their differences: the *thresholding* condition is a more strict constraint as it only allows synthetic candidates to replace the original pairs if they are predicted as exact equivalents, allowing for fewer revisions of divergent pairs in WikiMatrix. By contrast, the condition based on *margin* is a contrastive approach that allows for more revisions of the original data (i.e., a candidate might be a more fine-grained divergent of the source). The *ranking* criterion is the least successful method—this is expected as the divergence ranker is not trained as a regression model.

Impact of bi-directional candidates Considering both forward ($\mathcal{F}$) and backward ($\mathcal{B}$) translated candidates during selective replacement yields to further improvements (0.22-0.44 points) over bitext induced by the semantic equivalence condition with candidates from a single NMT model (i.e., rows 7-9 and 16-18). When forward and backward candidates are considered independently, they replace $34-37\%$ of the original pairs; in contrast, when considered together, they replace 50% of original WikiMatrix pairs. As a result, there is no perfect overlap between the original pairs replaced by the forward vs. backward model, which motivates the use of both to revise more divergences in WikiMatrix. This finding raises the question of whether using synthetic translations from both directions might benefit other scenarios, such as knowledge distillation.

6 Conclusion

This paper explored how synthetic translations can be used to revise bitext, using NMT models trained on the exact same data we seek to revise. Our extensive empirical study surprisingly shows that, even without access to further bilingual data or supervision, this approach improves the quality of the original bitext, especially when synthetic translations are generated in both translation directions and selectively replace the original using a semantic equivalence criterion. Specifically, our intrinsic evaluation showed that synthetic translations are of sufficient quality to improve over the original references, in addition to "normalizing" the bitext as suggested by prior work and corpus level statistics (Zhou et al., 2020; Xu et al., 2021). Extrinsic evaluations further show that the replaced synthetic translations provide more useful signals for BLI tasks and NMT training in two settings (i.e., training from scratch and continued training).

These findings provide a foundation for further exploration of the use of synthetic bitext. First, we focused our empirical study on language pairs and datasets where revising bitexts is the most needed and most likely to be useful: the resources available for these languages are not so large that mined bitext can simply be ignored or filtered with simple heuristics, yet there is enough data to build NMT systems of reasonable quality (i.e., $\sim$ 600K segments for EN-RO, and $\sim$ 750K for EN-EL). While in principle, selective replacement of divergent references with synthetic translations should port to high-resource settings, where NMT is as good or better than for the languages considered in this work, other techniques are likely needed in low-resource settings where NMT quality is too low to provide reliable candidate translations. Second, having established that the revised bitext improves the quality of the original bitext in isolation, it remains to be seen how to best revise bitexts in more heterogeneous scenarios with diverse sources of parallel or monolingual corpora. Overall, as synthetic data generated by NMT is increasingly used to improve cross-lingual transfer in multilingual NLP, our study motivates taking a closer look at the properties of synthetic samples to better understand how they might impact downstream tasks beyond raw performance metrics. All bitexts are available at: `https://github.com/Elbria/xling-SemDiv-Equivalize`.

A Details on bitext analysis

Complexity We follow Zhou et al. (2020) and compute the corpus complexity as a measure of translation uncertainty. Concretely, having access to an alignment model (here, `fast-align`), the complexity of a corpus d is computed by averaging the entropy of target words y conditioned on the source x, $L(d) = \frac{1}{|\mathcal{V}_x|}\sum_{x\in\mathcal{V}_x} H(y|x)$.

Coverage We follow Tu et al. (2016) and measure the coverage of each source-target parallel pair as the ratio of source words being aligned to target words, having access to an alignment model (here, `fast-align`). We compute the coverage for source-target and target-source bitexts separately. Corpus-level statistics correspond to average sentence-level results.

Grammatical Gender Pronouns The complete lists of grammatic gender pronouns we use for EL are: [ο, του, τον, αυτός, αυτού, αυτόν, εκέινος, εκέινου, εκείνον, οποίος, οποίου, οποίον] and [η, της, την, αυτήν, αυτής, αυτήν, εκέινη, εκέινης, εκείνην, οποία, οποίας, οποίαν].

Lexical Differences (LeD) We follow (Niu and Carpuat, 2020) and compute the Lexical Differences score between two sentences S_1 and S_2 as the percentage of tokens that are not found in both, LeD$= \frac{1}{2}(\frac{|S_1/\ S_2|}{|S_1|}) + \frac{|S_2/\ S_1|}{|S_2|}$.

B Result on development sets

Table 7 presents results on the main and secondary NMT tasks on TED developments sets. The refined bitext leads to consistent and significant improvements in BLEU across language-pairs and translation directions.

C Sockeye2 configuration details

We use the base Transformer architecture (Vaswani et al., 2017). with embedding size of 512, transformer hidden size of 2,048, 8 attention heads, 6 transformer layers, and dropout of 0.1. Target embeddings are tied with the output layer weights. We train with label smoothing (0.1). We optimize with Adam (Kingma and Ba, 2015) with a batch size of 4,096 tokens and checkpoint models every 1,000 updates. The initial learning rate is 0.0002, and it is reduced by 30% after 4 checkpoints without validation perplexity improvement. We stop training after 20 checkpoints without improvement. We select the best checkpoint based on validation BLEU (Papineni et al., 2002). All models are trained on a single GeForce GTX 1080 GPU. Tables 8 presents details of NMT training with `Sockeye2`.

E Data Statistics

Table 10 presents data statistics for WikiMatrix training data, and TED evaluation sets.

F Manual inspection of BLI

Table 12 presents manual analysis results on False Positives entries of the MUSE evaluation set for the EN-EL language-pair.

G Streamlining equivalization

Based on ablation analysis presented in Table 6 the best equivalization strategies consider candidates from two NMT models trained independently to translate in opposite directions. In Table 11 we show how our approach yields comparable results by replacing the two uni-directional models (UNI-NMT) with a single bi-directional model (BI-NMT) while reducing training by $\sim 30\%$.

Abstract

Recent work has identified properties of pretrained self-attention models that mirror those of dependency parse structures. In particular, some self-attention heads correspond well to individual dependency types. Inspired by these developments, we propose a new competitive mechanism that encourages these attention heads to model different dependency relations. We introduce a new model, the Unsupervised Dependency Graph Network (UDGN), that can induce dependency structures from raw corpora and the masked language modeling task. Experiment results show that UDGN achieves very strong unsupervised dependency parsing performance without gold POS tags and any other external information. The competitive gated heads show a strong correlation with human-annotated dependency types. Furthermore, the UDGN can also achieve competitive performance on masked language modeling and sentence textual similarity tasks [1].

1 Introduction

The goal of unsupervised dependency parsing is to induce dependency grammar from corpora that don't have annotated parse trees (Marecek, 2016). Although the task is difficult, one advantage of unsupervised methods is that they can leverage vast amount of unannotated raw corpus (Han et al., 2020). Thus, adapting the task into a pretraining framework is increasingly tempting. The induced dependency trees can also help solve other NLP problems such as unsupervised discourse parsing (Nishida and Nakayama, 2020), aspect-based sentiment analysis (Dai et al., 2021) and intent discovery (Liu et al., 2021). Furthermore, the task can also be used as a probe to verify cognitive theories for human language acquistition (Yang et al., 2020; Pate and Goldwater, 2013; Katzir, 2014; Solan et al., 2002).

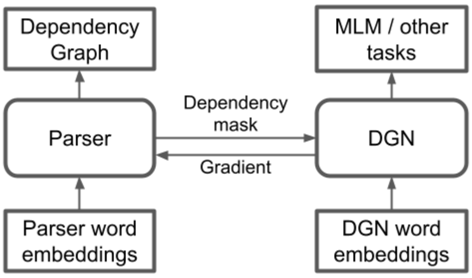

Figure 1: The architecture of Unsupervised Dependency Graph Network (UDGN). Given an input sentence, the parser can predict the dependency relation between tokens and generate a soft mask to approximate the undirected dependency graph. Conditioning on the mask, the DGN computes contextual word embeddings for the training task. Since the mask is soft, the gradient can be backpropagated from the DGN into the parser. Thus UDGN can induce grammar while training on masked language modeling or other downstream tasks.

Pretrained Language Models (PLMs) have become the foundation of modern natural language processing in the last few years (Bommasani et al., 2021). They dominate the most if not all NLP tasks. But Recent works show that, beyond pretraining big models on large-scale corpora, deep learning methods can improve performance by increasing models' awareness of syntactic information (Kuncoro et al., 2020). These methods either include known structural information as input to the model (Sundararaman et al., 2019; Bai et al., 2021), or incorporate structural prediction tasks into the training process (Wang et al., 2019a). However, these attempts require access to large datasets with supervised parses, which may be complicated and expensive.

Recent work also identified properties of pretrained self-attention models that mirror those of dependency parse structures (Htut et al., 2019; Hewitt

and Manning, 2019; Jawahar et al., 2019). StructFormer (Shen et al., 2020) shows that a transformer-based model can induce a good dependency structure. The belief that linguistic structure may be embedded in these models is of interest to the community. Furthermore, Dai et al. (2021) shows that the induced trees from finetuned RoBERTa outperform parser-provided trees on aspect-based sentiment analysis tasks. This result brings interest to study task-specific structures. From this perspective, the unsupervised acquisition of dependency structure from raw data or downstream tasks appears important and feasible.

Traditionally, dependency grammars consider the dependency types (a.k.a. syntactic functions) as primitive and then derive the dependency graph (Debusmann, 2000). Every head-dependent dependency bears a syntactic function (Mel'cuk et al., 1988). Htut et al. (2019) shows that some attention heads in BERT (Devlin et al., 2018) and RoBERTa (Liu et al., 2019) track individual dependency types. In other words, these heads model different syntactic functions. Inspired by this observation and syntactic functions, we introduce *competitive gated heads* to model different syntactic parts and the process of selecting the proper syntactic function for each edge. These heads include two key components:

- A set of gated heads that model different information propagation processes between tokens;
- A competitive controller that selects the most suitable gated head for each pair of tokens.

Building on these components, we propose a novel architecture, the Unsupervised Dependency Graph Network (UDGN). As shown in Figure 1, the UDGN is composed of two networks: a *parser* that computes the dependency head distribution p_i for each word w_i in the input sentence and then converts it to a matrix of edge probability m_{ij} that approximates an undirected dependency graph; a *Dependency Graph Network* (DGN) that uses the edge probabilities $\{m_{ij}\}$ and competitive gated heads to propagate information between words to compute a contextualized embedding h_i for each word w_i. While training with the masked language modeling or other objectives, the gradient can flow through the DGN to the parser network through its dependence on m_{ij}. As a result, UDGN can induce a dependency grammar while solely relying on the masked language modeling objective.

In the experiment section, we first train the UDGN with masked language modeling, then evaluate it on unsupervised dependency parsing. Our experimental results show that UDGN can: 1) achieve very strong unsupervised parsing results among models that don't have access to extra annotations (including POS tags); 2) learn attention heads that are strongly correlated to human-annotated dependency types; 3) achieve competitive performance on language modeling tasks. We also finetune the pretrained UDGN on Semantic Textual Similarity (STS) tasks. Our experiments show that UDGN outperforms a Transformer baseline trained on the same corpus.

2 Related Work

Unsupervised dependency parsing Unsupervised dependency parsing is a long-standing task for computational linguistics. Dependency Model with Valence (DMV; Klein and Manning 2004) is the basis of several unsupervised dependency parsing methods (Daumé III, 2009; Gillenwater et al., 2010). Jiang et al. (2016) updates the method using neural networks to predict grammar rule probabilities. While previous methods mostly require additional Part-of-Speech (POS) information, Spitkovsky et al. (2011) tackled the issue by performing clustering based on word context information and then assigning the cluster ID to each word as their tag. He et al. (2018) incorporate an invertible neural network into DMV model to jointly model dependency grammar and word embeddings. Recently, NL-PCFG (Zhu et al., 2020) and NBL-PCFG (Yang et al., 2021) combined neural network and L-PCFG to achieve good performance in a joint unsupervised dependency and constituency parsing setting. StructFormer (Shen et al., 2020) proposes a joint constituency and dependency parser and uses the dependency distribution to regularize the self-attention heads in the transformer model. This joint parser-language model framework can induce grammar from masked language modeling tasks.

The UDGN's architecture is similar to StructFormer, both models include a parser and masked language model. Our model, however, has three major differences: 1) it uses competitive gated heads to improve models performance on grammar induction; 2) it uses a neural head selective parser that can produce both projective and non-projective dependency trees, whereas the distance parser in StructFormer can only produce projective trees; 3) it uses a simplified method to generate an undirected dependency mask.

Transformers, Graph Neural Networks and Dependency Graphs In many Transformer-based models, attention masks are often used to limit the input tokens that a particular timestep can attend over. In Yang et al. (2019), for example, a mask derived from the permutation of inputs is used to induce a factorization over the tokens so that the resulting model is a valid probabilistic model. This attention mask can be viewed as an adjacency matrix over a graph whose nodes are the input tokens. From this perspective, Transformers are a form of Graph Neural Network (Scarselli et al., 2008) — specifically, a Graph Attention Network (GAT; Veličković et al. 2017), as it attends over the features of its neighbors. Several works have made this connection, and integrated dependency structures into transformers (Ahmad et al., 2021; Wang et al., 2019b; Tang et al., 2020). Results from Omote et al. (2019) and Deguchi et al. (2019) suggest that embedding these structures can improve translation models.

However, these dependency parses may not always be present to be used as input to the model. Strubell et al. (2018) trains the self-attention to attend the syntactic governor (head) of a particular token, resulting in a model that does not require dependency structure as input during inference time. We take a further step in our work and attempt to learn these structures in an unsupervised fashion from the MLM objective.

Differentiable Structured Prediction While the head selection is a good approximation of a tree structure, there are methods to obtain a relaxed adjacency matrix as the output of the parser. Previous work have used such methods for predicting structure. Koo et al. (2007) proposed using the Kirchoff matrix tree theorem for dependency parsing. They explain how the marginals of the edge potentials are computed, and these marginals have properties similar to a tree adjacency matrix (sum over the marginals are equal to $N-1$ for example, where N is the length of the sentence). Eisner (2016) describes how backpropagation can be used to compute marginals of some structured prediction algorithm. We also tried using the Kirchhoff method to normalize our dependency distributions in Appendix A.3. Corro and Titov (2018) uses similar notions but relaxes projective trees using Gumbel-softmax. Kim et al. (2017) proposed a structured form of attention and show that they are useful for certain sequence-to-sequence tasks. Mensch and Blondel (2018) gives a general theoretical treatment for these types of relaxations, while Paulus et al. (2020) gives a practical treatment of possible applications for these methods.

3 Model Architecture

As shown in Figure 2, the parser computes a dependency head distribution for each token and then converts it to a soft dependency mask m_{ij}. The DGN takes m_{ij} and the sentence as input and uses a competitive mechanism to propagate information between tokens.

3.1 Head Selective Parser

We use a simplified version of the Dependency Neural Selection parser (DENSE; Zhang et al. 2016) that only predicts unlabelled dependency relations. The parser takes the sentence $\mathbf{s} = w_1 w_2 ... w_T$ as input, and, for each token w_i, it produces a distribution p_i over all tokens in the sentence, resulting in a $T \times T$ weight matrix.

The parser first maps the sequence of tokens $w_1 w_2 ... w_T$ into a sequence of embeddings $[\mathbf{x}_1, \mathbf{x}_2, ..., \mathbf{x}_T]$. Then the word embeddings are fed into a stack of a bidirectional LSTM (BiLSTM):

$$\mathbf{h}_i = \mathrm{BiLSTM}(\mathbf{x}_i) \tag{1}$$

where $\mathbf{h}_i$ is the output of the BiLSTM at i-th timestep. Linear transforms are applied to the output of the BiLSTM to extract head and dependent information.

$$\mathbf{h}_i^{\mathrm{H}} = \mathbf{W}_{\mathrm{H}} \mathbf{h}_i + \mathbf{b}_{\mathrm{H}} \tag{2}$$

$$\mathbf{h}_i^{\mathrm{D}} = \mathbf{W}_{\mathrm{D}} \mathbf{h}_i + \mathbf{b}_{\mathrm{D}} \tag{3}$$

To map the head and dependents, we use bilinear attention:

$$e_{ij} = \frac{\mathbf{h}_i^{\mathrm{D}} \mathbf{h}_j^{\mathrm{H}}}{\sqrt{D}} \tag{4}$$

$$p_{ij} = \frac{\exp(e_{ij})}{\sum_k \exp(e_{ik})} \tag{5}$$

where p_{ij} is the probability that w_i depends on w_j, D is the dimension of hidden states. During the inference for parsing, the Chu-Liu/Edmonds' algorithm (Chu and Liu, 1965b) is used to extract the most likely directed dependency graph from the matrix p.

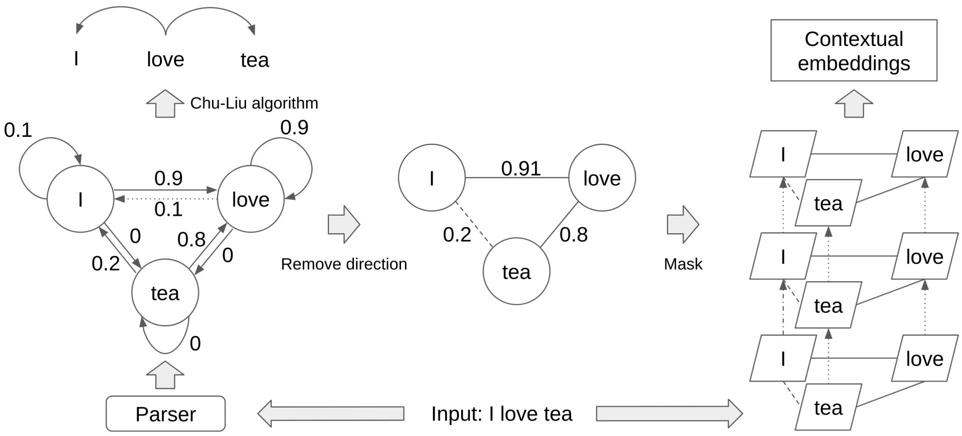

Figure 2: Details of the UDGN. Given the input sentence, the parser (left) produces a dependency head distribution for each token. These distributions form a distribution matrix p_{ij}. To do unsupervised parsing, the Chu-Liu algorithm (Chu and Liu, 1965a) generates the most likely dependency graph given p_{ij}. While training, however, we remove the direction of dependency in p_{ij} and obtain an undirected dependency mask m_{ij} (middle). m_{ij} is symmetric and with zeroes along the diagonal. The DGN (right) takes m_{ij} and the sentence as input and uses competitive gated heads to propagate information between tokens. m_{ij} controls the amount of information being propagated between nodes. If m_{ij} is small then less information will be communicated between x_i and x_j, and vice versa.

3.2 Dependency Mask

Given the dependency probabilities, StructFormer (Shen et al., 2020) uses a weighted sum of matrix p and $p^\top$ to produce a mask for self-attention layers in the transformer. We found that simply using the adjacency matrix of the undirected dependency graph provides better parsing results and perplexities. However, simply using the sum of the matrix and its transpose to create a symmetric weight matrix does not ensure that the attention mask has values < 1. When $p_{ij} = 1$ and $p_{ji} = 1$, for instance, the mask violates the constraints of a dependency mask. Thus, we treat p_{ij} and p_{ji} as parameters for independent Bernoulli variables, and we compute the probability that either w_i depends on w_j **or** w_j depends on w_i.

$$\begin{aligned} m_{ij} &= p(i \rightarrow j \quad \textbf{or} \quad j \rightarrow i) \\ &= p_{ij} + p_{ji} - p_{ij} \times p_{ji} \end{aligned} \tag{6}$$

3.3 Dependency Graph Network

To better induce and model the dependency relations, we propose a new Dependency Graph Network (DGN). One DGN layer includes several gated heads and a competitive controller. A gated head can process and propagate information from one node to another. Different heads can learn to process and propagate different types of information. The competitive controller is designed to select the correct head to propagate information between a specific pair of nodes.

We take inspiration from the linguistic theory that dependencies are associated with different syntactic functions. These functions can appear as labels, e.g. ATTR (attribute), COMP-P (complement of preposition), and COMP-TO (complement of to). However, DGN learns these functions from training tasks, which in our experiments is the masked language model objective. Since these objectives tend to be statistical in nature, these functions may not be correlated with ground truth labels given by human experts.

Inside each layer, the input vector h_i^{l-1} is first projected into N groups of vectors, where N is the number of heads. Each group contains four different vectors, namely, query $\mathbf{q}$, key $\mathbf{k}$, value $\mathbf{v}$ and gate $\mathbf{g}$:

$$\begin{bmatrix} \mathbf{q}_{ik} \\ \mathbf{k}_{ik} \\ \mathbf{v}_{ik} \\ \mathbf{g}_{ik} \end{bmatrix} = \mathbf{W}_{\text{head}_k} \mathbf{h}_i^{l-1} + \mathbf{b}_{\text{head}_k} \tag{7}$$

Gated Head To model the information propagation from node j to node i, we proposed a gated head:

$$\mathbf{c}_{ijk} = \sigma(\mathbf{v}_{jk}) \odot \text{sigmoid}(\mathbf{g}_{ik}) \tag{8}$$

where σ is a non-linear activation function, and gates $\text{sigmoid}(\mathbf{g})$ allows the i-th token to filter the extracted information. We also found that the gate effectively improves the model's ability to induce

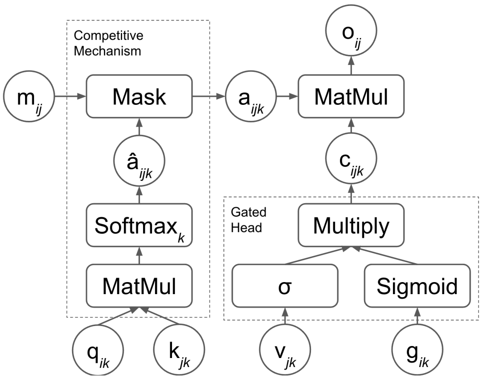

Figure 3: Competitive Gated Heads. Suppose that the information should be propagated from node j to node i, the competitive controller takes $\mathbf{q}_{i\cdot}, \mathbf{k}_{j\cdot}$ as input, output a probability distribution $\hat{a}_{ij}$ across different heads. This allows the model to select a head for the information propagation. Then the probability $\hat{a}_{ijk}$ is multiplied by dependency mask m_{ij} to get a_{ijk}. The mask m_{ij} functions as a macro gate to control the amount of information propagate between the node pair. For the k-th head, the node j send representation $\mathbf{v}_{jk}$, the node i uses a gate $\mathbf{g}_{ik}$ to filter the incoming representation.

latent dependency structures that are coherent to human-annotated trees. The activation function can be chosen from a wide variety of functions, including the identity function, tanh, ReLU, and ELU, etc. In our experiment, we found that tanh function provides the best overall performance. This is probably due to two reasons: a) tanh function provides a bounded output (between -1 and 1), and b) gates and head weights are more effective while controlling a bounded value.

Competitive Controller Lamb et al. (2021) proposed the idea of using a competition method to encourage heads to specialize over training iterations to learn different functions. This idea is coherent with our intuition different heads should model different dependency relations. In UDGN, a competitive controller is designed to select a head for each pair of nodes (i, j). However discrete assignment is hard to optimize, we replace it with a soft relaxation:

$$e_{ijk} = \frac{\mathbf{q}_{ik}\mathbf{k}_{jk}}{\sqrt{D}} \tag{9}$$

$$\hat{a}_{ijk} = \text{softmax}_k(e_{ijk}) \tag{10}$$

where $\hat{a}_{ijk}$ is the probability that the k-th head is assigned to propagate information from the j-th token to the i-th token. To obtain the actual head weights, we multiply the probability of edge existence with the probability of choosing a specific attention head:

$$a_{ijk} = \hat{a}_{ijk} \times m_{ij} \tag{11}$$

where a_{ijk} is the weight from the node j to the node i for k-th attention head.

Relative Position Bias Transformer models use positional encoding to represent the absolute position for each token. In DGN, we only model whether the token is before or after the current token. The motivating intuition is the association of different heads with different directions. In equation 10, we can introduce a relative position bias:

$$\hat{a}_{ijk} = \text{softmax}_k(e_{ijk} + b_k^{lr}) \tag{12}$$

$$b_k^{lr} = \begin{cases} b_k^l, & i > j \\ b_k^r, & i < j \end{cases} \tag{13}$$

where b_k^l and b_k^r are trainable parameters. The relative position bias allows the attention head k to prioritize forward or backward directions. A mere forward and backward differentiation may seem weak compared to other parameterizations of positional encoding (Vaswani et al., 2017; Shaw et al., 2018), but in conjunction with the dependency constraints, this method is a more effective way to model the relative position in a tree structure. As shown in Table 4, the relative position bias achieves stronger masked language modeling and parsing performance than positional encoding.

At the end, a matrix multiplication is used to aggregate information from different positions.

$$\mathbf{o}_{ik} = \sum_j a_{ijk}\mathbf{c}_{ijk} \tag{14}$$

Then, the output $\mathbf{o}$ from different heads are concatenated, and then projected back to the hidden state space with a linear layer.

$$\mathbf{h}_i^l = \mathbf{h}_i^{l-1} + \mathbf{W}_o \begin{bmatrix} \mathbf{o}_{i1} \\ \vdots \\ \mathbf{o}_{in} \end{bmatrix} + \mathbf{b}_o \tag{15}$$

where $\mathbf{h}_i^l$ is the output of the l-th gated self attention layers. The shared hidden state space can be seen as the shared global workspace (Goyal et al., 2021) for different independent mechanisms (heads).

Table 1: Masked Language Model perplexities on different datasets.

4 Experiments

4.1 Masked Language Modeling

Language Modeling tasks evaluate the model's general ability to model different semantic and syntactic phenomena (e.g., words co-occurrence, verb-subject agreement, etc.). The performance of MLM is evaluated by measuring perplexity on masked words. We perform experiments on two corpora: the Penn TreeBank (PTB) and Brown Laboratory for Linguistic Information Processing (BLLIP). In this experiment, we randomly replace each token with a mask token `<mask>`, such that the model is required to predict the original token. But we never replace `<unk>` token.

PTB The Penn Treebank (Marcus et al., 1993) is a standard dataset for language modeling (Mikolov et al., 2012) and unsupervised constituency parsing (Shen et al., 2018; Kim et al., 2019). It contains 1M words (2499 stories) from Wall Street Journal. Following the setting proposed in Shen et al. (2020), we preprocess the Penn Treebank dataset by removing all punctuations, lower case all letters, and replaces low frequency tokens (< 5) with `<unk>`. The preprocessing results in a vocabulary size of 10798 (including `<unk>`, `<pad>` and `<mask>`).

BLLIP The Brown Laboratory for Linguistic Information Processing dataset is a large corpus, parsed in the same style as the PTB dataset. It contains 24 million sentences from Wall Street Journal. We perform experiments on four subsets of BLLIP: BLLIP-XS (40k sentences, 1M tokens), BLLIP-SM (200K sentences, 5M tokens), BLLIP-MD (600K sentences, 14M tokens), and BLLIP-LG (2M sentences, 42M tokens). Following the same setting proposed in Hu et al. (2020) for sentence selection, each subset is a superset of smaller subsets. Models trained on different subsets are tested on a shared held-out test set (20k sentences, 500k tokens). We use a shared vocabulary for all splits to make the mask language modeling and parsing results comparable. Like the PTB dataset, we preprocess the BLLIP dataset by removing all punctuations and lower case letters. The shared vocabulary is obtained by counting word frequencies on the BLLIP-LG dataset and selecting the words that appear more than 27 times. The resulting vocabulary size is 30232 (including `<unk>`, `<pad>` and `<mask>`), and covers more than 98% tokens in BLLIP-LG split.

Table 2: Dependency Parsing Results on WSJ test set without gold POS tags. DMV-based baseline results are from He et al. (2018). DDA stands for Directed Dependency Accuracy. UDA stands for Undirected Dependency Accuracy. Unsupervised dependency parsing results with the knowledge of gold POS tags or other external knowledge are excluded from this table.

The mask rate is 30% when training on both corpora. In Section A.4, we further explore the relationship between mask rate and parsing results. Other hyperparameters are tuned separately for each model and dataset. Details are further described in Section A.1. Table 1 shows The masked language model results. UDGN outperforms the baselines on smaller datasets (PTB, BLLIP-SM), but underperforms against baselines trained on large datasets (BLLIP-MD, BLLIP-LG). However, in Section 4.5, we find that the UDGN pretrained on BLLIP-LG dataset can achieve stronger performance when finetuned on a downstream task. This result may suggest that our model learns more generic contextual embeddings.

4.2 Unsupervised Dependency Parsing

Following previous research (Shen et al., 2020), we use the model trained on the PTB training set (section 0-20, no punctuations) and test its parsing accuracy on section 23 of the PTB corpus. Punctuations are ignored during the evaluation. We convert the human-annotated constituency trees in the PTB test set (Marcus et al., 1993) to dependency trees with Stanford CoreNLP (Manning et al., 2014) and use the Directed Dependency Accuracy (DDA) as our metric. To derive valid trees from the attention

Transformer	0.43(0.00)	0.46(0.03)	0.46(0.12)	0.30(0.01)	0.39(0.15)	0.26(0.02)	0.28(0.01)	0.30(0.10)

Table 3: The *pearson correlation coefficients* between most frequent dependency types and their most correlated head. All results are average across four random seeds, standard derivation are in parentheses. Types are arranged from the highest frequency to lowest frequency. PCC heat maps between all types and all heads are in Appendix A.2.

mask, we use the Chu-Liu (Chu and Liu, 1965b) (or Edmonds' (Edmonds, 1967)) algorithm to obtain the maximum directed spanning tree.

Table 2 shows that our model outperforms baseline models. This result suggests that, given our minimum inductive bias (a token must attach to another, but the graph is not necessarily a tree), predicting missing tokens implicitly learns a good graph that correlates well with human-annotated dependency trees. In other words, some of the dependency relations proposed by linguists may correspond with efficient ways of propagating information through the sentence. Parsing examples of our model can be found in Appendix A.5.

4.3 Correlation Between Heads and Dependency Types

In this section, we test the correlation between heads and dependency types. We consider each dependency edge $i \rightarrow j$ (i depends on j) in the ground truth structure as a data point. Given all the edges, we can obtain three sets of quantities: head probabilities $A^k = \{\hat{a}^k_{ji}\}$ and type values $Y^l = \{y^l_{ij}\}$. $\hat{a}^k_{ij}$ is a real value between 0 and 1, represents the probability that heads k is used to model the information propagation from the child i to the parent j. Details about this value can be found at Equation 12. y^l_{ij} is a binary value, represents whether the label l is assigned to edge $i \rightarrow j$. We can then compute Pearson Correlation Coefficient (PCC) for every pair of A^k and Y^l across all ground truth edges $\{i \rightarrow j\}$:

$$\rho_{A^k,Y^l} = \frac{\mathrm{cov}(A^k, Y^l)}{\sigma_{A^k}\sigma_{Y^l}} \qquad (16)$$

where $\mathrm{cov}(\cdot)$ is the covariance function, $\sigma_\cdot$ is the standard deviation of the respective variable. Hence, ρ_{A^k,Y^l} measures the correlation between head k and dependency type l. $\rho_{A^k,Y^l} > 0$ means that the model tends to use head k for propagating information from child to parent for dependency edges of the type l. Here, we only consider the information propagation from child to parent even though information can propagate in both directions in masked language models. In Appendix A.2, we also computed the PCC for the parent to child direction.

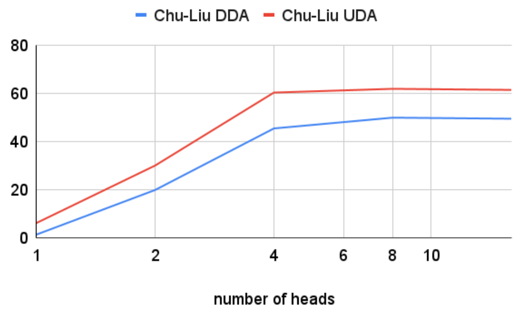

Figure 4: Relationship between the parsing performance and the number of heads in each layer. The hidden state size of heads are adjusted to maintain the same number of total parameters.

Table 3 shows the PCC between the most frequent dependency types and their most correlated heads. We can observe that all three models have heads that are positively correlated to human-annotated dependency types. This result is coherent with the observation of Htut et al. (2019). Meanwhile, the UDGN achieves a significantly better correlation than the StructFormer and the Transformer. This confirms our intuition that competitive gated heads can better induce dependency types.

4.4 Ablation Experiments

Figure 4 shows the relation between the number of heads in each UDGN layer and the model's unsupervised parsing performance. Table 4 shows the model's performance when individual components are removed. We can observe that the number of heads has the most significant influence on unsupervised parsing performance. While this is only one head, the model fails to learn any meaningful structure. Then the parsing performance increase as the number of heads increase. And we observe

Model	MLM	Argmax		Chu-Liu	
	PPL	DDA	UDA	DDA	UDA
UDGN	59.3(0.5)	52.7(0.9)	58.3(0.7)	49.9(1.6)	61.8(0.9)
- Gates	69.5(1.9)	31.5(2.2)	40.7(0.3)	26.1(2.1)	48.9(0.5)
- Competition	73.6(3.1)	44.7(1.9)	54.4(1.9)	40.4(1.6)	56.6(2.1)
- relative pos bias	62.1(1.0)	51.6(1.6)	59.8(0.8)	47.4(2.6)	62.1(1.1)

Table 4: The performance of UDGN after removing different components. "- Gates" means removing the gate $\mathbf{g}$ in gated heads. "- Competition" means using a non-competitive sigmoid function to replace the softmax in the competitive controller. "- relative pos bias" means removing the relative positional bias. "Chu-Liu" means that we use the Chu-Liu algorithm to extract the maximum directed spanning tree. "Argmax" means that we take the word at the maximum p value as the dependency head. This could result in non-tree structures, but we believe that this metric gives a better indication of how often the parser predicts the right head of each word.

Model	STS12	STS13	STS14	STS15	STS16	STS-B	SICK-R	Avg.
Transformer	76.17	61.48	73.97	74.35	53.72	64.26	80.00	69.14
UDGN (Freeze parser)	77.71	71.17	78.71	82.30	66.04	70.13	82.17	75.46
UDGN	80.51	75.02	80.54	82.16	64.73	72.49	81.94	76.77

Table 5: Sentence embedding performance on STS tasks. All models are pretrained on BLLIP-LG, and finetuned on STS. Freeze parser means that the parameters for the parser are not updated during finetuning.

marginal improvement after the number of heads reaching 8. The second most significant parsing performance decrease is caused by removing the gating mechanism. This change forces each head to always extract the same information from a given key node h_j, regardless of the query node h_i. This has a similar effect as the previous change, reducing the diversity of different functions that can be modeled by heads. These two observations may suggest that the diversity of information propagation function (multiple heads) is essential to induce a meaningful structure.

The competitive controller also has an important influence on parsing performance. Its non-competitive version is the sigmoid controller used in StructFormer. If we replace it with the non-competitive controller, the DDA decreases to 44.7 which is similar to the result of StructFormer (46.2). Another interesting observation is that removing relative position bias has the least influence on parsing and language modeling. This may suggest that the dependency structure already encoded certain positional information. More ablation experiment results can be found in Appendix A.3.

4.5 Fine-tuning

In this experiment, the goal was to determine if a better representation of semantics can be encoded if the model was constrained for structure. We pretrain a UDGN model on the BLLIP-XL dataset, and then finetune it on the STS-B (Cer et al., 2017) dataset. For a controlled experiment, we compare the results we attain with the previously mentioned Transformer model. We then evaluate the resulting classifier on the STS 2012-2016 (Agirre et al., 2012, 2013, 2014, 2015, 2016), the SICK-Relatedness (Marelli et al., 2014) dataset, and STS-B (Cer et al., 2017). We then report the Spearman correlation score for each dataset (the 'all' setting in Gao et al. 2021).

We find that the UDGN model performs better overall than the transformer model. While these are not state-of-the-art results for these tasks, our comparison aimed to examine the benefit of the UDGN model over the Transformer architecture. It's also interesting to notice that if parameters in the parser are frozen during the finetuning, the model will get worse performance. This result suggests that finetuning on STS forces pretrained language models to learn more task-oriented trees. Dai et al. (2021) observed similar results with finetuned RoBERTa on Aspect-Based Sentiment Analysis tasks.

5 Conclusion

In this paper, we proposed the Unsupervised Dependency Graph Network (UDGN), a novel architecture to induce and accommodate dependency graphs in a transformer-like framework. The model is inspired by linguistic theories. Experiment results show that UDGN achieves state-of-the-art dependency grammar induction performance. The competitive gated heads show a strong correlation to human-annotated dependency types. We hope these interesting observations will build new connections between classic linguistic theories and modern neural network models. Another interesting future research direction is exploring how the newly proposed components can help large-scale pretrained languages models.

A Appendix

A.1 Hyperparameters

Model	Hidden Size	head/Head Size	Dropout	DropAtt	lr	#tags	Feedforward Size
UDGN (PTB)	512	128	0.2	0.1	0.001	6	–
UDGN (BLLIP-XS,SM)	512	128	0.2	0.1	0.001	6	–
UDGN (BLLIP-MD,LG)	512	128	0.2	0.1	0.001	6	–
Transformer	512	64	0.1	0.1	0.0003	–	2048
StructFormer	512	64	0.1	0.1	0.0003	–	2048

Table 6: Hyperparameters used in Masked Language Modeling experiments. All model has 8 layers and 8 heads or attention heads. For UDGN, we apply dropout in front of all linear layers; dropatt randomly drops heads; the parser is a 3-layer biLSTM model, which has 6 tag embeddings, 1 of them is a zero vector, 5 of them are trainable. For transformer and structformer, the dropout is applied to the output of each sublayers; dropatt randomly drops attention weights; the size of their feedforward sublayers is 2048.

A.2 Correlation between Heads and Dependency Types

Models	prep	pobj	det	compound	nsubj	amod	dobj	aux
UDGN	0.45(0.15)	0.84(0.05)	0.59(0.08)	0.38(0.03)	0.47(0.08)	0.43(0.08)	0.32(0.04)	0.45(0.08)
StructFormer	0.28(0.04)	0.43(0.13)	0.38(0.06)	0.34(0.02)	0.30(0.03)	0.27(0.01)	0.19(0.02)	0.22(0.02)
Transformer	0.44(0.03)	0.31(0.05)	0.37(0.03)	0.32(0.00)	0.16(0.01)	0.28(0.01)	0.20(0.01)	0.26(0.03)

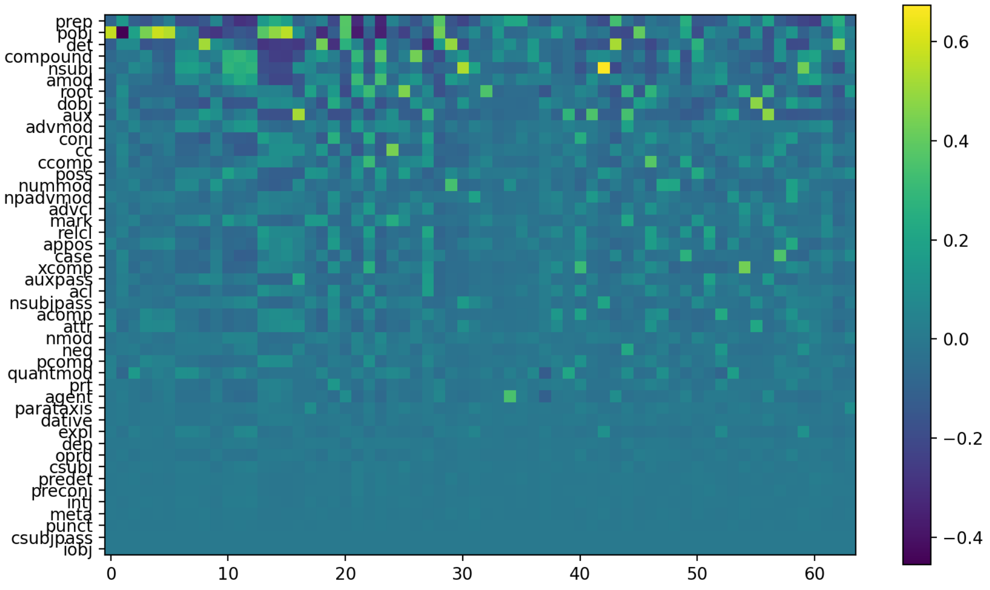
Table 7: The pearson correlation coefficients between most frequent dependency types (*the child to parent direction*) and their most correlated head. Types are arrange from the highest frequency to lower frequency.

A.3 More Ablation Experiments

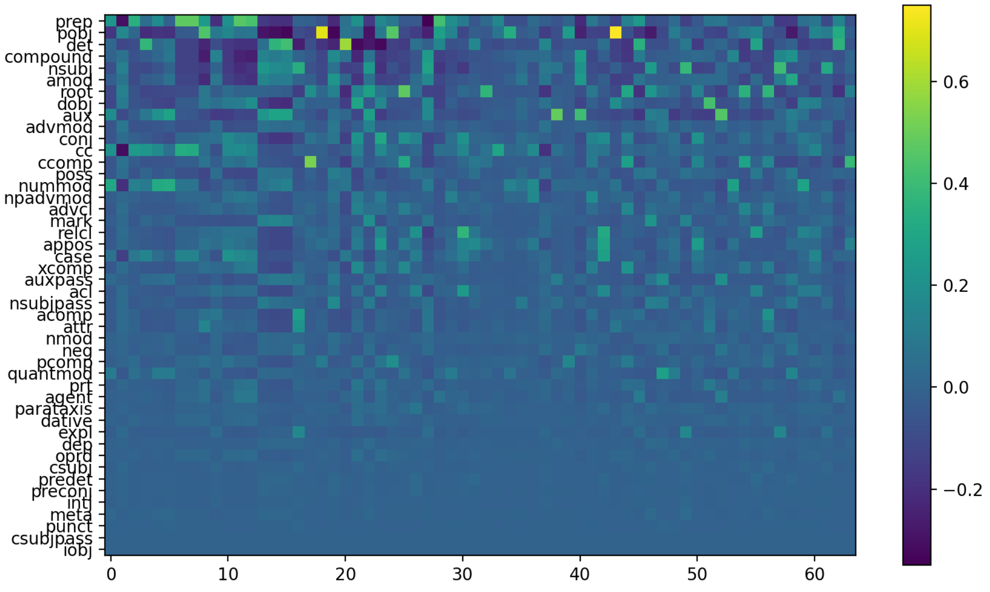
In this section, we evaluate UDGN's performance after removing the nonlinear function in gated heads, replacing relative positional bias with a standard positional encoding, and using Kirchhoff matrix tree theorem (Koo et al., 2007) to normalize the dependency probabilities. It's interesting to notice that, although Kirchhoff method can produce a valid marginal distribution for dependency probabilities, adding the normalization can't improve the unsupervised parsing performance. We believe it's due to the extra optimization complexity introduced by the matrix inversion in Kirchhoff method. Another observation is that relative position bias helps the model to achieve better perplexity and parsing performance in comparison with positional encoding. This may suggest that the combination of dependency graphs and relative positions is more informative than absolute positions.

Model	MLM	Argmax		Chu-Liu	
	PPL	DDA	UDA	DDA	UDA
UDGN	60.4(0.8)	52.5(0.7)	58.8(0.9)	50.2(1.5)	61.2(0.4)
- Nonlinear	61.2(1.0)	49.5(1.1)	56.8(1.4)	45.6(2.0)	60.8(1.4)
- relative pos bias + pos encoding	65.2(3.4)	47.1(7.3)	55.4(4.1)	44.8(7.2)	58.2(5.2)
+ Kirchhoff	59.7(0.5)	50.2(2.2)	58.4(1.2)	46.5(2.1)	60.7(1.2)

Table 8: The performance of UDGN after removing different components. "- Nonlinear" means remove the tanh activation function in gated heads. "- relative pos bias + pos enc" means using a trainable positional encoding to replace the relative position bias. "+ Kirchhoff" means using Kirchhoff matrix tree theorem (Koo et al., 2007) to compute the marginal probabilities of each edge, and these marginals have properties similar to a tree adjacency matrix (sum over the marginals are equal to N-1 for example, where N is the length of the sentence).



(a) PCC heat map for heads and child to parent dependency relations.



(b) PCC heat map for heads and parent to child dependency relations.

Figure 5: Pearson Correlation Coefficients heat maps. Dependency types are arranged from highest frequency to lowest. We can observe that high frequent types have more strongly correlated heads. Strongly correlated heads also evenly distributed across layers.

Dataset	#tokens	MLM	Argmax		Chu-Liu	
		PPL	DDA	UDA	DDA	UDA
BLLIP-XS	1M	133.7(3.1)	51.4(2.0)	57.6(1.6)	47.9(2.7)	61.2(1.6)
BLLIP-SM	5M	40.2(0.8)	53.7(2.5)	60.7(0.6)	50.9(5.3)	65.1(1.6)
BLLIP-MD	14M	24.2(0.5)	50.5(6.1)	59.8(2.9)	47.7(8.1)	63.0(4.2)
BLLIP-LG	42M	19.7(0.3)	45.6(2.9)	61.7(1.8)	41.6(4.2)	62.5(1.6)

Table 9: The performance of UDGN after trained on different BLLIP splits. Since all BLLIP splits share the same vocabulary and test set, results are comparable. While DDA have a high variance, UDA remain stable across different corpus sizes. This may due to the reason that DGN only use an undirected dependency mask, the choice of dependency direction could be arbitrary. This result may suggest that syntax can be acquired with a relatively small amount of data. It is possible then, that where extra data helps is in terms of semantic knowledge, like common sense.

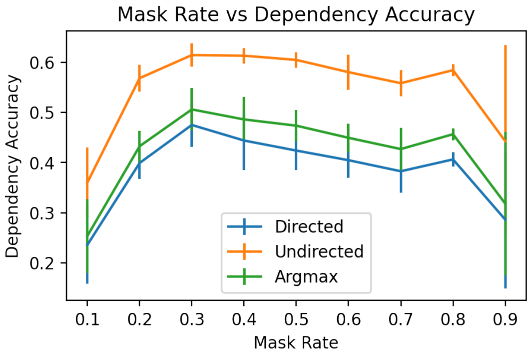


Figure 6: Relationship between the parsing performance and the mask rate for MLM.

A.4 Mask rate

One of the more surprising findings in our experiments with this architecture was the relationship between the word mask rate in the MLM task and how much the resulting parse trees corresponded to the ground-truth parse trees. We trained 5 models for different word masking rates from 0.1 to 0.9, in 0.1 increments, and computed the argmax, DDA, and undirected DDA (UDA) scores for each of these models. Figure 6 shows the plot for these results.

Firstly, we observe that the acceptable range of masking rate for achieving a decent UDA score was fairly large: the optimal was at about 0.3, but values of 0.2 up to 0.8 worked to induce tree structures that resulted in fairly good undirected trees. Secondly, as we move away from the optimum of 0.3-0.4, the variance of our results increases, with the highest variance when we mask at a rate of 0.9. Finally, our model supplies the attention mask as a symmetric matrix— the directionality of the mask is decimated when we perform Equation 6. Consequently, we find that the variance of the DDA is higher than UDA as the connectivity of the nodes in the tree is more important than the direction of the connection in our architecture.

Abstract

Multimodal Entity Linking (MEL) which aims at linking mentions with multimodal contexts to the referent entities from a knowledge base (e.g., Wikipedia), is an essential task for many multimodal applications. Although much attention has been paid to MEL, the shortcomings of existing MEL datasets including limited contextual topics and entity types, simplified mention ambiguity, and restricted availability, have caused great obstacles to the research and application of MEL. In this paper, we present WikiDiverse, a high-quality human-annotated MEL dataset with diversified contextual topics and entity types from Wikinews, which uses Wikipedia as the corresponding knowledge base. A well-tailored annotation procedure is adopted to ensure the quality of the dataset. Based on WikiDiverse, a sequence of well-designed MEL models with intra-modality and inter-modality attentions are implemented, which utilize the visual information of images more adequately than existing MEL models do. Extensive experimental analyses are conducted to investigate the contributions of different modalities in terms of MEL, facilitating the future research on this task. The dataset and baseline models are available at https://github.com/wangxw5/wikiDiverse.

1 Introduction

Entity linking (EL) has attracted increasing attention in the natural language processing community, which aims at linking ambiguous mentions to the referent unambiguous entities in a given knowledge base (KB) (Shen et al., 2014). It has been applied to a lot of downstream tasks such as information extraction (Yaghoobzadeh et al., 2016), question answering (Yih et al., 2015) and semantic search (Blanco et al., 2015).

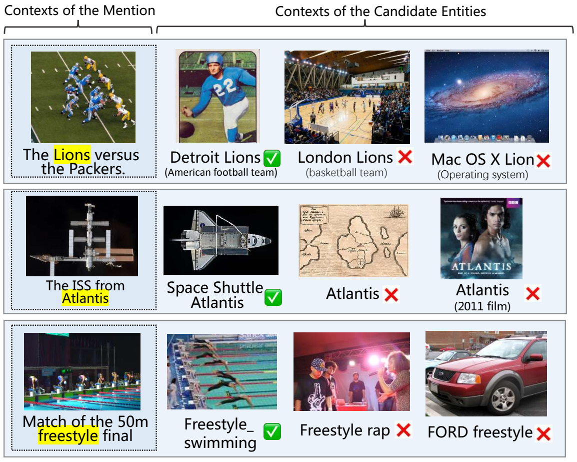

Figure 1: Several MEL examples with mentions highlighted in the caption and the first entity of each entity listed as the gold label.

As named entities (i.e., mentions) with multimodal contexts such as texts and images are ubiquitous in daily life, recent studies (Moon et al., 2018; Adjali et al., 2020a) turn their focus towards improving the performance of EL models through utilizing visual information, i.e., **Multimodal Entity linking (MEL)**[1]. Several MEL examples are depicted in Figure 1, where the images could effectively help the disambiguation for entity mentions of different types. Due to its importance to many multimodal understanding tasks including VQA, multimodal retrieval, and the construction of multimodal KBs, much effort has been dedicated to the research of MEL. Moon et al. (2018) first addressed the MEL task under the zero-shot setting. Adjali et al. (2020a) designed a model to combine the vi-

Table 1: Overview of EL and MEL datasets. T_m (T_e) and V_m (V_e) represent the textual and visual contexts of mentions m (or entities e) respectively, "Manual" denotes whether it is manually annotated, and "Open" denotes whether it is an open source.

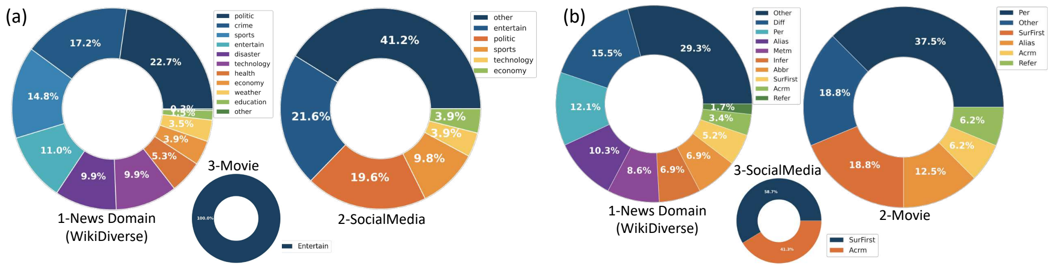

Figure 2: (a) compares the topic distribution of different domains. The statistics of social media are observed on sampled Twitter (Adjali et al., 2020a). The statistics of news domain are observed on WIKIDiverse. The statistics of Movie domain are observed on movie reviews sampled from IMDb. (b) compares the ambiguity distribution of different domains, where ten types of ambiguity are observed on our dataset, including different types of objects with the same name (Diff), persons with the same name (Per), Alias, metonymy (Metm), inferring (Infer), abbreviation (Abbr), surname or first name (SurFirst), acronym (Acrm), reference (Refer) and others.

sual, textual and statistical information for MEL. Zhang et al. (2021) designed a two-stage mechanism that first determines the relations between images and texts to remove negative impacts of noisy images and then performs the disambiguation. Gan et al. (2021) disambiguated visual mentions and textual mentions respectively at first, and then used graph matching to explore possible relations among inter-modal mentions.

Although much attention has been paid to MEL, the existing MEL datasets as listed in the middle rows of Table 1 have deficiencies in the following aspects, which hinder the further advancement of research and application for MEL.

- **Limited Contextual Topics.** As shown in Figure 2(a), the existing MEL datasets are mainly collected from social media or movie reviews, where there are only 5 topics in the social media domain and 1 topic in the movie review domain. But as we observed in the news domain, there are more than 10 topics including other popular topics like disaster and education. The lack of topics would limit the generalization ability of the MEL model.

- **Limited Entity Types.** Entities in the existing MEL datasets mainly belong to the types of "person (PER)" and "organization (ORG)". This restricts the application of the MEL models over other entity types such as locations, events, etc., which are also ubiquitous in common application scenarios.

- **Simplified Mention Ambiguity**: Some datasets such as Twitter (Adjali et al., 2020a) create artificial ambiguous mentions by replacing the original entity names with the surnames of persons or acronyms of organizations. Besides, limited entity types also lead to the limited mention ambiguity that only occurs with PER and ORG. According to our statistics of different domains as depicted in Figure 2(b), there are overall ten kinds of mention ambiguities in news domain such as Wikinews[2], while existing datasets collected from social media or movie reviews only cover a small scope of ambiguity.

- **Restricted Availability.** Most of the existing MEL datasets are not publicly available.

To enable more detailed research of MEL, we propose a manually-annotated MEL dataset named WIKIDiverse with multiple topics and multiple entity types. It consists of 8K image-caption pairs collected from WikiNews and is based on the KB of Wikipedia with ~16M entities in total. Both the mentions and entities are characterized by multimodal contexts. We design a well-tailored annotation procedure to ensure the quality of WIKIDiverse and analyze the dataset from multiple perspectives (Section 4). Based on WIKIDiverse, we propose a sequence of MEL models with intra-modality and inter-modality attentions, which utilize the visual information of images more adequately than the existing MEL models (Section 5). Furthermore, extensive empirical experiments are conducted to analyze the contributions of different modalities for the MEL task and visual clues provided by the visual contexts (Section 6). In summary, the contributions of our work are as follows:

- We present a new manually annotated high-quality MEL dataset that covers diversified topics and entity types.
- Multiple well-designed MEL models with intra-modal attention and inter-modal attention are given which could utilize the visual information of images more adequately than the previous MEL models.
- Extensive empirical results quantitatively show the role of textual and visual modalities for MEL, and detailed analyses point out promising directions for the future research.

2 Related Work

Textual EL There is vast prior research on textual entity linking. Multiple datasets have been proposed over the years including the manually-annotated high-quality datasets like AIDA (Hoffart et al., 2011), automatically-annotated large-scale datasets like CWEB (Guo and Barbosa, 2018) and zero-shot datasets like Zeshel (Logeswaran et al., 2019). To evaluate the EL models' performance, it is usual to train on the AIDA-train dataset, and test on the datasets of AIDA-test, MSNBC(Cucerzan, 2007), AQUAINT(Milne and Witten, 2008), etc. However, as mentioned in (Cao et al., 2021), many methods have achieved high and similar results within recent three years. One possible explanation is that it may simply be near the ceiling of what can be achieved for these datasets, and it is difficult to conduct further research based on them.

Multimodal EL In recent years, the growing trend towards multimodality requires to extend the research of EL from monomodality to multimodality. Moon et al. (2018) first address the MEL task and build a zero-shot framework, which extracts textual, visual and lexical information for EL in social media posts. However, its proposed dataset is unavailable due to GDPR rules. Adjali et al. (2020a,b) propose a framework of automatically building the MEL dataset from Twitter. The dataset has limited entity types and ambiguity of mentions, thus it is not challenging enough. Zhang et al. (2021) study on a Chinese MEL dataset collected from the Chinese social media platform Weibo, which mainly focuses on the person entities. Gan et al. (2021) release a MEL dataset collected from movie reviews and propose to disambiguate both visual and textual mentions. This dataset mainly focuses on characters and persons of the movie domain. Peng (2021) propose three MEL datasets, which are built from Weibo, Wikipedia, and Richpedia information and use CNDBpedia, Wikidata and Richpedia as the corresponding KBs. However, using Wikipedia as the target dataset may lead to the data leakage problem as many language models are pretrained on it.

Our MEL dataset is also related to other named entity-related multimodal datasets, including entity-aware image caption datasets (Biten et al., 2019; Tran et al., 2020; Liu et al., 2021), multimodal NER datasets (Zhang et al., 2018; Lu et al., 2018), etc. However, the entities in these datasets are not linked to a unified KB. So our research of MEL can enhance the understanding of named entities, thereby enhancing the research in these areas.

3 Problem Formulation

Multimodal entity linking is defined as mapping a mention with multimodal contexts to its referent entity in a pre-defined multimodal KB. Since the boundary and granularity of mentions may be con-

---

[2] https://www.wikinews.org. It is a free-content news wiki.

troversial, the mention span is usually pre-specified. Here we assume each mention has a corresponding entity in the KB, which is the *in-KB* evaluation problem.

Formally, let E represent the entity set of the KB, which usually contains millions of entities. Each mention m or entity $e_i \in E$ is characterized by the corresponding visual context V_m, V_{e_i} and textual context T_m, T_{e_i}. Here T_m and T_{e_i} represent the textual spans around m and e_i respectively. V_m is the image correlated with m and V_{e_i} is the image of e_i in the KB. In real life, entities in KBs may contain more than one image. To simplify it, we select the first image of e_i as V_{e_i} and leave MEL with multiple images per entity as the future work. So the referent entity of mention m is predicted through:

$$e^*(m) = \underset{e_i \in E}{\arg\max}\ \Psi\left(m\left(T_m, V_m\right); e_i\left(T_{e_i}, V_{e_i}\right)\right).$$

where $\Psi(\cdot)$ represents the similarity score between the mention and entity.

4 Dataset Construction

In this section, we present the dataset construction procedure. Many factors including annotation quality, coverage of topics, diversity of entity types, coverage of ambiguity are taken into consideration to ensure the research value of WIKIDiverse.

4.1 Data Collection

Data Source Selection 1) For the source of image-text pairs, considering news articles are widely-studied in traditional EL (Hoffart et al., 2011; Cucerzan, 2007) and usually cover a wide range of topics and entity types, we decide to use news articles. Wikinews and BBC are two popular sources of news articles. So we compared them from two aspects. As shown in Table 2, Wikinews has advantages in terms of alignment degree between image-text pairs and MEL difficulty. So we select the image-caption pairs of Wikinews to build the corpus. 2) For the source of KB, we use the commonly-used Wikipedia (Hoffart et al., 2011; Ratinov et al., 2011; Guo and Barbosa, 2018). We also provide the annotation of the corresponding Wikidata entity for flexible studies.

Data Acquisition 1) For the image-caption pairs, we collect all the English news from the year 2007 to 2020 from Wikinews with multiple topics including sports, politics, entertainment, disaster, technology, crime, economy, education, health and weather. The data cover most of the common topics in the real world. Finally, we obtain a raw corpus with 14k image-caption pairs. 2) For the KB, we use the Wikipedia[3]. The entity set consists of all the entities in the main namespace with the size of ~16M.

Source	Alignment Degree with Image			MEL Difficulty		
	Caption	Headline	First Sent.	No	Easy	Hard
Wikinews	99%	30%	23%	1%	5%	94%
BBC	82%	53%	53%	2%	30%	68%

Table 2: Comparing the alignment degrees and corresponding MEL difficulty of image-caption, image-news headline, and image-first sentence between Wikinews and BBC, where the MEL difficulty is measured through the surface form similarity between mentions and entities.

Data Cleaning For the image-caption pairs, we remove the cases that 1) contain pornographic, profane, and violent content; 2) the text is shorter than 3 words. Finally, we get a corpus with 8K image-caption pairs.

4.2 Annotation

Annotation Design The primary goal of WIKIDiverse is to link mentions with multimodal contexts to the corresponding Wikipedia entity. Therefore, given an image-text pair, annotators need to 1) detect mentions from the text (Mention Detection, MD) and 2) label each detected mention with the corresponding entity in the form of a Wikipedia URL (Entity Linking, EL). For mentions that do not have corresponding entities in Wikipedia, they are labeled with "NIL". Seven common entity types (i.e., Person, Organization, Location, Country, Event, Works, Misc) are required to be annotated. To avoid subjective errors, we design detailed annotation guidelines with multiple samples to avoid the controversy of mention boundary, mention granularity, entity URL, etc. Details can be found in the Appendix. We also hold regular communications to discuss some emerging annotations problems.

Annotation Procedure The annotators include 13 annotators and 2 experienced experts. All annotators have linguistic knowledge and are instructed with detailed annotation principles. Each image-caption pair is independently annotated by two annotators. Then an experienced expert goes over

---

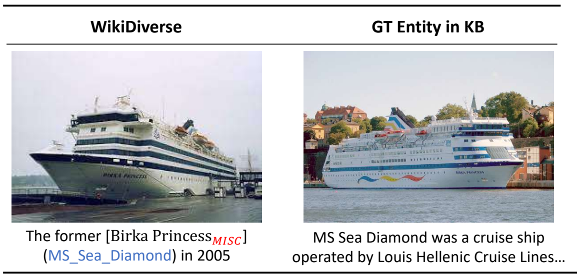

Figure 3: An example from WIKIDiverse. GT denotes the *ground truth* entity. The red text and blue text indicate the annotated entity type and Wikipedia entity respectively.

	Train	Dev.	Test	Total
# pairs	6377	796	796	7969
# ment. per pair	2.04	2.03	1.87	2.02
# words per pair	10.07	10.28	9.92	10.08

Table 3: Statistics of WIKIDiverse.

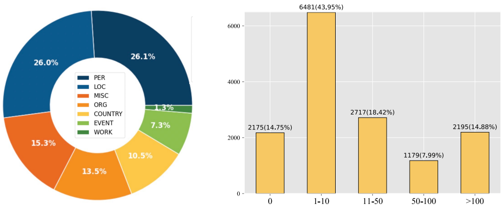
the controversial annotations, and makes the final decision. Following Ding et al. (2021), we calculate the Cohen's Kappa to measure the agreements between two annotators. The Kappa of MD and EL are 88.98% and 83.75% respectively, indicating a high degree of consistency.

4.3 Analysis of WIKIDiverse

Size and Distribution of WIKIDiverse We divide WIKIDiverse into training set, validation set, and test set with the ratio of 8:1:1. The statistics of WIKIDiverse are shown in Table 3. The collected Wikipedia KB has ~16M entities in total (i.e. $|E| \approx$16M). Besides, we report the entity type distribution in Figure 4(a) and report the topic distribution in Figure 2(a).

Difficulty Measure Firstly, we compare surface form similarity of mentions and ground-truth entities. 51.31% of the mentions have different surface forms compared with ground-truth entities. Specifically, 16.05% of the mentions are totally different from the ground-truth entities. The large difference of the surface form brings challenges for MEL.

Secondly, we report the #candidate entities for each mention in Figure 4(b). Intuitively, the more entities a mention may refer to, the more ambiguous the mention is, and the more difficult the EL/MEL is. Specifically, we generate a $m \rightarrow e$ hash list based on the (m, e) co-occurrence statistics from Wikipedia (See Section 5.1 for details).



(a) Entity type distribution. (b) Distribution of # candidates per mention.

Figure 4: More statistics of WIKIDiverse. (a) Entity type distribution. (b) Distribution of the number of candidates per mention

As shown in Figure 4(b), we can see that 1) 48.63% mentions have more than 10 candidate entities. 2) 15.26% mentions are not contained in the hash list, which means their candidates are the entire entity set of the KB.

Thirdly, we randomly sample 200 image-caption pairs from WIKIDiverse to evaluate the diversity of ambiguity. As shown in Figure 2(b), WIKIDiverse covers a wide range of ambiguity.

5 Methods

It is challenging to directly predict the entity from a large-scale KB because it consumes large amounts of time and space resources. Therefore, following previous work (Yamada et al., 2016; Ganea and Hofmann, 2017; Cao et al., 2021), we split MEL into two steps: 1) candidate retrieval (CR) is first used to guarantee the recall and obtain a candidate entity set consisting of the TopK entities that are most similar to the mention; 2) entity disambiguation (ED) is then conducted to guarantee the precision and predict the entity with the highest matching score.

5.1 Candidate Retrieval

Existing methods (Yamada et al., 2016; Ganea and Hofmann, 2017; Le and Titov, 2018) mainly utilize two types of clues to generate the candidate entity set E_m: (I) the $m \rightarrow e$ hash list recording prior probabilities from mentions to entities: $P(e|m)$. (II) the similarity between the contexts of mention m and entity e.

Following these works, we implement a series of baselines as follows: (I) $\mathbf{P(e|m)}$ (Ganea and Hofmann, 2017): $P(e|m)$ is calculated based on 1) mention entity hyperlink count statistics from Wikipedia; 2) Wikipedia redirect pages; 3) Wikipedia disambiguation pages. (II) **Baselines of textual modality**: we retrieve the TopK candidate entities with the most similar textual context of the

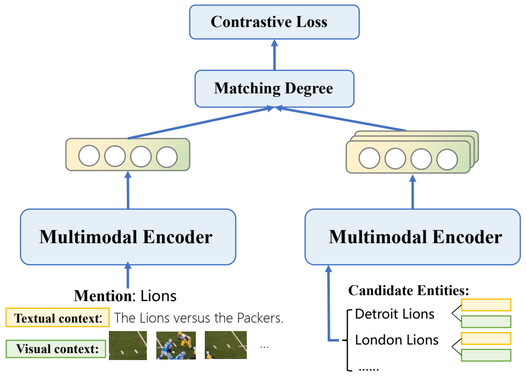


Figure 5: Framework of the introduced baselines.

mention based on BM25 (Robertson and Zaragoza, 2009), pretrained embeddings of words and entities obtained from (Yamada et al., 2020) (denoted as WikiVec) and BLINK (Wu et al., 2020). (III) **Baseline of visual modality:** we retrieve the TopK candidate entities with the most similar visual contexts of the mention based on **CLIP** (Radford et al., 2021).

5.2 Contrastive Entity Disambiguation

The interaction between multimodal contexts of mentions and entities is complicated. It may bring noises to the model without careful handling. So we also introduce several baselines to explore the fusion of multimodal information.

The key component of ED is to design the function $\Psi(m; e_i)$ that quantifies the matching score between the mention m and every entity $e_i \in E_m$. As shown in Figure 5, the backbone of $\Psi(m; e_i)$ includes different multimodal encoders of m and e_i respectively, followed by dot-production to evaluate the matching degree between them. Specially, a multi-layer perceptron (MLP) is then used to combine the $P(e|m)$. Formally, e^* of m is predicted through:

$$\mathbf{m} = \mathrm{Encoder_m}(T_m, V_m); \mathbf{e_i} = \mathrm{Encoder_e}(T_{e_i}, V_{e_i})$$
$$e^* = \underset{e_i \in E_m}{\arg\max}\ \mathrm{MLP}\left(\mathbf{m} \odot \mathbf{e_i}, P(e_i|m)\right) \tag{1}$$

So the multimodal encoders of mentions and entities are the most significant parts of MEL. They use the same structure but training with different parameters.

Multimodal Encoder Firstly, we get the textual context's embeddings. For the mention's textual context $T_m = \{w_1, \ldots, w_{L_1}\}$, we directly embed it with the word embedding layer of BERT (Devlin et al., 2019). While for e_i, we embed it as the pre-trained embeddings from Yamada et al. (2020), which have compressed the semantics of e_i's entire contexts from Wikipedia.

$$\{\hat{\mathbf{w}}_1, ..., \hat{\mathbf{w}}_{L_1}\} = \mathrm{BERT}_{EMB}(T_m) \tag{2}$$

Secondly, we get the visual context embeddings. Instead of the widely used region-based visual features, we adopt grid features following (Huang et al., 2020), which has the advantage of end-to-end. Specifically, the visual features are represented with the grid features from :

$$\{\hat{\mathbf{v}}_1, ..., \hat{\mathbf{v}}_{L_2}\} = \mathrm{Flat}(\mathrm{ResNet}(V)) \tag{3}$$

where $\mathrm{Flat}(\cdot)$ represents flatting the feature along the spatial dimension and L_2 indicates the number of grid features.

Finally, taking the embeddings of the two modalities as inputs, we capture the interaction between them. We adopt several backbones to fuse multiple modalities. 1) **UNITER** (Chen et al., 2020): the two modalities are concatenated and then fed into self-attention transformers to fuse them together. 2) **UNITER***: we apply separate self-attention transformers to the two modalities before UNITER for better feature extraction of each modality. 3) **LXMERT** (Tan and Bansal, 2019): the two modalities are fed into separate self-attention transformers at first and then interact with cross-modal attention. The design of intra-modal and inter-modal attention helps better alignment and interaction of multiple modalities.

After multiple layers of the fusion operation: $\mathrm{Fuse}\left(\{\hat{\mathbf{w}}_1, ..., \hat{\mathbf{w}}_{L_1}\}, \{\hat{\mathbf{v}}_1, ..., \hat{\mathbf{v}}_{L_2}\}\right)$, the hidden states of the mention's tokens $\{\mathbf{h}_i, ..., \mathbf{h}_j\}$ are obtained. Then we concatenate the hidden states of the first and the last tokens and feed them into a MLP to get the mention's embeddings: $\mathrm{MLP}\left([\mathbf{h}_i || \mathbf{h}_j]\right)$

Contrastive Loss We introduce contrastive learning (Karpukhin et al., 2020; Gao et al., 2021) to learn a more robust representation of both mentions and entities. It is widely acknowledged that selecting negative examples could be decisive for learning a good model. To this end, we utilize both hard negatives and in-batch negatives to improve our model's ability to distinguish between gold entities and hard/general negatives. Let $e_{i,j}$ represent the j^{th} candidate entity of the i^{th} mention in a batch and let P_i denote the index of m_i's gold

Modality	**Method**	**R@10**	**R@50**	**R@100**
P	$P(e\|m)$	83.34	87.59	88.15
T	BM25	38.37	48.78	53.34
T	WikiVec	16.23	20.56	23.11
T	BLINK	61.76	71.30	73.87
V	CLIP	17.34	26.82	31.38
T+V*	BLINK+CLIP	61.51	74.80	79.66
P+T+V*	$P(e\|m)$+BLINK+CLIP	**86.28**	**91.64**	**93.14**

Table 4: Performance of candidate retrieval. R@K represents recall of the TopK retrieved entities. The modality of P, T, V represent the $P(e|m)$, textual context and visual context respectively. T+V and P+T+V represent the ensemble of different sub-methods, the T of which is BLINK. Results with * are generated using grid search over the Dev. dataset to find the best combination of different sub-methods.

entity. The hard negatives are the other $K-1$ candidate entities retrieved in CR step except for the gold entity: $\{e^{-}_{i,k}\}^{k\in[1,K]}_{k\neq P_i}$. The in-batch negatives are gold entities of other $B-1$ mentions in the mini-batch: $\{e^{+}_{b,P_b}\}^{b\in[1,B]}_{b\neq i}$, where B represents the batch size. The optimization objective is defined as the negative log likelihood of the ground-truth entity:

$$\mathcal{L}(m_i,E_{m_i}) = -\log \frac{\mathrm{e}^{\Psi(m_i,e^{+}_{i,P_i})}}{\mathrm{e}^{\Psi(m_i,e^{+}_{i,P_i})} + \sum^{-}}$$

$$\sum^{-} = \underbrace{\sum_{k=1,k\neq P_i}^{K} \mathrm{e}^{\Psi(m_i,e^{-}_{i,k})}}_{\text{hard negatives}} + \underbrace{\sum_{b=1,b\neq i}^{B} \mathrm{e}^{\Psi(m_i,e^{+}_{b,P_b})}}_{\text{in-batch negatives}} \tag{4}$$

Besides the above baselines, we also compare with the following classic baselines: 1) **Baselines of Textual Modality** include REL (Le and Titov, 2018), BERT (Devlin et al., 2019), and BLINK (Wu et al., 2020). 2) **Baselines of Visual Modality** include ResNet-50 and CLIP. 3) **Multimodal Baselines** include MMEL18 (Moon et al., 2018), MMEL20 (Adjali et al., 2020b). Details of the baselines can be found in the Appendix.

6 Experimental Results

6.1 Candidate Retrieval Results

As shown in Table 4: 1) Our model achieves 93.14% of R@100, which indicates most related entities can be recalled from the large 16M KB. For retrieval, each mention takes about 12ms of P(e|m), 40ms of BM25, 183ms of WikiVec and CLIP, 60ms of BLINK; 2) As for ensemble of different modalities, T + V achieves better results than V and T, which verifies that the information of different modalities are complementary;

Modality	**Model**	**F1**	**P**	**R**
T→ T	REL	59.52	60.77	58.34
	BLINK	64.94	67.72	62.39
	BERT	56.16	59.80	52.94
V → V	ResNet-50	26.80	28.46	25.32
	CLIP	35.26	36.68	33.41
T+V→ T	MMEL18	51.22	53.27	48.78
T+V→ T+V	MMEL20	37.44	38.48	36.46
	UNITER	68.09	70.63	65.72
	UNITER*	68.76	73.27	64.80
	LXMERT	68.91	73.04	65.22
	UNITER †	68.97	71.95	66.23
	UNITER* †	69.59	72.65	66.77
	LXMERT †	**70.13**	**73.06**	**67.43**

Table 5: Comparison with baselines with results averaged over 5 runs. Models with † are enhanced with contrastive learning. All the models use the same candidate entity set retrieved through $P(e|m)$+BLINK+CLIP with $K = 10$.

In practice, we use grid search over the Dev. to find the best combination of different modalities. For example, when $K = 10$, the best E_m is generated with 80%P+ 10%T + 10%V.

6.2 Entity Disambiguation Results

Following previous work, we report micro F_1, precision, recall in Table 5. According to the experimental results, we can see that: First, the proposed multimodal methods outperform all the methods with a single modality, which benefit from multimodal contexts. Besides, contrastive learning can even improve the performance. We reckon that contrastive learning improves the ability to distinguish entities. Second, the textual baselines perform better that the visual ones, which indicates the textual context still plays a dominant role in MEL. Third, the methods using transformers to model the interaction between modalities perform better than those with simple interaction (Moon et al., 2018; Adjali et al., 2020a), which verifies the importance of fusing different modalities.

Type	Image of m	Caption of m	Image of e*	*e**
Object		The former Birka Princess in 2005, now called M/S Sea Diamond		MS_Sea_Diamond
Scene		Extra Match of the Women 50m freestyle finale.		Freestyle_swimming
Property		Vials of the COVID-19 vaccine with labels in English.		COVID-19
Scene & Property		The men's 400 m T53		Wheelchair_racing

Figure 6: Examples of the 'Visual Clues'.

6.3 Multimodal Analysis

We also conduct some experiments on the ED tasks as following.

Are the multiple modalities complementary? We draw a Venn diagram of different modalities in Figure 8. The circle of Method i is calculated through $\frac{\#Hit_i}{|Dataset|}$ and the interaction of two circles are calculated through $\frac{\#(Hit_i \cap Hit_j)}{|Dataset|}$. One can see that the textual modality is dominant, while the visual modality provides complementary information. Specially, the multimodal method predicts more new entities of 16.86%, which verifies the importance of fusing two modalities.

Is it better to have multimodal contexts of both mentions and entities? We conduct an ablation study and report the results in Table 6. We can see that the model with multimodal contexts of both mentions and entities achieves the best result. So linking multimodal mentions to multimodal entities is better than linking multimodal mentions to monomodal entities as done in (Moon et al., 2018).

What visual clues are provided by the visual contexts? We randomly select 800 image-caption pairs from the test dataset, and then ask annotators to label each mention with the types of visual clues. The visual clues include 4 types: 1) **Object**: the image contains the entity object. 2) **Scene**: the image reveals the scene that the entity belongs to (e.g. a basketball player of the 'basketball game' scene). 3) **Property**: the image contains some properties of the entity (e.g. an American flag reveals the property of a person's nationality). 4) **Others**: other important contexts. Note that the four types of clues can be crossed and a sample could have no clues. Examples of the visual clues can be found in Figure 6. We find that visual context is helpful for 60.54% mentions and 81.56% image-caption pairs. We report the contribution of different types of visual clues in Table 7. One can see that: 1) For property clues and object clues, the T+V is 11.20% and 8.48% higher than T. So the multimodal model benefits a lot from the information of objects and properties in the images. 2) For scene clues, the T+V is slightly worse than T, which shows implicit visual clues are not used well and indicates the direction of future research.

Model	Dev.	Test
LXMERT	68.75	68.97
w/o V_m	60.84	59.46
w/o V_e	58.16	61.07
w/o V_m and V_e	63.32	62.40
w/o T_m	20.51	20.86
w/o T_e	44.74	43.66
w/o T_m and T_e	24.67	25.80

Table 6: Ablation study to analyze modality absence of mention and entity. W/o $T_{m/e}$ or $V_{m/e}$ stands for LXMERT trained without the corresponding inputs.

6.4 Case Study

We present several examples where multimodal contexts influence MEL in Figure 7. Example (a) and (b) verify the helpfulness of the multimodal context. From the error cases, we can see that the

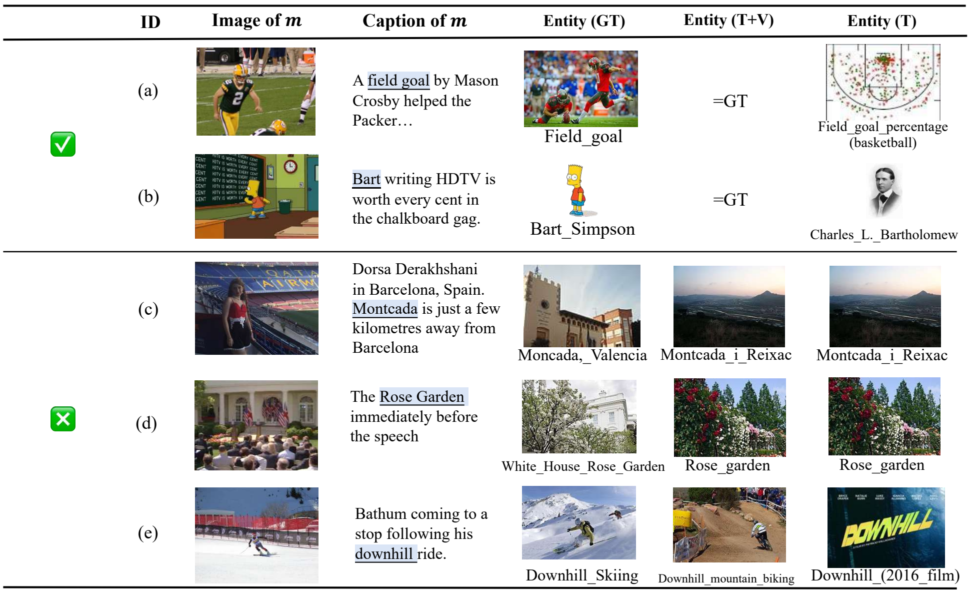

Figure 7: Case study. Successful predictions and failed predictions for the underlined mention are shown.

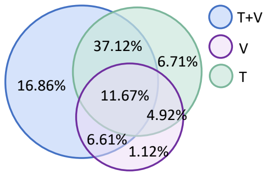

Figure 8: Venn diagram illustration of contributions of different modalities. We remove the input of the corresponding modality of LXMERT to get the results without re-training the model. To avoid the interference of $P(e|m)$, we also remove it from the model.

Visual Clues	**Proportion**	**F$_1$**	
		T	**T+V**
Object	45.40%	64.47	72.95
Scene	18.96%	60.62	60.33
Property	26.22%	55.25	66.45
Others	14.80%	60.00	64.00

Table 7: Model performance under different visual clues. T+V denotes the multimodal model LXMERT, and T represents the textual model BERT.

model still lacks such capabilities: 1) Eliminate the influence of unhelpful images (e.g., Example (c)); 2) Perform reasoning (e.g., inferring the "white house" from Example (d)'s image); 3) Alleviate over-reliance on $P(e|m)$ (e.g., Example (e)).

7 Conclusion and Future Work

We propose WIKIDiverse, a manually-annotated Wikipedia-based MEL dataset collected from Wikinews. To overcome the weaknesses of existing datasets, WIKIDiverse covers a wide range of topics, entity types and ambiguity. We implement a series of baselines and carry out multiple experiments over the dataset. According to the experimental results, WIKIDiverse is a challenging dataset worth further exploration. Besides multimodal entity linking, WIKIDiverse can also be applied to evaluate the pre-trained language model, multimodal named entity typing/recognition, multimodal topic classification, etc. In the future, we plan to 1) utilize more than one images of each entity 2) adopt finer-grained multimodal interaction models for this task and 3) transfer the model to more general scenarios such as EL in articles.

Acknowledgement

We thank all the reviewers for their valuable suggestions. This research was supported by the National Key Research and Development Project (No. 2020AAA0109302), National Natural Science Foundation of China (No. 62072323), Shanghai Science and Technology Innovation Action Plan (No. 19511120400), Shanghai Municipal Science and Technology Major Project (No. 2021SHZDZX0103) and Alibaba Research Intern Program.

Ethical Considerations

We collected publicly available Wikinews image-caption pairs without storing any personal data. During data cleaning, we remove the cases that contain pornographic, profane, and violent content.

We annotate the data using the crowdsourcing platform of Alibaba. To ensure that the crowd workers were fairly compensated, we paid them at an hourly rate of 15 USD per hour, which is a fair and reasonable rate of pay for crowdsourcing.

A Annotation Details

A.1 Annotation Guidelines

To avoid subjective errors, we designed detailed annotation guidelines with multiple samples to avoid the controversy of mention boundary, mention granularity and Wikipedia URL. The entire annotation guideline is summarized as follows.

1. Only label mentions with the entities that can be inferred from the image-caption pairs instead of the entities that can only be inferred from the entire news.
2. Label mentions that do not have corresponding entities in Wikipedia with 'NIL'.
3. Mention types include persons, organizations, locations, events, works, currency and others.
4. We assume that mentions are non-recursive and non-overlapping. So if a mention is embedded in another mention, only the top-level mention is annotated.
5. The mention boundary is detected with the smallest granularity while avoiding overlapping boundaries. An example is labeling "French President Nicolas Sarkozy" with both "French" and "Nicolas Sarkozy" instead of "French President Nicolas Sarkozy".
6. The title before mention is also part of the mention span.
7. Metonymy is needed. Metonymy is a figure of speech that replaces the name of a thing with the name of something else with which it is closely associated. An example is using England to represent the England national football team.

A.2 Details of Image Data Cleaning

During the data cleaning, we have also done some processing on the images:

- To prevent image processing tools from being unable to process certain types of images, we normalize the images with less popular formats (e.g. .svg, .tif, .gif) into the images with popular formats (i.e., .png, .jpg);
- As some "images" are videos actually, we manually select a certain frame of the videos as the image[4].

B Other Details of Experimental Settings

B.1 Details about the Baselines

In the ED step, we also compare with the following baselines:

- **Baselines of Textual Modality**: 1) **REL** (Le and Titov, 2018): it is a robust EL baseline that incorporates latent relation variables into the EL model for better understanding of the text. 2) **BERT** (Devlin et al., 2019): it is a widely acknowledged pre-trained language model. 3) **BLINK** (Wu et al., 2020): it applies cross-attention to the mention and entities for MEL.
- **Baselines of Visual Modality**: 1) **ResNet-50** (He et al., 2016): it is a widely acknowledge model with residual learning framework trained on the ImageNet (Deng et al., 2009). 2) **CLIP** (Radford et al., 2021): it is a model trained to predict the matching degree of texts and images, which also achieves competitive performance on visual tasks.
- **Multimodal Baselines**: 1) **MMEL18** (Moon et al., 2018) uses modality attention to fuse features from different modalities. 2) **MMEL20** (Adjali et al., 2020b) uses Sent2vec, BM25 and Inception-V3 to extract features of different modalities, then integrates different modalities together with the concatenation operation followed by MLP.

B.2 Implementations Details

We train all the models on the same device for 20 iterations with the early stopping mechanism. The learning rate is set as 1e-3. The batch size is set as 12. The model of UNITER consists of 12 layers of transformers. The UNITER* consists of 8 layers of textual transformers and visual transformers respectively, followed by the concatenation operation and 4 layers of transformers. The LXMERT consists of 8 layers of textual transformers and visual transformers respectively, followed by 4 layers of cross-modality attention mechanism.

C Supplementary Experimental Results

C.1 Detailed Main Results

To verify the robustness of out method, we report the model performance in Table 8.

---

[4] Only 14 instances contain videos, which account for a small proportion. We have tagged them in the dataset for users to decide whether to use them.

Modality	Model	F1	Precision	Recall	R@5
T → T	REL	59.52(.16)	60.77(.70)	58.34(.53)	71.64(.19)
	BLINK	64.94(.27)	67.72(.40)	62.39(.78)	71.21(.17)
	BERT	56.28(.12)	59.80(.11)	52.94(.12)	68.19(.82)

	CLIP	35.26(.72)	36.68(.50)	33.41(.14)	46.63(1.61)
T+V → T	MMEL18	51.22(.88)	53.27(.70)	48.78(.27)	70.48(.50)
T+V → T+V	MMEL20	37.44(1.20)	38.48(.56)	36.46(.85)	39.14(1.56)
	UNITER	68.09(.17)	70.63(.39)	65.72(.16)	73.98(.55)
	UNITER*	68.76(.15)	73.27(.83)	64.80(.82)	74.60(.89)
	LXMERT	68.91(.21)	73.04(.21)	65.22(.46)	74.58(.43)
	UNITER †	68.97(.28)	71.95(.08)	66.23(.53)	74.99(.56)
	UNITER* †	69.59(.10)	72.65(.44)	66.77(.40)	75.67(.64)
	LXMERT †	70.13(.12)	73.06(.38)	67.43(.49)	75.18(.42)

Table 8: Comparison with baselines with results averaged over 5 runs. Models with † are enhanced with contrastive learning. All the models use the same candidate entity set retrieved through $P(e|m)$+BLINK+CLIP with $K = 10$.

Method	First	First&Last	Average
F1	69.09	70.13	69.68

Table 9: Comparison of mention's pooling strategies.

C.2 Comparison of Mention's Pooling Strategies

After multiple layers of multimodal fusion, we get the hidden states of the mention's token sequence. Then a pooling operation is needed to get the representation of the entire mention. Here we compare three pooling methods: 1) the first token of the mention sequence (denoted as First); 2) the concatenation of the first and last of the mention sequence (denoted as First&Last); 3) the average of the entire mention sequence (denoted as Average). According to the result in Table 9, First&Last has achieved the best performance, which is thus selected in the final version of our model.

C.3 Analysis of the Contrastive Loss

To evaluate the influence of the contrastive loss, we also performed a detailed analysis. Specifically, we conducted experiments with different numbers of # hard negatives and # in-batch negatives. For expression convenience, we use K and B to represent their numbers. To prevent other factors from affecting the results, we do not change the batch size or the candidate entity number, but only change the number of negative instances.

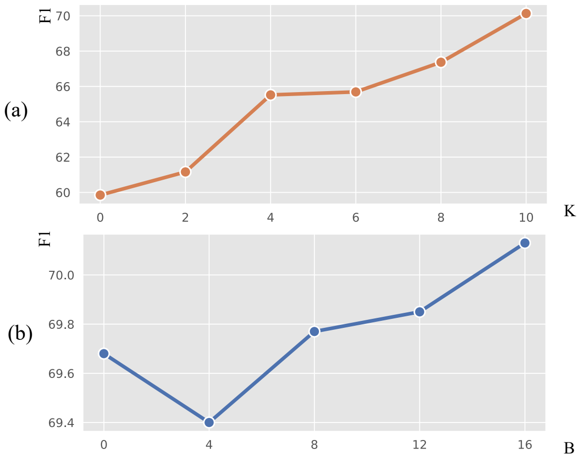

Figure 9: Model performance with different K and B.

Do hard negatives or in-batch negatives have a greater impact on the results? By comparing Figure 9(a) and Figure 9(b), we can find out that even without in-batch negatives, the model still achieves relatively good results. However, the decrease of hard negative leads to a sharp drop in model performance. Therefore, the hard negatives influence the model performance more.

Empirical analysis of the number of negative samples. We can see that no matter hard negatives or in-batch negatives, the more negative examples are introduced, the effect will be improved. Therefore, under the premise of sufficient GPU memory, negative examples should be increased as much as possible, especially for the number of hard negatives.

Rewire-then-Probe: A Contrastive Recipe for Probing Biomedical Knowledge of Pre-trained Language Models

Abstract

Knowledge probing is crucial for understanding the knowledge transfer mechanism behind the pre-trained language models (PLMs). Despite the growing progress of probing knowledge for PLMs in the general domain, specialised areas such as biomedical domain are vastly under-explored. To facilitate this, we release a well-curated biomedical knowledge probing benchmark, `MedLAMA`, constructed based on the Unified Medical Language System (UMLS) Metathesaurus. We test a wide spectrum of state-of-the-art PLMs and probing approaches on our benchmark, reaching at most 3% of acc@10. While highlighting various sources of domain-specific challenges that amount to this underwhelming performance, we illustrate that the underlying PLMs have a higher potential for probing tasks. To achieve this, we propose Contrastive-Probe, a novel self-supervised contrastive probing approach, that adjusts the underlying PLMs without using any probing data. While Contrastive-Probe pushes the acc@10 to 24%, the performance gap remains notable. Our human expert evaluation suggests that the probing performance of our Contrastive-Probe is underestimated as UMLS does not comprehensively cover all existing factual knowledge. We hope `MedLAMA` and Contrastive-Probe facilitate further developments of more suited probing techniques for this domain.[1]

1 Introduction

Pre-trained language models (PLMs; Devlin et al. 2019; Liu et al. 2020) have orchestrated incredible progress on myriads of few- or zero-shot language understanding tasks, by pre-training model parameters in a task-agnostic way and transferring knowledge to specific downstream tasks via fine-tuning (Brown et al., 2020; Petroni et al., 2021).

	Query	Answer(s)
Hard Queries	*Riociguat* **has physiologic effect** [Mask].	*Vasodilation*
	Entecavir **may prevent** [Mask].	*Hepatitis B*
	Invasive Papillary Breast Carcinoma **disease mapped to gene** [Mask].	*[ERBB2 Gene, CCND1 Gene]*
Easy Queries	*Posttraumatic arteriovenous fistula* **is associated morphology of** [Mask].	*Traumatic arteriovenous fistula*
	Acute Myeloid Leukemia with Mutated RUNX1 **disease mapped to gene** [Mask].	*RUNX1 Gene*
	Magnesium Chloride **may prevent** [Mask].	*Magnesium Deficiency*

Table 1: Example probing queries from `MedLAMA`. **Bold** font denotes UMLS relation.

To better understand the underlying knowledge transfer mechanism behind these achievements, many knowledge probing approaches and benchmark datasets have been proposed (Petroni et al., 2019; Jiang et al., 2020a; Kassner et al., 2021; Zhong et al., 2021). This is typically done by formulating knowledge triples as cloze-style queries with the objects being masked (see Table 1) and using the PLM to fill the single (Petroni et al., 2019) or multiple (Ghazvininejad et al., 2019) [Mask] token(s) without further fine-tuning.

In parallel, it has been shown that specialised PLMs (e.g., BioBERT; Lee et al. 2020, BlueBERT; Peng et al. 2019 and PubMedBERT; Gu et al. 2020) substantially improve the performance in several biomedical tasks (Gu et al., 2020). The biomedical domain is an interesting testbed for investigating knowledge probing for its unique challenges (including vocabulary size, multi-token entities), and the practical benefit of potentially disposing the expensive knowledge base construction process. However, research on knowledge probing in this domain is largely under-explored.

To facilitate research in this direction, we present a well-curated biomedical knowledge probing benchmark, `MedLAMA`, that consists of 19 thoroughly selected relations. Each relation contains 1k queries (19k queries in total with at most 10 answers each), which are extracted from

ID	Relation	Manual Prompt
1	`disease may have associated disease`	The disease [X] might have the associated disease [Y] .
2	`gene product plays role in biological process`	The gene product [X] plays role in biological process [Y] .
3	`gene product encoded by gene`	The gene product [X] is encoded by gene [Y] .
4	`gene product has associated anatomy`	The gene product [X] has the associated anatomy [Y] .
5	`gene associated with disease`	The gene [X] is associatied with disease [Y] .
6	`disease has abnormal cell`	[X] has the abnormal cell [Y] .
7	`occurs after`	[X] occurs after [Y] .
8	`gene product has biochemical function`	[X] has biochemical function [Y] .
9	`disease may have molecular abnormality`	The disease [X] may have molecular abnormality [Y] .
10	`disease has associated anatomic site`	The disease [X] can stem from the associated anatomic site [Y] .
11	`associated morphology of`	[X] is associated morphology of [Y] .
12	`disease has normal tissue origin`	The disease [X] stems from the normal tissue [Y] .
13	`gene encodes gene product`	The gene [X] encodes gene product [Y] .
14	`has physiologic effect`	[X] has physiologic effect of [Y] .
15	`may treat`	[X] might treat [Y] .
16	`disease mapped to gene`	The disease [X] is mapped to gene [Y] .
17	`may prevent`	[X] may be able to prevent [Y] .
18	`disease may have finding`	[X] may have [Y] .
19	`disease has normal cell origin`	The disease [X] stems from the normal cell [Y] .

Table 2: The 19 relations and their corresponding manual prompts in `MedLAMA`.

the large UMLS (Bodenreider, 2004) biomedical knowledge graph and verified by domain experts. We use automatic metrics to identify the hard examples based on the hardness of exposing answers from their query tokens. See Table 1 for a sample of easy and hard examples from `MedLAMA`.

A considerable challenge in probing in biomedical domain is handling multi-token encoding of the answers (e.g. in `MedLAMA` only 2.6% of the answers are single-token, while in the English set of mLAMA; Kassner et al. 2021, 98% are single-token), where all existing approaches (i.e., mask predict; Petroni et al. 2019, retrieval-based; Dufter et al. 2021, and generation-based; Gao et al. 2020) struggle to be effective.[2] For example, the mask predict approach (Jiang et al., 2020a) which performs well in probing multilingual knowledge achieves less than 1% accuracy on `MedLAMA`.

To address the aforementioned challenge, we propose a new method, **Contrastive-Probe**, that first adjusts the representation space of the underlying PLMs by using a retrieval-based contrastive learning objective (like '*rewiring*' the switchboard to the target appliances Liu et al. 2021c) then retrieves answers based on their representation similarities to the queries. Notably, our Contrastive-Probe does not require using the MLM heads during probing, which avoids the vocabulary bias across different models. Additionally, retrieval-based probe is effective for addressing the multi-token challenge, as it avoids the need to generate multiple tokens from the MLM vocabulary. We show that Contrastive-Probe facilitates absolute improvements of up-to ~5% and ~21% on the acc@1 and acc@10 probing performance compared with the existing approaches.

We further highlight that the elicited knowledge by Contrastive-Probe is not gained from the additional random sentences, but from the original pre-trained parameters, which echos the previous finding of Liu et al. (2021b); Glavaš and Vulić (2021); Su et al. (2021, 2022). Additionally, we demonstrate that different state-of-the-art PLMs and transformer layers are suited for different types of relational knowledge, and different relations requires different depth of tuning, suggesting that both the layers and tuning depth should be considered when infusing knowledge over different relations. Furthermore, expert evaluation of PLM responses on a subset of `MedLAMA` highlights that expert-crafted resources such as UMLS still do not include the full spectrum of factual knowledge, indicating that the factual information encoded in PLMs is richer than what is reflected by the automatic evaluation.

The findings of our work, along with the proposed `MedLAMA` and Contrastive-Probe, highlight both the unique challenges of the biomedical domain and the unexploited potential of PLMs. We hope our research to shed light on what domain-specialised PLMs capture and how it could be better resurfaced, with minimum cost, for probing.

2 `MedLAMA`

To facilitate research of knowledge probing in the biomedical domain, we create the `MedLAMA` benchmark based on the largest biomedical knowledge graph UMLS (Bodenreider, 2004). UMLS[3]

---

[2] Prompt-based probing approaches such as AutoPrompt (Shin et al., 2020a), SoftPrompt (Qin and Eisner, 2021), and OptiPrompt (Zhong et al., 2021) need additional labelled data for fine-tuning prompts, but we restrict the scope of our investigation to methods that do not require task data.

[3] Release version 2021AA: `https://download.nlm.nih.gov/umls/kss/2021AA/umls-2021AA-full.zip`

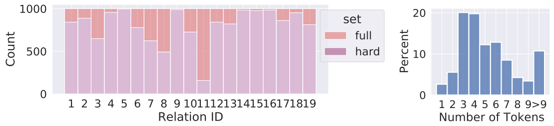

Figure 1: Left: Count over full and hard sets. Right: Percentage of answers over number of tokens.

is a comprehensive metathesaurus containing 3.6 million entities and more than 35.2 million knowledge triples over 818 relation types which are integrated from various ontologies, including SNOMED CT, MeSH and the NCBI taxonomy.

Creating a LAMA-style (Petroni et al., 2019) probing benchmark from such a knowledge graph poses its own challenges: (1) UMLS is a collection of knowledge graphs with more than 150 ontologies constructed by different organisations with very different schemata and emphasis; (2) a significant amount of entity names (from certain vocabularies) are unnatural language (e.g., *t(8;21)(q22;q22)* denoting an observed karyotypic abnormality) which can hardly be understood by the existing PLMs, with tokenisation tailored for natural language; (3) some queries (constructed from knowledge triples) can have up to hundreds of answers (i.e., 1-to-N relations), complicating the interpretation of probing performance; and (4) some queries may expose answers in themselves (e.g., answer within queries), making it challenging to interpret relative accuracy scores.

Selection of Relationship Types. In order to obtain high-quality knowledge queries, we conducted multiple rounds of manual filtering on the relation level to exclude uninformative relations or relations that are only important in the ontological context but do not contain interesting semantics as a natural language (e.g, taxonomy and measurement relations). We also excluded relations with insufficient triples/entities. Then, we manually checked the knowledge triples for each relation to filter out those that contain unnatural language entities and ensure that their queries are semantically meaningful. Additionally, in the cases of 1-to-N relations where there are multiple gold answers for the same query, we constrained all the queries to contain at most 10 gold answers. These steps resulted in 19 relations with each containing 1k randomly sampled knowledge queries. Table 2 shows the detailed relation names and their corresponding prompts.

Easy vs. Hard Queries. Recent works (Poerner et al., 2020; Shwartz et al., 2020) have discovered that PLMs are overly reliant on the surface form of entities to guess the correct answer of a knowledge query. The PLMs "cheat" by detecting lexical overlaps between the query and answer surface forms instead of exercising their abilities of predicting factual knowledge. For instance, PLMs can easily deal with the triple <*Dengue virus live antigen CYD serotype 1*, `may-prevent`, *Dengue*> since the answer is part of the query. To mitigate such bias, we also create a hard query set for each relation by selecting a subset of their corresponding 1k queries using token and matching metrics (i.e., exact matching and ROUGE-L (Lin and Och, 2004)). For more details see the *Appendix*. We refer to the final filtered and original queries as the **hard sets** and **full sets**, respectively. Figure 1 (left) shows the count of hard vs. full sets.

Approach	Type	Answer space	MLM
Fill-mask (Petroni et al., 2019)	MP	PLM Vocab	✓
X-FACTR (Jiang et al., 2020a)	MP	PLM Vocab	✓
Generative PLMs (Lewis et al., 2020)	GB	PLM Vocab	✗
Mask average (Kassner et al., 2021)	RB	KG Entities	✓
CONTRASTIVE-PROBE (Ours)	RB	KG Entities	✗

Table 3: Comparison of different approaches. Types of probing approaches: Mask predict (MP), Retrieval-based (RB) and Generation-based (GB).

The Multi-token Issue. One of the key challenges for probing `MedLAMA` is the multi-token decoding of its entity names. In `MedLAMA` there are only 2.6% of the entity names that are single-token[4] while in the English set of mLAMA (Kassner et al., 2021) and LAMA (Petroni et al., 2019) the percentage of single-token answers are 98% and 100%, respectively. Figure 1 (right) shows the percentage of answers by different token numbers.

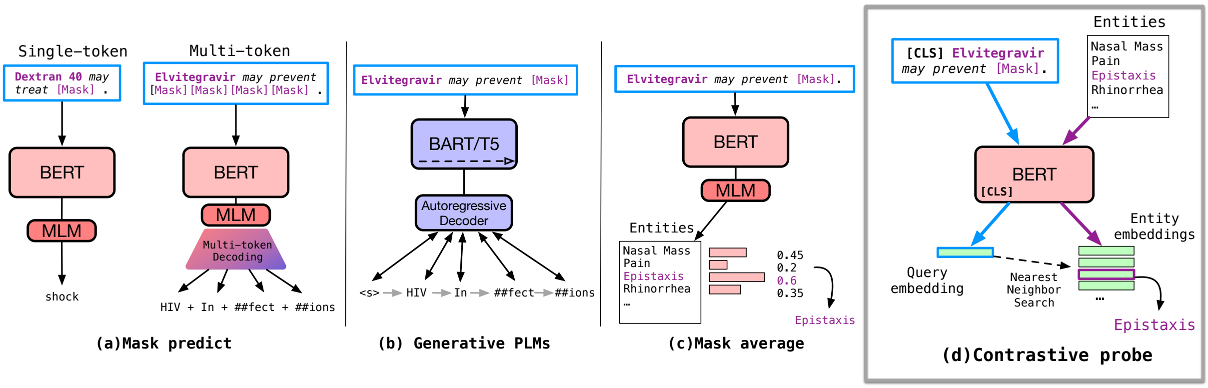
3 Existing Multi-token Knowledge Probing Approaches

While the pioneer works in PLM knowledge probing mainly focused on the single-token entities, many recent works have started exploring the solutions for the multi-token scenario (Kassner et al., 2021; Jiang et al., 2020a; De Cao et al., 2021). These knowledge probing approaches can be categorised, based on answer search space and reliance on MLM head, into three categories: *mask predict*, *generation-based*, and *retrieval-based*. Table 3 summarises their key differences.

Mask Predict. Mask predict (Petroni et al., 2019; Jiang et al., 2020a) is one of the most commonly

---

[4] Tokenized by Bert-base-uncased.



(a)Mask predict (b) Generative PLMs (c)Mask average (d)Contrastive probe

Figure 2: Comparison of different probing approaches. (d) is our proposed Contrastive-Probe.

used approaches to probe knowledge for masked PLMs (e.g. BERT). The mask predict approach uses the MLM head to fill a single mask token for a cloze-style query, and the output token is subjected to the PLM vocabulary (Petroni et al., 2019). Since many real-world entity names are encoded with multiple tokens, the mask predict approach has also been extended to predict multi-token answers using the conditional masked language model (Jiang et al., 2020a; Ghazvininejad et al., 2019). Figure 2(a) shows the prediction process. Specifically, given a query, the probing task is formulated as: 1) filling masks in parallel independently (*Independent*); 2) filling masks from left to right autoregressively (*Order*); 3) filling tokens sorted by the maximum confidence greedily (*Confidence*). After all mask tokens are replaced with the initial predictions, the predictions can be further refined by iteratively modifying one token at a time until convergence or until the maximum number of iterations is reached (Jiang et al., 2020a). For example, *Order+Order* represents that the answers are initially predicted by *Order* and then refined by *Order*. In this paper we examined two of these approaches, i.e. *Independent* and *Order+Order*, based on our initial exploration.

Generation-based. Recently, many generation based PLMs have been presented for text generation tasks, such as BART (Lewis et al., 2020) and T5 (Raffel et al., 2020). These generative PLMs are trained with a de-noising objective to restore its original form autoregressively (Lewis et al., 2020; Raffel et al., 2020). Such an autoregressive generation process is analogous to the *Order* probing approach, thus the generative PLMs can be directly used to generate answers for each query. Specifically, we utilize the cloze-style query with a single [Mask] token as the model input. The model then predicts the answer entities that correspond to the [Mask] token in an autoregressive manner. An illustration is provided in Figure 2(b).

Retrieval-based. Mask predict and Generation-based approaches need to use the PLM vocabulary as their search spaces for answer tokens, which may generate answers that are not in the answer set. In particular, when probing the masked PLMs using their MLM heads, the predicted result might not be a good indicator for measuring the amount of knowledge captured by these PLMs. This is mainly because the MLM head will be eventually dropped during the downstream task fine-tuning while the MLM head normally accounts for more than 20% of the total PLM parameters. Alternatively, the retrieval-based probing (Dufter et al., 2021; Kassner et al., 2021) are applied to address this issue. Instead of generating answers based on the PLM vocabulary, the retrieval-based approach finds answers by ranking the knowledge graph candidate entities based on the query and entity representations, or the entity generating scores. To probe PLMs on `MedLAMA`, we use *mask average* (Kassner et al., 2021), an approach that takes the average log probabilities of entity's individual tokens to rank the candidates. The retrieval-based approaches address the multi-token issue by restricting the output space to the valid answer set and can be used to probe knowledge in different types of PLMs (e.g. BERT vs. fastText; Dufter et al. 2021). However, previous works (Kassner et al., 2021; Dufter et al., 2021) only report results based on the type-restricted candidate set (e.g. relation) which we observed to decay drastically under the full entity set.

4 Contrastive-Probe: Cloze-style Task as a Self-retrieving Game

To better transform the PLM encoders for the cloze-style probing task, we propose Contrastive-

PROBE which pre-trains on a small number of sentences sampled from the PLM's *original pre-training corpora* with a contrastive self-supervising objective, inspired by the Mirror-BERT (Liu et al., 2021b). Our contrastive pre-training does not require the MLM head or any additional external knowledge, and can be completed in less than one minute on 2 × 2080Ti GPUs.

Self-supervised Contrastive Rewiring. We randomly sample a small set of sentences (e.g. 10k, see §5.2 for stability analysis of CONTRASTIVE-PROBE on several randomly sampled sets), and replace their tail tokens (e.g. the last 50% excluding the full stop) with a [MASK] token. Then these transformed sentences are taken as the queries of the *cloze-style self-retrieving game*. In the following we show an example of transforming a sentence into a cloze-style query:

> **Sentence:** Social-distancing largely reduces coronavirus infections.
> **Query:** Social-distancing largely [MASK].

where "reduces coronavirus infections" is marked as a positive answer of this query.

Given a batch, the *cloze-style self-retrieving game* is to ask the PLMs to retrieve the positive answer from all the queries and answers in the same batch. Our CONTRASTIVE-PROBE tackles this by optimising an InfoNCE objective (Oord et al., 2018),

$$\mathcal{L} = -\sum_{i=1}^{N} \log \frac{\exp(\cos(f(x_i), f(x_p))/\tau)}{\sum_{x_j \in \mathcal{N}_i} \exp(\cos(f(x_i), f(x_j))/\tau)}, \quad (1)$$

where $f(\cdot)$ is the PLM encoder (with the MLM head chopped-off and `[CLS]` as the contextual representation), N is batch size, x_i and x_p are from a query-answer pair (i.e., x_i and x_p are from the same sentence), $\mathcal{N}_i$ contains queries and answers in the batch, and τ is the temperature. This objective function encourages f to create similar representations for any query-answer pairs from the same sentence and dissimilar representations for queries/answers belonging to different sentences.

Retrieval-based Probing. For probing step, the query is created based on the prompt-based template for each knowledge triple , as shown in the following:

> **Triple:** <*Elvitegravir*, `may-prevent`, *Epistaxis*>
> **Query:** Elvitegravir may prevent [MASK].

and we search for nearest neighbours from all the entity representations encoded by the same model.

Approach	PLM	Full Set

5 Experiments

In this section we conduct extensive experiments to verify whether CONTRASTIVE-PROBE is effective for probing biomedical PLMs. First, we experiment with CONTRASTIVE-PROBE and existing probing approaches on `MedLAMA` benchmark (§5.1). Then, we conduct in-depth analysis of the stability and applicability of CONTRASTIVE-PROBE in probing biomedical PLMs (§5.2). Finally, we report an evaluation of a biomedical expert on the probing predictions and highlight our findings (§5.3).

CONTRASTIVE-PROBE Rewiring. We train our CONTRASTIVE-PROBE based on 10k sentences which are randomly sampled from the PubMed texts[5] using a mask ratio of 0.5. The best hyperparameters and their tuning options are provided in *Appendix*.

Probing Baselines. For the mask predict approach, we use the original implementation of X-FACTR (Jiang et al., 2020a), and set the beam size and the number of masks to 5. Both mask predict and retrieval-based approaches are tested under both the general domain and biomedical domain BERT models, i.e. Bert-based-uncased (Devlin et al., 2019), BlueBERT (Peng et al., 2019), BioBERT (Lee et al., 2020), PubMedBERT (Gu et al., 2020).[6] For generation-based baselines, we test five PLMs, namely BART-base (Lewis et al.,

---

[5] We sampled the sentences from a PubMed corpus used in the pre-training of BlueBERT (Peng et al., 2019).

[6] The MLM head of PubMedBERT is not publicly available and cannot be evaluated by X-FACTR and *mask average*.

2020), T5-small and T5-base (Raffel et al., 2020) that are general domain generation PLMs, and SciFive-base & SciFive-large (Phan et al., 2021) that are pre-trained on large biomedical corpora.

5.1 Benchmarking on MedLAMA

Comparing Various Probing Approaches. Table 4 shows the overall results of various probing baselines on MedLAMA. It can be seen that the performances of all the existing probing approaches (i.e. *generative PLMs*, *X-FACTR* and *mask predict*) are very low (<1% for acc@1 and <4% for acc@10) regardless of the underlying PLM, which are not effective indicators for measuring knowledge captured. In contrast, our Contrastive-Probe obtains absolute improvements by up-to ~ 5% and ~ 21% on acc@1 and acc10 respectively comparing with the three existing approaches, which validates its effectiveness on measuring the knowledge probing performance. In particular, PubMedBERT model obtains the best probing performance (5.71% in accuracy) for these biomedical queries, validating its effectiveness of capturing biomedical knowledge comparing with other PLMs (i.e. BERT, BlueBERT and BioBERT).

Benchmarking with Contrastive-Probe. To further examine the effectiveness of PLMs in capturing biomedical knowledge, we benchmarked several state-of-the-art biomedical PLMs (including pure pre-trained and knowledge-enhanced models) on MedLAMA through our Contrastive-Probe. Table 5 shows the probing results over the full and hard sets. In general, we can observe that these biomedical PLMs always perform better than general-domain PLMs (i.e., BERT). Also, we observe the decay of performance of all these models on the more challenging hard set queries. While PubMedBERT performs the best among all the pure pre-trained models, SapBERT (Liu et al., 2021a) and CoderBERT (Yuan et al., 2020) (which are the knowledge infused PubMedBERT) further push performance to 8% and 30.41% on acc@1 and acc@10 metrics respectively, highlighting the benefits of knowledge infusion pre-training.

Comparison per Answer Length. Since different PLMs use different tokenizers, we use char length of the query answers to split MedLAMA into different bins and test the probing performance over various answer lengths. Figure 3 shows the result. We can see that the performance of retrieval-based probing in Contrastive-Probe increases as the answer length increase while the performance of mask predict dropped significantly. This result validates that our Contrastive-Probe (retrieval-based) are more reliable at predicting longer answers than the mask predict approach since the latter heavily relies on the MLM head.[7]

Model	acc@1/acc@10	
	Full Set	**Hard Set**
BERT (Devlin et al., 2019)	1.95±0.40/6.96 ±0.96	0.67±0.19/3.27±0.54
BlueBERT (Peng et al., 2019)	4.87±0.43/19.87±0.62	4.12±0.46/18.18±0.77
BioBERT (Lee et al., 2020)	3.28±0.20/15.46±0.93	2.14±0.23/12.59±1.19
ClinicalBERT (Alsentzer et al., 2019)	1.83±0.15/8.64±0.79	0.71±0.13/5.45±1.06
SciBERT (Beltagy et al., 2019)	3.64±0.33/18.11±1.95	2.14±0.30/14.64±2.01
PubMedBERT (Gu et al., 2020)	5.71±0.58/24.31±1.29	4.49±0.49/21.74±1.21
UmlsBERT (Yuan et al., 2020)	2.94±0.21/11.64±0.46	1.80±0.11/7.75±0.42
SapBERT (Liu et al., 2021a)	7.80±0.38/**30.41**±1.23	5.15±0.27/**26.09**±1.17

Table 5: Benchmarking biomedical PLMs on MedLAMA (Full and Hard) via Contrastive-Probe. The bottom panel are knowledge-enhanced PLMs. The average performance and their standard deviation are reported based on rewiring over 10 different random sets.

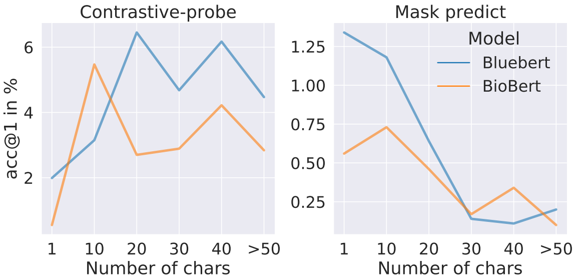

Figure 3: Performance over answer lengths.

5.2 In-depth Analysis of Contrastive-Probe

Since our Contrastive-Probe involves many hyperparameters and stochastic factors during self-retrieving pre-training, it is critical to verify if it behaves consistently under (1) different randomly sampled sentence sets; (2) different types of relations; and (3) different pre-training steps.

Stability of Contrastive-Probe. To conduct this verification, we sampled 10 different sets of 10k sentences from the PubMed corpus[8] and probed the PubMedBERT model using our Contrastive-Probe on the full set. Figure 4 shows the acc@1 performance over top 9 relations and the micro average performance of all the 19 relations. We can see that the standard deviations are small and the performance over different sets of samples shows the similar trend. This further highlights

---

[7] For the single-token answer probing scenario, Contrastive-Probe does not outperform the mask predict approach, particularly in the general domain. This is expected since most of the masked PLMs are pre-trained by a single-token-filling objective.

[8] The tuning corpus itself is unimportant, since we can obtain the similar results even using Wikipedia.

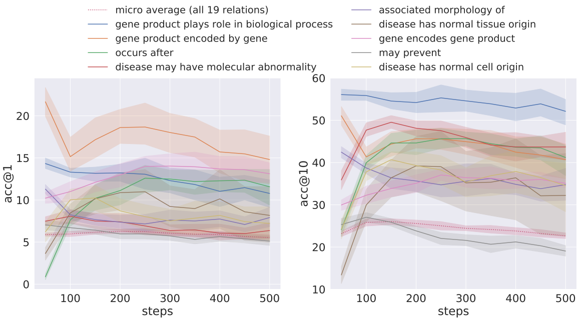

Figure 4: Performance over training steps on full set. The shaded regions are the standard deviations.

that the probing success of Contrastive-Probe is not due the selected pre-training sentences. Intuitively, the contrastive self-retrieving game (§4) is equivalent to the formulation of the cloze-style filling task, hence tuning the underlying PLMs makes them better suited for knowledge elicitation needed during probing (like 'rewiring' the switchboards). Additionally, from Figure 4 we can also observe that different relations exhibit very different trends during pre-training steps of Contrastive-Probe and peak under different steps, suggesting that we need to treat different types of relational knowledge with different tuning depths when infusing knowledge. We leave further exploration of this to future work.

Probing by Relations. To further analyse the probing variance over different relations, we also plot the probing performance of various PLMs over different relations of `MedLAMA` in Figure 5. We can observe that different PLMs exhibit different performance rankings over different types of relational knowledge (e.g. BlueBERT peaks at *relation 12* while PubMedBERT peaks at *relation 3*). This result demonstrates that different PLMs are suited for different types of relational knowledge. We speculate this to be reflective of their training corpora.

Probing by Layer. To investigate how much knowledge is stored in each Transformer layer, we chopped the last layers of PLMs and applied Contrastive-Probe to evaluate the probing performance based on the first $L \in \{3, 5, 7, 9, 11, 12\}$ layers on `MedLAMA`. In general, we can see in Figure 6 that the model performance drops significantly after chopping the last 3 layers, while its accuracy is still high when dropping only last one layer. In Figure 7, we further plot the layer-wise probing performance of PubMedBERT over different relations. Surprisingly, we find that different relations do not show the same probing performance trends over layers. For example, with only the first 3 layers, PubMedBERT achieves the best accuracy (>15%) on *relation 11* queries. This result demonstrates that both relation types and PLM layers are confounding variables in capturing factual knowledge, which helps to explain the difference of training steps over relations in Figure 4. This result also suggests that layer-wise and relation-wise training could be the key to effectively infuse factual knowledge for PLMs.

5.3 Expert Evaluation on Predictions

To assess whether the actual probing performance could be possibly higher than what is reflected by the commonly used automatic evaluation, we conducted a human evaluation on the prediction result. Specifically, we sample 15 queries and predict their top-10 answers using Contrastive-Probe based on PubMedBERT and ask the assessor[9] to rate the predictions on a scale of [1,5]. Figure 8 shows the confusion matrices.[10] We observe the followings: (1) There are 3 UMLS answers that are annotated with score level 1-4 (precisely, level 3), which indicates UMLS answers might not always be the perfect answers. (2) There are 20 annotated perfect answers (score 5) in the top 10 predictions that are not marked as the gold answers in the UMLS, which suggests the UMLS does not include all the expected gold knowledge. (3) In general, PubMedBERT achieves an 8.67% (13/150) acc@10 under gold answers, but under the expert annotation the acc@10 is 22% (33/150), which means the probing performance is higher than what evaluated using the automatically extracted answers.

Benchmark	# Rel.	# Queries	Avg. # Answer	% Single-Tokens
LAMA	41	41k	1	100%
BioLAMA	36	49k	1	2.2%
`MedLAMA`	19	19k	2.3	2.6%

Table 6: Statistics comparison among LAMA, BioLAMA and our `MedLAMA`.

5.4 Comparing with BioLAMA

During the writing of this work, we noticed a concurrent work to ours that also released a biomedical knowledge probing benchmark, called BioLAMA Sung et al. (2021). In Table 6, we com-

---

[9] A senior Ph.D. graduate in Cell Biology.

[10] In the *Appendix*, we provide examples with their UMLS gold answers, human annotated answers and probing predictions of different probing approaches.

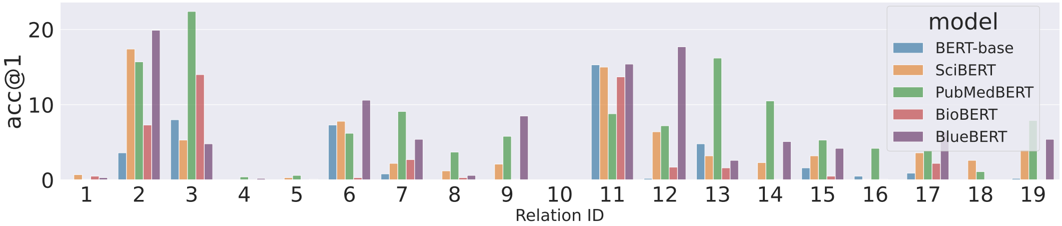

Figure 5: Performance of PLMs over different relations.

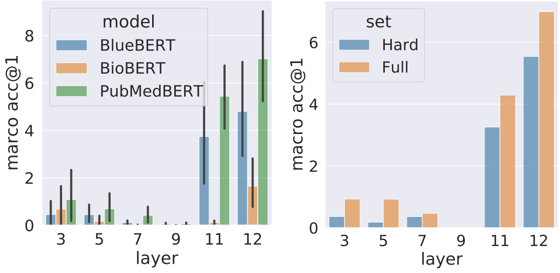

Figure 6: Performance over different layers.

pare `MedLAMA` with LAMA (Petroni et al., 2019) and BioLAMA in terms of data statistics. We found that there is only 1 overlapped relation (i.e., may treat) between BioLAMA and `MedLAMA`, and no overlap exists on the queries. We can see that, without additional training data from the biomedical knowledge facts, CONTRASTIVE-PROBE reaches a promising performance compared with OptiPrompt approach, which needs further training data. Additionally, since Mask Predict and OptiPrompt require using the MLM head, it is impossible to compare a model without MLM head being released (e.g. PubMedBERT). In contrast, our CONTRASTIVE-PROBE not only provides a good indicator of comparing these models in terms of their captured knowledge, but also makes layer-wise knowledge probing possible.

5.5 Limitations of CONTRASTIVE-PROBE

How to early stop? For fair comparison of different PLMs, we currently use checkpoints after contrastive tuning for a fixed number of steps (200, specifically). However, we have noticed that different models and different probing datasets have different optimal training steps. To truly 'rewire' the most knowledge out of each PLMs, we need a unified validation set for checkpoint selection. What the validation set should be and how to guarantee its fairness require further investigation.

Performance not very stable. We have noticed that using different contrastive tuning corpus as well as different random seeds can lead to a certain variance of their probing performances (see Table 5). To mitigate such issue, we use average performance of 10 runs on 10 randomly sampled corpus. Improving the stability of CONTRASTIVE-PROBE and investigating its nature is a future challenge.

Probe	Model	CTD		wikidata		UMLS	
		acc@1	acc@5	acc@1	acc@5	acc@1	acc@5
Mask Predict	BERT	0.06	1.20	1.16	6.04	0.82	1.99
	BioBERT	0.42	3.25	3.67	11.20	1.16	3.82

Table 7: Performance on BioLAMA benchmark. Note that both the mask predict and opti-prompt require using the MLM head and opti-prompt needs further training data, so it is impossible to compare a model without MLM head being released (e.g. PubMedBERT). In contrast, our CONTRASTIVE-PROBE make all these models comparable in terms of their captured knowledge.

6 Related Work and Discussion

Knowledge Probing Benchmarks for PLMs. LAMA (Petroni et al., 2019), which starts this line of work, is a collection of single-token knowledge triples extracted from sources including Wikidata and ConceptNet (Speer et al., 2017). To mitigate the problem of information leakage from the head entity, Poerner et al. (2019) propose LAMA-UHN, which is a hard subset of LAMA that has less token overlaps in head and tail entities. X-FACTR (Jiang et al., 2020a) and mLAMA (Kassner et al., 2021) extend knowledge probing to the multilingual scenario and introduce multi-token answers. They each propose decoding methods that generate multi-token answers, which we have shown to work poorly on `MedLAMA`. BioLAMA (Sung et al., 2021) is a concurrent work that also releases a benchmark for biomedical knowledge probing.

Probing via Prompt Engineering. Knowledge probing is sensitive to what prompt is used (Jiang et al., 2020b). To bootstrap the probing performance, Jiang et al. (2020b) mine more prompts and ensemble them during inference. Later works parameterised the prompts and made them train-

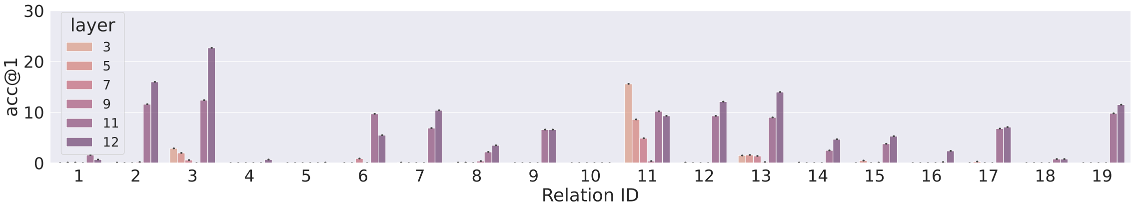

Figure 7: Performance of PubMedBERT over layers.

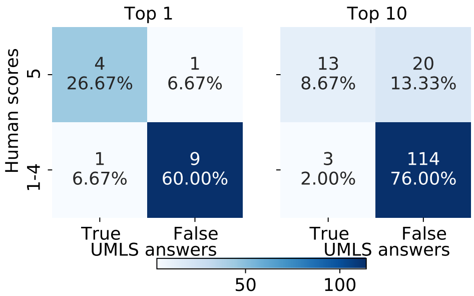

Figure 8: Confusion matrices of expert annotated scores versus the extracted UMLS answers. Five annotation score levels: 5-*Perfectly answer the query*; 4-*Similar to the gold answer, could somehow be the answer*; 3-*Related to the query but not correct*; 2-*Same domain or slight relation*; 1-*Completely unrelated*.

able (Shin et al., 2020b; Fichtel et al., 2021; Qin and Eisner, 2021). We have opted out prompt-engineering methods that require training data in this work, as tuning the prompts are essentially tuning an additional (parameterised) model on top of PLMs. As pointed out by Fichtel et al. (2021), prompt tuning requires large amounts of training data from the task. Since task training data is used, the additional model parameters are exposed to the target data distribution and can solve the set set by overfitting to such biases (Cao et al., 2021). In our work, by adaptively finetuning the model with a small set of raw sentences, we elicit the knowledge out from PLMs but do not expose the data biases from the benchmark (`MedLAMA`).

Biomedical Knowledge Probing. Nadkarni et al. (2021) train PLMs as KB completion models and test on the same task to understand how much knowledge is in biomedical PLMs. BioLAMA focuses on the continuous prompt learning method OptiPrompt (Zhong et al., 2021), which also requires ground-truth training data from the task. Overall, compared to BioLAMA, we have provided a more comprehensive set of probing experiments and analysis, including proposing a novel probing technique and providing human evaluations of model predictions.

7 Conclusion

In this work, we created a carefully curated biomedical probing benchmark, `MedLAMA`, from the UMLS knowledge graph. We illustrated that state-of-the-art probing techniques and biomedical pre-trained languages models (PLMs) struggle to cope with the challenging nature (e.g. multi-token answers) of this specialised domain, reaching only an underwhelming 3% of acc@10. To reduce the gap, we further proposed a novel contrastive recipe which rewires the underlying PLMs without using any probing-specific data and illustrated that with a lightweight pre-training their accuracies could be pushed to 24%.

Our experiments also revealed that different layers of transformers encode different types of information, reflected by their individual success at handling certain types of prompts. Additionally, using a human expert, we showed that the existing evaluation criteria could overpenalise the models as many valid responses that PLMs produce are not in the ground truth UMLS knowledge graph. This further highlights the importance of having a human in the loop to better understand the potentials and limitations of PLMs in encoding domain specific factual knowledge.

Our findings indicate that the real lower bound on the amount of factual knowledge encoded by PLMs is higher than we estimated, since such bound can be continuously improved by optimising both the encoding space (e.g. using our self-supervised contrastive learning technique) and the input space (e.g. using the prompt optimising techniques (Shin et al., 2020a; Qin and Eisner, 2021)). We leave further exploration of integrating the two possibilities to future work.

A Appendix

A.1 Details of the Hardness Metrics

In this paper, we use two automatic metrics to distinguish hard and easy queries. In particular, we first filter out easy queries by an exact matching metric (i.e. the exactly matching all the words of answer from queries). Since our `MedLAMA` contains multiple answers for queries, we use a threshold on the average exact matching score, i.e. **avg-match**>0.1, to filter out easy examples, where **avg-match** is calculated by:

$$\textbf{avg-match} = \frac{\textbf{Count}(\text{matched answers})}{\textbf{Count}(\text{total answers})}.$$

This metric can remove all the queries that match the whole string of answers. However, some common sub-strings between queries and answers also prone to reveal answers, particularly benefiting those retrieval-based probing approaches. E.g. <*Magnesium Chloride*, `may-prevent`, *Magnesium Deficiency*>. Therefore, we further calculate the **ROUGE-L** score (Lin and Och, 2004) for all the queries by regarding <query, answers> pairs as the <hypothesis, reference> pairs, and further filter out the **ROUGE-L**>0.1 queries.

A.2 Hyperparameters Tuning

We train our Contrastive-Probe based on 10k sentences which are randomly sampled from the original pre-training corpora of the corresponding PLMs. Since most of the biomedical BERTs use PubMed texts as their pre-training corpora, for all biomedical PLMs we sampled random sentences from a version of PubMed corpus used by BlueBERT model (Peng et al., 2019), while for BERT we sampled sentences from its original Wikitext corpora. For the hyperparamters of our Contrastive-Probe, Table 8 lists our search options and the best parameters used in our paper.

A.3 The Impact of Mask Ratios

To further investigate the impact of the mask ratio to the probing performance, we also test our Contrastive-Probe based on PubMedBERT over different mask ratios ({0.1, 0.2, 0.3, 0.4, 0.5}) under the 10 random sentence sets, the result of which is shown in Figure 9. We can see that over different mask ratios the Contrastive-Probe always reaches their best performance under certain pre-training steps. And the performance curves of mask ratios are different over the full and hard sets, but they all achieves a generally good performance when the mask ratio is 0.5, which validates that different mask ratios favour different types queries.

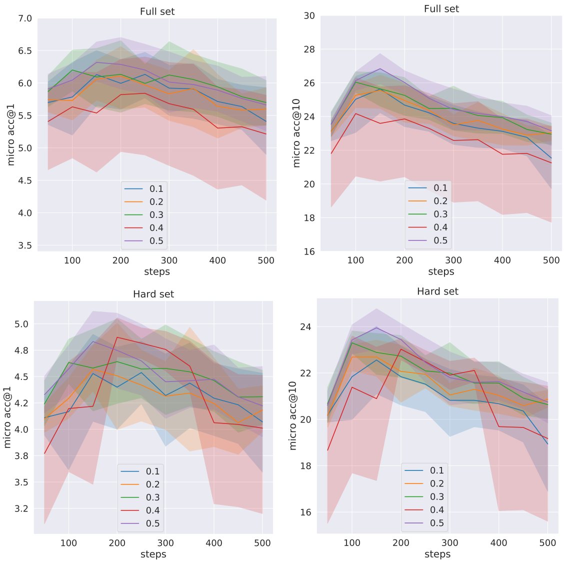

Figure 9: Performance of Contrastive-Probe based on PubMedBERT over different mask ratios. The shaded regions are the standard deviations under 10 different random sentence sets sampled from the PubMed corpus.

Fine- and Coarse-Granularity Hybrid Self-Attention for Efficient BERT

Jing Zhao, Yifan Wang, Junwei Bao,[*] Youzheng Wu, Xiaodong He
JD AI Research, Beijing, China
`{zhaojing857,wangyifan15,baojunwei,`
`wuyouzheng1,xiaodong.he}@jd.com`

Abstract

Transformer-based pre-trained models, such as BERT, have shown extraordinary success in achieving state-of-the-art results in many natural language processing applications. However, deploying these models can be prohibitively costly, as the standard self-attention mechanism of the Transformer suffers from quadratic computational cost in the input sequence length. To confront this, we propose FCA, a fine- and coarse-granularity hybrid self-attention that reduces the computation cost through progressively shortening the computational sequence length in self-attention. Specifically, FCA conducts an attention-based scoring strategy to determine the informativeness of tokens at each layer. Then, the informative tokens serve as the fine-granularity computing units in self-attention and the uninformative tokens are replaced with one or several clusters as the coarse-granularity computing units in self-attention. Experiments on GLUE and RACE datasets show that BERT with FCA achieves 2x reduction in FLOPs over original BERT with <1% loss in accuracy. We show that FCA offers significantly better trade-off between accuracy and FLOPs compared to prior methods[1].

1 Introduction

Transformer-based large pre-trained language models with BERT (Devlin et al., 2018) as a typical model routinely achieve state-of-the-art results on a number of natural language processing tasks (Yang et al., 2019; Liu et al., 2019; Clark et al., 2020), such as sentence classification (Wang et al., 2018), question answering (Rajpurkar et al., 2016, 2018), and information extraction (Li et al., 2020b).

Despite notable gains in accuracy, the high computational cost of these large models slows down their inference speed, which severely impairs their practicality, especially in the case of limited industry time and resources, such as Mobile Phone and AIoT. In addition, the excessive energy consumption and environmental impact caused by the computation of these models also raise the widespread concern (Strubell et al., 2019; Schwartz et al., 2020).

To improve the efficiency of BERT, the mainstream techniques are knowledge distillation (Hinton et al., 2015) and pruning. Knowledge distillation aims to transfer the “knowledge" from a large teacher model to a lightweight student model. The student model is then used during inference, such as DistilBERT (Sanh et al., 2019). Pruning technique includes: (1) structured methods that prune structured blocks of weights or even complete architectural components in BERT, for example encoder layers (Zhang and He, 2020), (2) unstructured methods that dynamically drop redundant units, for example, attention head (Voita et al., 2019) and attention tokens (Goyal et al., 2020). However, both types of methods encounter challenges. For the former, a great distillation effect often requires an additional large teacher model and very complicated training steps (Jiao et al., 2019; Hou et al., 2020). For the latter, pruning methods discard some computing units, which inevitably causes information loss.

In contrast to the prior approaches, we propose a self-motivated and information-retained technique, namely FCA, a fine- and coarse-granularity hybrid self-attention that reduces the cost of BERT through progressively shortening the computational sequence length in self-attention. Specifically, FCA first evolves an attention-based scoring strategy to assign each token with the informativeness. Through analyzing the informativeness distribution at each layer, we conclude that maintaining full-length token-level representations is progressive redundant along with layers, especially for the classification tasks that only require single-vector repre-

Volume 1: Long Papers, pages 4811 - 4820

sentations of sequences. Consequently, the tokens are divided into informative tokens and uninformative tokens according to their informativeness. Then, they are updated through different computation paths. The informative tokens carry most of the learned features and remain unchanged as the fine-grained computing units in self-attention. The uninformative tokens may not be as important as informative ones but we will not completely discard them to avoid information loss. Instead, We replace them with more efficient computing units to save memory consumption. Experiments on the standard GLUE benchmark show that FCA accelerates BERT inference speed and maintains high accuracy as well.

Our contributions are summarized as follows:

- We analyze the progressive redundancies in maintaining full-length token-level representations for the classification tasks.
- We propose a fine- and coarse-granularity hybrid self-attention, which is able to reduce the cost of BERT and maintain high accuracy.
- Experiments on the standard GLUE benchmark show that the FCA-based BERT achieves 2x reduction in FLOPs over the standard BERT with < 1% loss in accuracy.

2 Related work

There has been much prior literature on improving the efficiency of Transformers. The most common technologies include:

Knowledge distillation refers to training a smaller student model using outputs from various intermediate representations of larger pre-trained teacher models. In the BERT model, there are multiple representations that the student can learn from, such as the logits in the final layer, the outputs of the encoder units, and the attention maps. The distillation on output logits is most commonly used to train smaller BERT models (Sanh et al., 2019; Sun et al., 2019; Jiao et al., 2019; Sun et al., 2020). The output tensors of encoder units contain meaningful semantic and contextual relationships between input tokens. Some work creates a smaller model by learning from the outputs of teacher's encoder (Jiao et al., 2019; Sun et al., 2020; Li et al., 2020a). Attention map refers to the softmax distribution output of the self-attention layers and indicates the contextual dependence between the input tokens. A common practice of distillation on attention maps is to directly minimize the difference between the self-attention outputs of the teacher and the student (Jiao et al., 2019; Sun et al., 2020; Mao et al., 2020). This line of work is orthogonal to our approach and our proposed FCA can be applied to the distillate models to further accelerate their inference speed.

Pruning refers to identifying and removing less important weights or computation units. Pruning methods for BERT broadly fall into two categories. Unstructured pruning methods prune individual weights by comparing their absolute values or gradients with a pre-defined threshold (Mao et al., 2020; Gordon et al., 2020; Chen et al., 2020). The weights lower than the threshold are set to zero. Unlike unstructured pruning, structured pruning aims to prune structured blocks of weights or even complete architectural components in the BERT model. Voita et al. (2019) pruned attention heads using a method based on stochastic gates and a differentiable relaxation of the L0 penalty. Fan et al. (2019) randomly dropped Transformer layers to sample small sub-networks from the larger model during training which are selected as the inference models. Goyal et al. (2020) progressively reduced sequence length by pruning word-vectors based on the attention values. This work is partly similar to the fine-grained computing units in our proposed FCA. However they ignored the coarse-grained units that may cause information loss.

In addition, there are some engineering techniques to speed up the inference speed, such as Mixed Precision (Micikevicius et al., 2017) and Quantization (Zafrir et al., 2019; Fan et al., 2020). Using half-precision or mixed-precision representations of floating points is popular in deep learning to accelerate training and inference speed. Quantization refers to reducing the number of unique values required to represent the model weights, which in turn allows to represent them using fewer bits.

3 Preliminary

BERT (Devlin et al., 2018) is a Transformer-based language representation model, which can be fine-tuned for many downstream NLP tasks, including sequence-level and token-level classification. The Transformer architecture (Vaswani et al., 2017) is a highly modularized neural network, where each Transformer layer consists of two sub-modules, namely the multi-head self-attention sub-

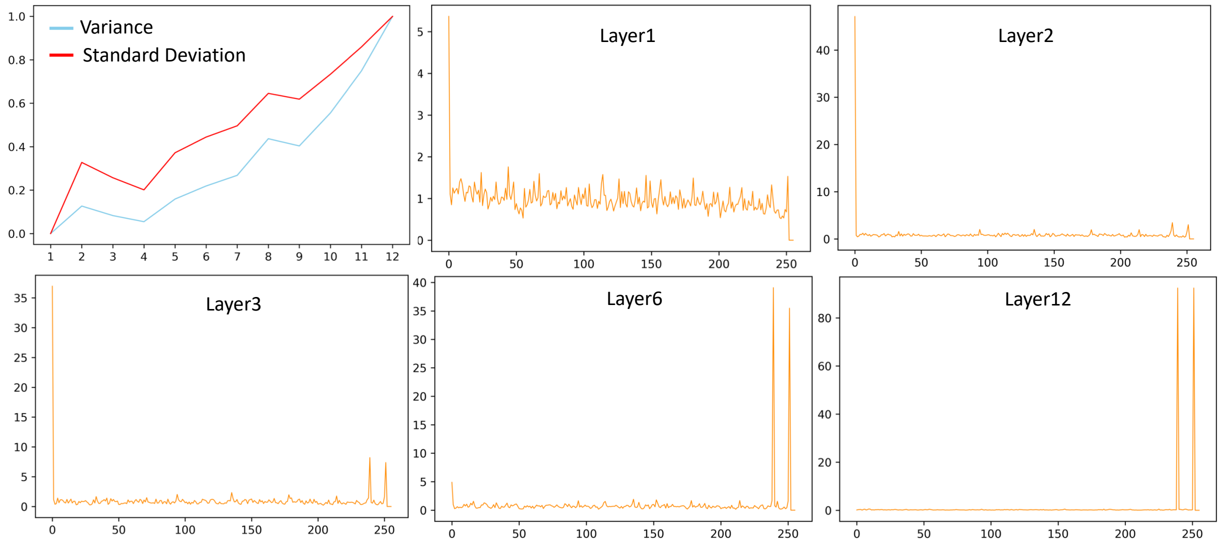

Figure 1: The first sub-figure is the normalized variance and standard deviation of informativeness with respect to BERT-base layers from 1 to 12. The last five sub-figures are the informativeness distributions on some layers.

layer (MHA) and the position-wise feed-forward network sub-layer (FFN). Both sub-modules are wrapped by a residual connection and layer normalization.

MHA. The self-attention mechanism allows the model to identify complex dependencies between the elements of each input sequence. It can be formulated as querying a dictionary with key-value pairs. Formally,

$$\mathrm{MHA}(Q,K,V) = \mathrm{Concat}(\mathrm{head}_1, ..., \mathrm{head}_h)W^O \tag{1}$$

where Q, K, and V represent query, key, and value. h is the number of heads. Each head is defined as:

$$\begin{aligned}\mathrm{head}_t &= \mathrm{Attention}(QW_t^Q, KW_t^K, VW_t^V) \\ &= \underbrace{\mathrm{softmax}(\frac{QW_t^Q(KW_t^K)^T}{\sqrt{d_K}})}_{A} VW_t^V\end{aligned} \tag{2}$$

where $W_t^Q \in \mathbb{R}^{d_h \times d_Q}, W_t^K \in \mathbb{R}^{d_h \times d_K}, W_t^V \in \mathbb{R}^{d_h \times d_V}, W^O \in \mathbb{R}^{hd_V \times d_h}$ are learned parameters. d_K, d_Q,and d_V are dimensions of the hidden vectors. The main cost of MHA layer is the calculation of attention mapping matrix $A \in \mathbb{R}^{n \times n}$ in Eq. 2 which is $O(n^2)$ in time and space complexity. This quadratic dependency on the sequence length has become a bottleneck for Transformers.

FFN. The self-attention sub-layer in each of the layers is followed by a fully connected position-wise feed-forward network, which consists of two linear transformations with a GeLU (Hendrycks and Gimpel, 2016) activation in between. Given a vector x_i in $[x_1, ..., x_n]$ outputted by MHA sub-layer, FFN is defined as:

$$\mathrm{FFN}(x_i) = \mathrm{GeLU}(x_iW_1 + b_1)W_2 + b_2, \tag{3}$$

where W_1, W_2, b_1, b_2 are learned parameters.

Previous research (Ganesh et al., 2021) has shown that in addition to MHA sub-layer, FFN sub-layer also consumes large memory in terms of model size and FLOPs. As a result, if we reduce the computational sequence length of MHA, the input and the consumption of FFN sub-layer will become less accordingly.

4 Methodologies

To shorten the computational sequence length of self-attention, our core motivation is to divide tokens into informative and uninformative ones and replace the uninformative tokens with more efficient units. This section introduces each module of our model in detail.

4.1 Scoring Strategy

Our strategy of scoring the informativeness of tokens is based on the self-attention map. Concretely, taking a single token vector x_i as an example, its attention head $x_i^{(t)}$ is updated by: $x_i^{(t)} = \sum_{j=1}^{n} a_{i,j} x_j^{(t)}$ (Eq. 2). $a_{i,j}$ is an element in attention map A. Therefore, $a_{i,j}$ represents the information contribution from token vector x_j to x_i over head$_t$. Intuitively, we define the informativeness of a token by accumulating along the columns of

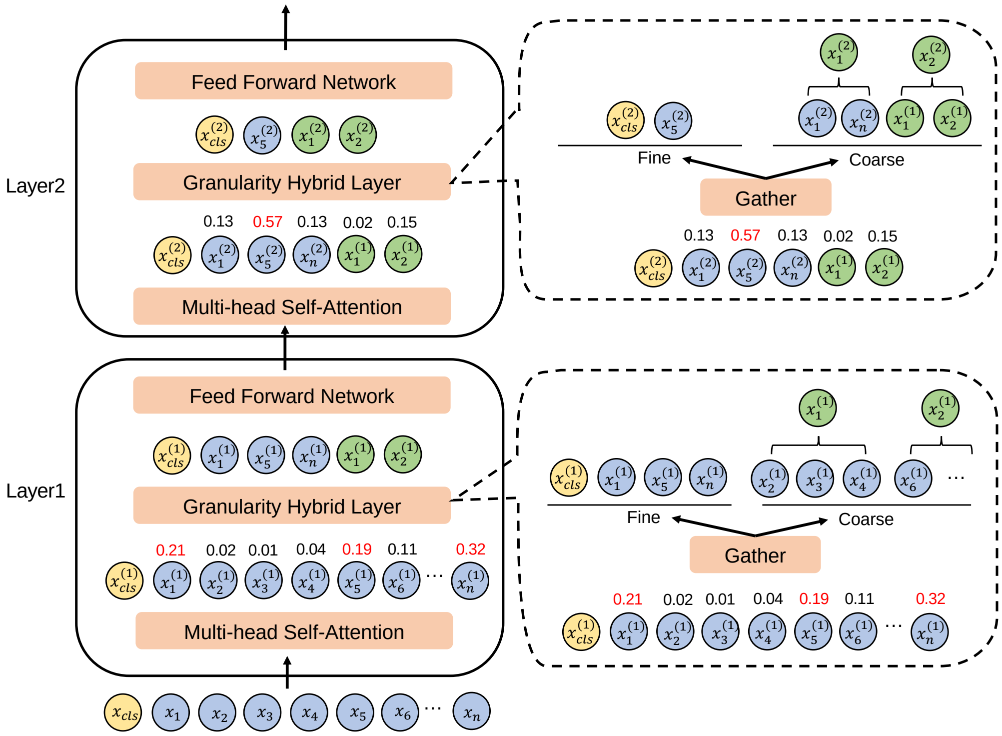

Figure 2: The architecture of FCA. The number marked above the tokens is its corresponding informativeness. The blue tokens are fine units and the green are coarse units. In this figure, we fix the number of coarse units to 2.

attention map A:

$$\mathrm{I}(x_j^{(t)}) = \sum_{i=1, i \neq j}^{n} a_{i,j} \tag{4}$$

The overall informativeness of x_j is defined as the average over the heads:

$$\mathrm{I}(x_j) = \frac{1}{h} \sum_{t=1}^{h} \mathrm{I}(x_j^{(t)}) \tag{5}$$

We next analyze some properties of defined informativeness in BERT-base. The first sub-figure in Figure 1 displays the normalized variance and standard deviation of informativeness of layers from 1 to 12 on RTE (classification dataset), which supports the phenomenon that the informativeness distributions at the bottom layers are relatively uniform and the top layers are volatile. The last five sub-figures further present the informativeness distributions of some BERT-base layers, where the first token is [CLS] and its representations are used for the final prediction. We can see that as the layers deepen, the informativeness is progressively concentrated on two tokens. This means that maintaining full-length token-level representations for the classification tasks may be redundant.

A straightforward approach for reducing the sequence length of self-attention is to maintain the informative tokens and prune the rest. We argue that this approach is effortless but encounters the risk of information loss, especially for lower layers.

4.2 FCA Layer

Instead of pruning, we propose to process the uninformative tokens with more efficient units. Figure 2 shows the architecture of FCA layer, which inserts a granularity hybrid sub-layer after MHA. At each layer, it first divides tokens into informative and uninformative ones based on their assigned informativeness. The CLS token is always divided into informative part as it is used to derive the final prediction.

Let $x_{cls}^{(l)} \oplus X^{(l)}$ be the sequence of token vectors input to l-th layer, where $X^{(l)} = [x_1^{(l)}, ..., x_n^{(l)}]$ and n is the sequence length of $X^{(l)}$. We gather the token vectors from $X^{(l)}$ with the top-k informativeness to form the informative sequence $X_{in}^{(l)}$ and the rest vectors to form the uninformative sequence $X_{un}^{(l)}$, where $X_{in}^{(l)} \in \mathbb{R}^{k \times d_h}$ and $X_{un}^{(l)} \in \mathbb{R}^{(n\text{-}k) \times d_h}$. The length of the uninformative sequence is reduced by performing certain type of aggregating operations along the sequence dimension, such as *average pooling*:

$$X'^{(l)}_{un} = \text{Pooling}(X^{(l)}_{un}) \tag{6}$$

or *weighted average pooling* with informativeness as weights:

$$\begin{aligned} \alpha_{x^{(l)}_{un}} &= \text{softmax}(\text{I}(x^{(l)}_{un})) \\ X'^{(l)}_{un} &= \text{Pooling}(\alpha X^{(l)}_{un}) \end{aligned} \tag{7}$$

where $x^{(l)}_{un}$ is the token vector in $X^{(l)}_{un}$. The aggregated sequence $X'^{(l)}_{un} \in \mathbb{R}^{k' \times d_h}$ and k' is a fixed parameter. After hybrid layer, token sequence is updated to $[x^{(l)}_{cls} \oplus X^{(l)}_{in} \oplus X'^{(l)}_{un}]$ and sequence length is shortened by n-k-k'. Therefore, in addition to the following layers, the computation cost of FFN in l-th layer is reduced as well. It should be noted that the relative position of uninformative tokens should be preserved, which contains their contextual features to a certain extent and they can be captured by aggregating operations.

The parameter k is learnable and progressively shortened. Inspired by Goyal et al. (2020), we train n learnable parameters to determine the configuration of k, denoted $R = [r_1, ..., r_n]$. The parameters are constrained to be in the range, i.e., $r_i \in [0; 1]$ and added after MHA sub-layer. Given a token vector x_i output by MHA, it is modified by:

$$x_i \leftarrow r_{pos(x_i)} x_i \tag{8}$$

where $pos(x_i)$ is the sorted position of x_i over informativeness. Intuitively, the parameter r_i represents the extent to which the informativeness of the token at i-th position is retained. Then, for the l-th layer, we obtain the configuration of k_l from the sum of the above parameters, i.e.,

$$\begin{aligned} k_l &= \text{ceil}(\text{sum}(l; R)) \\ s.t.\ \ k_{l+1} &\le k_l \end{aligned} \tag{9}$$

5 Loss Function

Let Θ be the parameters of the baseline BERT model and $\mathcal{L}(\cdot)$ be cross entropy loss or mean-squared error as defined in the original task. We adopt the multi-task learning idea to jointly minimize the loss in accuracy and total sequence length over all layers.

$$\underset{\Theta, R}{\text{Loss}} = \mathcal{L}(\Theta, R) + \lambda \sum_{l=1}^{L} l \cdot \text{sum}(l; R) \tag{10}$$

where L is the number of layers. $\mathcal{L}(\Theta, R)$ controls the accuracy and $\text{sum}(l; R)$ controls the sequence length of l-th layer. The hyper-parameter λ tunes the trade-off.

Dataset	**Task**	**Input Length**
CoLA	Acceptability	64
RTE	NLI	256
QQP	Similarity	128
SST-2	Sentiment	64
MNLI-m	NLI	128
QNLI	NLI	128
RACE	QA	512

Table 1: Statistics of Datasets.

The training schema of our model involves three stages, which are given in Algorithm 1.

Algorithm 1 Training Process

```
Input: D = training set
Initialize: $\Theta \leftarrow$ BERT parameters
Initialize: $R \leftarrow$ uniform distribution
1: fine-tune $\Theta$ on D with original loss $\mathcal{L}(\cdot)$
2: add $R$ after MHA sub-layer and fine-tune $\Theta$ and $R$ with Eq. 10
3: obtain the configuration of $k$ on each layer, then re-train FCA-layer based BERT with $\mathcal{L}(\cdot)$
```

6 Experiments

6.1 Datasets

Our experiments are mainly conducted on GLUE (General Language Understanding Evaluation) [2] (Wang et al., 2018) and RACE (Lai et al., 2017) datasets. GLUE benchmark covers four tasks: Linguistic Acceptability, Sentiment Classification, Natural Language Inference, and Paraphrase Similarity Matching. RACE is the Machine Reading Comprehension dataset.

For experiments on RACE, we denote the input passage as P, the question as q, and the four answers as $\{a_1, a_2, a_3, a_4\}$. We concatenate passage, question and each answer as a input sequence $[\text{CLS}]P[\text{SEP}]q[\text{SEP}]a_i[\text{SEP}]$, where $[\text{CLS}]$ and $[\text{SEP}]$ are the special tokens used in the original BERT. The representation of $[\text{CLS}]$ is treated as the single logit value for each a_i. Then, a softmax layer is placed on top of these four logits to obtain

---

[2] https://gluebenchmark.com/

the normalized probability of each answer, which is used to compute the cross-entropy loss.

The input length of BERT is set to 512 by default. However, the instances in these datasets are relatively short, rarely reaching 512. If we keep the default length settings, most of the input tokens are [PAD] tokens. In this way, our model can easily save computational resources by discriminating [PAD] tokens as the uninformative ones, which is meaningless. To avoid this, we constrained the length of the datasets. The statistic information of the datasets is summarized in Table 1.

6.2 Evaluation Metrics

For accuracy evaluation, we adopt Matthew's Correlation for CoLA, F1-score for QQP, and Accuracy for the rest datasets. For efficiency evaluation, we use the number of floating operations (FLOPs) to measure the inference efficiency, as it is agnostic to the choice of the underlying hardware.

6.3 Baselines

We compare our model with both distillation and pruning methods. Distillation methods contain four models DistilBERT (Sanh et al., 2019), BERT-PKD (Sun et al., 2019), Tiny-BERT (Jiao et al., 2019), and Mobile-BERT (Sun et al., 2020). All four models are distillation from BERT-base and have the same structure (6 transformer layers, 12 attention heads, dimension of the hidden vectors is 768). Pruning methods contain FLOP (Wang et al., 2020), SNIP (Lin et al., 2020), and PoWER-BERT (Goyal et al., 2020). PoWER-BERT (Goyal et al., 2020) is the state-of-the-art pruning method which reduces sequence length by eliminating word-vectors. To make fair comparisons, we set the length of our informative tokens at each layer same to the sequence length of PoWER-BERT.

6.4 Implementation Details

We deploy BERT-base as the standard model in which transformer layers L=12, hidden size d_h=512, and number of heads h=12. All models are trained with 3 epochs. The batch size is selected in list 16,32,64. The model is optimized using Adam (Kingma and Ba, 2014) with learning rate in range [2e-5,6e-5] for the BERT parameters Θ, [1e-3,3e-3] for R. Hyper-parameter λ that controls the trade-off between accuracy and FLOPs is set in range [1e-3,7e-3]. We conducted experiments with a V100 GPU. The FLOPs for our model and the baselines were calculated with Tensorflow and batch size=1. The detailed hyper-parameters setting for each dataset are provided in the Appendix.

6.5 Main Results

Table 3 and Table 2 display the accuracy and inference FLOPs of each model on GLUE benchmark respectively. As the FLOPs of PoWER-BERT is almost the same as that of FCA-BERT and the number of coarse units has little affect on FLOPs, Table 2 only lists the FLOPs of FCA-BERT.

Comparison to BERT. The results demonstrate the high-efficiency of our model, which almost has no performance gap with BERT-base (<%1 accuracy loss) while reduces the inference FLOPs by half on majority datasets. Table 4 presents the sequence length of FCA at each layer, which illustrates substantial reduction of computation length for standard BERT. For example, the input sequence length for the dataset QQP is 128. Hence, standard BERT needs to process 128*12=1536 tokens over the twelve layers. In contrast, FCA only tackles [85, 78, 73, 69, 61, 57, 54, 52, 46, 41, 35, 35] summing to 686 tokens. Consequently, the computational load of self-attention and the feed forward network is economized significantly.

Among our models, the weighted average pooling operation raises the better performance than the average pooling operation. The number of coarse units contributes the model accuracy for both two operations, especially for pooling operation. This is reasonable as when the number of coarse units increases, the information stored in each FCA gradually approaches the standard BERT. But overmuch coarse units grow FLOPs. Therefore, it is necessary to balance impact on FLOPS and performance brought by the coarse units.

Comparison to Baselines. We first compare our model to Distil-BERT. Our models dramatically outperform Distil-BERT in accuracy by a margin of at least 3 average score. As mentioned before, the line of distillation framework is orthogonal to our proposed method. We further investigate whether FCA is compatible with distillation models. Table 5 shows the results of Distil-BERT with FCA-Pool$_5$, which verify that FCA could further accelerate the inference speed on the basis of the distillation model with <1% loss in accuracy. As for the SOTA distillation models, Tiny-BERT and Mobile-BERT, our models still outperform them on average performance. Combined with the results of Table 2 where our models have slightly fewer

Table 4: Sequence length at each layer.

inference FLOPs than the distillation methods, it can be proved that FCA has better accuracy and computational efficiency than them.

We next compare our model to the SOTA pruning model PoWER-BERT. Their acceleration effects are comparable and we focus on comparing their accuracy. The results on Table 3 show that our models achieve better accuracy than PoWER-BERT on all datasets. This is because PoWER-BERT discards the computing units, which inevitably causes information loss. Instead of pruning, FCA layer stockpiles the information of uninformative tokens in a coarse fashion (aggregating operations). Moreover, we noticed that coarse units are not always classified as uninformative. In other words, they sometimes participate in the calculation of self-attention as informative tokens. This shows the total informativeness contained in uninformative tokens can not be directly negligible and can be automatically learned by self-attention.

In order to visually demonstrate the advantages of our model, Figure 3 draws curves of trade-off between accuracy and efficiency on three datasets. The results of FCA-BERT and PoWER-BERT are obtained by tuning the hyper-parameter λ. For DistilBERT, the points correspond to the distillation version with 4 and 6 Transformer layers. It can be seen that with the decrease of FLOPs, (1) PoWER-BERT and our model outperform DistilBERT by a large margin; (2) our model exhibits the superiority over all the prior methods consistently; (3) more importantly, the advantage of our model over PoWER-BERT gradually becomes apparent.

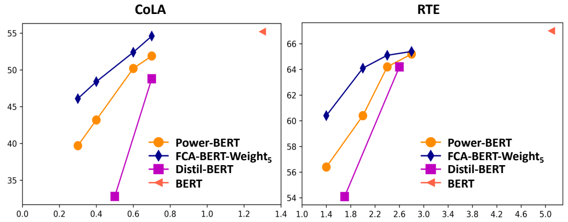

Figure 3: Trade-off between accuracy and FLOPs.

Dataset	CoLA	RTE	SST-2
BERT-large	60.4 (2.6G)	70.0 (10.2G)	94.1 (2.6G)
w/ FCA-Pool$_5$	59.8 (1.1G)	66.3 (4.4G)	93.6 (1.2G)
Speed-up	2.4x	2.3x	2.2x
Distil-BERT$_6$	48.8 (0.7G)	64.2 (2.6G)	89.9 (0.7G)
w/ FCA-Pool$_5$	50.2 (0.4G)	63.9 (1.7G)	90.4 (0.5G)
Speed-up	1.8x	1.6x	1.4x
ELECTRA-base	62.7 (1.3G)	75.5 (5.1G)	95.6 (1.3G)
w/ FCA-Pool$_5$	62.4 (0.6G)	75.2 (2.4G)	95.4 (0.7G)
Speed-up	2.2x	2.1x	1.9x

Table 5: Results on other pre-trained language models.

This is because PoWER-BERT prunes plenty of computation units to save FLOPs, which results in the dilemma of information loss. In contrast, our model preserves all information to a certain extent.

Extensions to Other PLMs. To explore the generalization capabilities of FCA, we extend FCA to other pre-trained language models (PLMs), such as distil-BERT, BERT-large, and ELECTRA-base (Clark et al., 2020). The test results are displayed in Table 5, which proves that FCA is applicable to a variety of models, regardless of model size and variety.

6.6 Pooling All Tokens

In this section, we explore that can we not differentiate between tokens and perform the average pooling on all tokens to reduce the computation cost. To make fair comparisons, we set the length of pooled sequence at each layer equal to the FCA-BERT-Pool$_5$. The results show that pooling all tokens decreases the model accuracy from 75.0 to 73.8. This is because the pooling operation weakens the semantic features learned by the informative tokens, which are often decisive for the final prediction. On the contrary, our model does not conduct pooling on informative tokens and instead delegates the burden of saving computational overhead to uninformative tokens. And this does not cause serious damage to the representative features learned by the model.

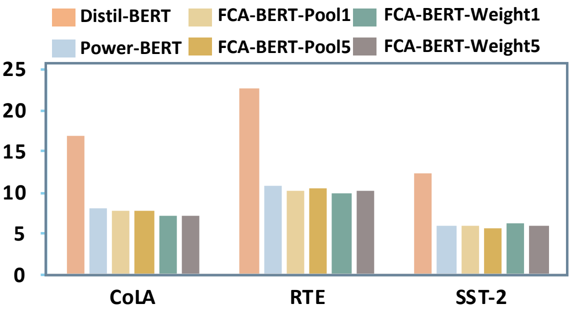

Figure 4: Distance with standard BERT.

6.7 Distance with Standard BERT

In this section, we further investigate the extent to which these compressed models can retain the essential information of the original BERT. Concretely, we adopt the Euclidean distance of the CLS representation between BERT and the compressed models as the evaluation metric, which is proportional to the information loss caused by model compression, formally:

$$\text{Distance(A,B)} = \sum_{k=1}^{M} \sqrt{\sum_{i=1}^{d_h} (\text{A}_{i,k}^{cls} - \text{B}_{i,k}^{cls})}$$

where M is the number of the instances in corresponding dataset. Table 4 shows the distance of baselines and our models with standard BERT. Combining the results in Table 3, it can be found that the distance is consistent with the test accuracy. Large distance leads to low accuracy and vice versa. This provides an inspiration, that is, we can add a distance regulation term to the objective function to forcibly shorten the distance between the compression model and the original BERT, i.e.,

$$\underset{\Theta,R}{\text{Loss}} = \mathcal{L}(\Theta, R) + \lambda \sum_{l=1}^{L} l \cdot \text{sum}(l; R) + \text{Distance}(\cdot)$$

However, the experimental results show that the accuracy has not been significantly improved. This may be because the information learned by the compressed model has reached the limit of approaching the BERT, and the regulation term can not further improve the potential of the compressed model.

7 Discussion

Our proposed FCA is dedicated to the classification tasks that only require single-vector representations, and it can not be directly applied to the tasks of requiring to maintain the full input sequence in the output layer, such as NER and extractive MRC. On these tasks, we need to make some modifications of only performing FCA operation over K and V in self-attention and maintaining the full length of Q. The Eq. 2 is modified to:

$$\text{head}_t = \text{Attention}(QW_t^Q, \text{FCA}(K)W_t^K, \text{FCA}(V)W_t^V) \tag{11}$$

We also attempted to maintain the full length of K and V and shorten Q, but the experimental results are unsatisfactory.

8 Conclusion

In this paper, we propose FCA, a fine- and coarse-granularity hybrid self-attention that reduces the computation cost through progressively shortening the computational sequence length in self-attention. Experiments on GLUE and RACE datasets show that BERT with FCA achieves 2x reduction in FLOPs over original BERT with <1% loss in accuracy. Meanwhile, FCA offers significantly better trade-off between accuracy and FLOPs compared to prior methods.

Abstract

The increasing size of generative Pre-trained Language Models (PLMs) have greatly increased the demand for model compression. Despite various methods to compress BERT or its variants, there are few attempts to compress generative PLMs, and the underlying difficulty remains unclear. In this paper, we compress generative PLMs by quantization. We find that previous quantization methods fail on generative tasks due to the *homogeneous word embeddings* caused by reduced capacity, and *varied distribution of weights*. Correspondingly, we propose a token-level contrastive distillation to learn distinguishable word embeddings, and a module-wise dynamic scaling to make quantizers adaptive to different modules. Empirical results on various tasks show that our proposed method outperforms the state-of-the-art compression methods on generative PLMs by a clear margin. With comparable performance with the full-precision models, we achieve 14.4× and 13.4× compression rates on GPT-2 and BART, respectively.

1 Introduction

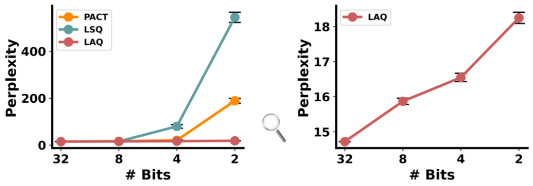

Figure 1: Performance of quantized GPT-2 with varying weight bit-widths and 8-bit activation, using different methods. The right figure takes a closer look at LAQ.

Transformer-based generative pre-trained language models (PLMs) show strong abilities of multi-task and few-shot learning, and achieve remarkable performances on various tasks (Radford and Narasimhan, 2018; Brown et al., 2020; Lewis et al., 2020; Raffel et al., 2020; Chen et al., 2021). However, they are usually expensive in terms of both computation and memory due to a large number of parameters, and the token-by-token generation process. Many methods have been proposed to compress PLMs, but mostly focus on understanding tasks like sentence classification with BERT (Lan et al., 2019; Sun et al., 2020b; Jiao et al., 2020; Shen et al., 2020; Hou et al., 2020). Recent works try to compress GPT-2 using tensor decomposition (Edalati et al., 2021), and knowledge distillation (Song et al., 2020), but the compression ratio achieved is much smaller than that of BERT. Yet the underlying difficulty remains unclear.

In this paper, we firstly explore compressing generative PLMs by quantizing the parameters from full-precision to lower bits. We find that directly applying previous quantization methods designed for BERT or computer vision tasks to generative PLMs lead to poor performance. Figure 1 shows that the performance drops sharply as the weight bit-width decreases. To investigate the difficulty of quantizing generative PLMs, we find that the learned embeddings tend to be homogeneous and hard to distinguish due to the reduced capacity caused by quantization, while the weight distributions also vary significantly across different modules and different Transformer layers. These problems are further magnified due to the nature of sequential left-to-right prediction of generative PLMs, as the quantization error will accumulate across time.

To alleviate the above problems, we propose a token-level contrastive distillation to contrast on tokens and make the word embedding distinguishable. Besides, we propose a module-wise dynamic scaling for the quantizer to better adapt to different modules. Empirical results on language modeling, next utterance prediction and summarization show that compared to the full-precision baseline, our quantized GPT and BART (abbreviated as Quant-GPT and QuantBART) achieve comparable performance for 8/4-bit weight, and have only a slight drop for 2-bit weight, while being over 13× smaller.

QuantGPT also clearly outperforms previous GPT compression methods on language modeling.

To summarize, our main contributions are: 1) We find that generative PLMs are hard to quantize due to *homogeneous word embedding* and *varied weight distribution*. 2) We then propose the token-level contrastive distillation and module-wise dynamic scaling, to make the word embedding more distinguishable and make quantizers adapt to different modules, respectively. 3) Empirical results on various tasks show the efficacy of our method.

2 Difficulty of Qunatizing Generative Pre-trained Language Models

In this section, we show that it is challenging to train a low-bit generative pre-trained model with conventional quantization approaches directly. Before diving into details, we first review the necessary backgrounds of quantization.

2.1 Network Quantization

In this paper, we apply the quantization-aware training (Courbariaux et al., 2015) to generative PLMs. Specifically, denote the vectorized full-precision weight as $\mathbf{w}$, each forward propagation first clips the weight by a positive clipping factor α, and then quantizes the clipped weight to b-bit as

$$\mathbf{w}_q = \alpha \cdot Q(\text{clip}(\mathbf{w}, -\alpha, \alpha)/\alpha), \qquad (1)$$

where Q is the quantization function that maps each entry in $\text{clip}(\mathbf{w}, -\alpha, \alpha)/\alpha$ to its closest quantized value in the set of uniform discrete values $\{-1, -\frac{n-1}{n}, \cdots, -\frac{1}{n}, 0, \frac{1}{n}, \cdots, \frac{n-1}{n}, 1\}$ with $n = 2^{b-1} - 1$. Then we compute the loss $\ell(\mathbf{w}_q)$ with $\mathbf{w}_q$. During back propagation, we use the gradient with regard to the quantized weight $\nabla\ell(\mathbf{w}_q)$ as the Straight-Through-Estimator (Bengio et al., 2013) to update full-precision weights $\mathbf{w}$ due to the non-differentiability of $Q(\cdot)$.

A good clipping factor is expected to take the majority of full-precision weight into account via clipping, *i.e.*, quantizing the range where data are densely distributed to reduce quantization error. To solve this problem, PACT (Choi et al., 2018) learns a parameterized clipping factor and achieves better results than setting a fixed clipping factor. Instead of learning the clipping factor, LSQ (Esser et al., 2020) learns the step size α/n, but requires a careful initialization and gradient update.

In practice, following previous works on BERT quantization (Zhang et al., 2020; Bai et al., 2021), we use layer-wise quantization (*i.e.*, one clipping factor for elements in each weight matrix) for all weight matrices in the Transformer layers and row-wise quantization (*i.e.*, one clipping factor for each word embedding) for the embedding layer. We use asymmetric uniform quantization for activations after self-attention and GeLU function whose elements are mostly positive, and symmetric uniform quantization for other activations. We do not quantize layer-normalization layers, skip connections, biases due to small computational overhead.

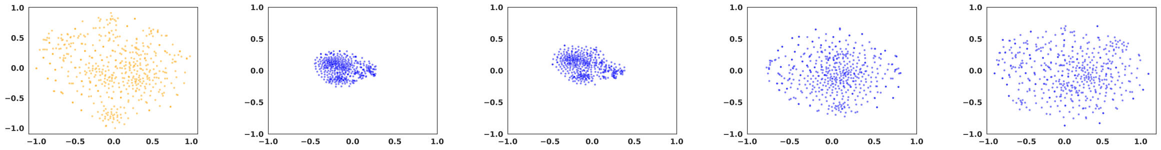
2.2 Difficulty Analysis

We compare the following representative quantization methods including (i) LAQ (Zhang et al., 2020) for BERT; (ii) PACT (Choi et al., 2018) and LSQ (Esser et al., 2020)) for computer vision tasks, to generative pre-trained model, GPT-2. Figure 1 shows the performance under different weight bit-widths, and the performance drops sharply as the bit-width decreases, especially for PACT and LSQ. In the following, we study the potential reasons behind the difficulty of quantizing generative PLMs, by empirically investigating the properties of the word embedding and model parameters.

Homogeneous Word Embedding. We first study the difficulty from the learned word embeddings of different models. In Figure 2, we visually compare the distributions of the word embeddings of the full-precision and quantized models under the same scale. As can be seen, the word embeddings of the full-precision model are scattered distinguishable, while those in previous quantization methods PACT, LSQ and LAQ learn homogeneous word embeddings which are clustered and less distinguishable, especially for PACT and LSQ. We speculate this is caused by the sequential computation nature of GPT. Specifically, unlike BERT which computes the representation of all tokens in parallel, GPT computes each token in left-to-right order, and the quantization error incurred in the previous tokens will pass on to future tokens, making the learning signal noisier over time, and finally less informative word embeddings.

A direct consequence of the homogeneous word embedding can be reflected in Figure 3. By comparing Figure 2 and Figure 3, we can find that the higher degree of homogeneity in the word embedding of a quantized model, the fewer dependencies among different tokens are kept.

As will be discussed in Section 3.1, we propose



(a) Full-precision. (b) PACT. (c) LSQ. (d) LAQ. (e) Ours.

Figure 2: T-SNE visualization of the most frequent 500 word embeddings, of the full-precision and different 2-bit quantized models trained on PTB dataset. Embeddings of different methods show different degrees of homogeneity.

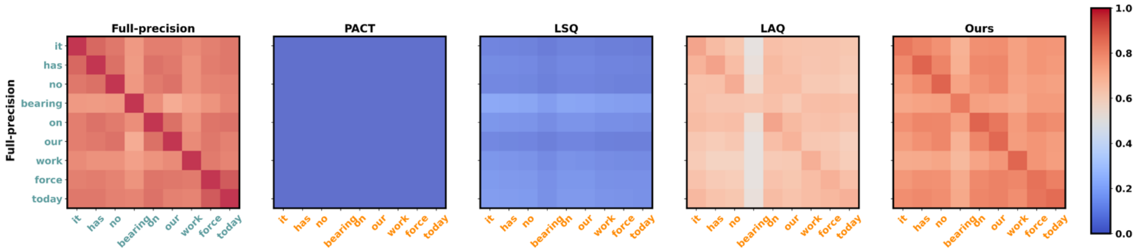


Figure 3: Matrices representing the cosine similarities between representations of all pairs of tokens in a sentence, between the full-precision model and 2-bit quantized models trained on PTB dataset. Token representations at the last decoder layer of GPT-2 are used. More visualizations are available in Appendix C.3.

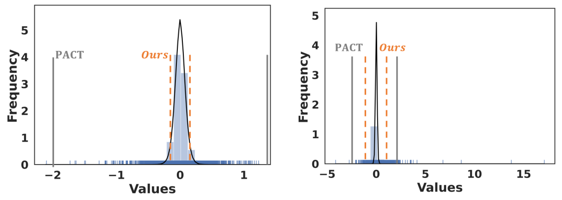
a token-level contrastive learning to alleviate this problem. Compared with PACT, LSQ and LAQ, our method not only aligns the token representations between the quantized and full-precision networks (*i.e.*, diagonal boxes), but also captures the dependencies among different tokens (non-diagonal boxes). More visualizations are available in Appendix C.3. The non-distinguishable word embeddings and poor ability to capture contextualized dependencies also make methods like PACT and LSQ more likely to generate incorrect tokens, *e.g.* illogical and repeated text (Section 4.4).



(a) $\mathbf{w}_o$ at Layer 4. (b) $\mathbf{w}_g$ at Layer 4.

Figure 4: Distributions of output projection matrix $\mathbf{w}_o$ in the multi-head attention module and the second linear layer $\mathbf{w}_g$ in the feed-forward network of the 4-th layer from the 12-layer full-precision GPT-2. Other modules in other layers exhibit similar patterns. Vertical lines indicate the clipping factors learned by PACT and our method. Black curves show the estimated distribution by kernel density estimation.

Varied Distribution of Weights. Besides the learned word embeddings, we also investigate the distribution of the weights in the full-precision model. Figure 4 shows that the weight distributions of a 12-layer full-precision GPT-2 are highly skewed with outliers. This causes difficulty in estimating the clipping factor α of the quantizer by heuristic methods, or even by PACT which learns the α through gradient descent. Specifically, in PACT, the approximated gradient of α only relies on the weights whose absolute values are larger than α. This solution ignores the effect of weights within $[-\alpha, \alpha]$ and depends heavily on the initialization of α. Figure 4 shows that an improper initialization together with the inaccurate gradient estimation of the clipping factor often make the learned α of PACT too large, and can not provide fine resolution to the majority of weights within the clipping range. The quantization error accumulated over time makes this problem more severe. In this work, we re-parameterize the clipping factor to make the quantizer adaptive to each module in the Transformer layers, and consider both weights outside and inside the clipping range when estimating the gradient of the clipping factor.

As will be discussed in Section 3.2, we propose a module-wise dynamic scaling to reduce the clipping factor's sensitivity to initialization, and an improved gradient estimation that also considers the weights within $[-\alpha, \alpha]$. Figure 4 shows that the clipping factor learned by our method gives finer resolutions to the majority of the weights.

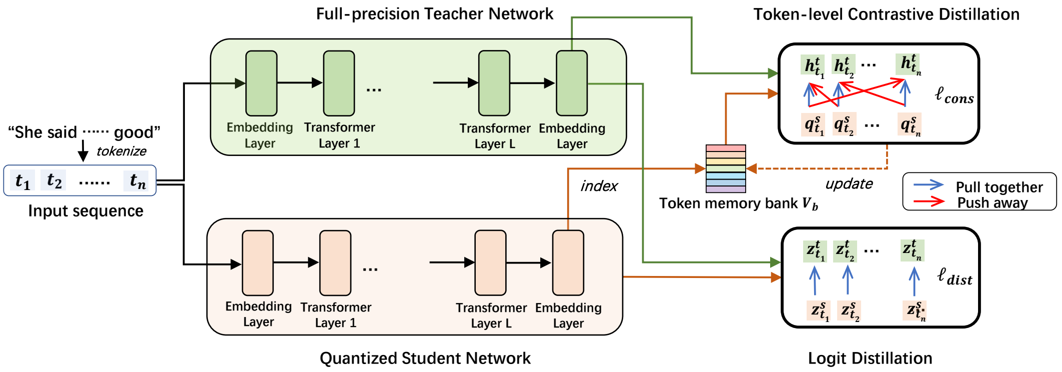


Figure 5: The training workflow of the proposed method. For each token in the quantized network, we compute both (i) the token-level contrastive distillation loss where the positive tokens and negative tokens are selected from the full-precision teacher network; and (ii) the distillation loss on the logits. The embedding layer and all weights in the Transformer layers are quantized with the proposed module-dependent dynamic scaling.

3 Proposed Method

Based on the observations in Section 2.2, we propose a quantization method which utilizes token-level contrastive distillation to make the word embedding distinguishable (Section 3.1) and a module-wise dynamic scaling adjustment to learn better clipping factors (Section 3.2).

3.1 Token-level Contrastive Distillation

The proposed token-level contrastive distillation contrast among tokens instead of sequences sequence, to learn distinguishable representations for each token. Inspired by Baevski et al. (2020), which uses in-utterance representation at different positions of the same utterance as negatives for speech feature learning, for each token of the quantized network, we use the representation of the same token from the full-precision teacher network as its positive, while representations of other tokens in the same sequence as negatives (Figure 5). Inspired by He et al. (2020) which uses a momentum encoder for more consistent representation, we build a memory bank to store momentum token representations from the quantized network. When computing the contrastive distillation loss, we load the representations of negative samples from the memory bank with cheap indexing operations.

Specifically, we use superscripts s and t to denote the quantized student network and full-precision teacher network, respectively. Denote the length-n input sequence of tokens as $(t_1, t_2, \cdots, t_n)$. For the i-th token t_i, suppose its hidden states of the last Transformer layer from the quantized and full-precision network are linearly projected to $(\mathbf{h}^s_i, \mathbf{h}^t_i) \in \mathbb{R}^d$, and $\mathbf{q}^s_i$ is the smoothed representation of $\mathbf{h}^s_i$ in the memory bank. Denote $\mathcal{S}_i$ as the indices of the sampled negatives for token i, the token-level contrastive distillation loss for the length-n sequence can be formulated as

$$\mathcal{L}_{cont} = -\sum_{i=1}^{n} \log \frac{\exp(s(\mathbf{q}^s_{t_i}, \mathbf{h}^t_{t_i})/\tau)}{\sum_{j\in\mathcal{S}_i} \exp(s(\mathbf{q}^s_{t_i}, \mathbf{h}^t_{t_j})/\tau)}, \tag{2}$$

where $s(\mathbf{x}, \mathbf{y}) = \frac{\mathbf{x}^\top \mathbf{y}}{\|\mathbf{x}\|\|\mathbf{y}\|}$ computes the cosine similarity, and τ is a fixed temperature parameter.

Then we update the representation of token t_i in the memory bank with the moving-average of token representations from the quantized network:

$$\mathbf{q}^s_{t_i} \leftarrow m\mathbf{q}^s_{t_i} + (1-m)\mathbf{h}^s_{t_i}, \tag{3}$$

where $m \in [0, 1)$ it the momentum coefficient that controls the smoothness of the token represenation.

Besides, we use an additional distillation loss $\mathcal{L}_{dist}$ over the logits. For the i-th token t_i, suppose the logits of the quantized and full-precision network are $\mathbf{z}^s_{t_i}, \mathbf{z}^t_{t_i} \in \mathbb{R}^{|V|}$, where $|V|$ is the vocabulary size. $\mathcal{L}_{dist}$ is computed with the soft cross-entropy loss:

$$\mathcal{L}_{dist} = -\sum_{i=1}^{n} \mathbf{z}^t_{t_i} \log(\mathbf{z}^s_{t_i}). \tag{4}$$

Thus the total training loss is

$$\mathcal{L} = \lambda\mathcal{L}_{cont} + \mathcal{L}_{dist}, \tag{5}$$

where λ is a trade-off factor set as 0.1 by default.

Intuitively, for each token in the quantized network, $\mathcal{L}_{dist}$ only encourages it to mimic its corresponding token of the teacher network, while $\mathcal{L}_{cont}$ not only pulls it close to its positive, but also pushes it away from its negatives. In this way, $\mathcal{L}_{cont}$ helps the student to capture more information from the teacher's representation, as is also theoretically discussed in Tian et al. (2019).

The proposed token-level contrastive distillation is crucial to the performance, and outperforms the sequence-level counterpart (as will be shown empirically in Section 5.1.1). We conjecture this is because (i) token-level contrast alleviates the problem of homogeneous word embedding (Figure 2) in the low-bit quantization; and (ii) similar to speech, the order of natural language is also sequential instead of spatial like images; and (iii) the self-attention mechanism allows other tokens to learn representations contextualized on the studied token, and these in-sequence negatives are harder than those from in-batch sequences, allowing more efficient representation learning.

3.2 Module-dependent Dynamic Scaling

Based on the observation of varied weight distribution in Section 2.2, we propose a simple-yet-effective dynamic scaling according to the statistics of each module weight. Specifically, instead of directly learning the original clipping factor α as PACT, we turn to learn a new scaling factor γ, which is multiplied with the average weight magnitude $\frac{\|\mathbf{w}\|_1}{n}$ to get clipping factor α:

$$\alpha = \gamma \cdot \frac{\|\mathbf{w}\|_1}{n}, \tag{6}$$

where $\|\cdot\|_1$ denotes ℓ_1 norm. The scaling γ is initialized as 1, which not only eases the initialization but also ensures the initial clipping factor α does not deviate far from the full-precision weights, regardless of the diversity of weight distribution.

Besides, we also design a more accurate gradient estimation of the scaling factor than PACT (Choi et al., 2018). Previous PACT only back propagates through weights whose absolute values are larger the clipping factor (*i.e.* $|w| \geq \alpha$). Instead, we also consider the weights inside the clipping range (*i.e.* $|w| < \alpha$) as:

$$\frac{\partial \ell}{\partial \gamma} = \begin{cases} \frac{\partial \ell}{\partial \mathbf{w}_q} Q(\mathbf{u}) \frac{\|\mathbf{w}\|_1}{n}, \mathbf{w} < -\alpha \\ \frac{\partial \ell}{\partial \mathbf{w}_q} [-\frac{\mathbf{w}}{\alpha} + Q(\mathbf{u})] \frac{\|\mathbf{w}\|_1}{n}, -\alpha \leq \mathbf{w} \leq \alpha, \\ \frac{\partial \ell}{\partial \mathbf{w}_q} Q(\mathbf{u}) \frac{\|\mathbf{w}\|_1}{n}, \mathbf{w} > \alpha \end{cases} \tag{7}$$

where ℓ is the total training loss and $\mathbf{u} = \text{clip}(\mathbf{w}, -\alpha, \alpha)/\alpha$ in Eq. (1). The detailed derivation can be found in Appendix A.

Intuitively, the update of clipping factor should be influenced by both weights outside and inside $[-\alpha, \alpha]$, since α controls the quantization error of both, *i.e.*, a large clipping factor results in small quantization error for weights outside $[-\alpha, \alpha]$, while large error for weights inside. Our new estimation of the gradient of γ in Eq. (7) considers weights both outside and inside $[-\alpha, \alpha]$. Additionally, the proposed scaling is less sensitive to the varied distribution of weight than PACT, since the gradient of scaling $\frac{\partial \ell}{\partial \gamma}$ is proportional to the average weight magnitude $\frac{\|\mathbf{w}\|_1}{n}$.

4 Experiments

4.1 Setup

Tasks and Models. In this section, we evaluate the efficacy of our proposed quantization method on three kinds of generative tasks on two kinds of generative pre-training models. Specifically, we perform the proposed quantization approach on language modeling and next utterance prediction tasks on GPT-2 (Radford and Narasimhan, 2018), and abstractive summarization using BART (Lewis et al., 2020), and call the resultant models Quant-GPT and QuantBART. The token-level contrastive distillation is performed on the hidden states of the last layer of GPT-2 or the BART decoder. More details about the datasets and model architectures can be found in Appendix B.1 and B.2.

Implementation Details. For each downstream task with our proposed method, we first fine-tune a full-precision network using the pre-trained checkpoint from huggingface[1] for both GPT-2 and BART. Then we use this fine-tuned network as the full-precision teacher network and to initialize the quantized student network. We train each task with 8 V100 GPUs based on the Pytorch framework. The detailed hyper-parameters for each task are available in Appendix B.3.

Compared Methods. Since there are very few attempts to compress generative PLMs, we self-implement three baseline quantization methods PACT (Choi et al., 2018), LSQ (Esser et al., 2020) and LAQ (Hou and Kwok, 2018) for comparison. Details about these methods are in Appendix B.4.

4.2 Language Modeling

The task of language modeling is to predict the probability distribution over a sequence of words.

Table 1: Results of language modeling on the test set of WikiText2, PTB and WikiText103 datasets, and next utterance prediction on the validation set of Persona-Chat dataset, with quantized GPT-2. "#Bits (W-E-A)" represents the bit-width for weights of Transformer layers, word embedding, and activations.

For language modeling, we experiment on WikiText2 (Merity et al., 2016), Penn Treebank (PTB) (Mikolov and Zweig, 2012) and WikiText103 (Merity et al., 2016). We use perplexity (PPL) to evaluate the performance for language modeling.

Comparison with the Full-precision Model. From Table 1, the performance of the proposed method with 8-bit weight is comparable to the full-precision counterpart on PTB and WikiText103, while drops slightly on WikiText2. A slightly more severe performance drop is observed as the bit-width decreases from 8 to 4, with a drop of around 1 PPL point on WikiText2 and WikiText103, and less than 0.1 PPL point on PTB. When the bit-width of weight further goes down to 2, our method has an average of 2 PPL points drop, but achieves 14.4× model size reduction.

Comparison with Other Quantization Methods. From Table 1, our method outperforms PACT, LSQ and LAQ for all bit-widths and tasks. As the bit-width decreases from 8 to 4, the PPL of LSQ greatly increases, with the average PPL of LSQ increasing by over 5 times. As the bit-width further decreases to 2, both LSQ and PACT fail on all datasets, despite their good performance on understanding tasks on BERT (Bai et al., 2021). We conjecture it is because though both PACT and LSQ have learnable parameters, the accumulated quantization error of generative PLMs makes the updates of these parameters by gradient descent less stable. On the other hand, the proposed module-wise dynamic scaling alleviates the problem.

Comparison with Other Compression Methods. In Table 2, we compare our quantization method against recent GPT-2 compression methods, including tensor decomposition method KnGPT2 (Edalati et al., 2021), as well as distillation methods DistilGPT2 and LightPAFF (Song et al., 2020). From the comparison, our method outperforms the others in terms of model size and performance, even when weights are compressed to only 2 bits.

Method	Size (MB)(↓)	WikiText2 PPL(↓)	PTB PPL(↓)	WikiText103 PPL(↓)
full-prec.	474.9 (1.0x)	14.4	14.6	13.9
KnGPT2	332.0 (1.4x)	-	-	20.5
DistilGPT2	329.6 (1.4x)	-	-	21.1
LightPAFF	268.0 (1.8x)	18.8	22.8	16.4
Ours(8-8-8)	121.4 (3.9x)	**15.3**	**14.9**	**14.6**
Ours(4-4-8)	62.4 (7.6x)	15.6	15.0	15.3
Ours(2-2-8)	33.0 (**14.4x**)	17.3	16.1	17.0

Table 2: Comparison between our proposed quatization method and other compression methods on GPT-2.

4.3 Next Utterance Prediction

The task of next utterance prediction predicts the next utterance given the dialogue context. It tests the language understanding ability of generative models. For this task, we use a large-scale dialogue dataset, Persona-Chat (Zhang et al., 2018).

From Table 1, all quantization methods incur a clear performance drop compared to the full-precision baseline, even in the 8-bit setting. As the quantization becomes more aggressive, *i.e.*, the bit-width gets smaller, the performance of PACT and LAQ decrease more significantly than ours. In particular, LSQ diverges for 2-bit weight and its accuracy is only 5%, which is no better than a random guess as there are 20 classes.

4.4 Abstractive Summarization

Abstractive summarization aims at generating a terse summary that captures the main ideas of the source article. We experiment on XSum (Narayan et al., 2018), whose ground-truth summarizations are highly abstractive and are challenging for many extractive strategies. ROUGE 1, 2, L are used to evaluate the performance of this task.

Method	#Bits (W-E-A)	Size (MB)(↓)	XSum

Table 3: Results of abstractive summarization on the test set of the XSum dataset, with quantized BART.

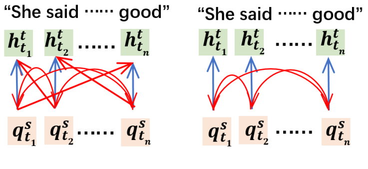
Table 3 shows the results of the abstractive summarization. As can be seen, our method constantly outperforms other methods again with a clear margin. Example generated summarizations of different methods in Appendix C.2 show that the summaries generated by QuantBART are logical and terse, while those from PACT have repeated texts.

5 Discussion

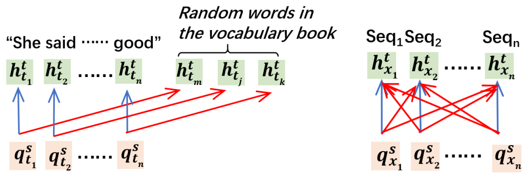
5.1 Ablation on Contrastive Learning

5.1.1 Choices of Negative Sampling

As shown in Figure 6, we ablate on how to choose negative samples in contrastive learning. Specifically, we compare our method with variants of token-level contrastive learning, which select negative samples of each token from (a) representations of other tokens in both the full-precision and quantized networks (*fp+quan.*); (b) representations of other tokens in the quantized network (*quan. only*); and (c) the whole vocabulary randomly for each training iteration (*global*). Besides, we compare with (d) sequence-level contrastive learning by pulling together representations of the same sequence, and pushing away representations of different ones from the teacher network (*in-batch*). Representation of a sequence is defined as the mean of representations of all tokens in the sequence.



(a) fp+quan. (b) quan. only.



(c) global. (d) in-batch.

Figure 6: Four variants of negative sampling.

-	Sampling method	WikiText2	PTB	WikiText103
-	*QuantGPT*	**17.30**	**16.12**	**16.98**
Tok-level	fp+quan.	17.38	16.51	17.13
	quan. only	17.35	16.54	17.15
	global	17.71	16.63	17.55
Seq-level	in-batch (bz=32)	17.62	19.23	18.97
	in-batch (bz=16)	17.48	17.11	18.16

Table 4: Ablation study on negative sampling for 2-bit weight, "bz" denotes for the batch size. "Tok" and "Seq" are abbreviation for token and sequence, respectively.

From Table 4, *"fp+quan."* and *"quan. only"* performs worse than QuantGPT, which uses full-precision representations of other tokens as negative samples. This indicates that noisy representations of tokens from the not-fully-trained quantized network may not be sufficient. *"global"* performs even worse, which we conjecture is because, for one token, negative tokens chosen from the same sequence are contextually related to it and more informative than random tokens. *"in-batch"* performs worse than all token-level variants, which may be because generative tasks make predictions in a token-wise manner and rely heavily in finer-grained token-wise representations. Interestingly, contrary to in-batch negative sampling in computer vision (Chen et al., 2020), we find that reducing the number of negative samples by reducing the batch size from 32 to 16 slightly improves performance.

5.1.2 Number of Negative Samples

In Figure 7, we plot the PPL of 2-bit *QuantGPT* on the PTB dataset, with varying number of negative samples. We plot the mean results with standard

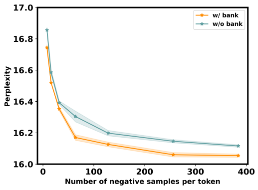


Figure 7: Effect of the number of negative samples.

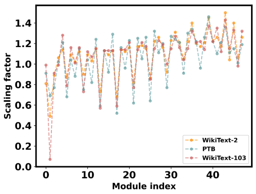

Figure 8: Scaling factors in the 2-bit QuantGPT.

Training loss	Training time (sec/iter) (↓)	Memory (MB) (↓)	PPL (↓)
$\mathcal{L}_{dist}$	0.61	14700	16.93
$\mathcal{L}_{dist} + \lambda\mathcal{L}_{cont}$	0.67	14839	16.12

Table 5: Efficiency study of the token-level contrastive learning. The results are reported on the PTB dataset on 2-bit GPT-2. "sec/iter" means the needed time in seconds per iteration. Memory denotes the GPU consumption per device.

deviations from 5 independent runs. As can be seen, the performance improves and converges gradually as the number of negative samples increases.

Figure 7 also shows that using the moving-average representations ($\mathbf{q}^s_{t_i}$ in Eq. (3)) of negative samples in the memory bank has better performance than using the immediate representations ($\mathbf{h}^s_{t_i}$ in Eq. (3)), because of a smoother and more consistent representation of tokens.

5.1.3 Training Cost of the Contrastive Loss

In Table 5, we report the training speed and memory consumption of training the GPT-2 model on the PTB dataset with and without the proposed token-level contrastive loss. Batch size is set as 4 per device, which can be increased by using GPUs with larger memory or reducing the sequence length of samples. As can be seen, with the proposed token-level contrastive loss, the performance clearly improves with only slightly slower training speed and more memory consumption.

5.1.4 Representations for the Contrastive Loss

In Table 6, we compare the different representations to perform the contrastive loss. The "decoder-last"(resp. "decoder-first") denotes performing the proposed token-level contrastive loss on the hidden states from the last decoder layer (resp. first decoder layer) followed by a linear transformation.

From Table 6, "decoder-last" performs better than "decoder-first". A possible reason is that the hidden states of the last decoder blocks contain rich information from all previous layers (Xiong et al., 2020). Since the experiments of abstractive summarization are conducted on BART, which has both encoder and decoder layers, we also study the contrastive loss on the "encoder-last" and "encoder-first". In the ablation on the encoder, the contrastive loss $\mathcal{L}_{cont}$ are computed on the source input (articles), instead of target input (summaries). From Table 6, "decoder-last" also has better ROUGE 1, 2, L values than other counterparts.

5.2 Ablation on Dynamic Scaling

Figure 8 shows the learned scaling γ of different modules in the 2-bit GPT-2 model. As can be seen, the scalings of different modules vary a lot, verifying the need for module-wise dynamic scaling.

In addition, we investigate the effect of the proposed dynamic scaling and the new estimation of the gradient in Eq. (7) with two variants: 1) $\mathcal{L}_{dist}$ *only* which removes the token-level contrastive learning; and 2) *Ours with PACT* which removes the contrastive learning, and estimates the gradient with PACT which only considers the weights whose absolute values are larger than the clipping factor α. As shown in Table 7, the performance gets worse without contrastive learning to learn the distinguishable representations of tokens. The performance drops significantly when using PACT to estimate the gradient of the proposed scaling, especially for the WikiText103 dataset, verifying the efficacy of the new gradient estimation.

6 Related Work

Compression of Generative Pre-trained Language Models. Some early explorations compress the generative pre-trained language models. KnGPT2 (Edalati et al., 2021) applies the Kronecker decomposition to compress the GPT. DistilGPT2 [2] distills a 12-layer GPT-2 to a 6-layer one, which is twice as fast during inference. LightPAFF (Song et al., 2020) proposes a distillation approach that the training loss is a combination of a maximum likelihood loss of the student model, and the KL divergence between the output of teacher and student models. SpAtten (Wang et al., 2021) proposes a sparse model with algorithm and architecture co-design, which removes uninformative tokens and attention heads. Compared with these methods, we not only study the difficulties of compression from the properties of generative tasks,

but also study both decoder and encoder-decoder generative models.

Quantization of Pre-trained Language Models. Quantization compresses a model by representing the 32-bit floating-point parameter with a low-bit representation, and has been widely used in various domains as it does not require designing a new model architecture. There have been many attempts to quantize task-specific BERT models (Zafrir et al., 2019; Shen et al., 2020; Zadeh et al., 2020) with only negligible performance drop on natural language understanding tasks. Recent works (Zhang et al., 2020; Bai et al., 2021) even push the weight bit-width down to as low as 1-bit. Despite the success of these approaches for BERT models, attempts to quantize generative PLMs are scarce, and the underlying difficulty remains unclear.

Contrastive Learning. Contrastive learning aims at pushing the representations of similar samples together while pulling those of dissimilar ones apart. and is widely used for large-scale self-supervised learning in various domains (Chen et al., 2020; Sun et al., 2020a; Baevski et al., 2020; Huang et al., 2022), and multi-modal learning (Radford et al., 2021; Jia et al., 2021). SimCLR (Chen et al., 2020) directly uses other in-batch samples as negatives, and sufficient large batch size is required to work well. MoCo (He et al., 2020) maintains a large number of negative samples in a queue and uses a moving average key encoder to improve consistency. Contrastive learning without negative samples is also proposed in BYOL (Grill et al., 2020) and SimSiam (Chen and He, 2021). Contrastive representation distillation (Tian et al., 2019) distills the knowledge from the teacher network to the student network by maximizing the mutual information between them.

The closest work with our token-level contrastive distillation is Wav2vec 2.0 (Baevski et al., 2020), which use in-utterance representations at different positions as negatives in speech learning. Besides the difference in the modality and tasks, our method also differs from theirs in (1) *Model:* We quantize the model parameters and activations while they do not; (2) *Representation:* For each sample, we use the output of the full-precision and the quantized networks as its two views, while they use the quantized and the contextualized representation. (3) *Loss:* We calculate loss over all tokens in an auto-regressive manner, while they only calculate over the masked tokens non-autoregressively.

7 Conclusion

This paper studies low-bit quantization of generative PLMs. We find that the difficulty of quantizing generative PLMs lies in homogeneous word embedding and varied distribution of weights. To alleviate the two problems, we propose token-level contrastive learning to learn more distinguishable token emebeddings, as well as a module-dependent dynamic scaling for more accurate quantization. Extensive experiments on language modeling, next utterance prediction and abstractive summarization demonstrate the efficacy of our proposed method. We hope our work sheds a light on the compression of generative PLMs in future exploration.

A Derivation of Gradient of Dynamic Scaling

In this section, we provide the derivation of the gradient of the proposed dynamic scaling γ. The quantization in the forward process can be written as

$$\begin{aligned} \alpha &= \frac{\|\mathbf{w}\|_1}{n}\gamma, \\ \mathbf{u} &= \text{clip}(\mathbf{w}, -\alpha, +\alpha)/\alpha, \\ \mathbf{w}_q &= Q(\mathbf{u})\alpha, \end{aligned}$$

where $Q(\cdot)$ is an uniform quantization function as described in Section 2.2. Based on the chain rule, the gradient of scaling γ w.r.t. the training loss function ℓ is:

$$\begin{aligned} \frac{\partial \ell}{\partial \gamma} &= \frac{\partial \ell}{\partial \mathbf{w}_q}\left[\frac{\partial \mathbf{w}_q}{\partial Q(\mathbf{u})}\frac{\partial Q(\mathbf{u})}{\partial \alpha}\frac{\partial \alpha}{\partial \gamma} + \frac{\partial \mathbf{w}_q}{\partial \alpha}\frac{\partial \alpha}{\partial \gamma}\right] \\ &= \frac{\partial \ell}{\partial \mathbf{w}_q}\left[\alpha\frac{\partial Q(\mathbf{u})}{\partial \alpha}\frac{\|\mathbf{w}\|_1}{n} + Q(\mathbf{u})\frac{\|\mathbf{w}\|_1}{n}\right] \quad (8) \\ &= \frac{\partial \ell}{\partial \mathbf{w}_q}\left[\alpha\frac{\partial Q(\mathbf{u})}{\partial \alpha} + Q(\mathbf{u})\right]\frac{\|\mathbf{w}\|_1}{n}. \end{aligned}$$

We use straight through estimator (STE) to estimate the gradient of uniform quantizer $Q(\cdot)$, *i.e.*, $\forall i, \frac{\partial Q(\mathbf{u}_i)}{\partial \mathbf{u}_i} = 1$. Thus the gradient $\frac{\partial Q(\mathbf{u})}{\partial \alpha}$ can be written as:

$$\frac{\partial Q(\mathbf{u})}{\partial \alpha} = \frac{\partial Q(\mathbf{u})}{\partial \mathbf{u}}\frac{\partial \mathbf{u}}{\partial \alpha} = \begin{cases} 0, \mathbf{w} \leq -\alpha \\ -\frac{\mathbf{w}}{\alpha^2}, -\alpha < \mathbf{w} < \alpha \\ 0, \mathbf{w} \geq \alpha \end{cases}. \quad (9)$$

By combining Eq. (8) and Eq. (9), we get

$$\frac{\partial \ell}{\partial \gamma} = \begin{cases} \frac{\partial \ell}{\partial \mathbf{w}_q} Q(\mathbf{u})\frac{\|\mathbf{w}\|_1}{n}, \mathbf{w} \leq -\alpha \\ \frac{\partial \ell}{\partial \mathbf{w}_q}\left[-\frac{\mathbf{w}}{\alpha} + Q(\mathbf{u})\right]\frac{\|\mathbf{w}\|_1}{n}, -\alpha < \mathbf{w} < \alpha \\ \frac{\partial \ell}{\partial \mathbf{w}_q} Q(\mathbf{u})\frac{\|\mathbf{w}\|_1}{n}, \mathbf{w} \geq \alpha \end{cases}$$

where $\frac{\partial \ell}{\partial \gamma}$ considers both the weight inside and outside the clipping value, and proportional to the weight magnitude $\frac{\|\mathbf{w}\|_1}{n}$.

B More Experimental Settings

B.1 Datasets

The train/val/test splits for different datasets are shown on Table 8.

B.2 Model Architectures

GPT-2. The vocabulary size of GPT-2 is 50527. We use GPT-2-small with 12 decoder layers and hidden state dimension as 768, for experiments in Sections 2.2, 4 and 5. GeLU (Hendrycks and Gimpel, 2016) is used as the activation function. In the experiments of Appendix C.1, we adopt GPT-2-base with 24 decoder layers and hidden state dimension as 1024, to evaluate the quantization ability on larger models.

Dataset	Training	Validation	Test
WikiText2	36,717	3,760	4,358
PTB	42,068	3,370	3,761
WikiText103	1,801,350	3,760	4,358
Persona-Chat	8,939	1,000	968
XSum	204,045	11,332	11,334

Table 8: Data splits of different datasets.

BART. The vocabulary size of BART is 50265. We use BART-base with 6 encoder layers, 6 decoder layers and hidden state dimension as 768 for experiments in Section 4. In the experiments of Appendix C.1, we adopt BART-large with 12 encoder layers, 12 decoder layers and hidden state dimension 1024, to evaluate the quantization ability on larger models.

B.3 Hyperparameters

Language Modeling. The sequence length is 512. The learning rate is initialized to 0.0005 (resp. 0.001) for the GPT-2 backbone parameters (resp. clipping factor γ) and then linearly decays to 0. The number of negative samples in each sequence is 64 for the PTB dataset, and 32 for the WikiText2 and WikiText103. The temperature τ and momentum coefficient m is 0.1 and 0.5 respectively. We train with the AdamW optimizer (Loshchilov and Hutter, 2017) with batch size 32. The training epochs for WikiText2, PTB and WikiText103 are set as 80, 120, 8, respectively.

Next Utterance Prediction. The sequence length is 512. The learning rate is initialized to 0.0005 (resp. 0.001) for the GPT-2 backbone parameters (resp. clipping factor γ) and then linearly decays to 0. The number of negative samples in each sequence is 32. The temperature τ and momentum coefficient m is 0.1 and 0.5, respectively. We train with the AdamW optimizer with batch size 16, for a total of 2 epochs.

Abstractive Summarization. We set the length of the source sequence (articles) as 512, and pad the target sequence (summaries) to maximum length. We use beam search to generate summaries, with beam size 6 and length penalty 1. The learning rate

is initialized to 0.0002 (resp. 0.001) for the BART backbone parameters (resp. clipping factor γ) and then linearly decays to 0. The number of negative samples is 32. The temperature τ and momentum coefficient m is 0.1 and 0.5, respectively. We train with the AdamW optimizer with batch size 128, for a total of 8 epochs.

B.4 Description of the Compared Methods

PACT. PACT (Choi et al., 2018) learns a learnable clipping factor for each module by gradient descent. To make the quantization more accurate, we adopt a flexible variant of the original PACT, with different positive and negative clipping factors $[-\alpha_{neg}, \alpha_{pos}]$, where both α_{neg} and α_{pos} are initialized as 2.5.

LSQ. LSQ (Esser et al., 2020) learns the step-size of quantizer for each module by gradient descent. We use the recommended initialization strategy of the step size as (Esser et al., 2020).

LAQ. LAQ (Hou et al., 2017; Hou and Kwok, 2018) is a loss-aware quantization method that views quantization as an optimization problem and solve it via proximal Newton algorithm. We use the approximate solver in (Hou and Kwok, 2018) to compute the quantized weights before each forward propagation.

For the self-implemented methods PACT, LSQ and LAQ, we adopt the commonly-used distillation loss adopted in (Hinton et al., 2015; Jiao et al., 2020). Note that these methods are only used for weights and embeddings, while the activations of these methods follow the same setting as our proposed method in Section 2.1. We also tried using the original language modeling loss w.r.t. the ground-truth labels, and distillation loss over the the attention as (Jiao et al., 2020). However, these two losses worsens the performance on all three methods.

B.5 Frameworks of Double-head GPT-2 and BART

Since we adopt double-head GPT-2 and BART for next utterance prediction and abstractive summarization, the frameworks for these tasks are slightly modified from that on language modeling due to the difference of tasks. In Figure 9 and 10, we illustrate the framework for double-head GPT-2 and BART, respectively. In the double-head GPT-2, we also quantize the final linear layer in the output head.

C More Experimental Results

C.1 Performance of Larger Models

In Table 9, we experiment with GPT-base and BART-large, which both have 24 Transformer layers. For all bit-widths, the training of our method converges successfully without gradient exploding/vanishing problems. QuantGPT outperforms PACT by a large margin in all tasks, especially for 2-bit weight. Our quantization method on larger models also has better performance than that on 12-layer GPT-2 and 12-layer BART in Section 4.

C.2 Examples of Summarizations

In Table 10, we provide the example summarizations on the XSum dataset. By comparing the articles, references and generations, the generated summaries by our quantized model are more logical and terse than PACT, LSQ and LAQ, which face problems of homogeneous word embeddings to some extent as discussed in Section 2.2.

C.3 More Visualizations for the Token Representations

In Figure 11, we provide the visualizations of token representations on more samples. The observations

Article: On Tuesday, a BBC Spotlight programme revealed that eight children had gone missing in Northern Ireland. Two of the girls were Somali teenagers who disappeared in 2005 and 2012. The Health and Social Care Board has said new guidelines are in place and add that no children have gone missing since 2014. Separated children are children outside their country of origin and separated from their parents or legal guardian. The term can also include unaccompanied asylum-seeking children and trafficked children. When they arrive in Northern Ireland they are taken into the care of the local health trust. Eight children have gone missing since 2005 and they remain missing. The SDLP's health spokesman Mark H Durkan said he would be raising the issue at the Northern Ireland Assembly's health committee and his party colleague Alex Attwood would be raising it at the justice committee. "The number of children who cannot be accounted for is something that needs urgent inquiry and investigation," he said. "There is a lot of very good work being done to look after the welfare of unaccompanied young people, but clearly we now have some very big questions that need to be answered." Ulster Unionist MLA Jo-Anne Dobson said it was "frankly appalling" to hear that eight children had gone missing. "I have written to Health Minister Michelle O'Neill on this issue to seek further clarification and to demand details of how the department, health trusts and the Health and Social Care Board have sought to address each of the cases involved in the investigation," she added. The Green Party leader Steven Agnew also said it was extremely worrying that children can disappear without a trace. Paula Bradshaw from the Alliance Party added that the health trusts and police "need to work closer over the handling of these cases". In a statement, the Police Ombudsman for Northern Ireland said: "Our director of investigations will be reviewing the contents of the programme to ascertain if there are any issues of police conduct which may need further investigation." The Police Service of Northern Ireland has said that in the two cases identified in the programme, investigations were robust and all information available at the time was followed. The Health and Social Care Board has said that new guidelines are in place and stress that no children have gone missing since 2014. BBC Spotlight's investigation is now available on BBC iPlayer.

Reference: An urgent inquiry is needed into separated children who have gone missing from care, the Social Democratic and Labour Party has said.

PACT: TheTheAAATheTheTheAnAnAnTheThe an an an been been been jailed.

LSQ: The SDLP has called for an urgent inquiry into the welfare of unaccompanied children in Northern Ireland.

LAQ: The SDLP has called for "urgent inquiry and investigation" into the handling of unaccompanied children in Northern Ireland.

Ours: The SDLP is calling for an urgent inquiry and investigation into the disappearance of unaccompanied young people.

Article: The dairies operation, which processes and distributes milk, is being sold to Germany's Mueller for Â£80m. It comes as profits at the UK's largest dairy food company fell 95% to Â£900,000 in the six months to September. Dairy Crest processes and delivers around 1.3 billion litres of milk a year for retailers and homes. Dairy Crest said in a statement that the deal was in the best interests of consumers, customers and dairy farmers. The dairies business accounts for about 70% of the company's revenues, which rose 1% to Â£682.1m during the six months. After the sale, which still needs shareholder approval and could take several months, Dairy Crest will focus on its profitable cheese and spreads operations. There are about 14,000 dairy farmers in the UK, producing 3.3 million litres a day. However, with milk prices having fallen, there has been much debate about whether the economics of the industry are sustainable. Investors approved of the Dairy Crest's decision to get out of a loss-making sector, sending its shares 10% higher in morning trading on Thursday. Muller said the deal would lead to lower costs and larger exports of dairy products made in the UK. Ronald Kers, chief executive of Muller UK & Ireland, said: "We are concerned that the dynamics of the UK fresh milk market are unsustainable for dairy processors in the mid to long term and this acquisition will allow us to reduce our costs, increase our efficiencies and invest in the future." Under the deal, Mueller's UK division - Muller Wiseman Dairies - will take over factories at Foston, in Derbyshire, Chadwell Heath, in Essex, and Severnside, near Gloucester. The deal also includes the Hanworth glass bottling site in Middlesex, where Dairy Crest is consulting with employees on the site's future, and 72 depots. Muller bought Robert Wiseman in 2012.

Reference: Dairy Crest, maker of Cathedral City cheese and Country Life butter, has announced a big slump in profits and the sale of its milk business.

PACT: More than than more more more than more than than than to be be be will will will be be are are are be be to the.

LSQ: Dairy Crest is to sell its Dairies business to a German company for an undisclosed sum.

LAQ: Dairy giant Dairy Crest is to sell its UK business to a German company for an undisclosed sum.

Ours: Dairy Crest, the world's largest dairy producer, is to sell its UK operations to a German firm.

Table 10: Example summaries generated by 2-bit BART quantized with different methods.

Abstract

Vision-language navigation (VLN) is a challenging task due to its large searching space in the environment. To address this problem, previous works have proposed some methods of fine-tuning a large model that pretrained on large-scale datasets. However, the conventional fine-tuning methods require extra human-labeled navigation data and lack self-exploration capabilities in environments, which hinders their generalization of unseen scenes. To improve the ability of fast cross-domain adaptation, we propose **Pro**mpt-**b**ased **E**nvironmental **S**elf-exploration (ProbES), which can self-explore the environments by sampling trajectories and automatically generates structured instructions via a large-scale cross-modal pretrained model (CLIP). Our method fully utilizes the knowledge learned from CLIP to build an in-domain dataset by self-exploration without human labeling. Unlike the conventional approach of fine-tuning, we introduce prompt-based learning to achieve fast adaptation for language embeddings, which substantially improves the learning efficiency by leveraging prior knowledge. By automatically synthesizing trajectory-instruction pairs in any environment without human supervision and efficient prompt-based learning, our model can adapt to diverse vision-language navigation tasks, including VLN and REVERIE. Both qualitative and quantitative results show that our ProbES significantly improves the generalization ability of the navigation model[*].

1 Introduction

Teaching a robot to navigate following a natural language instruction has a broad impact in the field of human-robotic interaction. Many related tasks have been proposed to delve into this problem. The vision-language navigation (VLN) task (Anderson et al., 2018) is proposed where an agent is required to navigate in a photo-realistic environment step-by-step following a natural language instruction. Recent tasks (Qi et al., 2020; Zhu et al., 2021) focus on target objects localization that asks an agent to identify an object in an unseen room.

Solving these tasks requires an agent to obtain a vision-text alignment ability that locates related objects and executes corrective actions according to the instruction. However, collecting a large-scale VLN dataset is difficult and laborious since annotating the semantic of a trajectory within a sentence costs times of labor than annotating an image. Existing navigation datasets are relatively small-scale, and learning on such datasets hinders the agent to obtain a good generalization ability. To solve this problem, EnvDrop (Tan et al., 2019) uses a speaker model to generate instructions for sampled trajectories in unseen environments, but the generalization ability is not strong with limited vision-language understanding ability. Recently, VLN-BERT (Majumdar et al., 2020) introduces a visio-linguistic model pretrained on Conceptual Captions (Sharma et al., 2018) dataset to learn from image-caption pairs, which are quite different from trajectory-instruction pairs from VLN. To address this, Airbert (Guhur et al., 2021) constructs a large-scale in-domain pretraining dataset with image-caption pairs collected from online marketplaces such as Airbnb to finetune ViLBERT. However, Airbert collects image captioning data on websites, which are still far from the scenario of vision-language navigation. Different from previous methods that collect human-labeled data to train a navigation model, we suggest that automatically generating instruction-trajectory pairs by self-exploration for pretraining not only helps the model obtain better generalization ability but also achieves fast adaptation to downstream tasks.

In this paper, we propose a method named

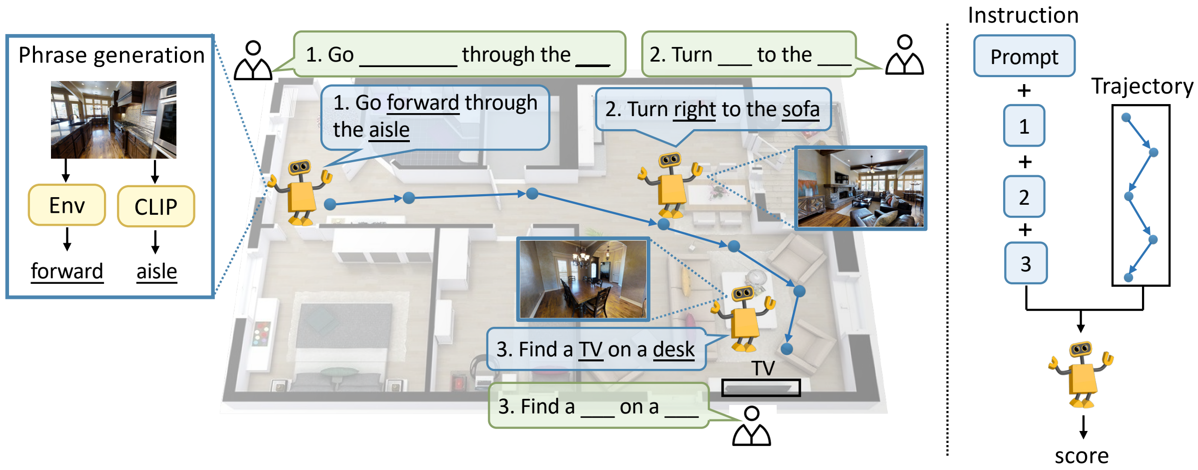

Figure 1: A demonstration of our prompt-based environmental self-exploration. In the left blue box, we sample trajectories from the environment and generate candidate phrases by a pretrained CLIP model. Then we fill templates by movements and the generated phrases during self-exploration. At last, we use the generated instruction-trajectory samples for pretraining.

prompt-based environmental self-exploration (ProbES) that generates navigation data with prior knowledge automatically and adapts pretrained model quickly to VLN tasks. An overview of our proposed framework is shown in Figure 1. By using this method, a pretrained visio-linguistic model is able to adapt to the VLN task automatically and efficiently. Specifically, we build an in-domain dataset by self-exploration without labeling or crawler. To build such a dataset. we first generate templates by masking visual and action words in labeled instructions. Then, we sample trajectories in the training environment. A pretrained CLIP (Radford et al., 2021) model is used to recognize rooms and objects in the sampled trajectories and match described phrases with them. We construct instructions by filling the matched phrases into sampled templates. By leveraging the prior knowledge learned by CLIP, we are able to build a dataset automatically with rich semantic information. Meanwhile, finetuning the whole pretrained model is time-consuming, we adopt prompt tuning (Li and Liang, 2021; Liu et al., 2021c,b), a lightweight alternative to finetuning. Our prompt-based method can distill task-relevant knowledge from pretrained model and achieve fast adaption to downstream tasks. We evaluate ProbES on R2R (Anderson et al., 2018) and REVERIE (Qi et al., 2020) datasets by discriminative and generative settings. Results show that ProbES can match or surpass the performance of finetuning with substantially less training time.

To sum up, our main contributions are as follows: (1) We propose ProbES, a novel self-exploration method to automatically build an in-domain dataset that reduces the domain gap between the pretraining dataset and VLN tasks without human labeling; (2) Compared with finetuning large pretrained model, our proposed prompt tuning can achieve fast adaptation; (3) Experiments are conducted on R2R and REVERIE datasets with generative and discriminative settings, and results indicate that our proposed ProbES can achieve better or comparable performance. Besides, our generated data can be used as augmented data which improves the generalization ability of the model.

2 Related Work

Vision-and-Language Navigation. Anderson et al. (Anderson et al., 2018) proposed the first Vision-Language Navigation (VLN) benchmark combining real imagery (Chang et al., 2017) and natural language navigation instructions. To solve this task, Wang et al. (Wang et al., 2020) proposed a novel SERL model to learn reward functions from the expert distribution. And combining imitation learning and reinforcement learning (Wang et al., 2019) has been proved to be beneficial for VLN. Since the VLN dataset is relatively small-scale, some works propose augmentation approaches (Fried et al., 2018; Tan et al., 2019; Liu et al., 2021a) to improve robustness. Auxiliary losses (Majumdar et al., 2020; Zhu et al., 2020; Liang et al., 2021) is used to take advantage of the additional training signals derived from the semantic information. Some pretraining methods (Huang et al., 2019; Hao et al.,

2020) have been proposed to learn generic cross-modal representations. This is further extended to a recurrent model that significantly improves sequential action prediction (Hong et al., 2021). However, the limited number of environments in pretraining constrain the generalization ability to unseen scenarios. Most related to this work, VLN-BERT (Majumdar et al., 2020) transfers knowledge from abundant, but out-of-domain image-text data to improve path-instruction matching. In contrast, we not only propose an effective method to build an in-domain dataset by sampling trajectory and generating instructions with templates, but also present a prompt-based pretraining strategy to improve VLN.

Vision-and-Language Pretraining. Vision-and-language pretraining has made great progress in recent years. Inspired by BERT (Devlin et al., 2019), much work has extended it to process visual tokens and pretrain on large-scale image-text pairs for learning generic visio-linguistic representations. Previous research introduces one-stream BERT models and two-stream BERT models. The former directly perform inter-modal grounding (Li et al., 2019; Su et al., 2019; Alberti et al., 2019; Li et al., 2020a; Chen et al., 2020; Zhou et al., 2020; Li et al., 2020b), while two-stream models process both visual and textual inputs in separate streams, and then fuse the two modalities in a later stage (Lu et al., 2019; Tan and Bansal, 2019). These models are often pretrained with self-supervised objectives akin to those in BERT: masked language modeling, masked object classification, and sentence-image alignment. In this work, the architecture of the ProbES model is structural similar to ViLBERT (Lu et al., 2019). We make several VLN-specific adaptations to ViLBERT so that pretrained weights can be transferred to initialize large portions of the model. Different from VLN-BERT which fine-tunes a ViLBERT on instruction-trajectory pairs to measure their compatibility in beam search setting, we introduce prompt tuning, which only tunes the continuous prompts.

Prompting. Natural language prompting freezes pretrained models and reformats the natural language input with example prompts. GPT-3 (Brown et al., 2020) introduces in-context learning, using manually designed and discrete text prompts. Sun et al. (Sun and Lai, 2020) also leverage prompts as keywords to control the sentiment or topic of the generated sentence. AutoPrompt (Shin et al., 2020) searches for a sequence of discrete trigger words and concatenates it with each input to elicit sentiment or factual knowledge from a masked LM. Different from the discrete text prompt, some methods examine continuous prompts (a.k.a. soft prompts) that perform prompting directly in the embedding space of the model. Prefix-Tuning (Li and Liang, 2021) prepends a sequence of continuous task-specific vectors as virtual tokens to the input. (Zhong et al., 2021; Qin and Eisner, 2021; Hambardzumyan et al., 2021) introduce continuous templates following manual prompt templates. P-tuning (Liu et al., 2021c) uses continuous prompts which are learned by inserting trainable variables into the embedded input. Ptr (Han et al., 2021) adopts manually crafted sub-templates and generates complete templates by logic rules. In ProbES, we prepend continuous task-specific vectors to the embedding of the input instruction and directly tune the embeddings of these vectors. After prompt tuning, the model can be adapted to VLN and REVERIE tasks.

3 Prompt-based Environmental Self-Exploration (ProbES)

3.1 Vision-Language Navigation

The Vision-and-Language Navigation (VLN) task gives a global natural sentence $I = \{w_0, ..., w_l\}$ as an instruction, where w_i is a word token while the l is the length of the sentence. The instruction consists of step-by-step guidance toward the goal. At step t, the agent observes a panoramic view $O_t = \{o_{t,i}\}_{i=1}^{36}$ as the vision input, which is composed of 36 RGB image views. Each of these views consists of image feature v_i and an orientation description ($sin\ \theta_{t,i}$, $cos\ \theta_{t,i}$, $sin\ \phi_{t,i}$, $cos\ \phi_{t,i}$). Candidates in the panoramic action space consist of k neighbours of the current node in the navigation graph and a stop action.

3.2 Instruction Generation with Templates

We first generate templates from instructions in the R2R dataset. Then we sample trajectories in the training environment. We generate the candidate noun phrases and actionable verbs for the sampled trajectories and full-fill the templates by the above words. A detailed demonstration of our instruction generation module is shown in Fig. 2.

Generating Templates We collect phrases and replace these phrases in human-annotated navigation instruction with blank masks to generate templates. Different from the Airbert (Guhur et al., 2021) that

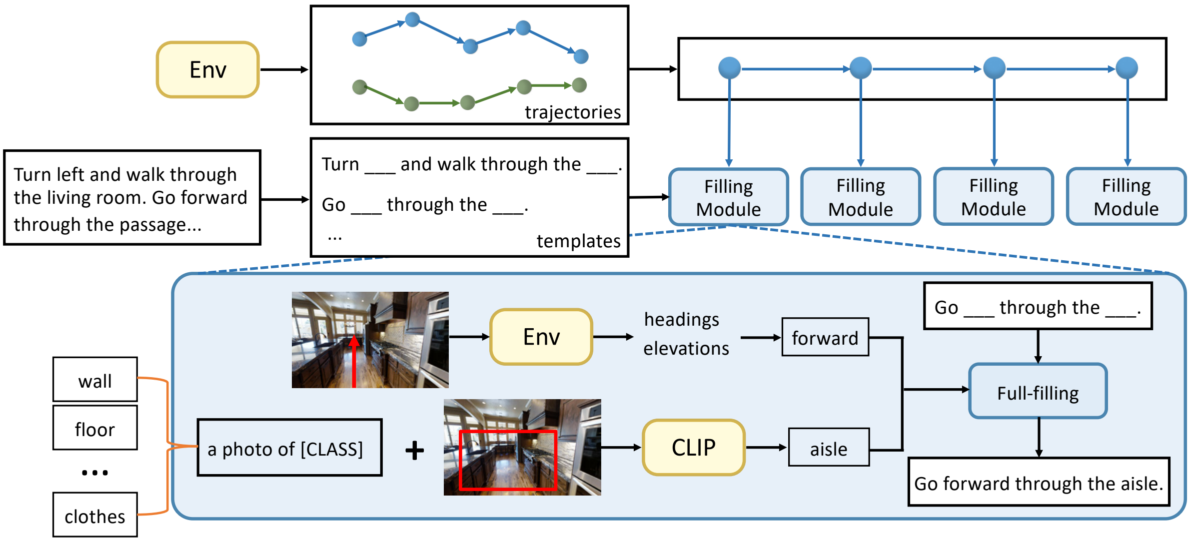

Figure 2: A detailed demonstration of the prompt-based full-filling process. We first sample trajectories from the environment, and generate templates by masking objects and actions. For each step of a trajectory, we generate candidate tokens for objects by CLIP and actions by the environment. Then we full-fill the template with candidate tokens by the rules as introduced in Sec. 3.2

only extracts noun phrases, we also mask action words like ‘left’, ‘right’, ’forward’, and ‘around’. We denote the O_{mask} as the mask for an object and A_{mask} is the mask for an action. The generated templates are like ‘Turn A_{mask} and walk past O_{mask}. Once out, walk A_{mask} O_{mask}. Stop once you reach O_{mask}’. More examples are shown in Table 1.

Sampling Trajectories and Actions We first sample the trajectories in the Matterport (Chang et al., 2017) Environment. We randomly sample the starting and ending positions, and collect tracks with lengths of less than 8 hops. Then we obtain the corresponding actions of each trajectory by first-person movement. If the agent chooses the front navigable position to move, we generate a ‘forward’ action. If the agent chooses the back navigable position to move, we generate an ‘around’ action. Otherwise, if the agent selects the right front navigable position to move for the next step, we generate an action sequence like {‘right’, ‘forward’}, which is used to fill actionable verbs during instruction generation.

Full-filling Template with Prior Knowledge Prior knowledge is the key to generating high-quality data without human labeling. ProbES introduces CLIP, a powerful vision-language alignment model learned from a large-scale image-caption dataset. To generate structured augmentation data, we full-fill the templates with phrases that describe the sampled trajectory and actions. A trajectory is denoted as $\{v_1, v_2, ..., v_n\}$, where v_i represents an observation viewpoint. We introduce CLIP (Radford et al., 2021) to select candidate phrases c and match them to each view v_i. We first embed the sentence ‘a photo of [c_{noun}]’ by CLIP, where the c_{noun} represents the noun-phrase candidates (room or object classes labeled in Matterport dataset). Then we embed the view image by the vision encoder of CLIP and calculate the similarity of the language embedding and vision embedding. We select the candidate with the highest matching score for the view v_i. Each view has two matched candidates, one for the detected room and another for an object. Then the description c_i of this view is written in 3 formats randomly: ‘[room]’, ‘[object]’ or ‘[room] with [object]’. Since trajectories are sampled in the environment, we can obtain actionable verbs a_i between two viewpoints via comparing headings and elevations.

We randomly select a template with the same or a close number of O_{mask} as the number of viewpoints in the sampled trajectory. The template has a sequence of object masks $\{O_{mask,1}, O_{mask,2}, ..., O_{mask,i}\}$ and a sequence of action masks $\{A_{mask,1}, A_{mask,2}, ..., A_{mask,j}\}$. Lengths of object masks and action masks are denoted as l and n respectively. The number of object masks and action masks is roughly balanced. Let n_v be the number of viewpoints in a sampled trajectory. Then the generated captions of this trajectory is written as $\{c_1, c_2, ..., c_{n_v}\}$. We

Table 1: Examples of generated templates.

	Templates
1	Walk A_{mask} O_{mask} and stop on O_{mask}.
2	Head A_{mask} until you pass O_{mask} with O_{mask} the turn A_{mask} and wait by O_{mask}.
3	Walk past O_{mask} and to O_{mask}. Walk in O_{mask} and stop.
4	Turn A_{mask} and walk through O_{mask}. Exit O_{mask}, turn A_{mask} and walk A_{mask} O_{mask}. Stop in O_{mask}.
5	Go A_{mask} O_{mask}, and go A_{mask}. Take A_{mask} into O_{mask}. Stop behind O_{mask}.
6	Leave O_{mask} and go through O_{mask}. Walk towards O_{mask} to O_{mask}. Stand in O_{mask}.

full-fill the templates by the following rules: 1) if $n_v \geq l$, we randomly sample l captions and fill the O_{mask} in the template sequentially; 2) if $n_v < l$, we randomly sample the O_{mask} and use all the caption phrases to fill them. After filling phrases, we can identify which viewpoint $A_{mask,i}$ may appear since viewpoints of $O_{mask,j}$ near it are already known. For example, if the template is like '$O_{mask,1}A_{mask,1}O_{mask,2}$' and captions of v_1 and v_2 are used to fill $O_{mask,1}$ and $O_{mask,2}$ respectively, then $A_{mask,1}$ is the sampled action between v_1 and v_2. In this way, we use generated actionable verbs to full-fill the templates and get final instructions. By the above method, we can generate diverse instructions without human labeling.

3.3 Prompt-based Architecture

Prompt tuning has been found effective on many natural language understanding (NLU) tasks. Motivated by this, we introduce a prompt-based architecture to achieve fast adaptation on the self-exploration dataset (e.g., Conceptual Captions) and downstream tasks. The architecture is ViLBERT-like and equipped with a prompt encoder for prompt tuning.

Given an instruction-trajectory pair, the visual and textual features can be extracted by the visual encoder E_v and textual encoder E_x in ViLBERT respectively. Especially, the textual input has two parts: prompt sequence $\{p_1, ..., p_n\}$ and word sequence $\{x_1, ..., x_m\}$, where p and x indicate a pseudo prompt token and a word token of a generated instruction respectively. n and m represent lengths of the prompt sequence and word sequence respectively.

We embed prompt sequence by the prompt encoder E_p and embed word sequence by the textual encoder E_x as follows:

$$\begin{aligned} e_{p,1}, ..., e_{p,n} &= E_p(p_1, ..., p_n) \\ e_{x,1}, ..., e_{x,m} &= E_x(x_1), ..., E_x(x_m), \end{aligned} \tag{1}$$

where E_p is composed of a LSTM head followed by a MLP head. Then the textual embedding is mapped to $e_t = \{e_{p,1}, ..., e_{p,n}, e_{x,1}, ..., e_{x,m}\}$, where $e_{p,1}, ..., e_{p,n}$ are trainable embedding tensors and enable us to find better continous prompts. Let e_v be denoted as visual embedding produced by visual encoder E_v. e_t and e_v are then passed to the co-attention transformer similar to ViLBERT. Then in the prompt tuning process, we only train E_p and fix the parameters of E_x for the language stream. For the vision stream, since the trajectory is represented as a sequence of panoramic image regions, which is different from VLMs pretrained on image-caption pairs, we also update the visual embedding during prompt tuning. The visual embedding contains image embedding and location embedding.

We sample hard negative paths based on distance in the environment for an instruction-trajectory pair, and the model is trained to choose the best path among them.

3.4 Downstream Tasks Adaptation

Our model can adapt to diverse downstream navigation tasks, including VLN, a step-by-step navigation task, and REVERIE, an object-oriented navigation task. In the step-by-step navigation task, our model receives an instruction sentence and navigates following the commands in the instruction sequentially. In the object navigation task, our model receives an object description and explores the house to find an object.

Also, our model can be adapted to both discriminative and generative navigation settings. In the discriminative setting, our model receives both an instruction and the observation sequence to represent a navigation trajectory and then output a score. In the generative setting, our model receives instruction and predicts actions sequentially.

4 Experiments

4.1 Experimental Setup

We experiment with our proposed ProbES on two downstream tasks: goal-oriented navigation task (R2R (Anderson et al., 2018)), and object-oriented navigation task (REVERIE (Qi et al., 2020)). ProbES can be easily applied to discriminative and generative models for these two tasks.

Evaluation Metrics A large number of metrics are used to evaluate models in VLN, such as Trajectory Length (TL), the trajectory length in meters, Navigation Error (NE), the navigation error in meters, Oracle Success Rate (OR), the rate if the agent successfully stops at the closest point, Success Rate (SR), the success rate of reaching the goal, and Success rate weighted by (normalized inverse) Path Length (SPL) (Anderson et al., 2018). VLN task regard SR and SPL as the primary metric, and the REVERIE task regard RGS and RGSPL as the primary metric.

Implementation Details Our training process is divided into two steps: Firstly, we pretrain our model on our generated self-exploration training set with prompt tuning for only 10 epochs. After that, we adapt our model to the downstream discriminative VLN task with only ranking loss for 20 epochs. The batch size is set as 64 and the learning rate is 4×10^{-5}. The generative navigation settings are the same as Recurrent VLN-BERT on both R2R and REVERIE. During pretraining, we use ProbES to 50k instruction-trajectory pairs. We use 32 NVIDIA V100 GPUs for pretraining and 8 GPUs for adaptation. Experiments with generative settings are conducted on a V100 GPU.

Table 4: Results by comparing ProbES with VLN-BERT in discriminative setting.

	Val Unseen				
	TL	NE↓	OSR↑	SR↑	SPL↑
VLN-BERT	9.60	4.10	69.22	59.26	55
ProbES	9.50	4.05	68.24	60.28	56

4.2 Comparison to state-of-the-art Methods

In this section, we compare our model with previous state-of-the-art methods. We compare the ProbES with two baselines (ViLBERT and VLN-BERT built on Recurrent VLN-Bert) and five other methods. A brief description of previous models is as followed: 1) Seq2Seq: A sequence to sequence model reported in (Anderson et al., 2018); 2) Speaker-Follower (Fried et al., 2018): a method introduces a data augmentation approach and panoramic action space; 3) PRESS (Li et al., 2019): a conventional fine-tuning method with stochastic instruction sampling; 4) EnvDrop (Tan et al., 2019): a method augment data with environmental dropout; 5) Recurrent VLN-Bert (Hong et al., 2021) on three different settings: OSCAR and ViLBERT pretrained on out-of-domain data, VLN-BERT pretrained on R2R. We compare the models on three splits in the R2R dataset: validation seen house, validation unseen house, and testing (where the houses are also unseen). We also compare ProbES with Seq2Seq, RCM (Wang et al., 2019), SMNA (Ma et al., 2019), FAST-MATTN (Qi et al., 2020), Recurrent VLN-Bert (Hong et al., 2021) on OSCAR on REVERIE dataset.

Results on R2R We compare ProbES with previous state-of-the-art methods on the R2R dataset in the generative setting, which predicts actions sequentially, as shown in Table 2. Rec indicates using Recurrent VLN-Bert (Hong et al., 2021) with different backbones or parameter initialization. In the validation seen split, compared to VLN-BERT under the same setting, our ProbES achieves 5% improvement on SR and 5% improvement on SPL. In the validation unseen split, we achieve 1% improvement on SR compared to VLN-BERT. In the testing split, ProbES shows competitive results. Note that the PREVALENT backbone is pretrained on an in-domain R2R dataset with scene features and fine-tuned with an additional action prediction task in a generative setting while ProbES does not use labeled R2R data or augmented data generated by speaker (Fried et al., 2018).

Results in Discriminative Setting We compare ProbES with VLN-BERT in the discriminative setting, which outputs scores for instruction-trajectory pairs, as in Table 4. In the validation unseen split, our method outperforms VLN-BERT, which indicates ProbES is able to improve the generalization ability for unseen scenes.

Results on REVERIE We compare ProbES with previous state-of-the-art methods on the REVERIE dataset, as shown in Table 3. In the validation unseen split, we achieve 0.42% improvement on RGS and 0.65% improvement on RGSPL. In the testing split, ProbES achieves 0.87% improvement on RGS and 0.69% improvement on RGSPL. We can see that ProbES benefits from prompt tuning with our generated instruction-trajectory pairs.

4.3 Ablation Study

Ablation of Learning Strategies. In Table 5, we ablate the performance gains from different learning strategies. PT and FT represent prompt tuning and fine-tuning respectively. Mask and Rank stand for masked multi-modal modeling loss and the ranking loss for path-selection task. We regard the model finetuned by ranking loss as our baseline.

Table 5: Ablation of different modules during pretraining and finetuning.

	Our data			R2R		SR on Val	
	PT	FT	Mask	Mask	Rank	Seen	Unseen
1	-	-	-	-	✓	55.4	39.5
2	-	-	-	✓	✓	**70.2**	59.3
3	-	-	✓	-	✓	69.1	57.9
3	-	✓	-	-	✓	68.7	59.0
4	✓	-	-	-	✓	68.4	**60.3**

The masked multi-modal modeling loss on our data and R2R data are able to improve the performance. And finetuning on our data is able to improve generalization ability since the success rate in the validation unseen split gets 1.1% improvement and achieves 59.0%. At last, we discover that pretraining on our data with prompt tuning improves the baseline performance by 20.8% in the validation unseen split, achieving the best performance. Our model outperforms the model fine-tuned on R2R dataset by 1.1% in unseen split, indicating that ProbES improves the generalization ability of the navigation model.

Ablation of Instruction Generation. Table 6 introduces comprehensive ablation experiments showing the impact of key steps in the strategy of generating instructions, and the experiments are performed in the baseline model: IL+RL from EnvDrop (Tan et al., 2019). Class indicates classes we use to feed into CLIP. M and P/O represent classes from Matterport and Place365/Objects365 datasets respectively. $G_{Template}$ denotes the strategy used to generate templates. 'ours' denote the strategy shown in Sec 3.2. For $S_{Template}$, 'random' and 'match' indicate sampling a template randomly and choosing a template with the same number of masks as the number of viewpoints.

As shown in Table 6, randomly selecting template without considering the number of masked tokens degrades the performance and introduces more noise in the data. Results show that equipped with our generated data (Row 3) improves the performance by a large margin. The model of using the rooms and objects from Places365 (Zhou et al., 2017) and Objects365 (Shao et al., 2019) (Row 4) performs worse than which uses the rooms and objects from Matterport. We infer from that Places365 and Objects365 contain many outdoor

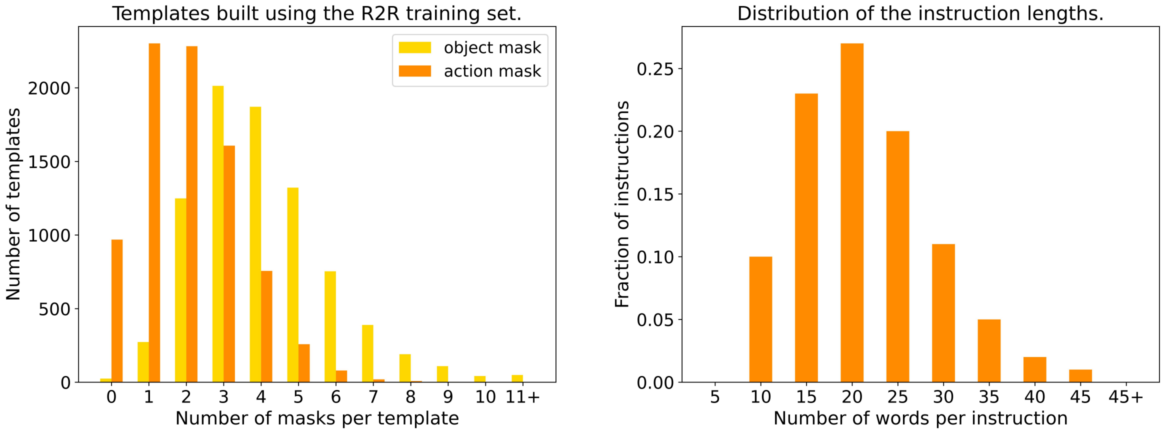

Figure 3: Statistical analysis of generated instructions.

Table 6: Comparison of different strategies during generating instructions.

	Class		$G_{Template}$	$S_{Instruction}$		SR on Val	
	M	P/O	ours	random	match	Seen	Unseen
1	-	-	-	-	-	55.3	46.5
2	✓	-	✓	✓	-	59.8	49.4
3	✓	-	✓	-	✓	60.5	50.7
4	-	✓	✓	✓	-	59.8	48.9

scenes and objects which are not suitable for VLN.

4.4 Qualititiva Analysis

Visualization of Data Distribution Figure 3 presents a statistical analysis of our generated instructions. We can see from the left figure that the number of object masks are larger than that of action masks, indicating that instructions contain more rich information generated by CLIP from sampled observations. The right figure shows the distribution of the instruction lengths. The lengths of most of the instructions range from 10 to 30, which matches the R2R dataset. The easy samples and hard samples in our generated instructions are balanced.

Visualization of Trajectory-instruction pairs Here we provide visualization of the data generated by ProbES. Figure 4 shows the instruction-trajectory samples generated with our strategy. For each sample, we visualize observations of the trajectory, captions generated with CLIP, the selected template, and the final instruction generated by ProbES. Generated object classes fit observed scenes well, thus we can infer that CLIP is able to extract key information from the observation. Also, our method can select a suitable template and generate diverse instructions that describe observations of trajectories correctly. The length of our generated instruction ranges from 1 to 3 sentences, which matches the data distribution of the R2R dataset.

5 Conclusion

In this work, we first introduce an effective way to generate in-domain data for pretraining the VLN model: leveraging a large pretrained CLIP model to generate captions for each viewpoint and sampling actions in the environment. Experiments show that the domain gap between pretraining data and VLN tasks can be mitigated. We also propose a prompt-based architecture, which introduces prompt tuning to adapt the pretrained model fastly. Our proposed ProbES achieves better results compared to baseline on both R2R and REVERIE datasets, and ablations show the contribution of each module and the effectiveness of the generated data.

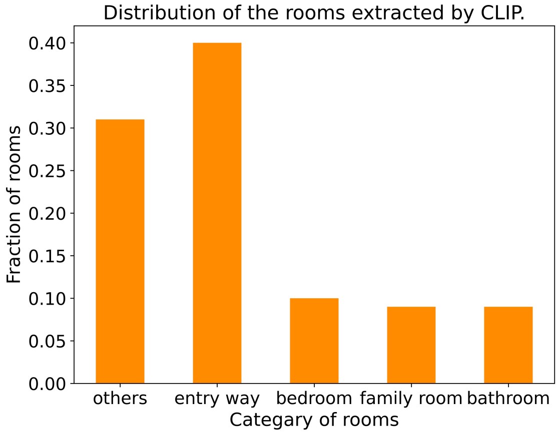

Figure 5: Statistical analysis of generated instructions.

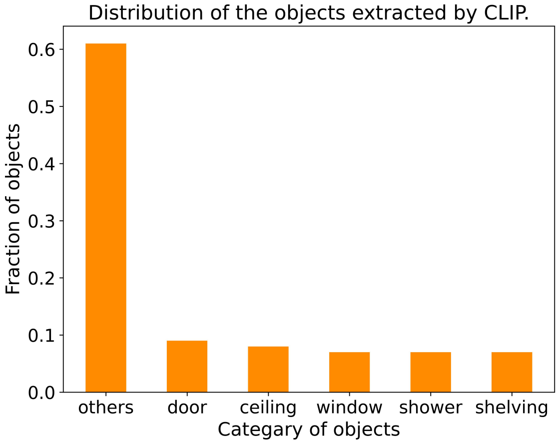

Figure 6: Statistical analysis of generated instructions.

A Appendix

In the Appendix, we present additional statistics and examples of our generated data. Then we discuss implementation details of prompt-based architecture.

A.1 Dataset Details

Additional Statistics As shown in Figure 5 and Figure 6, we summarise rooms and objects detected by CLIP in viewpoints of sampled trajectories. These rooms and objects appear in the indoor environment commonly, indicating the accuracy of the CLIP model.

Visualization of Captions We visualize generated captions for sampled viewpoints in Figure 7. We infer from the figure that the CLIP can identify scenes and prominent objects accurately. Our generated captions contain rich visual information, which improves the image-text alignment ability of the model.

Visualization of More Examples More examples of sampled trajectories and the corresponding generated instructions are shown in Figure 10 and Figure 11, which implies that our method can generate scenario-specific instructions automatically.

A.2 Architecture Details

We present implementation details of our proposed prompt-based architecture for both prompt tuning in the discriminative setting and finetuning in the generative setting, respectively.

A.2.1 Prompt-based Pretraining

As shown in Figure 8, the model is composed of a prompt encoder and a ViLBERT-like architecture. The prompt encoder consists of a bidirectional long-short term memory network (LSTM) and a ReLU activated two-layer multilayer perceptron (MLP). The output of the prompt encoder is prepended to the textual embedding. The ViLBERT-like architecture is similar to that of VLN-BERT. We choose ranking loss for the prompt tuning.

A.2.2 Finetuning in Generative Setting

As shown in Figure 9, the generative setting is similar to Recurrent VLN-BERT. Unlike Recurrent VLN-BERT, we introduce the prompt encoder, whose architecture is the same as the pretraining phase. During finetuning, the whole model is unfixed to achieve better results.

Abstract

Dialog response generation in open domain is an important research topic where the main challenge is to generate relevant and diverse responses. In this paper, we propose a new dialog pre-training framework called DialogVED, which introduces continuous latent variables into the enhanced encoder-decoder pre-training framework to increase the relevance and diversity of responses. With the help of a large dialog corpus (Reddit), we pre-train the model using the following 4 tasks, used in training language models (LMs) and Variational Autoencoders (VAEs) literature: 1) masked language model; 2) response generation; 3) bag-of-words prediction; and 4) KL divergence reduction. We also add additional parameters to model the turn structure in dialogs to improve the performance of the pre-trained model. We conduct experiments on PersonaChat, DailyDialog, and DSTC7-AVSD benchmarks for response generation. Experimental results show that our model achieves the new state-of-the-art results on all these datasets.

1 Introduction

Pre-trained language models (PLMs) have been widely explored both in natural language understanding (NLU) and generation (NLG) in recent years, this pre-training and fine-tuning paradigm sheds light on various downstream tasks in natural language processing (NLP). Compared with general pre-trained models, task-oriented pre-trained models (such as *Summarization*, *Dialog* and etc.), which is designed in line with task characteristics, may achieve better performance and be more robust. In this paper, we proposes a novel pre-trained dialog response generation model based on previous research.

Dialogue Response Generation (DSG) in open domain is a challenging task with a wide range of application scenarios. Recent advances in DSG utilize pre-trained language models (PLMs) such as BERT (Devlin et al., 2019) and GPT2 (Radford et al., 2019) in two major categories. The first one focuses on how to fine-tune PLMs in downstream tasks and address the various application-specific needs and challenges (Lin et al., 2020). The second one augments dialog specific tasks into the PLM training (Zhang et al., 2020; Bao et al., 2020) and then fine-tunes the new pre-trained model in downstream tasks. We study the latter in this paper.

There is a proverbial one-to-many problem in DSG, i.e., a single dialog context could be followed by multiple reasonable responses. Existing works introduce latent variables to model this problem. For example, VHRED (Serban et al., 2017) incorporates latent continuous variable into the sequence-to-sequence (Seq2Seq) RNN model to improve the diversity of generated responses. VAE-Seq2Seq (Bahuleyan et al., 2017) proposes variational attention to replace the vanilla encoder-decoder attention (Luong et al., 2015), to avoid attention to bypass the latent space and invalidate the latent variable. For controllability and interpretability, some discrete VAEs have also been proposed, such as (Oord et al., 2017; Vahdat et al., 2018).

Recently, PLATO (Bao et al., 2020) firstly introduces latent variables into their pre-training dialog model, where the authors introduce a K-way ($K = 20$) categorical latent variable, and the pre-trained model shows significant gains in multiple downstream response generation tasks. Continuous latent variables besides discrete latent variables is popularly used for modeling one-to-many mapping in dialog system, but the potential of incorporating continuous latent variables with large-scale language pretraining is less explored.

In this paper, we propose a pre-trained latent **V**ariable **E**ncoder-**D**ecoder model for **Dialog** generation, which is called DialogVED. In this model, we introduce a continuous latent variable into the

May 22-27, 2022

enhanced encoder-decoder pre-training framework and we adopt the optimization techniques based on the VAEs literature to learn the model with continuous latent variables. More specifically, we conduct the pre-training by optimizing the following 4 pre-training objectives simultaneously: 1) masked language spans loss to enhance the encoder's understanding of context, 2) response generation with n-gram loss to improve the decoder's planning ability, 3) Kullback-Leibler divergence loss to minimize the difference between the posterior and prior distribution of the latent variables, and 4) bag-of-words loss to reduce posterior distribution collapse. In addition, we also explore the effect of absolute and relative position embeddings specific for conversational data on the model performance.

We conduct experiments on three different kinds of conversation tasks: chit-chat, knowledge grounded conversation, and conversational question answering. Experimental results verify the effectiveness and superiority of our model compared with the previous state-of-the-art method. We further carry out ablation study to better understand the impact of different components in the DialogVED on model performance including latent space sizes, different decoding strategies, and position embeddings for turns and roles.

The main **contributions** of this paper can be summarized as follows: 1) We propose a pretrained dialog model, which incorporates continuous latent variables into the enhanced encoder-decoder pre-training framework; 2) We explore the impact of latent variable sizes, different decoding strategies, and position embeddings for turns and roles in our model; 3) Extensive experiments show that the proposed model achieves the new state-of-the-art (SOTA) in multiple downstream tasks, and our model has better performance both on relevance and diversity than previous SOTA in response generation.

2 Method

2.1 Model Architecture

In response generation, there are three elements: dialogue context c, response r and latent variable z. The dialogue context c may consist of several history utterances (i.e., multi turns) and the response r is one piece of appropriate reply towards the given context. Additionally, the latent variable z in the latent space represents many unobserved factors associating the context and the response.

We assume the latent variable z is continuous, which is different from PLATO (Bao et al., 2020), and portrays a certain conditional probability distribution related to the response given context. We then define the conditional distribution $p(r, z|c) = p(r|c, z)p(z|c)$ and our goal is to use encoder-decoder models (parameterized by θ) to approximate $p(r|c, z)$ and a multi-layer perceptron (parametrized by ϕ) to estimate $p(z|c)$, which is called the prior network in VAE literature. We call the final pre-trained model DialogVED, which is a transformer-based encoder-decoder model with an extra prior network for modeling the latent space. Figure 1 gives a overview of our model.

2.2 Encoder

We use multi-layer Transformer-based (Vaswani et al., 2017) encoder to encode the dialogue context. First, an input sequence of tokens is mapped to a sequence of embeddings, which are then passed into the encoder. The encoder consists of a stack of "blocks", each of which comprises two subcomponents: a self-attention layer followed by a small feed-forward network. Compared to the vanilla transformer encoder, our encoder has slight differences in position embeddings and self-attention layer in fine-tuning phase, which contains richer location information and will be introduced in § 2.7.

2.3 Decoder

Future predicting strategy has been concerned in recent research (Qi et al., 2020; Xiao et al., 2020), instead of predicting only the next token at each time step, the decoder using future predicting predicts n future tokens simultaneously.

Specifically, the original Seq2Seq model aims to optimize the conditional likelihood $P(r_t|r_{<t}, c)$, while future predicting strategy changes the optimization of predicting next single token to $P(r_{t:t+n-1}|r_{<t}, c)$ at each time step t, where $r_{t:t+n-1}$ denotes the next continuous n future tokens. The future n-gram prediction loss can explicitly encourage the model to plan for future token prediction and prevent over-fitting on strong local correlations (Qi et al., 2020).

We adopt the n-stream self-attention proposed in ProphetNet (Qi et al., 2020) in our decoder. The n-stream self-attention mechanism incorporates n extra self-attention predicting streams besides main stream to predict next n continuous future tokens respectively at each time step.

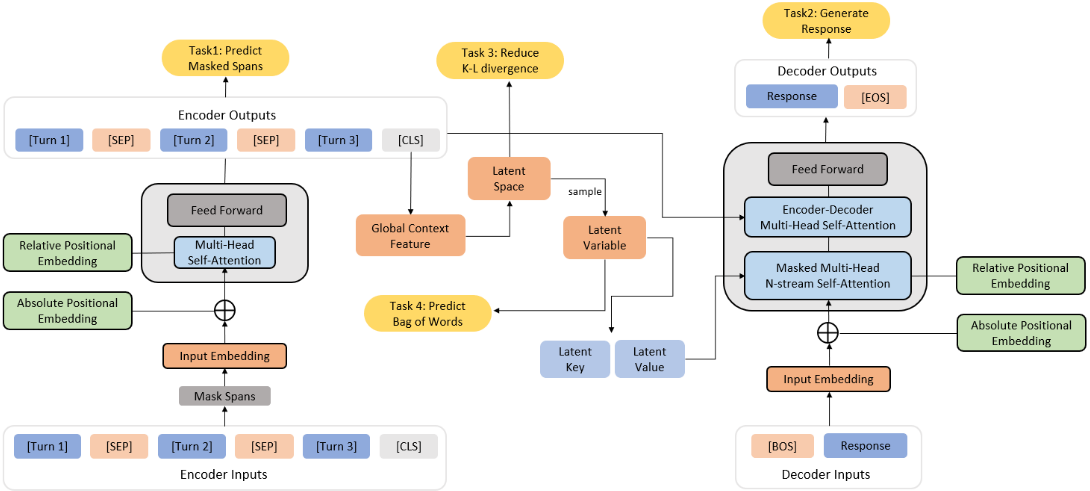

Figure 1: Pre-training and fine-tuning framework of DialogVED, the only difference between pre-training and fine-tuning is that in the fine-tuning stage, we do not mask the source thus the masked spans loss is discarded. It's worth noting that, to facilitate drawing, we put [CLS] at the end of the context, although we actually put it at the beginning.

Memory Scheme To incorporate the latent variable into decoder, we adopt a memory scheme similar to OPTIMUS (Li et al., 2020), where latent variable $z \in \mathbb{R}^P$ is mapped to a additional memory vector, denoted as h_{Mem}, which is an additional key-value pair for decoder to attend. We have memory vector

$$h_{Mem} = \begin{bmatrix} z_{key} \\ z_{value} \end{bmatrix} = W_M \, z \tag{1}$$

where $W_M \in \mathbb{R}^{H \times P}$ is the weight matrix, and the memory vector is shared and propagated across all layers in decoder as:

$$H^{(k+1)} = \textbf{MultiHead}(H^{(k)}, h^{(k)}_{Mem} \oplus H^{(k)}, h^{(k)}_{Mem} \oplus H^{(k)})$$

where $H^{(k)}$ refers to the hidden state of the k-th layer of decoder. The memory vector is equivalent to adding a virtual token during decoding to participate in the calculation of self-attention main stream, and the predicting streams are implicitly affected by h_{Mem} through interaction with the main stream. The latent variable guides the generation of each step of the decoder through the memory vector.

2.4 Latent Variable

Intuitively, introducing latent variables provides a hierarchical generation procedure: 1) sample a latent variable z from the prior network $p(z|c)$; 2) generate r through the decoder network $p(r|c,z)$. From previous research (Zhao et al., 2017a), $z \sim p(z|c)$ may determine the high-level semantics, and the auto-regressive decoding is followed to produce the output sentences with low-level syntactic and lexical details.

Similar to the Variational Autoencoders (VAEs), we learn the parameters θ by maximizing the marginal log likelihood:

$$\log p_\theta(r|c) = \log \int p_\phi(z|c) p_\theta(r|c,z) dz,$$

where p_ϕ involves an intractable marginalization over the latent variable z. (Kingma et al., 2016; Li et al., 2020), We will optimize its lower bound, which is equivalent to minimize the two terms below: reconstruction loss (or negative log-likelihood)

$$\begin{aligned} \mathcal{L}_{rc} &= -\mathbb{E}_{q(z)}[log\, p_\theta(r|c,z)] \\ &= -\mathbb{E}_{q(z)}[log \prod_t p_\theta(r_{t:t+n-1}|r_{<t}, c)] \end{aligned} \tag{2}$$

and K-L regularization term

$$\mathcal{L}_{kl} = KL(q(z)||p_\phi(z|c)). \tag{3}$$

Here $q(z)$ is a multivariable normal distribution with mean $\mu \in \mathbb{R}^P$ and diagonal variance matrix with diagonal taiking values $\sigma^2 \in \mathbb{R}^P$, denoted as $\text{diag}(\sigma^2)$.

To connect to the hidden space, we add a special classification token ([CLS]) to the beginning of the context, and the first hidden state denoted as $h_{[CLS]} \in \mathbb{R}^H$ in last-layer is used to represent the global dialog context. We assume

$$\begin{bmatrix}\mu \\ log(\sigma^2)\end{bmatrix} = \mathrm{MLP}_h\, h_{[CLS]} \tag{4}$$

where MLP_h is a multilayer perceptron and this multilayer perceptron is called the prior network in VAEs literature. We can then sample P random variables with each variable is from standard normal distribution and via transformation, we obtain samples of $z \in \mathbb{R}^P$ from $\mathcal{N}(\mu, \mathrm{diag}(\sigma^2))$, and feed them to the decoder.

2.5 Mask Language Spans

To improve the understanding ability of the encoder and the robustness to noise, we randomly mask part of the context before encoding. Recent research (Joshi et al., 2020; Lewis et al., 2020) on masked language models show the advantages of masking spans over masking individual words or subword units.

We adopt a simple method to mask spans: 1) randomly select n tokens in context, denote as $\mathcal{S}$; 2) for each token $t \in \mathcal{S}$, extend it to a text span with a fixed length of m; 3) mask all selected tokens after sorting, deduplication and boundary checking.

Following BERT (Devlin et al., 2019), the total number of masked tokens in the context accounts for approximately 15%, and we replace the masked token with: 1) the [MASK] token 80% of the time; 2) a random token 10% of the time; 3) the unchanged masked token 10% of the time. Then, the last-layer hidden states $h_x \in \mathbb{R}^H$ of each masked token x will be used to predict the original token and the encoder is trained to optimize the cross entropy loss:

$$\mathcal{L}_M = -\sum_{x} \mathrm{LSM}(W_2 \tanh(W_1 h_x + b_1))(x) \tag{5}$$

where $W_1 \in \mathbb{R}^{H \times H}$, $b_1 \in \mathbb{R}^H$ and $W_2 \in \mathbb{R}^{H \times |V|}$ denote the weight matrices of one fully-connected layer, $|V|$ is the vocabulary size, LSM is log softmax function and $\mathrm{LSM}(\dots)(x)$ means to take the log probability value corresponding to token x. In this paper, we share the parameters of W_2 with parameters of embedding layers in the encoder and decoder. Note that we only mask the context only the pre-training stage.

2.6 Reduce KL-vanishing

DialogVED allows the decoder to attend the hidden states of context (i.e., the output of the encoder), and thus direct training will cause the decoder to ignore the latent variable z, and the KL loss will rapidly decrease to 0 and the latent space loses its expressive power, which is called posterior collapse or KL-vanishing (Bowman et al., 2016). This paper adopts two methods developed in VAEs literature to reduce posterior collapse:

Free Bits (Kingma et al., 2016), which replaces the K-L regularization term in (3) with a hinge loss term that maximize each component of the original K-L term with a constant λ:

$$\mathcal{L}'_{kl} = -\sum_{i} max(\lambda, KL(q(z_i)||p_\phi(z_i|c))) \tag{6}$$

Bag-of-words Loss (Zhao et al., 2017b), which is used to encourage the latent variable to predict the words in response r in a non-autoregressive way:

$$\mathcal{L}_{BOW} = -\sum_{t=1}^{T} log\, f_{r_t} \tag{7}$$

where T is the number of tokens in response r, and f_{r_t} denotes the estimated probability of word r_t. More specifically, f is the function outputting the probability of words within the target response:

$$f = \mathrm{softmax}(\mathrm{MLP}_z[z \oplus h_{[CLS]}]) \in \mathbb{R}^{|V|} \tag{8}$$

where MLP_z is a multilayer perceptron and V refers to the whole vocabulary.

2.7 Position Embeddings

Absolute Position Embeddings Besides token-level learned position embeddings used in original Transformer, we also consider turn level and speaker-level position embeddings like PLATO (Bao et al., 2020). To better model the meaning of a turn in a dialog, We introduce embedding for turn position and role position in one conversation, the final input embedding of each token is the sum of corresponding turn, role and token embeddings.

Relative Position Embeddings It has recently become more common to use relative position embeddings, which produce a different learned embedding according to the offset between the "key" and "query" being compared in the self-attention mechanism (Shaw et al., 2018; Raffel et al., 2019). We extend the element of the original relative distance matrix in T5 (Raffel et al., 2019) to two-tuple.

$$\begin{aligned} e_{ij} &= \frac{x_i W^Q (x_j W^K + a_{ij}^K)^T}{\sqrt{d_z}}, \\ a_{ij}^K &= f(d_{token}, d_{turn}, x_i, x_j) \end{aligned}$$

In the mapping function f, we consider both token relative distance d_{token} and turn relative distance d_{turn}, where these tuples are mapped through a bucket function, and then a_{ij}^{K} is queried in pre-defined embedding layers.

2.8 Pre-training Objectives

Combining the losses detailed in the Equations (2) (5) (6) and (7), we have pre-training objective, which we use to pre-train the DialogVED on the large-scale conversation corpus:

$$loss = \mathcal{L}_{\mathrm{M}} + \mathcal{L}_{rc} + \mathcal{L}_{kl}^{'} + \mathcal{L}_{BOW} \tag{9}$$

To sum up, we mask text spans in the context c, sample a latent variable z from prior network, and then let the encoder and decoder predict the masked spans and response r respectively with the guidance of the latent variable z.

3 Experiments

In this section, we firstly introduce the pre-training datasets and fine-tuning benchmarks in § 3.1, and implement details in § 3.2. Then we present the main results in § 3.3. Lastly, we analyze the influence of parameters and position embeddings in § 3.4.

3.1 DataSets and Baselines

3.1.1 Pre-training Corpus

Large-scale Reddit comments dataset (Zhou et al., 2018; Galley et al., 2019) is employed for pre-training our dialog language model. This dataset has been proved to be helpful in various conversation downstream tasks (Bao et al., 2020; Zhang et al., 2020). We use the script provided by DialoGPT (Zhang et al., 2020) to obtain the latest Reddit comment data. We obtain 215 million[1] training samples (42GB in total) for pre-training.

To accelerate the training process and accommodate GPU memory limitations, we adopt two methods. First, we sort the samples according to the length of the context. Samples with similar length (i.e. number of tokens in context) are assembled into a batch to minimize the amount of padding. Secondly, due to the uneven distribution of sample lengths, we divide the Reddit corpus into two sub-datasets: **Reddit-Short** and **Reddit-Long** according to the length of context and response. with some statistics in Table 1, and optimize the batch size for each sub-dataset to avoid reserving a large amount of memory for a few long response samples during the training process. Within an epoch, we first pre-train on **Reddit-Short** with a larger batch size, and then pre-train **Reddit-Long** with a smaller batch size. We split the reddit comment dataset here mainly for efficiency.

Task	Dataset	# Examples	# Turns	# Tokens
Pre-train	Reddit-Short	214M	2.6	28.6/16.0
	Reddit-Long	726K	6.9	137.1/21.2
Fine-tune	DailyDialog	76K	5.9	75.6/15.0
	Persona-Chat	122K	8.4	95.1/12.2
	DSTC7-AVSD	76K	10.9	102.1/10.7

Table 1: Dataset statistics used for pre-training and fine-tuning in this paper, where # Turns means avg. turns, and # Tokens means avg. tokens of context and response (separated by slashes) after WordPiece tokenization (Devlin et al., 2019).

3.1.2 Fine-tuning Benchmarks

Following PLATO (Bao et al., 2020), we select three datasets as our benchmarks:

DailyDialog (Li et al., 2017), a chit-chat dataset, which contains high-quality human conversations about daily life.

Persona-Chat (Zhang et al., 2018), a knowledge grounded conversation dataset. It provides both manually annotated conversations and corresponding persona profiles (background knowledge), where two participants chat naturally and try to get to know each other.

DSTC7-AVSD (Alamri et al., 2019a), a conversational question answering dataset, shorts for Audio Visual Scene-aware Dialog of the DSTC7 challenge. The system needs to generate an answer given dialogue context and background knowledge. There are multiple reference responses for each context in DSTC7-AVSD test set.

For evaluation, we use the same metrics as used in PLATO, except for knowledge-related metrics, since this paper does not focus on utilizing knowledge. So we will focus the following metrics:

BLEU-1/2 (Papineni et al., 2002), which measures the relevance of generated text to the reference text by calculating the 1/2-gram overlapping between them.

Distinct-1/2 (Li et al., 2016a), which measures the diversity of a generated sentence by focusing on the number of distinct 1/2-gram of a sentence

---

[1] Given an instance containing multiple turns of dialogue $\{t_1, t_2, ..., t_n\}$, we extract $n-1$ samples (i.e. context-response pairs), where the context c is $\{t_1, t_2, ..., t_{i-1}\}$, and the response r is $\{t_i\}$, for $i = \{2, 3, ..., n\}$.

and thus penalizing sentences with lots of repeated words.

Other word-overlap-based metrics, METEOR, ROUGE-L, and CIDEr, which are also reported for the DSTC7-AVSD dataset, same as DSTC7 reviews (Alamri et al., 2019b).

3.1.3 Baselines

Vanilla sequence to sequence (Seq2Seq) models, dialog pre-training models, and general natural language pre-training models are used as our baselines: **Seq2Seq** (Vinyals and Le, 2015) is a sequence-to-sequence model with attention. **iVAE$_{\text{MI}}$** (Fang et al., 2019) is an implicit deep latent variable model based on Variational Autoencoder for better latent representations and diverse responses. **LIC** (Golovanov et al., 2019) obtains the best performance during the contest, and is one transformer based generation method. **PLATO** (Bao et al., 2020) utilizes a discrete latent variable for dialog generation pre-training to address the one-to-many problem. **ProphetNet** (Qi et al., 2020) is a pre-trained LM model with predicting more than one future tokens as the pre-training objective. We fine-tune ProphetNet-Large model released in (Qi et al., 2020) with downstream training data directly.

For benchmark DSTC7-AVSD, we include AVSD Baseline (Alamri et al., 2019a) system provided by the the challenge organizer, as well as the best performing model developed by the team of CMU Sinbad's (Sanabria et al., 2019).

3.2 Model Configuration

DialogVED is composed of a 12-layer encoder and a 12-layer decoder, with 1024 embedding/hidden size and 4096 feed-forward filter size. The dimension P of hidden states z is set to 64 and we will analyze the effect of P in § 3.4.1. We use Adam optimizer (Kingma and Ba, 2014) with a learning rate of 3×10^{-4} for pre-training. We set ngram as 2 following ProphetNet (Qi et al., 2020). The pre-training of dialogue generation is carried out on 32 Nvidia Telsa V100 32G GPU (4 nodes) for 6 epochs, taking about 5 days to reach convergence. Mixed precision training is also adopted for efficiently training and inference, and we use the Fairseq (Ott et al., 2019) framework to conduct all experiments. We use the BERT-uncased dictionary, and replace some unused tokens to custom special symbols (such as [SOT], denoting the beginning of the conversation, which is suitable for conversation datasets containing knowledge, like PersonaChat and DSTC7-AVSD). We used package WordPiece (Devlin et al., 2019) for tokenization.

For fine-tuning, we use exactly the same hyperparameter settings in all three datasets, and they are slightly different from the hyperparameter in pre-training. The learning rate is set to 1×10^{-4}

and the batch size is fixed to 512. We also adopt an additional warmup strategy where we linearly increase the learning rate from initial learning rate (1×10^{-7}), the number of warmup updates is set to 2000. For each dataset, we train 10 epochs, and select the checkpoint with the lowest validation loss for inference.

3.3 Main Results

In Table 2, we compare several DialogVED variants with baseline models. **DialogVED** represents inferencing DialogVED with beam search. Compared with DialogVED, **DialogVED w/o latent** is not equipped with latent variable, thus the loss function does not include bag-of-words loss and K-L loss. **DialogVED Greedy** means DialogVED inference with greedy search. For **DialogVED Sampling**, we sample from the top K tokens with the highest output probability at each decoding step. For the latent space, we always sample each latent variable from the prior distribution standard normal distribution. Here, beam size is set to 5 and K is set to 100.

As shown in Table 2 and Table 3, our model DialogVED is very competitive compared to PLATO and other models. In particular, decoding using Top-K ($K = 100$) sampling with DialogVED beats the PLATO in BLEU-1/2 and Distinct-1/2 on DailyDialog and PersonaChat (see in Table 2). In fact, as K increases, the overlap of n-grams decreases and the diversity increases. Based on our observations, K taking 100 is a good balance, Table 4 shows more detailed results.

On the DSTC7-AVSD, the diversity of the responses is not as important as the accuracy. From Table 3, We observe that DialogVED w/o latent variable perform the best in overall metrics. However, DialogVED equipped with beam search or greedy search, can still easily beat PLATO even though it has a post-generation ranking component.

There are 2 essential components that contribute greatly the success of our model: Firstly, We adopt a newly developed pretrained LM as the initializer and further continue its pretraining pipeline on our dialog dataset (Reddit) and thus we have a really powerful encoder-decoder. This is demonstrated in the fact that our model (DialogVED w/o latent variable) beat PLATO (w/o latent variable) in all metrics on all the three datasets.

Secondly, the special structure of our model combines the benefits of both seq2seq models and VAE models. Compared to general VAEs, DialogVED allows encoder-decoder interaction in the decoding, which avoids insufficient representation of low-dimensional latent variable. At the same time, compared with seq2seq model, predicting the bag of words pushes the latent variable to give extra guidance to decoder. This is demonstrated by the fact that when compared with DialogVED w/o latent variable, we observe the additional gains in terms of both accuracy and diversity (see Table 2).

Overall, our DialogVED achieves new state-of-the-art results in all three downstream tasks of dialogue response generation.

3.4 Parameters and Position Analysis

3.4.1 Balancing Accuracy and Diversity with Sampling

We investigate the effect of latent space sizes, P, defined as the dimension of the latent variable z and the different K in sampling.

The results in Table 4 show that smaller latent size ($P = 32$) is more dominant in n-gram based metrics (BLEU-1/2), while larger latent size generates more diverse texts. From the results of top-K sampling, we see that the two metric (BLEU-1/2 and Distinct-1/2) have a negative correlation.

We can flexibly choose the decoding strategy depends on specific scene.

P	Top-K	BLEU-1	BLEU-2	Distinct-1	Distinct-2
32	5	**0.448**	**0.385**	0.042	0.289
	20	0.443	0.376	0.045	0.317
	50	0.442	0.375	0.047	0.332
	100	0.439	0.374	0.051	0.347
64	5	0.442	0.383	0.046	0.308
	20	0.437	0.374	0.050	0.340
	50	0.434	0.371	0.054	0.364
	100	0.431	0.370	**0.058**	**0.372**

Table 4: The results of different latent size and Top K on DailyDialog dataset. P is the dimension of the latent variable.

3.4.2 Position Embeddings

We study the impact of position embeddings as described in section 2.7, we define two types of position embeddings: absolute position embeddings (APE) and relative position embeddings (RPE). We report the metrics of their different combinations, these independent components are TurnAPE (turn absolute embedding), RoleAPE (role absolute embedding), TokenRPE (token relative embedding) and TurnRPE(turn relative embedding) respectively.

As the results shown in Table 5, the combination of TurnAPE and RoleAPE achieve the best performance. Both absolute and relative position embeddings improve model performance, nevertheless, including them at the same time can be harmful.

Turn APE	Role APE	Token RPE	Turn RPE	BLEU-1/2	Distinct-1/2
				0.481/0.421	**0.042/0.232**

3.5 Human Evaluation

Automated metrics (BLEU 1/2, Distinct-1/2, etc.) have limitations for evaluating open-domain dialog tasks. To make it more convincing, we conduct a human evaluation. Specifically, we randomly select 100 dialogue contexts and generate responses with the following methods: PLATO, DialogVED and DialogVED-Sampling. Following PLATO, annotators are asked to compare the response (win, tie or lose) quality from four aspects: fluency, coherence, informativeness and overall.

The results of human comparison are shown in Table 6, where the average Cohen's kappa (Kraemer, 2014) of group 1 and 2 is 0.729 and 0.743 respectively, indicating annotators have reached moderate agreement. It can be seen that most of the time they are tied, and the three models sometimes generate exactly the same response. For DialogVED, it beats Plato more in coherence but with close informativeness; while DialogVED-sampling beats Plato significantly in informativeness but with a slightly weaker coherence.

	Group 1		Group 2	
	Win	Lose	Win	Lose
Fluency	**0.16**	0.11	**0.19**	0.13
Coherence	**0.38**	0.16	0.22	**0.24**
Informativeness	**0.13**	0.11	**0.31**	0.14
Overall	**0.26**	0.14	**0.24**	0.17

Table 6: Human evaluation of DialogVED vs. PLATO (Group 1) and DialogVED-sampling vs. PLATO (Group 2).

In general, DialogVED can generate both relevant and diverse response, we show some case study to help illustrate the effectiveness of our model in Appendix A.

4 Related Work

Encoder-Decoder dialog models Unlike retrieval based dialogue systems (Boussaha et al., 2019; Chen et al., 2021), encoder-decoder models are widely used in dialog response generation, but it tends to generate generic responses and dull responses (e.g., I don't know). To enhance encoder-decode models and generate diverse responses, researchers have tried different approaches: using diversity promotion objectives (Li et al., 2016a), using different decoding algorithms (Li et al., 2016b), adding additional contents (Xu et al., 2019), or introducing large-scale knowledge graphs into dialog generation (Liu et al., 2018; Wu et al., 2020).

Another class of methods is using the latent variable to address the one-to-many problem in response generation. These models introduce discourse-level diversity and are able to generate diverse dialog responses (Serban et al., 2017; Zhao et al., 2017a, 2018; Gao et al., 2019). In this paper, we also adopt this approach and further we incorporate the latent variables both in the pre-training and fine-tuning.

Pre-trained Dialog Models Pre-trained language models have been successfully used in NLG and NLU tasks (Devlin et al., 2019; Radford et al., 2019). Recently, various new pre-trained language models have been pre-trained including BART (Lewis et al., 2020), ProphetNet (Qi et al., 2020), T5 (Raffel et al., 2020). In these papers, they demonstrate that better performance can be obtained with fine-tuning PLMs than training from scratch.

Due to the fact that there are many important applications in the dialog domain and the dialog corpus has different linguistic features from general documents, pre-trained dialog models with open domain dialog data such as Reddit is very important. DialoGPT (Zhang et al., 2020) continues to pre-train GPT-2 model directly on Reddit comments data, and the new pre-trained model achieves better performance on downstream tasks including several dialog response generation benchmarks.

PLATO (Bao et al., 2020) proposes a new model specifically for dialog generation, which introduces a discrete variable for one-to-many relationship modeling. The pre-trained model helps to achieve state-of-the-art results on several response generation tasks. This is the closest work in literature to ours. However, in our paper, we introduce continuous latent variables during pre-training on dialog corpus instead of a discrete latent variable.

5 Conclusion

This paper proposes a new pre-training framework for dialogue response generation called DialogVED. The latent variable is incorporated into the sequence-to-sequence framework based on Transformer, and obtains a robust and diverse response generation model through 4 training targets. our pre-trained model has achieved new state-of-the-art in multiple downstream tasks of dialogue response generation. Extensive experiments prove the effectiveness of our model. Additional human evaluation demonstrates the advantages of our proposed model.

This work is partially supported by Natural Science Foundation of China (No.6217020551, No.61906176), Science and Technology Commission of Shanghai Municipality Grant (No.20dz1200600, 21QA1400600, GWV-1.1, 21511101000) and Zhejiang Lab (No. 2019KD0AD01).

Ethical Statement

In this paper, different ethical restrictions deserve discussion.

All data used in our pre-training are available online and other dialog corpus in this paper are publicly available sources. We strictly followed the platform's policies and rules when crawling data from web platforms. We did not employ any author-specific information in our research.

Our corpus may includes some bias, such as political bias and social bias, and our model might have inherited some forms of these bias. In order to limit these bias as much as possible, we filter controversial articles and removed data with offensive information when possible.

A Case Study

We demonstrate the responses generated from our model as well as other baseline models in Table 7, 8 and 9, respectively. The results in Table 8 and 9 show that our model accurately outputs the knowledge information contained in context although we do not model knowledge explicitly. Compared with beam search or greedy decoding, decoding with top-K sampling not only generates bolder and more diverse response, but also can maintain good relevance, as showed in Table 7 and 8.

Context	[P2] have you seen the new cosmo magazine that i was reading this morning ? [P1] i think i may have seen it on the kitchen table . [P2] you're right , thanks . there's an interesting interview with a top director about his latest film that i want to finish . [P1] who's the director ?
GOLD	it ' s martin scorsese . you liked his film , the departed , didn ' t you ?
Model	**Response**

Abstract

We study the problem of coarse-grained response selection in retrieval-based dialogue systems. The problem is equally important with fine-grained response selection, but is less explored in existing literature. In this paper, we propose a **C**ontextual **F**ine-to-**C**oarse (CFC) distilled model for coarse-grained response selection in open-domain conversations. In our CFC model, dense representations of query, candidate contexts and responses is learned based on the multi-tower architecture using contextual matching, and richer knowledge learned from the one-tower architecture (fine-grained) is distilled into the multi-tower architecture (coarse-grained) to enhance the performance of the retriever. To evaluate the performance of the proposed model, we construct two new datasets based on the Reddit comments dump and Twitter corpus. Extensive experimental results on the two datasets show that the proposed method achieves huge improvement over all evaluation metrics compared with traditional baseline methods.

1 Introduction

Given utterances of a query, the retrieval-based dialogue (RBD) system aims to search for the most relevant response from a set of historical records of conversations (Higashinaka et al., 2014; Yan et al., 2016; Boussaha et al., 2019). A complete RBD system usually contain two stages: coarse-grained response selection (RS) and fine-grained response selection (Fu et al., 2020). As shown in Figure 1, in coarse-grained RS stage, the retriever identifies a much smaller list of candidates (usually dozens) from large-scale candidate database (up to millions or more), then the ranker in fine-grained RS stage selects the best response from the retrieved candidate list.

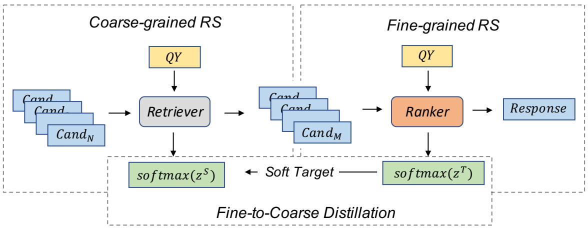

Figure 1: A common structure of retrieval-based dialogue system, where coarse-grained RS provides a much smaller ($M \ll N$) candidate set for fine-grained RS. *QY* and *Cand* are the abbreviations of *query* and *candidate* respectively.

Recent studies (Whang et al., 2020; Xu et al., 2020, 2021; Whang et al., 2021) pay more attention on fine-grained RS and various complex models are proposed to compute the similarities between the query and candidates for response selection. Although promising improvements have been reported, the performance of fine-grained stage is inevitably limited by the quality of the candidate list constructed. Therefore, a high-quality coarse-grained RS module is crucial, which is less explored in existing literature (Lan et al., 2020).

In this paper, we focus on the task of coarse-grained response selection, i.e., dialogue response retrieval. There are two major challenges. First, different from general text matching tasks such as ad-hoc retrieval (Hui et al., 2018) or question answering (QA) retrieval (Karpukhin et al., 2020), keywords overlapping between context and response in dialogue are potentially rare, such as when a topic transition (Sevegnani et al., 2021) occurs in response. This makes it difficult to directly match the query with candidate responses. Second, compared with fine-grained RS, coarse-grained RS deals with much larger number of candidates. Therefore, it is impractical to apply complex matching model that jointly process query and response for the similarity computation like in fine-grained RS, due to the retrieval latency (traverse millions of candidates on-

line). Instead, the efficient BM25 system (Robertson and Zaragoza, 2009) based on sparse representations is the mainstream algorithm in coarse-grained text matching.

To mitigate the above mentioned two problems, we propose a **C**ontextual **F**ine-to-**C**oarse (CFC) distilled model for coarse-grained RS. Instead of matching query with response directly, we propose a novel task of query-to-context matching in coarse-grained retrieval, i.e. *contextual matching*. Given a query, it is matched with candidate contexts to find most similar ones, and the corresponding responses are returned as the retrieved result. In this case, the potential richer keywords in the contexts can be utilized. To take the advantage of complex model and keep the computation cost acceptable, we distillate the knowledge learned from fine-grained RS into coarse-grained RS while maintaining the original architecture.

For the evaluation, there is no existing dataset that can be used to evaluate our model in the setting of contextual matching, because it needs to match context with context during training, while positive pairs of context-context is not naturally available like context-response pairs. Therefore, we construct two datasets based on Reddit comment dump and Twitter corpus. Extensive experimental results show that our proposed model greatly improve the retrieval recall rate and the perplexity and relevance of the retrieved responses on both datasets.

The main contributions of this paper are threefold: 1) We explore the problem of coarse-grained RS in open domain conversations and propose a Contextual Fine-to-Coarse (CFC) distilled model; 2) We construct two new datasets based on Reddit comment dump and Twitter corpus, as a new benchmark to evaluate coarse-grained RS task; 3) We construct extensive experiments to demonstrate the effectiveness and potential of our proposed model in coarse-grained RS.

2 Related Work

Fine-grained Response Selection In recent years, many works have been proposed to improve the performance of fine-grained selection module in retrieval-based chatbots (Zhang et al., 2018; Zhou et al., 2018; Tao et al., 2019; Whang et al., 2019; Yuan et al., 2019). Owing to the rapid development of pre-trained language models (PLMs) (Radford et al., 2019), recent works (Gu et al., 2020; Whang et al., 2021; Sevegnani et al., 2021) achieve the state-of-the-art (SOTA) results by utilizing PLMs such as BERT (Devlin et al., 2018) to model cross-attention and complex intersection between the context and response.

Coarse-grained Response Selection On the other hand, coarse-grained dialogue retrieval is an important but rarely explored field. Limited by efficiency, there are usually two methods for coarse-grained response selection, i.e., the sparse representations based method represented by BM25 (Robertson and Zaragoza, 2009), and the dense representations based method represented by dual-Encoder (Chidambaram et al., 2018; Humeau et al., 2019; Karpukhin et al., 2020; Lan et al., 2020; Lin et al., 2020).

3 Method

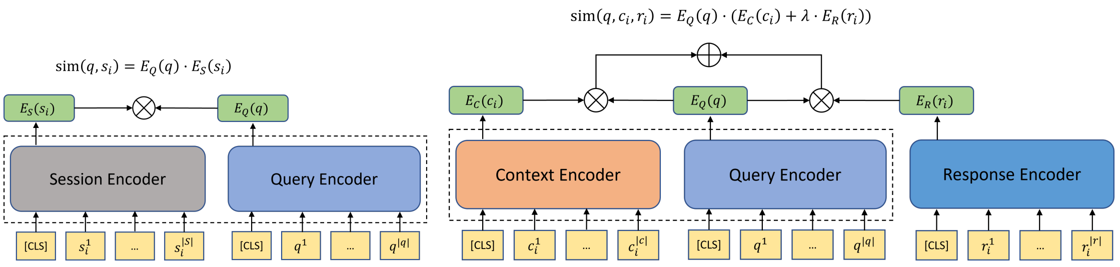
In coarse-grained response selection, there is a fixed candidate database containing a large number of *context-response* pairs. Formally, given a *query*, i.e., a new context, the goal is to retrieve Top-K most suitable *responses* for the *query* from the candidate database.

We propose a contextual fine-to-coarse distillation framework for the task of coarse-grained RS. First, we formulate the problem as a task of **contextual matching**, i.e., match query with context instead response; Second, we utilize a **multi-tower architecture** to deal with the similarity computation of query and candidates in contextual matching; Third, we utilize **knowledge distillation** to leverage the deep interaction between query and response learned in one-tower architecture.

3.1 Contextual Matching

An intuitive idea of coarse-grained RS is to treat all responses as candidate documents and directly use query to retrieve them, while this non-contextual approach results in a quite low retrieval recall rate (Lan et al., 2020). Inspired by recent studies of context-to-context matching in fine-grained RS (Fu et al., 2020), we propose contextual matching in coarse-grained RS, which is to match the query with candidate contexts, and return the responses corresponding to the most similar contexts. We consider three ways of contextual matching.

Query-Context (QC) In QC matching, we treat contexts instead of responses as candidate documents. At run-time, we calculate the similarities between query and candidate contexts, and the re-



(a) Two-tower model based on QS matching

(b) Three-tower model based on DQS matching

Figure 2: Multi-tower architecture with independent encoders, the hidden representation of the [CLS] token of each sequence is passed through a linear layer followed by a hyperbolic tangent (Tanh) activation function to get the dense representations (embeddings) of the entire sentence.

sponses corresponding to the Top-K most similar contexts are returned as the retrieved results. The motivation of using QC matching is similar contexts may also share similar responses.

Query-Session (QS) A **session** represents the concatenated text of context and corresponding response (Fu et al., 2020), which we think is more informative than context alone. In QS matching, we treat sessions as candidate documents and return the responses in Top-K most similar sessions as the retrieved results.

Decoupled Query-Session (DQS) Apart from QS matching, we also consider a decoupled way to match query with candidate sessions. In DQS matching, we treat contexts and responses as independent candidate documents. Similarities between query and contexts, query and responses are first calculated independently, then the query-session similarity can be obtained by the weighted sum. QS and DQS matching are actually two different ways to calculate query-session similarity.

3.2 Multi-Tower Architecture

For the retriever to search large-scale candidates with low latency, neural-based retrievers are usually designed as (or limited to) *multi-tower* architecture (Figure 2). In multi-tower models, the query and the candidates are independently mapped to a common vector space by different encoders, where similarity can be calculated. After training, the embeddings of large-scale candidates can be **pre-calculated offline**, and only the embedding of query needs to be calculated online. In this way, fast sublinear-time approximation methods such as approximate nearest neighbor search (Shrivastava and Li, 2014) can be utilized to search for Top-K vectors that are most similar to the query, which can achieve an acceptable retrieval latency during inference.

3.2.1 Two-Tower Model

For QC and QS matching, *two-tower* architecture is adopted. Taking QS matching as an example (Figure 2(a)), the dense *session encoder* $E_S(\cdot)$ maps any candidate session to real-valued embedding vectors in a d-dimensional space, and an index is built for all the N session vectors for retrieval. At run-time, a different dense *query encoder* $E_Q(\cdot)$ maps the query to a d-dimensional vector, and retrieves k candidate sessions of which vectors are the closest to the query vector. We use the *dot product* of vectors as the similarity between query and candidate session following (Karpukhin et al., 2020).

3.2.2 Three-Tower Model

For DQS matching, dense representations of query, context and response are independently calculated, the architecture is thus designed as *three-tower* with three encoders, which is *query encoder* $E_Q(\cdot)$, *context encoder* $E_C(\cdot)$ and *response encoder* $E_R(\cdot)$ (Figure 2(b)). Similarly, context and response vectors are calculated and cached offline respectively and two indexes are built for retrieving them. The final similarity of query and session is weighted by the dot product of query-context and query-response. The weighting coefficient λ can be adjusted to determine whether it is biased to match the context or match the response[1].

3.2.3 Training Multi-Tower Model

We unify the training of the two-tower and three-tower models by formalizing them into a same *met-*

---

[1] In all experiments in this paper, λ is set to 1 to treat candidate context and response equally.

ric learning problem (Kulis et al., 2012). The goal is to learn a matching space where similarities between positive pairs is higher than negative ones, by learning a better embedding function. We use the training of three-tower model (DQS matching) as an example. Formally, we denote the training set as $\mathcal{D} = \{q_i, \{k_i^+, k_i^-\}\}_{i=1}^N$. Each training instance contains a query q_i, a set of positive examples k_i^+ and a set of negative examples k_i^-. Among them, k_i^+ contain several positive contexts and several positive responses, similarly, k_i^- contain several negative contexts and several negative responses. We optimize the loss function as the sum of negative log likelihood of all positive pairs simultaneously:

$$\mathcal{L}(q_i) = -log \frac{\sum_{k' \in \{k_i^+\}} e^{\mathrm{sim}(q_i, k')}}{\sum_{k' \in \{k_i^+, k_i^-\}} e^{\mathrm{sim}(q_i, k')}} \quad (1)$$

where the similarity function is defined as:

$$\mathrm{sim}(q_i, k') = E_Q(q_i) \cdot E(k'). \quad (2)$$

The embedding function $E(\cdot)$ of k' in Equation 2 can be $E_C(\cdot)$ or $E_R(\cdot)$, depending on the type of k'.

Positive and negative examples The core issue of training multi-tower models for contextual matching is to find positive pairs of query-context (or query-session). In this paper, we assume that contexts with exactly the same response are positive samples of each other, which is a cautious but reliable strategy. Formally, given a response r, if there are multiple contexts whose response is r, then we can randomly selected one context as the query q, and the other contexts are **positive contexts** of q, and r is the **positive response** of q. Negative samples of contexts and responses can be obtained from in-batch (Karpukhin et al., 2020) or random sampling from database. Similarly, positive query-session is obtained by replacing the context in positive query-context with the whole session.

3.3 Distillation from One-Tower Model

In multi-tower architecture, the query and candidates are expressed by their embeddings independently, which may cause the loss of information, and their monotonous way of interaction (inner product) further limits the capability (Lin et al., 2020). Comparing with multi-tower model, one-tower model takes both the query and the candidate as a concatenated input and allow the cross attention between query and candidate in self-attention layer. Despite fewer parameters, one-tower model have been shown to learn a more informative representations than multi-tower model, thus it is preferred in fine-grained RS (Yang and Seo, 2020). To leverage the richer expressiveness learned by the one-tower model, knowledge from one-tower model is distilled into multi-tower model to enhance the retriever.

3.3.1 Training One-Tower Model

Before distillation, we need to train teacher models based on one-tower architecture. Let's take the training of teacher model for QS matching as an example. A single encoder is trained to distinguish whether the query and the session are relevant (positive), and the form is exactly same as the next sentence prediction (NSP) task in the BERT (Devlin et al., 2018) pre-training. Formally, given a training set $\mathcal{D} = \{q_i, s_i, l_i\}_{i=1}^N$, where q_i is the query, s_i is the candidate session and $l_i \in \{0, 1\}$ denotes whether q_i and s_i is a positive pair. To be specific, given a query q and candidate session s, the encoder obtains the joint representation of the concatenated text of q and s, and then computes the similarity score through a linear layer, the training objective is binary cross entropy loss.

We summarize the **main difference** between one-tower and multi-tower as follows: one-tower model is more expressive, but less efficient and cannot handle large-scale candidates. The main reason is that feature-based method of calculating similarity scores rather than inner product limits the capability of offline caching. For new queries, the similarities with all candidates can only be calculated by traversal. The huge latency makes it impossible to use one-tower model in coarse-grained response retrieval. To leverage the expressiveness of one-tower model, we propose fine-to-coarse distillation, which can learn the knowledge of one-tower model while keeping the multi-tower structure unchanged, thereby improving the performance of the retriever.

3.3.2 Fine-to-Coarse Distillation

Take the two-tower **student** model (denoted as S) for QS matching as an example, suppose we have trained the corresponding one-tower **teacher** model (denoted as T). For a given query q, suppose there are a list of sessions $\{s^+, s_1^-, ..., s_n^-\}$ and the corresponding label $y = \{1, 0, ..., 0\} \in \mathcal{R}^{n+1}$, that is, one positive session and n negative sessions. We denote the similarity score vector of query-sessions computed by student model S (Equation 2) as $z^S \in \mathcal{R}^{n+1}$, then the objective of Equation 1 is equivalent to maximizing the Kullback–Leibler (KL) divergence (Van Erven and Harremos, 2014) of the two distributions: $\mathrm{softmax}(z^S)$ and y, where softmax function turns the score vector to probability distribution.

The one-hot label y treats each negative sample equally, while the similarity between query with each negative sample is actually different. To learn more accurate labels, we further use teacher model T to calculate the similarity score vector between q and S, denoted as $z^T \in \mathcal{R}^{n+1}$. We then replace the original training objective with minimizing KL divergence of the two distributions $\mathrm{softmax}(z^S)$ and $\mathrm{softmax}(z^T)$ (Figure 1), where the temperature parameter is applied in softmax function to avoid saturation.

The method of fine-to-coarse distillation is to push the student model (multi-tower) to learn the predicted label of teacher model (one-tower) as a soft target instead of original one-hot label. By fitting the label predicted by the teacher model, the multi-tower model can learn a more accurate similarity score distribution from the one-tower model while keeping the structure unchanged.

4 Datasets Construction

To evaluate the performance of the proposed model, we construct two new datasets based on the Reddit comments dump (Zhang et al., 2019) and Twitter corpus[2]. We create a training set, a multi-contexts (MC) test set and a candidate database for Reddit and Twitter respectively. For Reddit, we create an additional single-context (SC) test set. The motivation for these settings is explained in § 5.3. The size of our candidate database is one million in Twitter and ten million in Reddit respectively, which is very challenging for response retrieval. Table 1 shows the detailed statistics. We use exactly the same steps to build dataset for Reddit and Twitter, and similar datasets can also build from other large dialogue corpus in this way.

MC test set We first find out a set of responses with multiple contexts from candidate database, denoted as R. For each response r in R, we randomly select one context c from its all corresponding contexts C_r to construct a context-response (CR) pair, and put the others contexts (denoted as C_r^-) back to the database. Our MC test set consists of these CR pairs. Each response in MC test set has multiple contexts, which ensures that there exits other contexts in the database that also correspond to this response, so the retrieval recall rate can be computed to evaluate the MC test set.

Datasets	Training set	Test set MC	Test set SC	Database
Reddit	300K	20K	20K	10M
Twitter	20K	2K	-	1M

Table 1: Data statistics of our new constructed datasets.

SC test set We create another test set (SC) for Reddit dataset. Contrary to the MC test set, each response in SC test set has only one context, i.e., there is no context in the database that exactly corresponds to the response. Obviously, the retrieval recall rate is invalid (always zero) on SC test set. We introduce other methods to evaluate SC test set in § 5.2. The SC test set is a supplement to the MC test set which can evaluate the quality of retrieved responses given those “unique" contexts.

Candidate database To adapt to different retrieval methods, the candidate database is designed with 4 fields, namely *context*, *response*, *session*. Our candidate database consists of random context-response pairs except those in the MC and SC test sets. Besides, as mentioned above, those unselected context-response pairs (C_r^-) are deliberately merged into the database.

Train set The construction of training set is intuitive and similar to test set. It consists of responses and their corresponding multiple contexts. Formally, the training set can be denote as $D = \{r_i, c_{i,1}, ..., c_{i,q}\}_{i=1}^N$, r_i is a response and $\{c_{i,1}, ..., c_{i,q}\}$ are all contexts with response r_i, where q depends on r_i, and $q \geq 2$.

It is worth noting that there is no overlap between the contexts in the database and the contexts in the training set, which may prevent potential data leakage during training process to overestimate the evaluation metrics. The details of dataset construction are introduced in Appendix A.

5 Experiments

We conduct extensive experiments on the constructed datasets. In this section, we present experimental settings, evaluation metrics, model performance, human evaluation, etc. to demonstrate the effectiveness of the proposed models.

5.1 Compared Models

For baselines, we select BM25 (Robertson and Zaragoza, 2009) as sparse representations based method, which is widely used in real scenarios in text matching. Based on BM25 system and the two matching methods (QC and QS matching), two retrievers can be obtained, denoted as BM25-QC and BM25-QS respectively. We choose multi-tower models as dense representations based methods. They are **b**i-**e**ncoder based two-tower models for QC matching and QS matching (denoted as BE-QC and BE-QS), and **t**ri-**e**ncoder based three-tower model for DQS matching (denoted as TE-DQS). In addition, to demonstrate the advantages of contextual matching, we also report the results of query-response (QR) matching, two retrievers are build based on BM25 system and two-tower model (denoted as BM-QR and BE-QR).

There are three variants of our proposed CFC models, they are the distilled versions of BE-QC, BE-QS and TE-DQS, which are called CFC-QC, CFC-QS and CFC-DQS respectively. The distillation of each student model needs to train the corresponding teacher model. In particular, the distillation from TE-DQS to CFC-DQS requires two teacher models, because the similarity between both query-context and query-response needs to be calculated.

We summarize the details of compared models and provide training details in Appendix B.

5.2 Evaluation Metrics

Following previous work (Xiong et al., 2020; Karpukhin et al., 2020), **Coverage@K** is used to evaluate whether Top-K retrieved candidates include the ground-truth response. It is equivalent to recall metric $R_M@K$ that often used in fine-grained RS, where N is the size of candidate database. However, Coverage@K is only suitable for evaluating the MC test set, and it is incapable for evaluating the overall retrieval quality due to the one-to-many relationship between context and response. As a supplement, we propose two automated evaluation metrics based on pre-trained models, i.e., **Perplexity@K** and **Relevance@K**. For retrieved Top-K responses, DialogGPT (Zhang et al., 2019) is used to calculate the conditional perplexity of the retrieved response given the query. DialogGPT is a language model pre-trained on 147M multi-turn dialogue from Reddit discussion thread and thus very suitable for evaluating our created Reddit dataset. Perplexity@K is the average perplexity of Top-K retrieved responses. In addition to Perplexity, we also evaluate the correlation between the query and retrieved response. We use DialogRPT (Gao et al., 2020), which is pre-trained on large-scale human feedback data with the *human-vs-rand* task that predicts how likely the response is corresponding to the given context rather than a random response. Relevance@K is the average predicted correlation degree between query and Top-K retrieved responses. Perplexity@K and Relevance@K are average metrics based on all Top-K retrieved responses, so they can reflect the overall retrieval quality.

5.3 Overall Performance

We demonstrate the main results in Table 2 and Table 3 and discuss model performance from multiple perspectives.

Dense vs. sparse It can be seen that the performance of dense retrievers far exceed that of the BM25 system, which shows rich semantic information of PLMs and additional training can boost the performance of the retriever. For example, compared with BM25 system, the best undistilled dense retrievers (BE-QS) have a obvious improvement in three metrics. For Coverage@K, the Top-500 recall rate of BE-QS on the MC test set of Reddit and Twitter increase by 12.1% and 17.4% absolute compared with BM25-QS. For Perplexity@K, the Top-20 average perplexity of BE-QS on the MC and SC test sets of Reddit is reduced by 8.1 and 8.5 absolute compared with BM25-QS. For Relevance@K, the Top-20 average relevance of BE-QS on the MC and SC test sets on Reddit increase by 6.3% and 6.5% absolute compared with BM25-QS. Coverage@K measures the retriever's ability to retrieve gold response, while Perplexity@K and Relevance@K measure the overall retrieval quality. Our results show the consistency of the three metrics, namely, the recall rate and the overall retrieval quality have a positive correlation.

Matching method Compared with contextual matching, query-response (QR) matching has a

	MC Test Set								SC Test Set

CFC-QC	24.2	39.1	48.6	58.2
CFC-QS	**28.8**	**43.7**	**52.8**	**62.6**
CFC-DQS	28.2	43.3	52.5	61.9

Table 3: Automated evaluation metrics on Twitter test set, we report Coverage@1/20/100/500 on the MC test set.

much lower retrieval recall rate, which is also verified in (Lan et al., 2020). We think it is because that response is usually a short text of one-sentence and contains insufficient information, and there may be little keywords that overlap with the query. Therefore, it is important to consider contextual matching in the RBD system.

Compared to QC matching, QS and DQS matching should be encouraged in practice due to the additional information provided by the response. However, the BM25 system can not make good use of the information of response, as BM25-QS model does not show obvious advantages over BM25-QC on both Reddit and Twitter datasets. In contrast, dense retrieval models can effectively utilize the response. For example, BE-QS outperforms BE-QC greatly by 7.9% absolute in terms of Top-500 response retrieval recall rate in MC test set of Reddit. For QS and DQS matching, there is little difference in performance. Especially for SC test set on Reddit and MC test set on Twitter, the performance difference is minimal. One potential advantage of DQS is that it can utilize positive query-response pairs, whose number is much larger than positive query-context pairs.

Distillation benefit We further focus on the performance gain from fine-to-coarse distillation. The distilled models achieve obvious improvement in all three metrics. An obvious pattern is that the distilled models get more larger improvement with a smaller K. Take Twitter dataset as example, the Top-500 retrieval recall rate of CFC models increase by 1.5∼2.4 after distillation, while the Top-1 retrieval recall rate increased by 4.6∼6.7. On Perplexity@K and Relevance@K, our CFC models has similar performance. The significant improvement in the retrieval recall rate at small K's is especially beneficial to fine-grained response selection, because it opens up more possibility to the ranker to choose good response while seeing fewer candidates. The above results indicate that our student models benefit from learning or inheriting fine-grained knowledge from teacher models. To more clearly demonstrate the performance gains of our model after distillation, we provide the specific values of these gains in Table 8 in Appendix C.

Difference between Reddit and Twitter Since DialogGPT and DialogRPT is not pre-trained on Twitter, Perplexity@K and Relevance@K are not

Retriever	Coverage@K			
	Top-1	Top-20	Top-100	Top-500
BE-QC	1.31	5.28	8.12	12.26
↪ share	1.29	5.26	8.12	12.26
TE-DQS	1.47	**5.52**	**9.74**	**18.12**
↪ share	**1.49**	5.51	9.73	18.11

Table 4: Impact of parameter sharing on model performance.

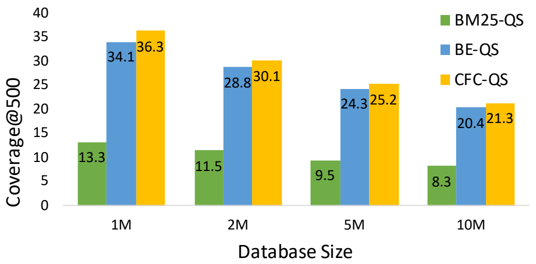

Figure 3: The Impact of database size on Coverage@500 metric of BM25-QS, BE-QS, CFC-QS.

suitable for evaluating Twitter dataset. Therefore, we do not build SC test set for Twitter. Compared to Twitter, the Reddit dataset we use is much larger with more common multi-turn conversations, and significantly higher retrieval difficulty. The Top-500 retrieval recall rate on Twitter reach 60%, while Reddit only reached about 20%, which indicates that the coarse-grained response retrieval task in open domain conversations still has great challenges.

6 Further Analysis

6.1 Parameter Sharing

Sharing parameters in dual-encoder structure is a common practice. As shown in Figure 2, for the encoders in the dotted line, sharing parameters may be beneficial. We try parameter sharing settings on the BE-QC and TE-DQS models, respectively. We add two sets of experiments on the MC test set of Reddit, as shown in Table 4. The results show that whether or not to share parameters has little impact on Coverage@K. Therefore, we can share encoder parameters to reduce model complexity with little loss of performance.

Our guess is as follows, the sampling strategy (with replacement) create a certain probability that the query and the context are exactly the same, so the multi-tower model can learn that two identical samples are positive samples for each other, even if the parameters of the encoders are not shared.

	Avg. Rank	Cohen's Kappa
CFC-QS	1.448	0.728
BE-QS	2.056	0.647
BM25-QS	2.494	0.626

Table 5: Human average rank score of BM25-QS, BE-QS and CFC-QS.

	Win	Loss	Cohen's Kappa
CFC-QS vs. BE-QS	0.747	0.253	0.634
CFC-QS vs. BM25-QS	0.816	0.184	0.672

Table 6: Human pairwise comparison of BM25-QS, BE-QS and CFC-QS.

6.2 Effect of Database Size

We discuss the impact of the size of candidate database on the performance of the model. For different candidate database size (from one million to ten million), we compare the Coverage@500 metric of BM25-QS, BE-QS, and CFC-QS on the MC test set of Reddit (Figure 3). It can be seen that Coverage@500 shows a slow downward trend as the database size increases. Increasing the size of the database will not make the model performance drop rapidly, which shows the effectiveness and robustness of our models.

6.3 Human Evaluation

To further evaluate and compare our models, we conduct a human evaluation experiment. We random select 1000 queries from the MC and SC test set (500 each) of Reddit dataset, and retrieve the Top-1 response by the BM25-QS, BE-QS and CFC-QS models respectively. Three crowd-sourcing workers are asked to score the responses. For each query, the annotator will strictly rank the retrieved responses of the three models. We report the average rank scores (between 1 and 3, the smaller the better) and the winning rate in pairwise comparison. Each two annotators have a certain number (about 200) of overlapping annotated samples. To evaluate the inter-rater reliability, the Cohen's kappa coefficient (Kraemer, 2014) is adopted.

Table 5 and Table 6 report the average ranking score of each model and pairwise comparison between models respectively. The average ranking score of CFC-QS is the highest, and CFC-QS can beat BE-QS and BM25 in most cases (74.7%∼81.6%), which indicates CFC-QS occupies a clear advantage in Top-1 retrieval. All Cohen's Kappa coefficients is between 0.6 and 0.7, indicating annotators reach moderate agreement. The results of human evaluation further verify the performance improvement brought by distillation to the model. We select several examples with human evaluation as case study and these results are presented in Appendix D.

6.4 Retrieval efficiency

We compare the retrieval latency of BM25-QS and BE-QS on the reddit MC test set, which represent the efficiency of the sparse and dense retriever respectively. We fix the batch size to 32 and retrieve top 100 most similar candidates. With the help of FAISS index, the average retrieval time of each batch by BE-QS is 581.8ms. In contrast, the average retrieval time by BM25 system using file index is 1882.6ms, about three times that of BE-QS. This indicates that the dense retriever also has an advantage in retrieval efficiency.

The relatively inferior of dense retriever is that it needs to compute the embeddings of the candidate database and establish the FAISS index, which is quite time-consuming and it takes about 9 hours for BE-QS to handle 10 million candidates with 8 GPUs, while it only takes about 10 minutes to build a BM25 index.

Since distillation does not change the structure of the retriever, it will not affect the retrieval efficiency. The cost of distillation is mainly reflected in the training of the teacher model and the extensive forward calculation in the distillation process.

7 Conclusion

In this paper, we propose a Contextual Fine-to-Coarse (CFC) distilled model. In CFC model, we adopt matching on both query-response and query-context. Considering the retrieval latency, we use multi-tower architecture to learn the **dense representations** of queries, responses and corresponding contexts. To further enhance the performance of the retriever, we distill the knowledge learned by the one-tower architecture (fine-grained) into the multi-tower architecture (coarse-grained). We construct two new datasets based on Reddit comment dump and Twitter corpus, and extensive experimental results demonstrate the effectiveness and potential of our proposed model. In the future work, we will further explore how the enhancement of coarse-grained RS can help fine-grained RS.

Ethical Statement

In this paper, different ethical restrictions deserve discussion.

The datasets we created are derived from large dialogue corpus that publicly available on the Internet, and we strictly followed the platform's policies and rules when obtaining data from web platforms. We did not use any author-specific information in our research.

Online large dialogue corpus may includes some bias, such as political bias and social bias, and our model might have inherited some forms of these bias. In order to limit these bias as much as possible, we filter controversial articles and removed data with offensive information when possible.

A Dataset Construction Details

To filter boring and dull content and speed up the retrieval speed, we set a limit for the length of contexts and responses. We limit the context to contain at least 5 words and less than 128 words, and the response contains at least 5 words and less than 64 words. It is specially beneficial to limit the length of the response, since according to our statistics, many short responses such as "*Fair Enough*" and "*Thanks :D*" may have large number (*tens of thousands*) of different contexts.

Besides, we also limit the upper limit of the number of contexts corresponding to the response. The number of contexts of each response in the MC test set is limited to no more than 50, which is to prevent the selected responses from being a meaningless universal response. The detailed construction of the two test sets is described in Algorithm 1.

To construct the training set, we need to find out responses that corresponding multiple contexts. We use dict to implement it, where the key is the response and the value is the list of corresponding contexts. During the training of the multi-tower model, in each iteration, a batch of keys is randomly sampled from the dict. For each key (i.e., each response) in the batch, two contexts are randomly selected from the corresponding value (i.e., the list of contexts), one of which is used as the query and the other is used as a positive context, and the key is used as a positive response. The other contexts and responses in the batch are all negative instances of the query.

Algorithm 1 Construction of SC & MC test set.

```
$R$: A set of unique responses.
$SC' = \varnothing$
$MC' = \varnothing$
for each $r \in R$ do
    $C_r = \text{FindAllContexts}(r)$    ▷ Find all contexts whose response is $r$.
    if $|C_r| > 1$ then
        $C_r^-, c = \text{Split}(C_r)$    ▷ Random pick one context $c$ from $C_r$, the remaining contexts is denoted as $C_r^-$.
        $MC' = MC' \cup \{c, r\}$
    else
        $SC' = SC' \cup \{c \in C_r, r\}$
    end if
end for each
$MC = \text{RandomSample}(MC')$
$SC = \text{RandomSample}(SC')$
return $SC$, $MC$
```

B Model Details

Due to the different matching methods, the training of different retrievers requires slightly different input. Taking BE-QC as an example, given a query, positive and negative contexts are needed to learn the representation of query and contexts, while in BE-QS, positive and negative sessions are required. Besides, the distillation of each student model requires training corresponding teacher model, and the data of training teacher model is consistent with the student model. We summarize the input, output, and training objectives of student and teacher models in Table 7.

To implement the BM25 method, we use Elasticsearch[3], which is a powerful search engine based on Lucene library (Białecki et al., 2012). For dense

	TE-DQS	--→	CFC-DQS	+6.7	+4.9	+3.0	+1.5	-	-	-	-

Table 8: Model performance gain after distillation on the MC test set of Reddit and Twitter dataset.

Number	Query	Method	Response	Rank
Case 1	My pc Isn’t good enough unfortunately	Gold	How old is your computer ?	-
		CFC-QS	what are your PC specs ?	1
		BE-QS	Idk but apps aren’t great on ps4 . My roku ultra is much faster for whatever reason .	2
		BM25	I’ m on the edge . deals are good , but good enough to reactivate my pc ?	3
Case 2	Can I get Spider Man 2099	Gold	Good trade , thanks !	-
		CFC-QS	You got it PM sent !	1
		BE-QS	Sure , 1 by Paypal pls : xxx@hotmail.com	2
		BM25	right now , Spider man 2099 is the best written spider man .	3
Case 3	Gut Knife Scorched FT , worth 19keys	Gold	No thanks . Sorry	-
		CFC-QS	I only have 15keys .	1
		BE-QS	Add me on steam ! Nvm I added you .	2
		BM25	Nah only keys , knives are meh to me , all of’em .	3
Case 4	The email is returning failures to deliver	Gold	Should be working now .	-
		CFC-QS	THE email ? It’s just email ! !	3
		BE-QS	It asks for your username I think , doesn’t it ? Try just enter your username you used to register instead of the email and let me know if that works .	1
		BM25	did you get my email with the pic ?	2

Table 9: Four retrieved cases on our human evaluation set. We report Top-1 retrieved response of the three models as well as gold response. The Rank column is the ranking of the three responses given by the annotator (the lower the better).

retrieval methods, FAISS (Johnson et al., 2019) toolkit is used to retrieve candidate vectors. All encoders in our tower models (including one-tower, two-tower and three-tower) are initialized with *bert-base*[4], which includes 12 encoder layers, embedding size of 768 and 12 attention heads. For dense models (BE-QC, BE-QS, TE-DQS), we use the same batch size of 32 for Reddit and Twitter, and we train 30 epochs on Reddit and 10 epochs on Twitter. For all teacher models, we use the same batch size of 16, and we train 40 epochs on Reddit and 20 epochs on Twitter. For the distillation (CFC-QC, CFC-QS, CFC-DQS), we train additional 10 epochs on reddit and 5 epochs on twitter respectively, starting from the early checkpoints (20 epochs in Reddit and 5 epochs in Twitter for fair comparison) of BE-QC, BE-QS, TE-DQS. We use Adam (Kingma and Ba, 2014) optimizer with learning rate of 2e-4 and the warmup steps of 200 to optimize the parameters. We set the knowledge distillation temperature to 3 and the rate of distillation loss to 1.0. All experiments are performed on a server with 4 NVIDIA Tesla V100 32G GPUs.

C Distillation Benefit

To more clearly show the performance gains of our model after distillation, we present the specific values of these gains in Table 8. Readers can compare the results in this table when reading the Distillation Benefit part in § 5.3. Positive Coverage@K and Relevance@K, and negative Perplexity@K all represent the improvement of model performance. After the distillation, the accuracy and correlation between the retrieved responses and the query increase, and the conditional perplexity decreases, indicating the huge benefits of distillation.

D Case Study

As sparse representations base method, BM25 system tends to retrieve responses that overlaps with the context. For some complicated cases, BM25 cannot correctly retrieve those seemingly unrelated, but are the best answer in the current context.

In second case of Table 9, BM25 selects the response that contains "Spider Man 2099" in the query. But in the context of the forum, "Can I get Spider Man 2099" is actually looking for the e-book files of this comic. Compared to the comments of Spider Man 2099 given by BM25, our model retrieves "You got it PM (private message) sent!" is a harder to find, but more accurate response.

The third case is an in-game item trading query. In related forums, "keys" are used as currency. "Knife Scorched FT" and "19keys" in query respectively represent an item to be sold and its expected price. The result of BM25 covers "knife" and "key", but the meaning of the whole sentence does not match the query. On the other hand, our model selected "I only have 15keys", a standard bargaining, perfectly match the query.

There are also some examples such as case 4. Our model gives worse results than BM25. In case 4, CFC-QS retrieves a worse result, and the response retrieved by BE-QS is relatively better.

Abstract

Summarizing biomedical discovery from genomics data using natural languages is an essential step in biomedical research but is mostly done manually. Here, we introduce Textomics, a novel dataset of genomics data description, which contains 22,273 pairs of genomics data matrices and their summaries. Each summary is written by the researchers who generated the data and associated with a scientific paper. Based on this dataset, we study two novel tasks: generating textual summary from a genomics data matrix and vice versa. Inspired by the successful applications of k nearest neighbors in modeling genomics data, we propose a kNN-Vec2Text model to address these tasks and observe substantial improvement on our dataset. We further illustrate how Textomics can be used to advance other applications, including evaluating scientific paper embeddings and generating masked templates for scientific paper understanding. Textomics serves as the first benchmark for generating textual summaries for genomics data and we envision it will be broadly applied to other biomedical and natural language processing applications.[1]

1 Introduction

Modern genomics research has become increasingly automated through being roughly divided into three sequential steps: next-generation sequencing technology produces a massive amount of genomics data, which are in turn processed by bioinformatics tools to identify key variants and genes, and, ultimately, analyzed by biologists to summarize the discovery (Goodwin et al., 2016; Kanehisa and Bork, 2003). In contrast to the first two steps that have been automated by new technologies and software, the last step of summarizing discovery is still largely performed manually, substantially slowing down the progress of scientific discovery (Hwang et al., 2018). A plausible solution is to automatically summarize the discovery from genomics data using neural text generation, which has been successfully applied to radiology report generation (Wang et al., 2021; Yuan et al., 2019) and clinical notes generation (Melamud and Shivade, 2019; Lee, 2018; Miura et al., 2021).

In this paper, we study this novel task of generating sentences to summarize a genomics data matrix. Several excisting approaches demonstrate encouraging results in generating short phrases to describe functions of a set of genes (Wang et al., 2018; Zhang et al., 2020; Kramer et al., 2014). However, our task is fundamentally different from these: the input of our task is a matrix that contains tens of thousands of genes, which could be noisier than a set of selected genes; the outputs of our task are sentences instead of short phrases or controlled vocabularies.

To study this task, we curate a novel dataset, Textomics, by integrating data from PMC, PubMed, and Gene Expression Omnibus (GEO) (Edgar et al., 2002) (**Figure** 1). GEO is the default database repository for researchers to upload their genomics data matrices, such as gene expression matrices and mutation matrices. Each genomics data matrix in GEO is a sample by feature matrices, where samples are from often humans or mice that are sequenced together to study a specific biological problem, and features are genes or variants. Each matrix is also associated with a few sentences that are written by researchers to summarize this data matrix. After pre-processing, we obtain 22,273 matrix summary pairs, spanning 9 sequencing technology platforms. Each matrix has on average 2,475 samples and 22,796 features. Each summary has on average 46 words.

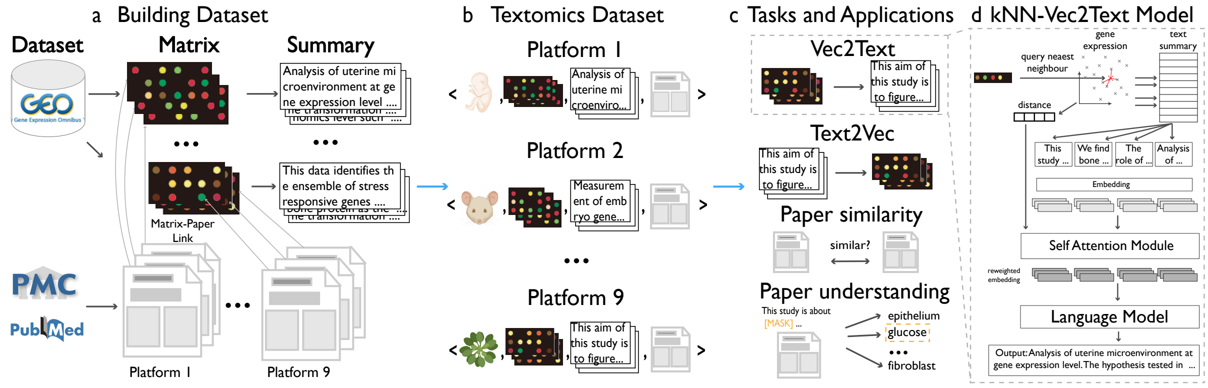

Figure 1: **Flow chart of Textomics.** a. Genomics data matrices and summaries are collected from GEO. Scientific papers are collected from PMC and PubMed. Each data matrix is associated with a unique summary and a unique scientific paper in Textomics. b. Textomics is divided into 9 sequencing platforms, spanning over various species. Data matrices in the same platforms share the same features and can therefore be used to train a machine learning model. c. Textomics can be used as the benchmark for a variety of tasks, including Vec2Text, Text2Vec, measuring paper similarity, and scientific paper understanding. d. kNN-Vec2Text is developed to address the task of Vec2Text, by first constructing a reference summary using similar genomics data matrices and then unifying these summaries to generate a new summary.

We further propose a novel approach to automatically generate a summary from a genomics data matrix, which is highly noisy and high-dimensional. k nearest neighbor (kNN) approaches have obtained great success in genomics data by capturing the hidden modules within it (Levine et al., 2015; Baran et al., 2019). The key idea of our method is to find k nearest summaries according to the genomics data similarity and then exploit the attention mechanism to convert these k nearest summaries to a new summary. Our method obtained substantial improvement in comparison to baseline approaches. We further illustrated how we can generate a genomics data matrix from a given summary, offering the possibility to simulate genomics data from textual description. We then introduced how Textomics can be used as a novel benchmark for measuring scientific paper similarity and evaluating scientific paper understanding. To the best of our knowledge, Textomics and kNN-Vec2Text together build up the first large-scale benchmark for genomics data summary generation, and can be broadly applied to a variety of natural language processing tasks.

Our paper is written as follows: We first introduce the Textomics dataset (section 2) and describe the Text2Vec and Vec2Text tasks (section 3). We then propose a baseline model and kNN-Vec2Text model for Vec2Text task (section 4.1) and the model for Text2Vec task. We then evaluate our method (section 5) and provide two applications (section 6) based on Textomics dataset. We then discussed the related works and the potential direction of future works (section 7 and 8).

2 Textomics Dataset

We collected genomics data matrices from Gene Expression Omnibus (GEO) (Edgar et al., 2002). The feature of each data matrix represents the expression level of a gene or other genomic measurements of a variant (typically real numbers). The sample of each matrix is an experimental subject, such as an experimental animal or a patient. Each data matrix is associated with an expert-written summary, describing this data matrix. We obtained in total 164,667 matrix-summary pairs, spanning 12,219 sequencing platforms.

Samples in different platforms have different features. However, data matrices belonging to the same sequencing platform are from the same species and share the same set of features, thus can be used together for model training. To further alleviate the missing feature problem, we kept the top-20000 features with a lower missing rate and filtered out the rest. We further selected 9 platforms with the average lowest rate of missing value and the largest amount of matrix-summary pairs to guarantee the quality and the scale of the dataset. After all, we imputed the resulted data matrices using averaging imputation across different features.

Data matrices belonging to the same platform have distinct samples (e.g., patient samples collected from two hospitals). To make them comparable and provide fixed-size features for machine learning models, we empirically used a five-number summary to represent each data matrix. In particular, we calculated the smallest, the first quartile, the median, the third quartile, and the largest value of each feature across samples in a specific data matrix. We then concatenated these values of all features, resulting in a 100k-dimensional feature vector for each data matrix. Compared with other statistics such as mean, median, and mode of the features, the five number statistics maintain the patterns hidden in the raw matrices better. This vector will be finally used as the input to the machine learning model.

All genomics data summaries we collected were written by the biologists who generate the corresponding genomics data matrices. Therefore, these summaries can properly reflect biologists' descriptions of their datasets. Since the summary is the first piece of information that one can learn about the dataset, authors often tend to clearly characterize their dataset in the summary. However, directly leveraging raw data of these summaries is questionable. On the syntactic level, the lengths of summary for each sample are different and comments are often used in genomics descriptions. In order to align our data and leverage the advanced Transformer model that requires fix-length sentences as well as simplifies the structure of the summary, we empirically removed the text in the brackets and truncated the summaries length to 64 words (the percentage of summaries with a length greater than 64 is 41%). On the semantic level, there could be non-informative summaries such as a simple sentence *'Please see our data below'* and some outliers that are substantially different from other summaries. In order to increase the quality of these genomics data summaries, we manually inspected and removed the non-informative summary and excluded the outliers based on the pairwise BLEU (Papineni et al., 2002) scores through a progressive automated procedure. Specifically, for every summary, we treated it as the query text and calculated the pairwise BLEU-1 scores with all other summaries, filtered out those median that is lower than 0.09, and then re-applied the procedure with a higher threshold of 0.13. Finally, each of the 9 platforms contains 471 matrix-summary pairs on average, presenting a desirable number of training samples to develop data summary generation models. We summarized the statistics of these 9 platforms in **Supplementary Table** S1.

Some of the data matrices are associated with a scientific paper, which describes how the authors generated and used the data. Therefore, the data matrix and the summary can be used to help embed these papers. We additionally retrieved these papers from PubMed and PMC databases according to the paper titles enclosed in GEO. We obtained the full text for those 7,691 freely accessible ones (**Supplementary Table** S1). We will introduce two applications that jointly use scientific papers and matrix-summary pairs in section 6.

3 Task Description

We aim to accelerate genomics discovery by generating a textual summary given the five-number summary-based vector of a genomics data matrix. We refer to the five-number summary-based vector as a gene feature vector for simplicity.

Specifically, consider textual summary domain $\mathcal{D}$ and gene feature vector domain $\mathcal{V}$, let $\mathbf{D} = \{\mathbf{D}_{\mathcal{D}}, \mathbf{D}_{\mathcal{V}}\} = \{(\mathbf{d}_i, \mathbf{v}_i)\}_{i=1}^{N} \overset{dist}{\sim} \mathbb{P}(\mathcal{D}, \mathcal{V})$ be a dataset containing N summary-vector pairs sampled from the joint distribution of these two domains, where $\mathbf{d}_i \triangleq \langle d_i^1, d_i^2, ..., d_i^{n_{d_i}} \rangle$ denotes a token sequence and $\mathbf{v}_i \in R^{l_v}$ denotes the gene feature vector. Here $d_i^j \in C$, C is the vocabulary. We now formally define two cross-domain generation tasks, Vec2Text and Text2Vec, based on our

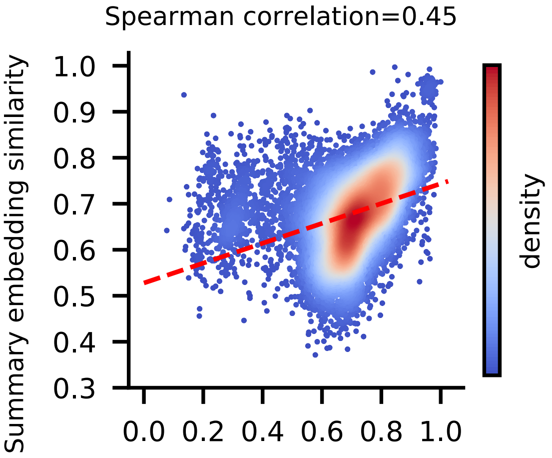

Figure 2: Density plot showing the Spearman correlation between text-based similarity (y-axis) and vector-based similarity (x-axis) on sequencing platform GPL6246. Each dot is a pair of data samples. A larger Spearman correlation indicates this Enc$_d$ is more accurate in embedding scientific papers.

dataset. Given a gene feature vector $\mathbf{v}_i$, Vec2Text aims to generate a summary $\mathbf{d}_i$ that could best describe this vector $\mathbf{v}_i$; given a textual summary $\mathbf{d}_i$, Text2Vec aims to generate the gene feature vector $\mathbf{v}_i$ that $\mathbf{d}_i$ describes. Since we are studying a novel task on a novel dataset, we first examined the feasibility of this task. To this end, we obtained the dense representation of each textual summary using the pre-trained SPECTER model (Cohan et al., 2020) and use these representations to calculate a summary-based similarity between each pair of summaries. We also calculated a vector-based similarity based on the gene feature vector using the cosine similarity. We found that these two similarity measurements show a substantial agreement (**Figure** 2, **Supplementary Table** S2). After filtering out the outliers, all 9 platforms achieved a Spearman correlation greater than 0.2, suggesting the possibility to generate textual summary from the gene feature vector and vice versa.

4 Methods

4.1 Vec2Text

We first introduce a baseline model that tries to encode gene feature vectors into the semantic embedding space and then decodes it to generate text. The baseline model contains a word embedding function Emb(.), a gene feature vector encoder $\text{Enc}_v(.)$ and a decoder $\text{Dec}_v(.)$. Given a gene feature vector $\mathbf{v}_i$, the encoder will first embed the data into a semantic representation space $\mathbf{s}_i^{(0)} = \text{Enc}_v(\mathbf{v}_i)$, and then the decoder will start from this representation for the text generation. The generation process is autoregressive. It generates j-th word $\hat{d}_i^{(j)}$ and its embedding $\mathbf{s}_i^{(j)}$ as:

$$P(\hat{d}_i^{(j)}|\mathbf{s}_i^{(<j)}) = \text{Dec}_v(\mathbf{s}_i^{(<j)}), j = 1, ..., n_{d_i}. \quad (1)$$

Then we sample the next word and obtain its embedding as:

$$\mathbf{s}_i^{(j)} = \text{Emb}(\hat{d}_i^{(j)}),\ \hat{d}_i^{(j)} \overset{sample}{\sim} P(\hat{d}_i^{(j)}|\mathbf{s}_i^{(<j)}). \quad (2)$$

This model is trained using the following loss function:

$$\mathcal{L}_{\text{baseline}} = -\frac{1}{|\mathbf{D}_\mathcal{V}|} \sum_{i=1}^{|\mathbf{D}_\mathcal{V}|} \sum_{j=1}^{n_{d_i}} \log P(\hat{d}_i^{(j)}|\mathbf{s}_i^{(<j)}). \quad (3)$$

4.1.1 kNN-Vec2Text Model

The baseline model attempts to learn an encoder that projects a gene feature vector to a semantic representation. However, the substantial noise and the high-dimensionality of the gene feature vector pose great challenges to effectively learn that projection. k-nearest neighbors models have been extensively used as the solution to overcome such issues in genomics data analysis (Levine et al., 2015; Baran et al., 2019). Therefore, one plausible solution is to explicitly leverage summaries from similar gene feature vectors to improve the generation. Inspired by the encouraging performance in using k-nearest neighbors (kNN) in seq2seq models (Khandelwal et al., 2020, 2021) and genomics data analysis (Levine et al., 2015; Baran et al., 2019), we propose to convert the Vec2Text problem to a Text2Text problem according to the k-nearest neighbor of each vector.

For a given gene feature vector $\mathbf{g}$, we use $e_i \in R$ to denote its Euclidean distance to another gene feature vectors $\mathbf{v}_i$ in $\mathbf{D}$. We then select the summaries of k samples that have the minimum Euclidean distances as the reference summary list $\tilde{\mathbf{t}} = [\mathbf{d}_{j_1}, ..., \mathbf{d}_{j_k}]$, where $j_m \in \{1, 2, ..., |\mathbf{D}|\}$ denotes the index of ordered summaries w.r.t the Euclidean distance, i.e, $e_{j_1} \leq e_{j_2} \leq ... \leq e_{j_{|\mathbf{D}|}}$.

In addition to alleviating the noise in genomics data using the reference summary list (Levine et al., 2015; Baran et al., 2019), our method explicitly converts the Vec2Text problem to a Text2Text problem, and can thus seamlessly incorporate many advanced pre-trained language models into our framework. The resulted problem we need to solve is a k sources to one target generation problem. One naive solution is to concatenate the k reference summaries together. However, this concatenation will make the source text much longer than the target text and how to order each summary during concatenation also remains unclear. Instead, we propose to transform this problem into k one-to-one generation problem and then use attention-based strategy to fuse them. Concretely, let $\mathbf{n_j} = \mathbf{max}\{n_{j_1}, ..., n_{j_k}\}$ be the maximum length among all the reference summaries. We first get the representation of each summary $\mathbf{x}_{j_m} = \text{Emb}(\mathbf{d}_{j_m}) = \langle \mathbf{x}_{j_m}^{(1)}, ..., \mathbf{x}_{j_m}^{(\mathbf{n}_j)} \rangle$ for $m = 1, ..., k$. Here $\mathbf{x}_{j_m}^{(i)}$ denotes the vector embedding of the i-th word in m-th summary. We construct fixed-length reference summaries by padding after the end of each summary with length less than $\mathbf{n_j}$. We then utilize self-attention module (SA) (Vaswani et al., 2017) to get the aggregated embedding of each reference with their embeddings as well as the gene feature vector distance e_i. Let Q_r, K_r, V_r be the query, key, value matrices of embedding sequence $\mathbf{r} = \langle \mathbf{r}^{(1)}, ..., \mathbf{r}^{(l_r)} \rangle$, we have:

$$\mathrm{SA}(\mathbf{r}) = \mathrm{Attention}(Q_r, K_r, V_r). \tag{4}$$

We then calculate the attention score as following:

$$\mathbf{a}_{j_m} = \mathrm{SA}(\langle \mathbf{x}_{j_m}^{(1)}, ..., \mathbf{x}_{j_m}^{(n_{j_k})} \rangle), \tag{5}$$

$$\mathrm{sc}_j = \mathrm{SA}(\langle e_{j_1} \cdot \mathbf{a}_{j_1}, ..., e_{j_k} \cdot \mathbf{a}_{j_k} \rangle), \tag{6}$$

where $\mathrm{sc}_j = [\mathrm{sc}_{j_1}, ..., \mathrm{sc}_{j_k}] \in R^k$. Here we used a 2-layer self attention scheme to first acquire the aggregated feature of each summary and then calculate the attention score based on that. The final score is then calculated based on the attention scores and temperature τ as:

$$w_{j_m} = \frac{\exp(\tau \cdot \mathrm{sc}_{j_m})}{\sum_{l=1}^{k} \exp(\tau \cdot \mathrm{sc}_{j_l})}. \tag{7}$$

Then, we aggregate embedding sequences by taking weighted averages:

$$\tilde{\mathbf{x}}_j^{(l)} = \sum_{m=1}^{k} w_{j_m} \mathbf{x}_{j_m}^{(l)}, l = 1, ..., \mathbf{n_j}. \tag{8}$$

Let $P_{<l,x}(\mathbf{d}) = P_{\theta_{LM}}(d^{(l)} | d^{(<l)}, \mathbf{x}), 0 < l < n_d$ be the probability distribution of $d^{(l)}$ output by the language model θ_{LM} conditioned on the sequences of the embedding vectors $\mathbf{x}$ and the first $l - 1$ sequence tokens. We feed the aggregated embedding sequences into the language model to reconstruct the summary $\mathbf{d}$ using an autoregressive-based loss function:

$$\mathcal{L}_{k\text{NN-Vec2Text}} = - \sum_{\mathbf{d} \in \mathbf{D}_{\mathcal{D}}} \sum_{l=1}^{n_d} \frac{\log P_{<l, \tilde{x}_j}(\mathbf{d})}{|\mathbf{D}_{\mathcal{D}}|}. \tag{9}$$

4.2 Text2Vec

We model the reverse problem of generating the gene feature vector $\mathbf{v}$ from a textual summary $\mathbf{d}$ as a regression problem. Our model is composed with a semantic encoder $\mathrm{Enc}_d(.)$ and a readout head $\mathrm{MLP}(.)$. Specifically, the encoder will embed the textual summary into dense representation $\mathbf{x} = \mathrm{Enc}_d(\mathbf{d})$, and the readout head will map the representation to the gene feature vector $\hat{\mathbf{v}} = \mathrm{MLP}(\mathbf{x})$. Then we train this model by minimizing the rooted mean squared errors (RMSE):

$$\mathcal{L}_{\mathrm{v}} = \sqrt{\frac{1}{|\mathbf{D}_{\mathcal{V}}|} \sum_{\mathbf{v}_i \in \mathbf{D}_{\mathcal{V}}} ||\hat{\mathbf{v}}_i - \mathbf{v}_i||_2^2}. \tag{10}$$

5 Results

5.1 Vec2Text

To evaluate the performance of kNN-Vec2Text on the task of Vec2Text, we compared it to the baseline models in 4.1. For the baseline models, we used a one layer MLP network as its encoder, and tested with different decoder structure, including canonical Transformer (decoder of T5) (Vaswani et al., 2017), GPT-2 (Radford et al., 2019), and Sent-VAE (Bowman et al., 2016). For kNN-Vec2Text, we directly used both the encoder and the decoder of T5 (Raffel et al., 2020), one of the state-of-the-art Transformer style models. we set $k = 4$ and $\tau = 0.1$ as this setting achieved the best empirical performance, though it is worth noting that our model is robust on the choices of k (from 1 to 4) and τ (from 0 to 1). For all 9 platforms, we reported the average performance under 5-fold cross validation to evaluate the robustness of our method. The results of BLEU-1 score (Papineni et al., 2002) are summarized in **Figure 3a**. We found that kNN-Vec2Text substantially outperformed other methods by a large margin. Specifically, kNN-Vec2Text obtained a 0.206 BLEU-1 score on average while none of the other three methods achieved an average BLEU-1 score greater than 0.150. The prominent performance of our method demonstrates the effectiveness of using a k-nearest-neighbor approach to convert the Vec2Text problem to a Text2Text problem.

To further understand the superior performance of the kNN-Vec2Text model, we presented a case study in **Table 1**. In this case study, the generated summary is highly accurate compared to the ground truth summary. By examining the summaries of the 4 nearest neighbors in the gene feature vector space, we found that the generated summary is composed of short spans from each individual neighbor, again indicating the advantage of using a k-nearest neighbor for this task. Our method leveraged an attention mechanism to unify these four neighbors, thus offering an accurate generation. We also observed consistent improvement of our method over comparison approaches on other metrics and summarized the results in **Supplementary Table** S3.

5.2 Text2Vec

We next used the Text2Vec task to illustrate how our dataset can be used to compare the performance of different pre-trained language models. In particular, we compared a recently proposed scientific paper embedding method SPECTER (Cohan et al., 2020), which has demonstrated prominent performance in a variety of scientific paper analysis tasks, with SciBERT (Beltagy et al., 2019), BioBERT (Lee

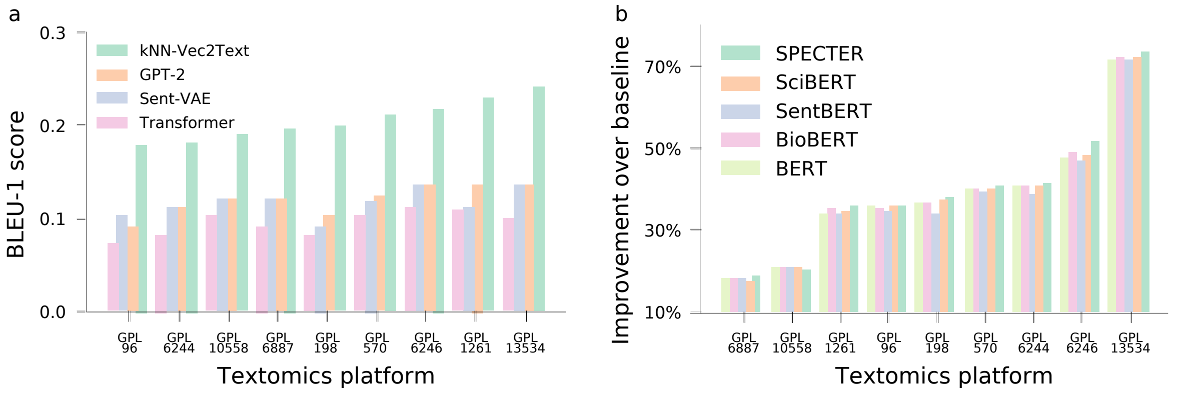

Figure 3: Performance on Vec2Text (a) and Text2Vec (b) using Textomics as the benchmark. a. Bar plot comparing our method kNN-Vec2Text with existing approaches on the ask of Vec2Text across 9 platforms in Textomics. b. Truth:	Analysis of uterine microenvironment at gene expression level. The hypothesis tested in the present study was that Tregs orchestrated the immune response triggered in presence of embryo.

et al., 2020) and SentBERT (Wang and Kuo, 2020) and the vanilla BERT (Devlin et al., 2019). While the other language models directly take the token sequence as the input, SPECTER model needs to take both the abstract and the title. To make a fair comparison, we concatenated the title and the summary as the input for models other than SPECTER. For all 9 platforms, we reported the average performance under 5-fold cross validation. We further implemented a simple averaging baseline approach that predicts the vector for a test summary according to the average vectors of training samples. This baseline does not utilize any textual summary and can thus help us assess the effect of using textual summary information in this task. We used RMSE to evaluate the performance of all methods. We reported the RMSE improvement of each method over the averaging baseline model in **Figure 3b**. We found that all methods outperform the baseline approaches by gaining at least 15% improvement, indicating the importance of considering textual summary in this task. SPECTER achieved the best overall performance among all five methods, suggesting the advantage of separately modeling the title and the abstract when embedding scientific papers.

6 Applications

6.1 Evaluate paper embedding via Textomics

Embedding scientific papers is crucial to effectively identify emerging research topics and new knowledge from scientific literature. To this end, many machine learning models have been proposed to embed scientific papers into dense embeddings and then applied these embeddings for a variety of downstream applications (Cohan et al., 2020; Lee et al., 2020; Wang and Kuo, 2020; Beltagy et al., 2019; Devlin et al., 2019). However, there is currently limited golden standard that can measure the similarity between two papers. As a result, existing approaches use surrogate metrics such as citation relationship, keywords, and user activities to evaluate their paper embeddings (Cohan et al.,

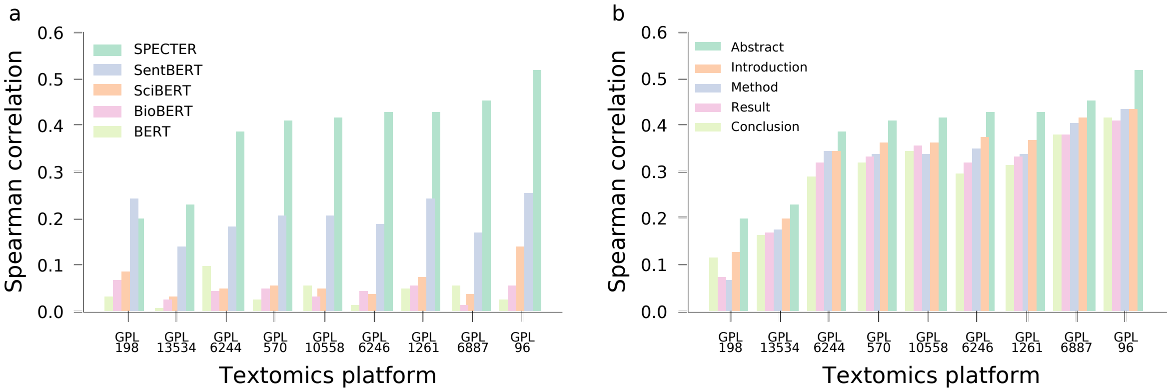

Figure 4: Performance on using Textomics as the benchmark to evaluate scientific paper embeddings. (A). Bar plot showing the comparison on embedding scientific papers using Textomics as the benchmark. (B). Bar plot showing the comparison on SPECTER embedding of different paper sections using Textomics as the benchmark.

2020; Chen et al., 2019; Wang et al., 2019).

Textomics can be used to measure these paper embedding approaches by examining the consistency between the embedding-based paper similarity and the embedding-based summary similarity since both the paper and the summary are written by the same authors. In particular, for a pair of summaries $\mathbf{d}_i, \mathbf{d}_j \in \mathbf{D}_{\mathcal{D}}$, let $\mathbf{t}_i, \mathbf{t}_j$ be the text (e.g., abstracts) extracted from their corresponding scientific papers. Let Enc_d be the encoder of the paper embedding method we want to evaluate. We first get their embeddings as:

$$\mathbf{s}_{d_i}, \mathbf{s}_{d_j} = \text{Enc}_d(\mathbf{d}_i), \text{Enc}_d(\mathbf{d}_j) \quad \in R^{l_s}, \tag{11}$$

$$\mathbf{s}_{t_i}, \mathbf{s}_{t_j} = \text{Enc}_d(\mathbf{t}_i), \text{Enc}_d(\mathbf{t}_j) \quad \in R^{l_s}. \tag{12}$$

We then compute the pairwise Euclidean distance between all pairs of summaries and all pairs of paper text as:

$$\mathbf{s}_{d_{i,j}} = \sqrt{\sum_{k=1}^{l_s} (s_{d_i}^{(k)} - s_{d_j}^{(k)})^2} \quad \in R, \tag{13}$$

$$\mathbf{s}_{t_{i,j}} = \sqrt{\sum_{k=1}^{l_s} (s_{t_i}^{(k)} - s_{t_j}^{(k)})^2} \quad \in R. \tag{14}$$

To evaluate the quality of the encoder Enc_d, we can calculate the Spearman correlation between the pairwise summary similarity and the pairwise text similarity. A larger Spearman correlation means the summary / textual contents of two samples in the pair are better aligned with each other, which indicates this Enc_d is more accurate in embedding scientific papers. As a proof-of-concept, we obtained the full text of 7,691 papers in our dataset from the freely accessible PubMed Central. We segmented each paper into five sections, which included abstract, introduction, method, result and conclusion. We first compared different paper embedding methods using the abstract of a paper. The five embedding methods we considered are introduced in section 5.1. Since SPECTER takes both the title and paragraph as the input we used the first sentence of the summary as a pseudo-title when encoding the summary. The results are summarized in **Figure 4a**. We found that SPECTER was substantially better than other methods on 8 out of the 9 platforms. SPECTER is specifically developed to embed scientific papers by processing the title and the abstract separately, whereas other pre-trained language models simply concatenated the title and the abstract. The superior performance of SPECTER suggests the importance of separately modeling paper title and abstract when embedding scientific papers. SentBERT obtained the best performance among four pre-trained language models, partially due to its prominent performance in sentence-level embedding. We further noticed that the relative performance among different methods is largely consistent with the previous work evaluated on other metrics (Cohan et al., 2020), demonstrating the high-quality of Textomics.

After observing the superior performance of SPECTER, we next investigated which section of the paper can be best used to assess paper similarity. Although existing paper embedding approaches often leverage the abstract for embedding, other sections, such as introduction and results might also be informative, especially for papers describing a specific dataset or method. We thus applied SPECTER to embed five different sections of each scientific paper and used Textomics to evaluate which section can best reflect paper similarity. We observed a consistent improvement of using the abstract section in comparison to other paper sections (**Figure** 4B), which is consistent with the intuition that the abstract represents a good summary of the scientific paper, again indicating the reliability of using Textomics to evaluate paper embedding methods.

6.2 Scientific paper understanding

Creating masked sentences and then filling in these masks can examine whether the machine learning model has properly understood a scientific paper (Yang et al., 2019; Guu et al., 2020; Ghazvininejad et al., 2019; Bao et al., 2020; Salazar et al., 2020). However, one challenge in such research is how to generate masked sentences that are relevant to a given paper while also ensuring the answer is enclosed in the paper. Our dataset could be used to automatically generate such masked sentences using the summary, which is highly relevant to the paper but also not overlapped with the paper. In particular, we can mask out keywords from the summary and then use this masked summary as the question and let a machine learning model to find the answer from the non-overlapping scientific paper. Let C_{bio} be a dictionary that contains biological keywords we want to mask out from the summary, $(\mathbf{d}_i, \mathbf{t}_i)$ be a pair of textual summary and paragraph text extracted from its corresponding scientific paper. If the j-th word $w_i = d_i^{(j)} \in C_{\text{bio}}$ in the summary belongs to C_{bio}, our proposed task is to predict which word in C_{bio} is the missing word in $\mathbf{d}_{\text{masked}}$ given $\mathbf{t}_i$. The masked summary $\mathbf{d}_{\text{masked}}$ is the same as $\mathbf{d}_i$ except its j-th word is substituted with [PAD]. For simplicity, we only mask at most one token in $\mathbf{d}_i$. We, therefore, form our task as a multi-class classification problem. Similar to section 6.1, we used the paper abstract as the paragraph text $\mathbf{t}_i$. To generate C_{bio}, we leveraged a recently developed biological terminology dataset Graphine (Liu et al., 2021), which provides the biological phrases spanning 227 categories. We selected 10 categories that can produce the largest number of masked sentences in Textomics. We manually filtered ambiguous words and stop words. On average, each category contains 317 keywords. We used a fully connected neural network to perform the multi-class classification task. The input feature is the concatenation of the masked summary embedding and the paragraph embedding. We used SPECTER to derive these embeddings as it has obtained the best performance in our previous analysis. The results are summarized in **Figure 5**. We observed improved accuracy on all ten categories, which are much better than the 0.4% accuracy by random guessing, indicating the usefulness of our benchmark in scientific paper understanding. Finally, we found that the performance of each category varied across different platforms, suggesting the possibility to further improve the performance by jointly learning from all platforms.

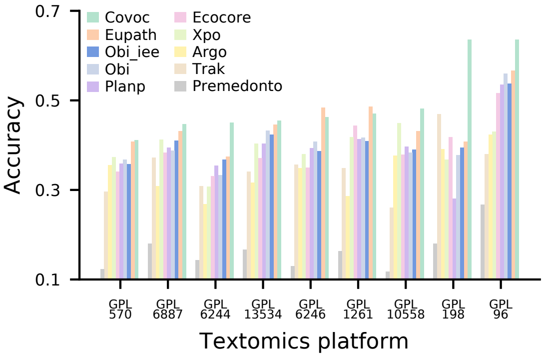

Figure 5: Bar plot showing the accuracy of filling the masked sentences of ten biomedical categories across 9 platforms using Textomics as the benchmark.

7 Related work

Our task is related to existing works that take structured data as the input and then generate the unstructured text. Different input data modalities and related datasets have been considered in the literature, including text triplets in RDF graphs (Gardent et al., 2017; Ribeiro et al., 2020; Song et al., 2020; Chen et al., 2020)), text-data tables (Lebret et al., 2016; Rebuffel et al., 2022; Dusek et al., 2020; Rebuffel et al., 2020; Puduppully and Lapata, 2021; Chen et al., 2020), electronic medical records (Lee, 2018; Guan et al., 2018), radiology reports (Wang et al., 2021; Yuan et al., 2019; Miura et al., 2021), and other continuous data modalities without explicit textual structures such as image (Lin et al., 2014; Cornia et al., 2020; Ke et al., 2019; Radford et al., 2021), audio (Drossos et al., 2020; Manco et al., 2021; Wu et al., 2021; Mei et al., 2021), and video (Li et al., 2021; Ging et al., 2020; Zhou et al., 2018; Li et al., 2020). Different from these structures, our dataset takes a high dimensional genomics feature matrix as input, which doesn't exhibit structure and is thus substantially different from other modalities. Moreover, our dataset is the first dataset that aims to convert genomics feature vector to textual summary. The substantial noise and high-dimensionality of genomics data matrices further pose unique challenges in text generation.

Our kNN-Vec2Text model is inspired by the recent success in applying kNN-based language models to machine translation (Khandelwal et al., 2021) and language models (Khandelwal et al., 2020; He et al., 2021; Ton et al., 2021). The main difference between our methods and their approaches is that while we try to leverage kNN in the genomics vector space to construct reference text, they use kNN in the text embedding space during the autoregressive generation process to help adjust the sample distribution. Some other methods can be used to generate text from vectors, such as (Bowman et al., 2016; Song et al., 2019; Miao and Blunsom, 2016; Montero et al., 2021; Zhang et al., 2019). Their inputs are latent vectors that need to be inferred from the data and do not have specific meanings, which are different from our gene feature vectors.

8 Conclusion and future work

In this paper, we have proposed a novel dataset Textomics, containing 22,273 pairs of genomics matrices and their corresponding textual summaries. We then introduce a novel task of Vec2Text based on our dataset. This task aims to generate the textual summary based on the gene feature vector. To address this task, we propose a novel method kNN-Vec2Text, which constructs the reference text using nearest neighbors in the gene feature vector space and then generates a new summary according to this reference text. We further introduce two applications that can be advanced using our dataset. One application aims at evaluating scientific paper similarity according to the similarity of its corresponding data summary, and the other application leverages our dataset to automatically generate masked sentences for scientific paper understanding.

To the best of our knowledge, Textomics and kNN-Vec2Text serve as the first large-scale genomics data description benchmark, and we envision it will be broadly applied to other natural language processing and biomedical tasks. On the biomedical side, we provide the benchmark to develop new NLP tools that can generate the description for a genomics data. Since each public genomics data needs a description, such tools will substantially accelerate this process. Also, descriptions generated from Textomics could contain new knowledge. While humans write the description almost solely based on that single dataset, description generation models jointly consider thousands of datasets, enabling the transfer of knowledge from other datasets. The generated description can guide biologists to write more informative descriptions, which ultimately leads to better and larger genomics description data. When biologists start to obtain the generated description from NLP tools, they will be able to write more informative descriptions with the assistance from these NLP tools. On the NLP side, the relationship between a summary and a dataset is analogous to the relationship between an abstract and a scientific paper. A high-quality summary ideally contains all perspectives of a study, including problems, methods, and discoveries. Moreover, our work will bridge the NLP and the genomics community and motivate people to analyze genomics data using NLP methods based on the multi-modality dataset introduced in this paper. Textomics could also be used to help scientific paper analysis tasks, such as paper recommendation (Bai et al., 2019), citation text generation (Luu et al., 2020), and citation prediction (Suzen et al., 2021).

Our method searches for the nearest neighbours by calculating the Euclidean distance between five-number summary vectors of the genomics feature matrices. However, this might lose useful information hidden in the original matrices. It's challenging and worth exploring end-to-end approaches that can learn embeddings from the genomics feature matrices instead of representing them as five-number summary vectors. On the Text2Vec side, one remaining challenge that could be the future direction of our work is to directly generate the whole genomics feature matrix instead of the five-number summary vector. Also, it would be interesting yet challenging to jointly learn the Text2Vec and the Vec2Text tasks, and one potential solution is to further decode the generated vector to reconstruct the embedding of summaries in Text2Vec, and leverage the resulted decoder to predict the embedding of text by using kNN method in the text embedding space. Also, it is interesting to jointly model data from multiple platforms, which might lead to beneficial results by transferring biological insights learned from different platforms.

A Appendices

We provided more details here about our dataset and related experimental results here. In Table S1, we summarized the statistics information of 9 Textomics platforms. There are 3 different species

Platform	Species	#Matrix (All)	#Matrix (PMC)	# Matrix (Vec2Text)	#Feature	Missing rates
GPL96	Homo Sapiens	1,371	353	240	100K	0.19
GPL198	Arabidopsis Thaliana	1,081	194	250	100K	0.03
GPL570	Homo Sapiens	5,822	1,879	1,004	100K	0.12
GPL1261	Mus Musculus	4,563	1,326	1,059	100K	0.09
GPL6244	Homo Sapiens	1,831	659	307	100K	0.10
GPL6246	Homo Sapiens	2,366	850	388	100K	0.08
GPL6887	Mus Musculus	1,150	407	240	100K	0.09
GPL10558	Homo Sapiens	2,580	1,261	519	100K	0.11
GPL13534	Homo Sapiens	1,509	762	234	100K	0.26

Table S1: Statistics of the Textomics data. Each row is a sequencing platform in Textomics. All, PMC, Vec2Text represent number of samples without filtering, with associated PMC full text article, and after using automated filtering, respectively.

Textomics platform	GPL 96	GPL 198	GPL 570	GPL 1261	GPL 6244	GPL 6246	GPL 6887	GPL 10558	GPL 13534
Spearman correlation	0.36	0.20	0.24	0.34	0.44	0.45	0.22	0.38	0.30

Table S2: The result of Spearman correlation between gene data matrices and text summaries on 9 platforms.

Platform	BLEU-1	ROUGE-1	ROUGE-L	METEOR	NIST
GPL96	0.179	0.233	0.166	0.143	0.817
GPL198	0.198	0.257	0.192	0.168	0.889
GPL570	0.212	0.269	0.205	0.182	0.936
GPL1261	0.229	0.283	0.226	0.202	0.980
GPL6244	0.183	0.250	0.179	0.156	0.750
GPL6246	0.219	0.269	0.210	0.187	0.950
GPL6887	0.198	0.260	0.196	0.171	0.847
GPL10558	0.191	0.257	0.177	0.165	0.842
GPL13534	0.242	0.332	0.279	0.260	1.124

Table S3: More results on evaluating Vec2Text task on Textomics.

across 9 platforms, including Homo sapiens, Arabidopsis thailiana, and Mus musculus. #Sample (All) represents the entire number of samples for 9 platforms, #Sample (Vec2Text) represents the number of samples in the subset after BLEU filtering, and #Sample (PMC) represents the number of samples in the subset with full scientific articles.
